The occasion should be utilized for the permanent remedy of certain evils arising from municipal parsimony—in neglecting to provide a properly located and adequate isolation hospital for contagious diseases. It has been heretofore demonstrated in these pages that the hospital treatment of smallpox affords the patient a better chance for recovery than treatment at home—to say nothing of the advantages accruing to the community from the thorough isolation of cases which only the hospital can secure.

But other things must be equal. It goes without

saying that compulsory removal to hospital is justifiable only when the hospital environment is at least as healthful as that from which the patient is removed; in the matters of abundant ventilation—and of hospital ventilation it has been aptly said that “too much is little enough”—in skilled nursing and in expert medical attendance the hospital should excel the home. Owing to false ideas of municipal economy this is not always the case; the belief seems to be that anything is good enough for an isolation hospital, and appropriations for its establishment and maintenance are, as a rule, given grudgingly and grumblingly.

The Health Department of Milwaukee should make the most of its present opportunity to secure what is coming to be recognized as the measure not only of a city's sanitary status but of its civilization—a properly constructed and adequately maintained isolation hospital for the reception and treatment of cases of the contagious diseases. If this shall be another one of the results of the work of the anti-vaccinists, it will go far to solve the present mystery of their creation and existence.

THE BRITISH MEDICAL ASSOCIATION.

The British Medical Association met in Bristol at its last session, exactly thirty-one years after its former meeting in that city, and the *British Medical Journal* of August 4 says:

“The British Medical Association again meets in Bristol, on this occasion under the accomplished and able presidency of Dr. E. LONO FOX, Consulting Physician to the Royal Infirmary. This is the third occasion on which the capital of the West has hospitably received the Association. It met there for the first time in 1833, shortly after the formation of the Association. The number of members of the Association was then a little more than 400, while the attendance ran up to 200. It is curious to note that at present, when the Association numbers upwards of 15,000, the attendance at an annual meeting so interesting as this is not expected to amount to a proportion of as much as 5 per cent. of the total number of members as compared with 50 per cent. in the earlier days of the Association. Further, the general business was then conducted in the presence of nearly the full number of attending members, while on the present occasion the most important part of the business can only command the attendance, out of the 900 members in the town, of from 30 to 40 in the body of the hall, and, including the members of Council on the platform, of between 50 and 60 in all—a smaller number, in fact, than goes to make up an ordinary well-attended meeting of any of the larger branches when similar subjects are under discussion. The fact appears to be that for all discussions of a political or business character the center of interest is displaced from the annual meeting, which mainly concerns itself with scientific discussions in the Sections and the hearing of the annual addresses, to the branch meetings. The branches have now become the main centers and determining power in the solution of the social and administrative problems with which the Association concerns itself. This decentralization of power and the localization of such discussions in the cities and the counties which are the seats of the branches is in full accord with the democratic spirit of the

times and the democratic constitution of the Association. Inasmuch as the executive body of the Association is elected by the branches, each assembled in its own seat of residence, and is constituted of their representatives, the reports of the Council and its committees, when approved by it, are really the authentic records of executive acts and administrative opinions derived from the true source of power in the Association—the wishes of the members as expressed by their elected representatives.”

The record of the proceedings of the general sessions reads so like a leaf from the proceedings of our own beloved ASSOCIATION, as to bring a tear to the eye. We read, following the report of the Treasurer:

“SURGEON-MAJOR INCE moved the following amendment:

‘That this meeting regrets the great and growing increase in the annual expenditure as compared with the income of the Association, and suggests to the Council the expediency of a careful and substantial reduction thereof in all departments, especially in the matter of the editorial and office expenses, which appear out of all proportion to the needs and nature of the *British Medical Journal*.’

“DR. INCE commenced by a criticism upon the *Journal*, which he said was not the golden article it had been represented to be. The tone of some articles he considered as undignified, often vulgar. He objected, for example, to a leading article written upon the HARNES case, and in response to cries of ‘Read, read,’ he quoted sentences from the article in which HARNES was referred to as—(cheers and cries of ‘hear, hear!’)—‘that champion impostor,’—(renewed cheers)—‘this egregious quack,’—(hear, hear)—the sentiments contained in the quotations being apparently warmly indorsed by the audience. DR. INCE would leave MR. HARNES and pass on to criticise an article headed, ‘A Superior Person, and the Journalism of the Future,’ which appeared on January 28, and which he described as ‘arrogant and satirical.’ The *Journal* was outdone in size by the *Lancet*, which contained 3,212 pages of reading matter last year as against 3,024 in the *Journal*, or 188 pages in excess. He commented on the ‘undisguised personality’ of the editor of the *Journal*. MR. ERNEST HART, in his last year's address on journalism, had spoken of ‘modesty and self-effacement.’ He added that he thought that would ‘fetch them.’ With regard to the financial statement, he complained that it was meager. There was no statement of the investments, while their furniture was put down at its cost, without any allowance for depreciation. There was something wrong in the accounts. He absolved the Treasurer in every way. MR. BUTLIN was reappointed last year at his (DR. INCE's) suggestion, and he had the fullest confidence in his integrity, his probity and discrimination. There was, however, still room for retrenchment, and it was a great mistake not to allow individual members who were desirous of doing so to inspect the accounts. One item that should be cut off immediately was the expense incurred by the peregrinations of their editor. DR. INCE having by this time somewhat exhausted the patience of his audience, was called upon to conclude, which he did by moving the resolution.

“After a long pause, MR. BRINDLEY JAMES seconded the amendment.”

And then the *Journal* was ably defended, (as if it needed any defense!) by DR. BRIERLY, MR. BUTLIN, and the veteran editor, MR. ERNEST HART, after which the mover withdrew the resolutions. All of which took up about two hours time of the general sessions; but the *Journal* had been attacked, and the assailant duly defeated; both sides having thus done their full duty the business of the session was resumed.

THE NECESSITY FOR WORK.

This year the members of the ASSOCIATION should make extraordinary efforts to increase the membership and swell the subscription list of the JOURNAL. A little personal effort will accomplish great things. The only ASSOCIATION in our country having direct connection with the State medical societies of the Union, there can be no question of its representative character.

Membership is now practically unlimited by any technical barrier, and every principle of patriotic pride should urge us to have one of the strongest medical associations in the world. We gained largely at San Francisco by the accessions from the Pacific coast; let us hold fast to what we have gained, by every member promptly remitting his annual subscription. Our ASSOCIATION would long ago have had ten thousand members if it were not that by sheer inattention many of those who join at these annual meetings allow their membership to lapse.

The JOURNAL was greatly enlarged last year, and it will soon move into better quarters, and be printed on its own presses. It will be a source of pride to the members to know that, notwithstanding the gloomy prognostications made after the Milwaukee meeting, by certain critics, the affairs of the JOURNAL were never more flourishing, or its prospects brighter, but it must not lag in the race. "A strong pull, and a pull all together," will soon bring the ASSOCIATION and its JOURNAL to a fair and friendly rivalry with the British Association, whose continued prosperity excites our highest admiration.

AS IT STRIKES THEM IN FRANCE.

M. MARCEL BAUDOUIN, of *Le Progrés Médical* also makes merry over the fact commented upon in the JOURNAL of June 30, under the heading, "Is This a Sanitary Utopia?" In a recent number of his lively journal he says it becomes his duty "to record a sufficiently extraordinary fact; one that is, most assuredly, not on the point of being at once reproduced in France"—that is, the establishment of systematic courses of instruction in sanitary science for the members of the German Legislature. M. BAUDOUIN says:

"In Paris we have, it is true, a course on social hygiene at the *Hôtel de Ville*; but PROFESSOR A. J. MARTIN would astonish us mightily were he to write us that his habitual audience included the majority of the Municipal Council! Can you fancy seeing PROFESSOR PROUST holding forth at the *Palais-Bourbon*? When he is obliged to speak there as a Commissioner of the Government he is listened to for a little while at least, because he knows how to manage the most refractory of audiences. But does any one suppose for a moment that were he not speaking on behalf of electors, large numbers of the people's representatives would think it worth while to come and wear out their trousers on the benches of the dynamited hall, under the pretence of learning how to avoid infecting Paris with dirty water? What would thenceforth

become of the famous interpellations, with a similar caliber to those of the *Seine-et-Oise* Deputies?"

He facetiously closes—"A post to be filled of which I had not dreamed: Professor of Deputy's Hygiene! I claim it, if, peradventure, it be not already bespoken. Berlin is an amusing place; one does not there get bored!"

There are other countries, it may be remarked, whose legislators need instruction in public health matters more than do those of France. In a late issue (July 21) we recounted the formation of an extra-Parliamentary committee of physicians, members of the French Parliament, to investigate pending questions relating to the profession, to poor-relief organization and to the protection of the public health. Among the twelve Senators and twenty-two Deputies who participated in the formation of this committee were many of equal celebrity in medicine and hygiene with those who are lecturing to the German Legislature, and *Le Progrés* itself announces the recent election of another medical man, DR. MARFAN of the Aude, to the Chamber of Deputies, and the appointment of DRs. LOURTIES and VIGER to the French Cabinet—the former as Minister of Commerce.

The recognition of medical men and medical matters in the British Parliament is too well known to need more than mention, and in Italy and elsewhere on the Continent the profession exerts an important influence in matters of legislation and the affairs of government.

CORRESPONDENCE.

LETTER FROM WASHINGTON.

Tenure of Medical Offices—Health Officer—Sanitary Affairs—Other Matters.

WASHINGTON, D. C., Aug. 4, 1894.

To the Editor:—The Commissioners of the District of Columbia have adopted a rule limiting the term of service of police surgeons, physicians to the poor, and health officer to three years. Heretofore there has been no limitation to time of service—the new rule does not prevent re-appointment to office.

Dr. C. M. Hammett, who three years ago succeeded Dr. Smith Townshend as Health Officer, tendered his resignation to the Commissioners on July 31, and it has been accepted. Dr. Hammett has been a successful practitioner in this city for twenty-five years and is a very accomplished gentleman. During his term of service in the health office he had many opportunities to exhibit his skill and judgment which he always did to the entire satisfaction of the profession and the public. He greatly improved the system of medical care of the poor, re-arranging the districts and filling all vacancies in the staff with physicians of the highest ability. His kindness and courtesy will always be remembered by those who had business with his office. He was, upon acceptance of his resignation, appointed to the office of Coroner.

Dr. W. C. Woodward who for the past few months had the office of Coroner, resigned and was appointed Health-Officer to succeed Dr. Hammett. He is a graduate of the

Medical Department of the Georgetown University, Class of 1889, and late Resident Physician in the Emergency Hospital, is very popular as a physician and will have an opportunity to distinguish himself in his new position.

The conference report on the appropriation bills for the city is agreed to and contains a number of interesting matters. One thousand dollars is allowed for horse hire and expenses of Coroner's Department, with salary of \$1,800.

The additional appropriation of \$60,000 proposed by the Senate for the collection of garbage was stricken out, and a clause inserted requiring the Commissioners to specially investigate the best methods of collecting and disposing of garbage, and to receive proposals under such methods and report the result at the next session of Congress. The Senate amendment legalizing the ordinances of the late Board of Health of the District was agreed to.

For work on the receiving reservoir of the aqueduct \$52,500 was provided, and the requirement inserted that the work shall be completed within the fiscal year, at a cost of \$90,000. For protecting the conduit at waste weir No. 1, \$5,000 was provided.

The emergency fund of the District was increased to \$25,000, and the fund for the support of convicts fixed at \$25,000.

For transportation of paupers \$3,500 was provided.

The item of \$1,710 for a new family building for the Reform School for boys was omitted and the Senate amendment was stricken out, which transfers the management and control of the Reform School to the Commissioners.

It was provided that not exceeding \$300,000 of the surplus revenues of the District on July 1, 1894, shall be applied to the payment of the principal of the debt incurred for increasing the water supply. The Senate item of \$1,000 for five members of the plumbing board was omitted. The Superintendent of Charities received a messenger at \$840.

An appropriation of \$165,000 was provided for assessment and permit work, and the Senate provision regulating such work was retained.

For relief sewers and replacing obstructed sewers, \$65,000 was agreed upon, and for main and pipe sewers, \$90,000. Authority was granted to enter into a contract for the construction of the Rock Creek intercepting sewer at \$80,000, and \$20,000 was appropriated to commence the work. The provision of the House concerning the paving of streets between the rails and tracks of street railways was omitted. The Senate amendment requiring fenders on street cars was retained.

The Senate provision concerning the condemnation of lands through the Prospect Hill Cemetery for the extension of North Capitol Street was retained.

For sweeping, sprinkling and cleaning streets \$137,500 was provided, and the Senate provision that \$5,000 of the amount may be used in the suburbs was omitted. The appropriation for gas and electric lighting was fixed at \$190,000, the price for street lamps fixed at \$20.50 per annum and electric lamps at 40 cents per night.

The bathing beach received \$1,000, and the public pumps \$4,000.

The disputed charities appropriations were agreed upon as follows: For the Emergency Hospital, \$12,000; for an addition to Columbia Hospital, \$10,000; for the National Homeopathic Hospital, \$8,000; for expenses of the Girls' Reform School, \$9,425; for child-caring institutions and the board of children's guardians, \$56,500. The provision of the Senate placing the management and control of the Freedman's Hospital under the board of incorporators was stricken out.

The recent ruling of Attorney-General Olney to the effect that the entire direction and control of the Freedman's Hospital and Asylum is vested in the Commissioners by virtue

of the act of Congress making appropriations for the past fiscal year, grew out of a question as to whether the transfer from the jurisdiction of the Interior Department extended to general control or only contemplated supervision of expenditures.

Superintendent of Charities Tracey, in his last report, recommended that the transfer of the institution to the jurisdiction of the Commissioners be completed, he being of the opinion that the clause in the appropriation act only contemplated supervision of expenditures.

The Attorney-General's recent opinion, however, holds that entire control was necessarily contemplated, and in view of this opinion no further legislation is necessary. In speaking of the appropriations for charities in the District appropriation bill, now in the President's hands, Col. Tracey expressed himself as entirely satisfied with the sums allotted, as in every instance the amount appropriated is identical with his recommendations.

For the enforcement of the provisions of an Act entitled "An Act to prevent the spread of scarlet fever and diphtheria in the District of Columbia," approved December twentieth, eighteen hundred and ninety, four thousand dollars.

That the ordinances of the late Board of Health of the District of Columbia, as legalized by joint resolution of Congress, approved April twenty-fourth, eighteen hundred and eighty, be, and the same are hereby, declared to have the same force and effect within the District of Columbia as if enacted by Congress in the first instance, and that the powers and duties imposed upon the late Board of Health in and by the said ordinances, are hereby conferred upon the Health Officer of said District, and that all prosecutions for violations of said ordinances and regulations shall be in the police court of the District of Columbia in the name of the said District: *Provided*, That said regulations shall not be enforced against established industries and the carrying on of any business therein mentioned, which is not a nuisance in fact.

H. L. E. JOHNSON.

A Word for the General Practitioner.

To the Editor:

"What the General Practitioner Should Know About Eye Diseases."

The above title has appeared at the head of numerous articles by as many authors within the last few years. It has recurred with such frequency as to nauseate the one for whom it was intended. A careful analysis of the articles oftentimes reveals a stupendous amount of ignorance and inexperience, either or both of which are reprehensible. They begin something after this fashion: "The object of this paper is to instruct the general practitioner what diseases and conditions of the eye he should send to an oculist and what the oculist is willing that the general practitioner shall treat." Then will probably follow a rehearsal of some cases where a general practitioner is held up to public view because of an error of diagnosis and treatment. Fortunately these cases are very rare in the oculist's practice, if from the practice of thoroughly informed physicians. They are too common if from the practice of those Ishmaelites, the itinerant and advertising quack. The articles above referred to then deal with the different diseases of the eye sometimes very elaborately, and before one is through reading them he is impressed with the irresistible conclusion that it is not safe for a general practitioner to treat any eye disease, and that he had better send all eye cases to the author of the article for treatment; for these articles are not primarily intended to be read by oculists, but by general practitioners and for this reason they very rarely appear in journals devoted exclusively to ophthalmic science, but in

journals which the general practitioner is most likely to read. These articles subserve no good purpose in advancing the progress of ophthalmic science. They are written, as Dr. Joseph Eastman said, in the Section of Gynecology at the last meeting of the AMERICAN MEDICAL ASSOCIATION, like the tariff bill "of these Democratic Senators, a tariff for revenue only."

The time has come when the better class of oculists should cry out against this debauchery of ophthalmic science. This advice will apply to all specialties. The attempt is to narrow the field of usefulness of the general practitioner until the only recourse for him will be to make a specialty of general practice. Because operations have been rendered easy and comparatively successful, specialists have often become egotists. No doubt this spirit of egotism has prompted the publication of the articles above mentioned.

The well-informed general practitioner can often teach a specialist more in a minute than the specialist can teach him in an hour. The great advances in ophthalmic science within the last fifty years have been due very largely to the general practitioner. Some of the most valuable hints, those hints which often do more for a surgeon's reputation than the most formidable operation he may perform have come to us from general practitioners. You perhaps have never seen in a text-book on the eye that when a foreign body is lodged under an eye-lid, by rubbing the other eye it will often be dislodged and removed, and trouble the eye no more forever. The rhinologist perhaps has never read in a text-book of laryngology that an acute coryza may be very quickly and efficiently broken up by the inhalation of the fumes of iodine crystals placed in a bottle. These valuable hints were given the author by a prominent practitioner of this place whose modesty has prevented him from writing a lengthy article advising the specialist what he should know of general practice. Very many other hints might be given similar to the two above.

All honor to our general practitioners. May their shadows never grow less. May the bulk of their knowledge on eye diseases continually increase. May the size of their pocket book be more plethoric. May those who limit their practice exclusively to a certain disease, because of *circumstances not their own*, reverence the general practitioner, the old-fashioned family physician, whose skill has pulled us through many rough experiences on beds of pain. It is to be wondered at why general practitioners have not filled the pages of our medical journals with articles entitled thus: "WHAT THE SPECIALIST SHOULD KNOW OF GENERAL PRACTICE."

GEO. F. KEIPER, M.D.

SOCIETY NEWS.

Twelfth International Medical Congress.—The next International Medical Congress will be held in Moscow, Russia, in August, 1896.

Medical Society Missouri Valley.—The annual meeting of the Medical Society of the Missouri Valley will be held in Council Bluffs, Iowa, Thursday, Sept. 20, 1894.

Medical Society of the State of West Virginia.—The Medical Society of the State of West Virginia convened in its twenty-seventh annual session at Berkeley Springs, W. Va., July 10 and 11. Ten new members were admitted to the Society, making a total of 221. President R. W. Hazlett delivered his annual address. The following papers were read:

"New Remedies," by Dr. E. H. Fravel; "The Prevention of Consumption," by Dr. N. D. Baker; "The Prevention of Tuberculosis," by Dr. A. S. Maddox; "A Synopsis of Practical Bacteriology with Demonstrations," by Dr. J. Schwynn;

"A Plea for the Old Physician," by Dr. C. F. Ulrich; "Antiseptics in Normal Labor," by Dr. W. P. Hogue; "A Witness in Court," by Dr. D. P. Morgan; "O'Dwyer's Operation, with Report of Three Cases," by Dr. R. H. Cummins; "The Influence of Bacteriology upon Surgical Practice," by Dr. R. J. Reed; "Legislation for the Prevention of Blindness," by Dr. G. A. Aschman.

Resolutions attached to the above paper, similar to those adopted by a number of other State societies for the prevention of blindness, were unanimously adopted and referred to the Committee on Legislation.

Dr. J. D. Myers, of Huntington, informed the Society of his intention of issuing a monthly medical publication, *The West Virginia Journal of Medicine and Surgery*.

The following officers were elected for the ensuing year:
President: Dr. D. Mayer, of Charleston.

Vice-Presidents: First District, Dr. R. H. Cummins, of Wheeling; Second District, Dr. C. S. Hoffman, of Keyser; Third District, Dr. V. T. Churchman, of Charleston; Fourth District, Dr. W. S. Keefer, of Parkersburg.

Secretary: Dr. G. A. Aschman, of Wheeling.

Treasurer: Dr. J. A. Campbell, of Wheeling.

Next year's meeting will be held at Elkins, W. Va., and Dr. B. M. Smith was appointed Chairman of the Committee of Arrangements. The exact date will be left to the decision of the officers.

PUBLIC HEALTH.

Cholera Disinfection.—Inasmuch as all researches on the subject go to prove that the cholera bacterium dies at 50 degrees C., and very quickly at 70 degrees C., and seeing that a mixture of one part of choleraic matter with ten of boiling water preserves a temperature of not less than 85 to 55 degrees for an hour (which is long enough to kill the stoutest cholera microbe), Dr. Valaëff, after thorough experiment, proposes to disinfect cholera stools by means of boiling water, which can be procured pretty nearly everywhere. Instead of being placed in corrosive sublimate solution, all linen soiled by cholera dejections should be plunged in boiling water, and allowed to remain submerged for fifteen or twenty minutes.

The Situation.—Public health conditions in the United States remain free from sensational features, despite the efforts of an occasional daily paper to create alarm by its headlines. Even in Milwaukee, where the anti-vaccinists have done some mischief as elsewhere detailed in this issue of the JOURNAL, it appears from the latest report of Dr. U. O. B. Wingate, Secretary of the Wisconsin State Board of Health, that there have been only 55 cases of smallpox with 6 deaths since January last, and a total of 135 cases and 33 deaths in the entire State. (*Abstract of Sanitary Reports*, Aug. 10, inst.)

A British "tramp" steamer, from Liverpool via Colon, Belize, Honduras and Vera Cruz, has given the New Orleans health authorities some little concern on account of the development on board of a suspicious case of sickness after her arrival at the city pier; she had been detained at quarantine for seven days for cleansing and fumigation and was supposed to be free from infection. While there were some characteristic symptoms of yellow fever lacking, the case was sufficiently suspicious to warrant the return of the vessel, crew, and sick man to the quarantine station, which was done on the 14th.

There is little to add to last week's summary of the cholera situation in Europe. Only in Russia may the disease properly be called epidemic, although its spread in Austria-Hungary, in the crown-land of Galicia, is becoming threat-

ening—resembling in its features of extension, the invasion of 1872-3 in the fourth pandemic of the disease. There is also some increase, both in the number of cases and of infected localities, in Holland, Belgium and France. English and Continental sanitary authorities—except, possibly, those of Eastern Europe—still seem to be able to cope with the situation and to afford a sufficient measure of protection for this country.

Cremation Sanctioned.—The advocates of the substitution of cremation for earth burial, on the score of the sanitary advantages of the former will be gratified at the recent decision of Mr. Asquith, the Home Secretary for England, on an application for a faculty authorizing the interment of an urn, containing cremated remains, beneath the floor of a church. The faculty was granted and a precedent is thereby established which, at least in a country so largely influenced by precedent, can not fail to give a fresh impetus to the practice of cremation.

Congress of Hygiene at Buda-Pest.—From a recent bulletin of information concerning the forthcoming International Congress of Hygiene and Demography at Buda-Pest, it is learned that already 725 papers have been notified, of which 593 belong to the hygienic, and 132 to the demographic group of the Congress. A total of 290 public bodies with 620 delegates, including 26 Governments, have given notice of their intention to be officially represented. Many important towns—Berlin, Hamburg, Brünn, Paris, Montpellier, Venice, Odessa, Alexandria and San Louis de Potosi, have promised to send in plans and models of their public sanitary works. Of the papers and lectures the following are given special mention: 1. Dr. Ernest Hart (London), Protection against Cholera in the Orient, and the Hypothesis of its Epidemic Diffusion; The Propagation of Cholera by River Communication and by Railway Lines; the direct connection between the Propagation of Cholera and of Typhoid Fever by Water, Milk and Food, together with the proved connection between the Suppression of Cholera and Typhoid Fever, and the Improvements in the System of Drainage, etc.; 2. By Prof. Dr. E. Leyden, Med. Privy Councillor (Berlin), On Provisions made by large Towns for Consumptives; 3. Prof. Dr. George Mayr (Strassburg), On Statistics and Social Science; 4. Baurath Herzberg, C.E. (Berlin), The Civil Engineer's Work in Hygiene; 5. Prof. E. Levasseur (Paris), The History of Demography; 6. Prof. Dr. E. T. Erisman (Moscow), The Struggle with Death; 7. Prof. Dr. C. Lombroso (Turin), The Criminal.

Tobacco as a Bactericide.—Can cigars be made a medium for the propagation of the cholera infection? is the question which Dr. Wernicke answers (*Hygienische Rundschau*) in the negative, after a series of careful experiments. He made cigars, using in the preparation of the tobacco leaves, water to which the cholera bacilli had been added, and also by placing within the cigars a small piece of cloth impregnated with a culture in broth for one day, and rolling up the last or outer layer or leaf with hands moist with water containing the specific bacilli. After remaining twenty-four hours in the oven the cigars were used to inoculate cakes of gelatine. The inoculation was effective only with the pieces of cloth placed within the cigar; on the tobacco leaves the cholera bacilli were already destroyed by the development of other microorganisms. In all cases the spirillum was found dead after three hours of drying; it survived longest (two hours) in cigars made from Havana tobacco; one hour was sufficient to kill in Sumatra and seed-leaf tobaccos and thirty minutes in that from Brazil. It is worthy of note, in connection with the theory of the acid prophylaxis of cholera, that the last three kinds of tobacco had an acid re-

action while that from Havana was alkaline. Wernicke also sought in vain for the presence of cholera bacilli in cigars manufactured in Hamburg, when the epidemic there was most severe, and while the cigars were still moist and contained a great number of other species of bacteria.

Kitasato's Discovery.—The "bill of particulars," which the *JOURNAL* last week intimated the bacteriologic world was awaiting with respect to the discovery of the specific plague bacillus, is furnished editorially by the *Medical Press* (Eng.) of August 1, inst. Soon after the appearance of the disease in Hong Kong the Japanese Government despatched Professors Kitasato and Aoyama to the island in order to study the disease. Both observers are well-trained bacteriologists. Dr. Kitasato, after taking his degree in medicine at Tokio, spent seven years at Koch's institute in Berlin, where he devoted his time to the bacteriology of infectious diseases. His fellow-worker, Dr. Aoyama, spent four years in similar studies under Prof. Koch. After much laborious work Dr. Kitasato is said to have discovered in the blood of a patient a bacillus which he believes to be the specific pathogenic organism of plague. This interesting microbe is found in the blood on the second day of the disease and proceeds to attack the principal internal organs of its host. It is described as being composed of very slender straight filaments of short length, of the form known among the Germans as a "stäbchen" bacterium. Both investigators are agreed that no such bacillus has yet been described in the human blood. Experiments made by Dr. Kitasato by subcutaneous injections of pure cultures of the bacillus have invariably killed the inoculated animal within two days. The resulting symptoms are stated to have been those of plague, although the symptoms of vomiting, diarrhea, and buboes were absent, possibly owing to the rapid development of the disease. Kitasato's discovery is made the occasion of a tribute to Japan by the journal quoted, which says: "The mere fact of such a discovery being possible from that quarter of the globe is itself an eloquent testimony to the intellectual powers of a versatile and capable nation. A short generation ago medical science, as such, simply did not exist in Japan. To-day it is provided with universities and schools, where all branches of learning are taught by trained and highly educated natives. The identification of the plague bacillus is likely to be merely a matter of time, that is to say, if the conclusions of the two learned professors should not be upheld by later investigators. They may be congratulated, however, even at this stage of affairs, on the energy and learning which they have brought to bear upon the elucidation of an obscure etiologic problem. To our own mind there is no more marvelous phase of the modern development of Japan than that which enables it to join the foremost ranks of scientific thought and investigation."

NECROLOGY.

PHILIP H. PFARRE, M.D., of Brooklyn, died June 8, aged 24 years, at the home of his family, 196 Lincoln Place. He received a detail as interne of the Brooklyn Hospital in 1893, where he was still on duty when ill-health forced him to leave the institution. The fatal issue is reported to have been consequent upon an influenzal attack in December last, with endocarditis supervening. He was a graduate of the Long Island College Hospital, in the class of 1890.—Julius Wolfenstein, M.D., of Cleveland, Ohio, August 12.—R. M. Straus, M.D., of Chapmanville, August 5, aged 42.—W. Y. Royer, M.D., of Monticello, Ill., August 11, aged 56.

Blank Applications for membership in the ASSOCIATION at the *JOURNAL* office.

MISCELLANY.

A Doctor's Footsteps.—The laborious nature of a busy practice is illustrated by the story of a Swiss doctor, who is said to have counted his footsteps during the year by means of a pedometer. The total is a large one, namely, 9,760,900, or average of 26,740 daily. Of this number 600,000 to 700,000, or from 1,500 to 2,000 daily, are said to have been taken up by staircases.

Red Noses.—A German physiologist—or physiognomist—one Dr. Kelling, has, according to the *Journal de Médecine de Paris*, discovered a simple method of saving abstemious people who are afflicted with red noses from being mistaken for confirmed toppers. According to Kelling, the "jolly red nose" is caused by a contraction of the venioles, producing sanguineous stasis of the capillaries and consequent loss of tone in the muscular parietes of these latter. His method of treatment, for which he claims entire success in upward of a score of cases, is as follows: A continuous current of medium (supportable) strength is passed through the pectant organ for from five to eight minutes, the two rheophores being the while freely promenaded all over the tinted surface. Sittings take place every two or three days, the violet-red color disappearing after from ten to fifteen applications.

Removal of Li Hung Chang.—If it be true, as reported by cable dispatches, that Li Hung Chang has been deprived of his premiership of the Chinese Empire, the cause of western medicine in the Far East will suffer a distinct loss. It was through his efforts that the Imperial Medical School at Tientsin was established and is now holding its first session in accordance with approved European methods of medical instruction. The Viceroy, who has been called the "Bismarck of China," is one of the most remarkable men of the age, having risen from obscure and humble parentage to be the actual ruler and chief administrator of an empire of 400,000,000 souls. Made Viceroy in 1863, at the age of 40, he has been the persistent friend and advocate of modern civilization; has permitted coal mining and coast steamer traffic to be carried on by the English, and has been favorable to the railroads; has founded a steamship line and is not opposed to European exploration of the Empire. No negotiations between China and other powers have been conducted of late years without his participation, and often the ambassador or ministers never got further than his palace at Tientsin. He represents the progressive party in China and his introduction of the telegraph, machinery, and European industrial methods has been accomplished with the greatest opposition from the mandarins of every degree. Naturally, he has incurred the enmity of these ultra-conservatives, who have probably made his alleged inactivity in the Korean difficulty the pretext for his present disgrace by the Emperor, Kuang Hsu—a young man of weak and yielding disposition, surrounded by courtiers who sedulously exclude from him all knowledge of the world of the nineteenth century and especially of the life of his people. It is recalled that the Viceroy was once before—in 1870, after the Tientsin massacre—similarly disgraced and his titles taken from him, on the ground that he had not properly assisted the general then in command. He remained in disfavor, however, less than two years, when he was restored to his office with increased power. As he is now in his seventy-second year and the present Emperor is so largely under the influence of the mandarins, such an event is not likely to be repeated; and it is to be feared that not only the Imperial Medical School will suffer but that medical missionaries in common with other civilizing agencies, will

be driven from the Flowery Kingdom if Li Hung Chang has been deprived of his yellow jacket and the authority it symbolizes.

The Supply Table of the Army Medical Department.—The Surgeon-General of the Army has issued a new edition of the "Supply Table of the Medical Department," an octavo pamphlet of fifty-one pages. In turning over its pages one is impressed with the liberality of the Government to the sick soldier. Everything needful for his treatment is on the list, with the complete outfit of a dispensary and hospital wards. The allowance for a year of the various articles of the materia medica is given for posts having an official population of from 100 to 1,000; the phrase "official population" including those other than soldiers entitled to medical attendance and medicines. The list of drugs in this edition of the "Supply Table" differs from its predecessors in two notable particulars; in the use of the official or pharmacopœial instead of the English name of the article, and in the adoption of the metric system of weights and measures. Thus, instead of "iron chlorid tincture, in 1 pound bottles" we now find, "ferri chlorid tinctura in 500 c.c. bottles," and instead of "silver nitrate, molded, in 1 ounce bottles," we have "argenti nitras fusus in 25 gram bottles," and so on. Following the medicines are lists of antiseptics and disinfectants, hospital stores, microscopic accessories, stationery, surgical instruments, appliances and dressings, furniture, bedding and clothing and miscellaneous articles, the last beginning with such items as bandage winders and bath bricks and ending with washtubs. The routine giving out of disinfectants to be scattered about a military post is prohibited. Not long ago the Surgeon-General notified his officers to give no countenance to the mistaken idea prevalent among officers and non-commissioned officers of the Army, that disinfectants are required for general post sanitation. In the absence of infection there is no need for disinfectants. Sulphate of iron and other cheap deodorants may be used when necessary, but the necessity for their use is a reproach on the sanitary police of a military post. The remedy for offensive water-closets, bad smelling urinals and foul drains is cleanliness and strict sanitary police, not disinfectants. Sterilized dressings are not issued; their preparation being so simple and so well understood they are expected to be prepared as needed. Medical and surgical chests are to be kept in perfect order for immediate service in the field. The Bausch and Lomb Universal is the microscope now issued by the Army Medical Department, although the Investigator of the same makers and a few of Beck's Binocular are still in use. A chemic and a bacteriologic set are issued to enable medical officers to carry out original investigations and to throw light on such sanitary questions or medical cases as may require special inquiry. No list of medical books is included in the "Supply Table," as it is considered that owing to the rapid advances in medicine a large part of any fixed list soon becomes obsolete. Such new books as may be selected by the Surgeon-General are furnished to military posts. The *Index Medicus* is supplied all posts, in order that medical officers may be informed and make use of the latest additions to the library, books from which may be obtained on application and payment of express charges both ways.

The Weather in 1893.—The annual summary of the weather for 1893, edited by Prof. Cleveland Abbe, has just been issued from the office of the Weather Bureau. The barometric pressure was below the normal .02 to .05 in the southwest, the interior valleys and the upper lake region, but above the normal by .02 or .03 in the extreme northeast and at several Pacific coast stations. The mean temperature was highest in Florida, Arizona and Southern Texas, the

maximum being 76.9 degrees at Key West, Fla. The isotherm of 60 degrees Fahr. passed from Hatteras, N. C., westward through Central Arkansas, Oklahoma to Southern California. The isotherm of 40 degrees passed from Central Maine westward over Lake Huron, Central Wisconsin, Northern Montana and thence northwestward through Alberta. The lowest annual averages within the United States were 29.9 degrees at St. Vincent, Minn., 35 degrees at Moorhead, Minn., and 37.4 degrees at Duluth, Minn., and at Sault Ste. Marie, Mich. The mean annual temperature was above the normal in the South Atlantic and Gulf States and the Eastern Rocky Mountain slope, the maximum excess being 2.2 degrees at Abilene, Texas. Elsewhere, temperature was usually below the normal, the maximum deficit being 4 degrees at St. Vincent, Minn., 2.9 degrees at Portland, Me., 2.4 degrees at Chicago, Ill.

The maximum temperatures of the year were noted at Fort Yuma, Ariz., 111 degrees June 7 and August 2; Tucson, Ariz., 107 degrees, June 7 and July 1; Miles City, Mont., 107 degrees, July 25; Dodge City, Kan., 106 degrees, June 23 and Red Bluff, Cal., 106 degrees, August 4. The lowest temperatures were—45 degrees at Havre and Miles City, Mont., February 1;—42 degrees at Helena, Mont., January 31 and St. Vincent, Minn., February 1; and—41 degrees at Bismarck, N. D., January 1. The range of temperature was least in Florida and on the Pacific Coast, greatest in Montana and North Dakota. The smallest ranges noted were 39 degrees at Key West, Fla., 40 degrees at Eureka, Cal., 50 degrees at San Diego, Cal., 54 degrees at San Francisco, Cal., and 55 degrees at Galveston, Texas. The largest annual ranges were Miles City, Mont., 152 degrees; Havre, Mont., 148 degrees; Helena, Mont., and Bismarck, N. D., 144 degrees; Moorhead, Minn., 140 degrees and St. Vincent, Minn., 138 degrees. The greatest annual rainfalls were 104 inches at Tatoosh Island, Wash., and 118 inches at Neah Bay, Wash. The precipitation exceeded 80 inches on the coast of Washington and 40 inches on the coast of California. It was from 2 to 10 inches in Nevada, from 10 to 40 inches in Idaho, and from 5 to 20 inches in Arizona; on the eastern slope of the Rocky Mountains from 5 to 15, increasing as we go eastward until in the Mississippi Valley it ranged from 25 at the northern and to 45 or 50 inches at the southern. Along the Atlantic coast the fall was generally about sixty inches, diminishing northeastwardly to Eastport, Me., which had about thirty inches and southwardly to Key West, Fla., which had 22 inches. The annual rainfall was generally deficient particularly so in Louisiana, Kansas, the interior of Georgia and Southern Florida; only in the north Pacific districts was there an excess of rainfall.

Collective Investigation of the Continued Fevers.—A most interesting class of diseases and one, as yet, but imperfectly defined, are the long continued fevers of the South. A special committee of the Orleans Parish (La.) Medical Society has been created for their collective investigation, and Dr. F. W. Parham, of New Orleans, Chairman of the committee makes (*New Orleans Medical and Surgical Journal*) a preliminary announcement of the plan of the work. Physicians will be requested to record accurate data of their cases of continued fever and keep clinical charts. Blank forms will be drawn up by the committee and sent throughout the State asking for information on important points in the pathology and treatment of this class of fevers, to the end that the investigation may be as complete and as thorough as possible. The pathologic investigation will be conducted by the pathologists of the committee, Drs. Archinard, Pothier, Bruns and McShane, who will study especially the means of differentiation of this from malarial and other fevers of Louisiana, having particular reference to the diagnostic data furnished

by the bacteriologic investigation of the discharges and the minute examination of the blood. The clinicians of the committee, Drs. Matas, Chassignac, Salomon, Martin and Bloch, will gather all other data bearing on the subject, and the whole committee will collate the results of the investigation and present its conclusions at the annual meeting of the Orleans Parish Medical Society next spring.

The committee will undoubtedly avail itself of the results of the work done in this direction by the U. S. Marine-Hospital Service in 1888-90, under the following order:

RECORD AND CLASSIFICATION OF CONTINUED AND REMITTENT FEVERS.

1888. Department No. 65.] Treasury Department.

OFFICE SUPERVISING SURGEON-GENERAL, MARINE-HOSPITAL SERVICE.

WASHINGTON, D. C., June 7, 1888.

To Medical Officers and Acting Assistant Surgeons:

With a view of formulating a more precise symptomatology of the "continued" and "remittent" fevers, from and after July 1, 1888, you are directed to take full and accurate notes of all cases of "continued" and "remittent" fevers, treated by you among patients of the Marine-Hospital Service and to make special semi-annual reports of all such cases to this office.

The cases of fever should be classified, as far as practicable, according to the symptoms in each case, into simple continued, enteric, remittent, etc., and every symptom noted.

The presence or absence of the following symptoms relative to enteric fever should be carefully noted, together with the dates of their respective appearance:

| | |
|------------------------|-------------------------------------|
| Eruption; | Enlargement of spleen; |
| Diarrhea; | Delirium (character); |
| Tympanites; | Mode of onset (gradual or sudden), |
| Intestinal hemorrhage; | presence or absence of initial |
| Peritonitis; | chill; |
| Temperature range; | Necropsy; |
| | Presence or absence of intestinal |
| | lesions, and if present, give exact |
| | location. |

JOHN B. HAMILTON,

Supervising Surgeon-General.

Approved:

C. S. FAIRCHILD, Secretary.

The reports thus provided for were continued up to June 30, 1890, and cover a total of 339 cases—241 of the enteric group, 87 of the remittent group and 11 of the simple continued fevers, the details of which will be found in the Annual Reports of the Supervising Surgeon-General for the years 1889 (p. 243) and 1890 (p. 96).

Positive Proof Necessary to Warrant Revocation of License.—Gradually the courts are teaching medical licensing bodies the forms of procedure to be observed, the competency of evidence, the methods of pleadings and the rights of individuals, in trials involving the tenure of the license to practice. Another important and valuable lesson on this subject is contained in the decision of the Supreme Court of Montana, rendered March 17, 1894, in the case of the State v. Kellogg. This was an appeal to the Court against the revocation of Kellogg's license by the State Board of Medical Examiners on a complaint of "unprofessional, dishonorable or immoral conduct." The complaint, as it reached the Court, charged that the defendant, a licensed physician, 1, threw into a furnace with intent to destroy it, a human acephalous fetus seven months old; 2, that, at a coroner's inquest upon this fetus, he certified that it was three months and a week old, and refused to give the name of the mother, but promised to divulge the name to the coroner the next day, who could use his discretion; 3, that, at the inquest on the following day, he testified that the woman whose name was demanded had left the State and, without her presence to explain her condition at the time the fetus was taken from her, his answer, under the circumstances, would incriminate him and be testimony against him. Upon trial of these charges before the Board the defendant was found guilty of immoral, unprofessional and dishonorable con-

duct, and his license to practice medicine in Montana was revoked. The evidence upon which this judgment was based was not presented to the Court, which had before it only the complaint embodying the charges above set forth. The Court analyzes these charges *seriatim*, and finds nothing in the complaint inconsistent with the theory of innocence of wrong doing or intent on the part of the defendant. The Court severely criticizes the manner and form of the complaint and its ineptitude. It is said to hint at guilt, but to leave open the hypothesis of innocence. If true, the defendant might be guilty and he might be innocent. Pleading of such a nature, it was said, would not do in a civil case, and it surely must not be allowed in a quasi-criminal case. Concede that the facts set up in the complaint raise a grave suspicion of the commission of an abortion by the defendant. Must he prepare for trial upon a suspicion? To be a member of an honorable profession, such as that of medicine, should raise his conduct above suspicion. But if circumstances arise which may, under one construction, cast a suspicion upon a physician, and if the circumstances are susceptible also of a construction consistent with his innocence, then, if the construction of guilt is to be adopted, the guilt should be charged, and not left to inference. And while extending all approval to legislation intended to exclude immoral and dishonorable conduct from an honorable profession, yet the spirit of our American law is such that the Court must hold that a doctor, to be tried for professional misfeasances, is as much entitled to a clear charge and specifications against him as has a burglar or murderer the right to a definite, specific indictment. The judgment of the Board was reversed.

The Metric System in Pharmacy.—At a recent Council meeting of the Pharmaceutical Society of Great Britain, Mr. W. Martindale moved the following resolution: "That after Jan. 1, 1895, a practical knowledge of the metric system of weights and measures shall be required of all candidates for the Minor Examination in the subjects of prescriptions and practical dispensing, and that the Board of Examiners be instructed to require from candidates a general knowledge of posology in terms of the metric as well as the British system of weights and measures as defined by the British Pharmacopœia, 1885; and in practical dispensing 'to weigh, measure and compound medicines' by the metric as well as the British system of weights and measures." After some discussion the resolution was altered to the effect that the Board of Examiners should be requested to consider the advisability of acquiring a practical knowledge of the metric system of weights and measures for the Minor Examination. In this form it was carried.—*British Medical Journal*.

A Wide-awake Hospital Administration in Madagascar.—The following are some points taken from a report, prepared by Drs. S. B. Fenn and C. F. A. Moss, relative to their work at the hospital supported by three English missionary societies at Antananarivo, Madagascar. These two gentlemen, with some aid from English laymen and from natives trained by themselves, have been enabled to build up a hospital with four or more dispensaries, and training schools for nurses and for physicians and surgeons. They show in their work great energy, enterprise and shrewdness:

"1. *In-patient Work.*—The hospital is always open the year round, for the reception of patients. A few years ago the reluctance shown by the people to enter a hospital was great, as they did not like the necessary restrictions and rules. But this, we are glad to say, is gradually but surely giving way, and with this larger and better hospital we are often over-crowded, and are obliged to refuse admittance to some. Many, too, come from great distances, and these we are always glad to see, for they carry back with them to their distant homes accounts of what they have seen and

heard. Short services are held in each ward morning and evening, and as opportunity offers the good seed is also sown by private talks with the patients.

Let me add that the hospital, being also a training institution, is worked very much on the same plans as our hospitals at home. There are staff nurses, nurses and probationers, also clerical clerks among the students. Temperature charts, notes, and histories of cases are all carefully made and kept, and as far as the time and strength of two doctors and one lady superintendent permit, the work is done thoroughly.

"2. *Out-patient Work.*—There are four dispensaries connected with the Medical Mission. One is at the hospital itself, where patients are seen three days a week. Another is situated at the north end of the town, near the great market-place, and is opened three times a week also. A third dispensary is at the extreme southern end of the city, where patients are seen on Mondays and Thursdays, and a fourth is at the little town of Ilazaina, about eight miles north of the capital.

"3. *Teaching of Students.*—The training department of our work, viz., that of young women as nurses and midwives just mentioned, and that of young men as doctors, is perhaps the most important of all. There are at present over fifty students in the Medical Missionary Academy, under the management of a conjoint board, representing three societies in England. The students have to pass an examination on general education before entering on their medical studies. If this is done successfully, the first year is devoted to science subjects, viz., botany, physics, chemistry, zoölogy, also Latin and English. If they pass the examination in these subjects and have proved to be worthy men, they are allowed to commence their medical studies proper. These are pursued for at least four more years. The first two are spent in studying anatomy, physiology, histology and materia medica, and the last two are especially devoted to clerical work in the hospital, medicine, surgery, midwifery and gynecology. A final examination is held once a year, after which the successful candidates publicly receive the diploma of the Academy. Over twenty young men now hold this diploma. Some have practices in town, and many are settled in country districts and doing excellent work. Thus by spending our time and labor on the few we are, in reality, benefiting the many.

"4. *Outside Work.*—Not much need be said on this point. My esteemed colleague, Dr. C. F. A. Moss, and myself, find our time more than fully occupied with the direct work of the Mission. Still, there are missionary families and others to be attended to in illness, and occasionally visits have to be paid to Malagasy patients at their homes. A little literary work, too, is done from time to time, and the preparation of suitable text-books for the students is slowly advancing."

There is a band of forty Malagasy women who have been trained to serve as a nursing staff at the hospital and dispensaries.

Washington Notes.

CITY PUMPS.—A number of pumps for drinking water have been closed by order of the Commissioners because they were found more or less contaminated by surface drainage, and others have been marked for inspection by the District chemist.

ASSISTING UNREGISTERED PHYSICIANS.—It has come to the notice of the Health Department that an unregistered physician was attending a case which died, and as he could not sign the death certificate secured the signature of a friend, a registered physician. The matter will be investigated.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—The monthly report for July shows the following: Number of new cases, 1,121; number of visits, 3,011; number of prescriptions, 2,496; ambulance calls, 34; number of deaths from all causes, 6; number of autopsies, 6; number of emergency cases, 316; number of operations, 164; number of redressings for minor cases, 207.

CAPITAL WATER SUPPLY ENDANGERED.—Col. John M. Wilson, in charge of public buildings and grounds, has called the attention of the Commissioners to the fact that Eckington and Soldiers' Home Railroad Company, in constructing

the new track at Florida Avenue and North Capitol Street, has placed ties apparently immediately over the four-inch water main which conveys the drinking water from the Capitol Spring to the Capitol. Col. Wilson says the pipe will probably be broken as soon as cars are run over the track. The pipe was laid by the United States about fifty years ago, the right of way having been purchased by the Government.

BURIAL PERMITS INACCURATE.—It has been found by the Health Department that in some cases where the certificate of death showed that the deceased was to be buried in a given cemetery it was afterward found that the remains were in another. A case in point showed a body supposed to have been buried at Mount Olivet was in reality buried at Arlington. These cases are for some reason quite frequent. The matter will be investigated. A heavy fine is the penalty for such an offense.

MIDSUMMER DEATH RATIO.—The health conditions of the city as shown by the returns of the Health Department for the past week are good. Infant mortality is on the decline. Contagious diseases, as well as those of the lungs, are seen to be in almost complete abeyance, only one death from diphtheria and one from whooping cough being reported. Number of deaths, 127; white, 60; colored, 67; death rate per 1,000 per annum, white, 17.9; colored, 34.7; total population, 23.1; 44 were under 5 years of age; 33 under 1 year and 25 over 60 years. Twenty-six deaths occurred in hospitals or public institutions. The deaths by classes were as follows: Zymotic, 36; constitutional, 24; local, 49; developmental, 9; violence, 9; principal causes were: Croup, 1; diphtheria, 1; consumption, 8; diarrhea, 16; typhoid fever, 13; malarial, 2; congestion of lungs, 1; bronchitis, 1; whooping cough, 1; kidney diseases, 4; meningitis, 2; cancers, 6; births, 90; white males, 31; females, 24; colored males, 17; females, 18; marriages, 36; white, 29; colored, 7; still births, 2 white and 8 colored.

GARBAGE DISPOSAL.—Considerable friction exists between the Health Departments of Washington and Alexandria, Va., growing out of the anchoring of garbage scows too near the latter city. Upon the failure of the contractor to abate the nuisance, after due notice, the Alexandria authorities attempted to burn the boats; they were so wet that fire failed so dynamite was resorted to and the objectionable, foul smelling scows scattered. The present contract of the garbage company is in force until July 1, 1897. In the District appropriation bill, as it passed the House, \$29,500 was provided for the collection of garbage, being the amount of the company's yearly contract, with a slight addition for extra daily collections during the summer months. When the bill reached the Senate the sum of \$30,500 was added to provide for the disposal of the garbage by cremation or otherwise within the limits of the District, making a total appropriation of \$60,000. When the bill went to conference, the Senate amendment was knocked out and the bill was finally passed with the item for garbage the same as provided by the House, and the Commissioner directed to further investigate the matter of garbage disposal and report with plans and estimates to the next session of Congress. The Commissioners think, however, that they will be able to secure the additional appropriation desired before the present session adjourns.

Deaconess' Hospital, Dayton, Ohio.—The trustees of the Deaconess' Hospital, Dayton, Ohio, held their regular monthly meeting August 7. The Superintendent's report was as follows: Number of patients in hospital June 30, 19; admitted in July, 29. Total number treated, 48. Dismissed, 17; died, 3. Number remaining in hospital August 1, 28.

THE PUBLIC SERVICES.

Postponement of Examinations for the Army Medical Department.—Candidates for permission to appear before an Examining Board for entrance into the Medical Corps of the Army have received the following letter, signed by Major Charles Smart, from the office of the Surgeon-General:

SIR:—I have the honor to inform you, by direction of the Surgeon-General, that the number of assistant surgeons in the Medical Corps of the Army was reduced by recent Act of Congress from 125 to 110. There being therefore no vacancies to be filled, no Examining Board will be convened at present, nor until the number of assistants is reduced by casualty below 110 (there are now 115). It is impossible to say when this will occur, but due notice of the next Board will be given in the medical press, so that you can renew your application if then eligible. It is expected that the age limit will hereafter be 22 to 29.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from August 4, 1894, to August 10, 1894.

Capt. WILLIAM J. WAKEMAN, Asst. Surgeon U. S. A., granted one month's leave of absence, on completion of his duties at Ft. Thomas Rifle Range, Ky.

Capt. W. FITZHUGH CARTER, Asst. Surgeon, is granted leave of absence for one month, to take effect about Aug. 5, 1894.

A board of medical officers to consist of Major VALERY HAVARD, Surgeon; Major JOHN VAN R. HOFF, Surgeon; Major GEORGE H. TORNEY, Surgeon, is, by direction of the Secretary of War, appointed to meet at West Point, N. Y., Aug. 15, 1894, or as soon thereafter as practicable, for the physical examination of the cadets of the first and third classes; the cadets of the second class on their return from furlough, and such other cadets of the Military Academy, and candidates for admission thereto, as may be ordered before it.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 11, 1894.

Medical Inspector F. L. DuBois, detached from U. S. S. "Chicago," ordered home and granted two months' leave.

ORIGINAL ARTICLES.

A STUDY OF THE EFFECTS OF POISONED AIR, IN THE CAUSATION OF INEBRIETY.

Read in the Section on State Medicine, at the Forty-fifth Annual Meeting
of the American Medical Association, held in San Francisco,
June 5-8, 1894.

BY T. D. CROTHERS, M.D.

SUPERINTENDENT WALNUT LODGE HOSPITAL, HARTFORD, CONN.

The statement, so often repeated, that inebriety is the result exclusively of alcohol is not true. Careful studies of individual cases indicate a great variety of complex causes which are unrecognized in most cases. Inebriety is a symptom in many instances, which disappears when certain causes are removed. In certain cases, the ejection of a tapeworm has been followed by total abstinence of the person. The removal of a spicula of bone pressing on a nerve; the trephining of the skull; the operation and removal of a stricture; the curing of hemorrhoids; constipation; diarrhea and many other conditions, have been followed by recovery from inebriety. Conditions of exhaustion, anemia, poisoning from malaria, and degenerations following acute disease, frequently break out in continuous drinking which subside when these states are removed.

It is also true that alcohol, taken any length of time, will produce degenerations which demand its continuous use. A single excessive use is often followed by a craze for spirits that is a literal inebriety. From a degenerative soil inebriety grows most luxuriantly, and the previous degenerations are intensified to an unknown degree. Sanitary conditions are always influential, and in many cases exercise a marked power over the intensity and duration of the case. Experience shows that a certain number of cases of inebriety recover, from a change of surroundings and living. I have described, in Vol. iv, *Journal of Inebriety*, four cases of persons who always drank near the sea coast, but who had no desire for spirits and did not drink when living in mountain regions. Change of occupation has frequently been followed by complete restoration from inebriety. What conditions and influences in the person and his surroundings exist in such cases are at present unknown.

The influence of poisoned air is seen in many ways by all observers. How far it may be an exciting or predisposing cause in disease is not always clear. In certain cases very marked results follow the improvement of aeration. In the two cases following are embodied some very significant hints which suggest a line of study for sanitarians and others, that is comparatively new:

A professional man of ability, temperate and healthy in every way, moved to New York city and occupied a fashionable house four rooms deep in a rich section of the city. He slept in one of the middle rooms without sunlight, and only

ventilated from the other rooms opening on the front and rear of the house. He worked very hard mentally and lived regularly, avoiding all excesses. The next year he became anemic, suffered from insomnia, and began to use spirits to encourage sleep. A year later he was considered an inebriate and drank to excess every night. He suffered from chronic gastritis, the urine was loaded with albumen, and his mind was on the border of delirium all the time. He was in bed for days at a time, in a dark room with heavy curtains about and gas burning all the time. A closet near gave a suspicious odor, and great anxiety was manifest to avoid a draft of air, and the possibility of acute pneumonia. His pulse was 120, temperature 100, body bathed in perspiration; insomnia and semi-delirium was present most of the time. Milk punches, brandy and eggs, morphia and other drugs, also alcoholic baths were given freely. I advised that he be taken to the country and placed in a large sunny room with southern exposure and all spirits withdrawn; baths every day, foods and salines and massage. Recovery followed rapidly, and in three months he went back to his office retaining his residence in the country. Two years after he was a vigorous temperate man doing business in the city and living in the country. The inebriety in this case was largely due to the poisoned air of the sleeping rooms; the rapid recovery and subsequent good health in a well ventilated house confirms this. It will occur to any one how clearly these sources of imperfect aeration would produce general disturbances of the functional activities, for which the narcotic of alcohol would be most grateful.

In five years I have been called twice to advise concerning inebriates in a rich home of an aristocratic section of New York city. In both cases, father and son occupied very ill-ventilated sleeping rooms, and suffered from insomnia and general weakness, for which spirits were ordered as a tonic and medicine. The father died and the son became melancholy and was sent to an insane asylum. The history seemed to point to some close connection between the bad air of his home and the first use of drinking.

Two young men, temperate and well, left their country home to become coachmen in New York, sleeping in a bad ill-ventilated stable room. They became inebriates and were discharged, returning to the country, recovered, and are now temperate and well.

Many cases of similar character will occur to every one, and while it may be difficult to trace back the origin of the excessive use of spirits to this particular cause, viz., bad air and bad ventilation, there is evidence of a very intimate association and undoubted influence as an active predisposing force.

The early use of spirits in many cases follow states of exhaustion and weakness, and the use of alcohol covers up these conditions, conveying the impression of relief. This physiologic impression is more powerful than theory or reasoning, and readily leads to a repetition of the use of spirits and inebriety. Bad air and bad ventilation always leave the system debilitated, favor auto-intoxications, and the formation of compounds in the blood and tissues that are distinctly poisonous. Alcohol used at this time may bring to the system germs and soil for the culture and growth of still more poisonous states. In all events it brings increased weakness and degeneration with diminished power of resistance.

Inebriates from crowded tenements and basement residences are always more degenerate. Inebriates from homes of wealth, in wealthy sections of cities,

where possible bad ventilation exists, are equally exhausted and worn out. Both of these classes make rapid recoveries in well-ventilated rooms, and seem to have been suffering largely from poisoned air.

Clerks, business men, and persons who have ill-ventilated offices, where they spend many hours each day, are far more inclined to use spirits than others in better surroundings.

A case was reported to me by an eminent New York physician, of a merchant who tried to abstain from all use of spirits at home without success. He worked steadily in his office and lived in a rich house up town, where apparently, every condition of healthy living was present. After several ineffectual efforts to give up the use of spirits; he went out camping in the White Mountain region. In a few days all taste for spirits left him, and for the first time in twenty years he became a total abstainer. On the return to the city he drank again and could not stop. The next season he moved out in the country and all taste for spirits left him. Finally, he gave up his city residence and lives out in the country coming to the city for a few hours at a time, and has become a total abstainer, not having any taste or desire for spirits. It seems most rational to suppose that poisoned air and defective ventilation were the exciting causes of the drink craze in this case. No other condition of surroundings and living could explain his ability to stop drinking in the country and not in the city.

Another incident, well verified, seemed to bring out the same fact:

A delicate, nervous child, supposed to be inclined to consumption, was guarded with extraordinary care against colds and the open air, in a rich city home. At 15 years of age, a strong taste for spirits developed, and at 20 he was an inebriate. His mother died and he was forced to go into the country to live. He became a total abstainer at once, and is now at 26 years a strong temperance man. It would appear that in this case some condition of cell and tissue starvation began from defective aeration, and continued until the surroundings changed.

I think the poison from defective oxidation of the blood, together with imperfect elimination of waste products is a very active factor in inebriety. In all rational treatment, efforts to remove these possible causes should precede all other means of treatment. The continual inhalation of impure and defective air is always followed by the accumulation of poisons, which in many ways unknown, cause reflex nerve disturbances and reactions. The heart contracts more frequently, respiration is accelerated, and elaboration of nutritive material is altered in all the cells of the body. Fatigue, depression and lowered vitality follow. Alcohol at this time is a grateful narcotic, which not only conceals the real condition, but brings increased degeneration with new bacteria formations and diminished resistance to disease. The brain and nervous system suffers as much as any other part of the body although this is not recognized.

The inebriety of any one in poisoned air may be in part or entirely due to this one cause. This can be demonstrated with a very strong probability of correctness. Pauperism, criminality, and the varying degrees of idiocy, with other of the degenerative diseases all are known to originate in a large degree from this source.

We are fast recognizing the fact that diseases of the brain and nervous system are not all the result of mysterious psychical forces. The delirious maniac, the melancholia, or the wild varying alcoholic, all spring from physical causes and conditions that are in many cases as tangible as the germs of typhoid or diphtheria.

The alcoholic or inebriate possessed with the one impulse to use spirits, manifests simply a symptom of some brain condition which seeks relief. The in-

ebriate, as the result of his use of spirits, will neglect all hygienic care and be more or less oblivious to bad poisoned air, bad food, and dangerous environments. Breaking up and changing all these bad surroundings is always followed by an improvement, and if the surroundings and conditions of living can be kept up to a high level of health, restoration will follow, simply by the operation of natural forces. Inebriety means, in every sense, poisoning by many very complex agents, both from without and within. Sometimes these agents originate externally to the body, or within the body, and the use of alcohol is a signal flag of danger, a sign of degeneration going on and a demand for relief.

The workmen in a clock factory, employed in a certain room where enamel was used and the heat kept up to a fixed point, were noticed to become beer and spirit drinkers more than all others. For a long time the men in this work were often discharged for drunkenness. It was noticed that they abstained when employed in other factories at other work. The fact was finally made clear that the ill-ventilated, poisoned air of this room was the factor or real cause of the spirit drinking. By changing the room and alternating the workmen the previous inebriety of this class disappeared.

A case came under my observation in which this fact seemed confirmed:

A poor man had three children born in a crowded tenement house where all the conditions of air and surroundings were bad. They were weak defective neurotics; one was an inebriate. Two other children born later, after he had moved into the country, where the conditions of living were excellent, became vigorous healthy persons. It seemed that the bad surroundings of early life had much to do in causing the defects of the first three children, and the later children were vigorous in a large degree from the better surroundings of early life and living.

The efforts of sanitarians to improve and regulate the surroundings of all classes, also point out the dangers from imperfect aeration, are always very effectual measures to prevent and control the evils of drink. Abundance of pure air at all times and places and no oxygen starvation will raise the vigor of the race and increase the resistance to disease, that will show itself in all disease and mortuary statistics.

The fact I wish to emphasize is that in the causation of inebriety there are always to be found many exact physical conditions, which can be seen and controlled. That oxygen starvation is of far more importance than other supposed causes. No amount of training, culture, religious or secular, can overcome the injury from deficient oxygen and the presence of poisonous gases.¹

Reforms carried on down in the slums of crowded cities, or in the palace homes of the wealthy, where the air is vitiated and poor are useless. Medical treatment is equally worthless where the victims live in such surroundings. Oxygen nutrition is of equal importance to that of food, and the brain suffers more quickly from deficient air than diminished food supplies. Those who use alcohol are more incapacitated to take up and utilize the oxygen brought to the lungs. The blood cells, by virtue of the absorption of the watery contents from alcohol, are unable to take up the usual amount of oxygen, and hence the tissues are starved in all cases more or less. Every inebriate is oxygen starved, and like the chronic dyspeptic, whose digestion is impaired and unable to utilize the nutrients of the food, he is unable to ap-

appropriate the oxygen of the air to meet the demands of the body. Both the dyspeptic and inebriate are anemic for the same reason. Both are starved and suffer from diminished nutrition. The more indigestible the food, the greater the debility of the dyspeptic. The struggle with him is always to procure some food that will be assimilated easily, and a vast number of predigested foods and remedies are on the market to meet this condition. The inebriate, in like manner, grows worse in air that becomes more and more vitiated; venous congestion and many other external hints of defective oxygenation are always present.

The failure of the blood cells to absorb oxygen, and the air to supply the oxygen necessary, are conditions that must be overcome if restoration ever follows. This explains, in some measure, why men in prison who are forcibly kept from spirits for long periods often drink to excess the moment they are liberated. The bad air of prisons has still farther increased the degeneration of the inebriate, and made him more incapacitated for recovery.

The experience of all insane asylums indicate a great diminution of all the acute symptoms of insanity where the inmates can go out into the open air freely. One central principle of all treatment of these obscure brain disorders is to promote the nutrition, not alone by food, but by abundant supplies of oxygen. The sick and wounded in the late war recovered more rapidly in tents than in the best hospital buildings, because the supply of air was better and more abundant. I have known excessive drinkers to recover out on the plains herding cattle, and sleeping in the open air—persons who came from luxurious surroundings, and who had tried various means of treatment without success. There can be no doubt that the increased vigor from pure air was an important factor in the causation.

A lawyer of eminence who drank to excess at regular periods of three months, found by accident that the drink craze was milder and more under his control in a summer house high up in the Catskill Mountains. The drink paroxysm was preceded by excessive irritation several days in advance, during which he would stop all business and go to this place. The house was five miles back from the railroad station; this distance he would walk, and after a sponge bath retire in a large barn room with no windows, if it was summer. The next day would be spent dozing in the open air, heavily clothed, on some high mountain peak. On the third or fourth day all desire for spirits would disappear and he would recover. In the winter he would sleep in an open wood-house, and seemed to crave the stimulus of the open air. For four years this man has been able to remain free from drink, and he is firmly convinced that it is particularly due to the pure air of the mountains. After any special exertion and debility from overwork he goes up to this mountain place and spends a few days entirely in the open air and returns restored.

I have seen many cases where persons who had been inebriates previously, declare that in certain surroundings they could not abstain. A lawyer always drank after trying a case in a certain court room which was badly ventilated; a mechanic drank daily in a certain factory; in another factory of the same class, higher up the stream in excellent surroundings he could abstain. In both cases the impression prevailed that it was entirely due to the different air. How far this is correct it is impossible to

determine. This impression is very positive in the minds of many people, and the only tangible reason for it is the previous poor surroundings they have lived in.

Vegetarians and others who have extreme confidence in the power of selected food to prevent disease and lengthen out life, often overlook the value of oxygen and pure air. They fail to recognize the complexities of foods, and the inability at present to understand their relations and values. The air we breathe is far more tangible, and its effects can be studied and realized with more certainty and exactness.

A society of aerationists, who would seek to show how disease could be prevented and life lengthened by always breathing pure air, would do some real work for the elevation of humanity. Specific hunters and reformers will find an open field and unlimited scope for research in the study of the air we breathe and its influence in increasing or diminishing disease. That inebriety is caused by bad air in some cases, and is largely influenced by both good and bad air in all cases, is a fact unquestioned. That in the study of the causes of inebriety and its treatment, the questions of the air and its quality which have been used are of great importance there can be no doubt.

Rational medicine demands a study of all conditions of living and surroundings in the questions of diagnosis; it demands that disease and diseased conditions should be regarded as physical entities, and that causes tangible and preventable be sought and found; then the questions of treatment will rise above the present empiric methods and become an exact science, in which means and measures can be applied along lines of natural laws.

STATE MEDICINE; ITS RELATION TO PATENT MEDICINE.

Read in the Section on State Medicine, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY SAMUEL P. DUFFIELD, M.D.

DEARBORN, MICH.

At the request of your esteemed President, Dr. Geo. W. Stoner, I have prepared a few notes for your meeting, on which I hope your honorable body will not only take action, but also bring the matter before the appropriate committee of the general body of the ASSOCIATION in such a way that a remonstrance may be forwarded to the Attorney-General of the United States, asking him to rule in the matter and take such steps as will best put a stop to the dangerous and fatal methods of dispensing medicines through the mails or otherwise.

I will, therefore, without any preamble and as briefly as possible, detail the cases which have called forth this paper, and without any appeals or moralizing leave the matter in your hands, feeling sure such a statement of facts will be well weighed and acted upon by your honorable body.

On Sept. 1, 1892, in the city of Detroit, a married lady who had previously been in good health, called for help as she was taken suddenly and seriously sick. She was attended by one of our reputable physicians who soon called one or two others in consultation. She was taken with spasms and they increased rapidly and in greater severity up to the time of her death. As these physicians had not administered any drug which could have provoked such a state of affairs, and as they were at a loss to determine what was the cause of death, I was consulted, being the health officer of the city at

that time. At their request I viewed the body and heard their descriptions of the form of convulsion or spasm which resulted in her death, and without giving you the reasons in detail, I decided that she had died of poisoning by strychnia or its salts. One of my consultants took exception to my opinion, and while the others indorsed it as the only plausible cause of death, I deferred acting in the matter until they had made a post-mortem and assured them that should they not find any cause of death in the body, I would myself in my private laboratory make a full toxicologic analysis of the organs of the body (the stomach and liver and see if we could in any way solve the mystery which seemed to shroud the cause of death. On Sept. 2, 1892, about midnight one of the physicians brought me the stomach in a clean Mason jar tightly sealed, with the request to proceed with the matter as I judged best.

On examination of the stomach I found it to contain some grapes and some cake, a light supper, which was only partially digested.

A carefully conducted analysis enabled me to detect the presence of the alkaloid strychnia and the separated poison was used to produce the characteristic spasms in a *rana esculenta*, common frog, and resulted in his death. I had in addition all the chemical tests which identify and detect strychnin. As soon as I had arrived at this point, I communicated the fact to the coroner who began the legal investigation of the matter. The detectives were set at work to find where the poison had been bought and by whom. They could not find that she or her husband ever purchased strychnia from any drug store and it was evident that it had not been prescribed by any of the physicians.

I asked the husband who seemed to feel that a cloud hung over him, and as if my detection of the strychnia in his dead wife's stomach was a false accusation of him, not to say casting reflections also upon his wife, to bring me all the medicines which were in the house and of which she had partaken. Medicine after medicine was analyzed without finding any poison, and one daily paper even opened its columns in a tirade against the health officer for suggesting such an idea. I still insisted the woman had been poisoned. One day the husband brought me some ovoid, pink, sugar-coated pills put up in a wooden, turned box with the remark: "I do not suppose, Doctor, that these will do you any good. I know she took these as a tonic and they did her good." I began the analysis and had enough strychnia in one pill to meet all the definite chemie reaction, and another pill produced the physiologic action upon a frog. The pill contained a salt of iron and strychnia and the mystery of her death was solved.

The coroner's verdict was that the woman had come to her death by taking these pills probably in larger doses than intended, not knowing the contents to be poisonous.

The wrapper and directions of this patent medicine gave no intimation that it contained such a potent alkaloid. It has been and now is advertised through the daily papers as doing more than any doctor's prescription could do. (We admit this for it killed this woman.)

The proprietor of this medicine called upon me, bearing letters of introduction to me from two prominent wholesale drug houses of Detroit, assuring me he was a gentleman and worthy to be treated as such, and that he desired to have a private consultation with me. In that private consultation he stated he had built up a large trade which was bringing in a good revenue and that this analysis I had made would hurt him severely, and intimated that I was in danger of getting prosecuted. I replied that there was a higher moral duty I had to perform and that I felt no fear. He said that they did not put it in such quantity as to be poisonous in the dose assigned. But he admitted that they did not state these pills contained strychnia. I understand he has sold out for a handsome sum to another firm who still manufacture. This ASSOCIATION could do no better work than to try and have the contents of these drugs printed upon them, and the Patent Office should not issue a patent to *any one* for a general public medicine which contains such potent alkaloids as strychnin, aconitin, atropin, colchicin, pilocarpin, etc.

The second case has not resulted in physical death but its bearing is of such a character that I think you will admit it produces a moral gangrene which leaves the patient in worse condition sometimes, than death.

Of late, these men who benefit humanity (at \$10 a case to start with), have been using the mail for their deceptions, and I was a committee of one, detailed to investigate. I made the investigations and analyses which proved that the main drugs they used were lupulin, for quieting nervous conditions; pills containing aloes and iron, and a sugar-coated pill of phosphorus which was to restore "lost vitality"; they did not say anything about "lost morals."

Their circulars, etc., I put up a *straw man* to get, and I give them to you as Exhibit A, and Exhibit B. They are for the committee to read and act upon, not to be reproduced in print.

By addressing the Attorney-General he was induced to refuse them the use of the mails, and for a short time we had them shut out of the mails. I understand lately that Roberts & Compton, those who sent out the sugar tablets, went to Washington with their attorney and admitted they had not been doing right and now proposed to resume upon the plan of first getting their patient and then prescribing for him. I understand that they have spent nearly \$2,500 and are about to start again. The arch fiend,—Page, whose circulars are in the exhibit, encouraged by the success of the sugar tablets, made an effort and has had his order revoked, and his old advertisement is again seen in the papers.

The Attorney-General for the Post Office Department took the ground that their method of doing business was not that of honest institutions, without reference to the remedy, and on that basis issued an order. The magnitude of the business will surprise you. Page alone, has cleared it is stated \$100,000, starting from nothing.

Just what point or argument was used to induce the Attorney-General to rescind or suspend the order, I am unable to say. There is now a bill before the committee in Congress looking to the exclusion of all such advertisements, but these men in this lucrative business have, it is said, a powerful lobby at Washington and I should fear unless our ASSOCIATION takes hold and memorializes Congress that the bill will never get out of the committee. Perhaps the better way would be to have the AMERICAN MEDICAL ASSOCIATION through the Section on State Medicine appoint a committee to look after the committee in Washington.

Is it not a deplorable state of affairs, when the Patent Office issues the right to manufacture and sell medicines so powerful that they work death to an innocent citizen, and when the Post Office Department becomes a common central sewer into which such filthy advertisements of a medical deception are freely poured without let or hindrance? "*Amicus Plato sed magis amica veritas.*"

International Courtesy.—Dr. William Osler, of the Johns Hopkins, in speaking on behalf of the visitors at the recent meeting of the British Medical Association, said that he hoped that consideration would be given to the idea of holding a meeting of the Association at Montreal in the course of a year or two. They would, he assured them, receive in his native town as warm a welcome as had been accorded to the members of the British Association for the Advancement of Science.

THE PHYSICIAN AND THE STATE.

Read in the Section on State Medicine, at the Forty-fifth Annual Meeting of the American Medical Association held at San Francisco, June 5-8, 1894.

BY CHAS. E. WINSLOW, M.D.
ALBUQUERQUE, NEW MEXICO.

"An ounce of prevention is worth a pound of cure," is a truth that can not be gainsaid. The Great Physician had that in view, when from Sinai's Mount he gave Moses the sanitary laws that were to govern the Hebrew children.

If laws for public health were necessary, then, how much more are they needed now. With the great advance in intelligence, ways of living have changed which call for better sanitary care. The onward march of civilization has blotted out the plague and pestilence of olden times, but with this new civilization have come new diseases, which must be controlled by the best scientific methods of the times. A large amount of the sickness that falls to the lot of humanity is preventable. The value of preventive medicine has been repeatedly proved. More people die of disease caused by neglect of the laws of health than by war.

"A little fire is quickly trodden out, which being suffered, rivers can not quench." From squalid surroundings may spring diseases that will spread, destroying thousands of lives; epidemics that come as punishments to communities for neglecting the rules of health must be stamped out at once. Many sin through ignorance, but thinking men are beginning to realize that the question of preserving the public health is one of the first duties of a civilized people. Let an army threaten to invade our shores, and the people with hearts aglow with patriotism will spring to arms, offering money and lives to their country.

When danger of pestilence and death threaten us, then should we rise in our patriotic might and drive it from our land. The best way to prevent war is to be prepared for war. The best way to prevent disease is to be prepared for disease. Then build the bulwarks and arm for the invasion before an epidemic, carrying destruction and death, like a mighty army sweeps down upon us.

Few men appreciate what good sanitation means. Public attention must be awakened to the knowledge that sanitation means less sickness and longer life, that it preserves health and prevents disease, that unhealthy men make an unhealthy nation. A ruined castle may be picturesque but a ruined man, temple of God, is a sad spectacle. The glory of man is his strength, and to preserve that strength is a glorious victory.

Man owes certain duties to man that must be acknowledged. He did not make himself, but he can help preserve what God has given him. Every man and every class of men has a niche to fill in this republic. The business men of America are planning and striving to better the financial condition of the nation; the mechanics and laboring men are working for the physical comfort of our homes; the pastors, on sanitary principles, attempt to prevent their flocks from suffering the burning fevers of hell; the lawyers are busy tangling and untangling the complicated affairs which mankind is heir to, while the physicians aid them all, working for the "greatest good to the greatest number." Some one has said "public health is public wealth." Show to the

business man that disease obstructs business, and sacrifices lives that are valuable to the State, prove to him that sanitary reform will save money and lives and he will listen to you.

The American people, notwithstanding Barnum to the contrary, do not want to be humbugged. They are seekers after truth, though having been deceived so often they are inclined to be suspicious. Come to them in an honest way with honest figures.

The Government must be taught that it is economy to keep the people of a community in good health, for though an epidemic may be confined to one section of the country, its effects are felt upon the life and commerce of the whole nation.

It is a fact that healthy nations are wealthy nations, proving that public health is of great commercial value. This being true, is it not worthy of a place in the Cabinet?

To build a substantial structure we must commence with a good foundation; to build up a nation of strong healthy people, we must begin with the children. There are hundreds of thousands of youth in this land of ours whose minds are being filled with knowledge. What an opportunity to sow the right kind of seed! Then "what will the harvest be?" Give them common sense text-books that teach them the true way to preserve health. Do not cram their little brains full of all the hard names in anatomy and physiology. Make the study of sanitary science simple and attractive. Mix it all through the education of the youth, weave and interweave the principles of hygiene in the studies until the young men and maidens are saturated with ideas of how to preserve their health. Then they will exert an expanding influence that will be felt, not only in the present generation, but by the millions to come. Body and mind must be developed together. Have a department of public health in every college, that while the youths are growing in intellect, care will be taken that they develop strong healthy bodies.

We, as a nation, need to exercise the greatest care in regard to our sanitary laws, on account of the thousands flocking to our shores coming as they do from every clime, many being the very scum of other countries, coming from districts tainted with epidemic disease, which only slumbers waiting to be awakened.

The study of public sanitation brings the physician into closer relation with the masses. The people must be taught. Often those who are considered authority on other subjects are ignorant in regard to public health. The physician must be the educator; then to the work. "Be instant in season and out of season," "here a little, there a little," shoulder to shoulder, pressing forward to the "mark of our high calling," elevating the medical profession, and raising the standard of the people in general, instilling into their minds the laws of good health until in every nook and corner, hovel and mansion, Hygeia reigns supreme.

Every physician should be a wise impulse to enthuse the people along the line of sanitation. It is the duty of every true physician to prevent as well as to cure disease. While the duties of curative medicine give the active practitioner time for little else, yet his influence dropped here and there will be seed that may find root in good soil and bring forth an hundred fold.

Medical intelligence has produced great changes in

medicine, and necessity has been a great stimulus in seeking after truth. In the wonderful advance of the science of curative medicine, we must not forget the science of preventive medicine. While the causes of disease may be difficult to discover, the conditions favoring disease are known. Every citizen has the same right to be protected from disease as from violence.

It is unjust to endanger health and life by defective drainage, impure water and poor ventilation. The physicians are the conservators of the public health. They can advocate the best sewerage system, and quietly produce a public sentiment in its favor, impressing upon the communities that impure water is detrimental to good health.

The medical men came into existence because of the Macedonian cry for help, and they must accomplish the object for which they came, working earnestly and wisely to free man from sickness and suffering. Let us put on the whole armor and fight the invasions of the enemies of mankind,—standing between the people and danger, protecting our homes and our native land; ever in the front, fighting boldly all that tends to lower the vitality of our nation, aiding all that will better the condition of men, living so that in dying we leave behind us the imprints of our lives in a more healthy, moral and stronger race of men. Let us be thinking men, keeping up with the onward march of civilization, not hinderers but helpers in progress, making our profession grander and nobler for having been one of the number.

To-day we can advance new ideas in regard to medicine without fear of torture or imprisonment, but we must carefully weigh our theories, and before giving them to the public, be sure that the facts obtained from our investigations are accurate, for "human experience proves that all false systems fail," and we can not afford to be crushed in the failure. We may be called visionary, but if we are in the right we shall expose some false and evil ideas.

A true physician is a reformer in his profession, always searching after truth, never knowingly aiding an injustice, nor endangering another's health. To allow a preventive disease to come, and make no cry of warning, is an injustice to the people.

The relation between the physician and public can not be too closely connected. The masses look to the physician as authority on medical knowledge. He who professes to try to prolong human life and ameliorate the sufferings of humanity, should be well qualified to advise in regard to all rules of health.

The public must be protected from medical impostors. Medicine must be elevated by the medical man alone. It is his duty to protect the ignorant from the quack, for ignorance and quackery go hand in hand, and like the "blind leading the blind both will fall into the ditch."

To protect the state, the state must protect itself by making and enforcing such stringent laws that an uneducated and unprincipled physician will be unknown. While many of our States have fairly good laws they are far from perfect. Let us diligently strive to create a public sentiment electing those to office who favor such laws, and demanding from our law-makers protection for the people. "If, at first we don't succeed, try, try again" until the legislatures, like the unjust judge, grant our request because of our importunity.

Nothing is so important to a nation as public health, and yet our government recognizing the importance of public school and charitable institutions does not realize, as it ought, the necessity of protecting our inhabitants from disease and death. The Government has financially encouraged the experimental study of the diseases of domestic animals, assisting those in that department, until the contagious diseases of animals have been almost stamped out. In agriculture the Government, and nearly every State spend large sums of money in experiments. Not one dollar is spent for experimental study of prevention of disease in the human family.

Is it just to endanger the lives of the American people, when it is well known that whole tribes and races of men have been swept away by epidemics that could have been prevented? No objection can be made to the use of money by the Government in researches that will benefit the nation. To be just to all it should lend its aid to find out why yellow fever, cholera and other epidemic diseases seem to have a preference for one location and not another; why one season of the year and not another; what produces and propagates different diseases and what will control them. Then prevent the spread of disease by official measures. If the improvement and preservation of plant and animal life are important enough to need a representative in the Cabinet, vastly more important is that which prevents sickness, prolongs life, protects homes, uplifts humanity, adds wealth to the state, and is the life blood of the nation.

Human rights, in the name of justice, demand a Secretary of Health.

As we meet here to-day coming from all parts of the nation, casting our mites into the tithing box, exchanging ideas and gathering golden thoughts, laying up a fund from which to draw pleasure and profit, aiding in building up the noblest profession God has given man, let us exert an influence that will grow in power until the nation rouses and "old things pass away and all things become new," expanding "more and more unto the perfect day." Let us press forward, onward and upward, growing broader minded in regard to our views of humanity, true to self and true to state, for:

"A wise physician, skilled our wounds to heal,
Is more than armies to the public weal."

A FEW REMARKS ON LEPROSY.

Read in the Section on State Medicine, at the Forty-fifth Annual Meeting of the American Medical Association, held in San Francisco, June 5-8, 1894.

BY H. S. ORME, M.D.

LOS ANGELES, CAL.

Owing to failure in receiving replies to several letters of inquiry and to other pressing demands upon my time, I have been unable to complete the supplement to my former report on leprosy, which I expected to offer at this meeting. I shall, however, add a few facts and observations to what was written four years ago.

Since 1890, evidence has been accumulating in favor of the theory then advanced, that the most important factor in the causation of leprosy is contagion, and it is now generally admitted that it is the only factor deserving serious consideration. The most noteworthy testimony to this effect is the report of the Indian Commission of 1892, based upon in-

vestigations made the previous year. The most important conclusions reached were that leprosy is not kindred to syphilis or tuberculosis, that it is contagious, and that it is not diffused by hereditary transmission.

They also report that the disease is not increasing in India, but apparently slowly decreasing, though no adequate measures of segregation are practiced. The explanation of this paradox is, that the people have long been acquiring a tolerance and resistance on the principle of natural selection and survival of the fittest. There is ample reason to believe that the same principle applies to other diseases. Even during the present generation, syphilis has become milder than it is remembered by some of the oldest now living.

The ravages of smallpox among the Indians of the United States have at times almost swept away whole tribes, during its earliest visitations; but among the natives of New Mexico who are substantially the same race, but who have been almost constantly subjected to its influence more than three centuries, it is so far from formidable that mothers voluntarily expose their young infants in order that they may take the disease and be through with it before they are weaned.

But I do not regard this observation as justifying the let alone method of dealing with preventable diseases of a dangerous nature. There is abundant proof that the plan of segregation will in time cause leprosy to disappear, provided it be enforced (rigorously). Though not carried out with absolute strictness in Europe during the Middle Ages, the results were so nearly perfect that the belief in its contagiousness gradually died out, the restrictions were relaxed, and the re-appearance of the disease in successive generations in certain families of the lowest class led to the theory of inheritance.

In the present period the plan of segregation in Norway and New Brunswick, though not enforced with absolute rigor, is causing a gradual diminution of cases, and the same effect has begun in the Hawaiian Islands.

Between 1856 and 1880, the number of lepers in Norway declined from 2,863 to 1,582, as I showed in my report of 1890.

At the focus in New Brunswick the number of lepers in 1875 was thirty-six; in 1885 it was twenty-five; and a recent letter informs me that the number in 1894, is twenty-one in hospital and three at large.

It has disappeared from Tracadie, where it was most prevalent a few years ago, but new cases have appeared in surrounding districts. Isolation is now practiced more strictly than before, and the authorities expect to stamp out the malady more rapidly.

The let alone policy is illustrated by the recent rapid increase of leprosy in the United States of Columbia. In two of these states alone, the number of lepers is estimated at 30,000, and the Government is now considering the advisability of planting a leper colony on one of the islands off the coast.

We are informed that a hospital for lepers has been established at Rio de Janeiro, equipped with a laboratory for study of the disease.

At the present time Louisiana contains probably more lepers than all the other States of the Union together, except perhaps California or New York.

It is recently reported that there are thirty-five to forty lepers in the city of New Orleans, and about

fifty more in three of the parishes (counties) situated in the southern part of the State. In 1889, forty-two cases were found in New Orleans, and fifteen to eighteen cases were traced in the country, with the probability that more were undiscovered. It is believed that the disease has existed for several generations among certain families of the lowest class of Creoles in Southern Louisiana. In 1892 the State Legislature passed an act of which the following is a copy:

An Act to prevent the spread of leprosy and to provide for the treatment of the same and for isolation of persons afflicted with said diseases and penalties for non-compliance with this Act.

SECTION 1.—*Be it enacted, etc.,* That whereas the disease known as leprosy which is contaminating and dangerous to public health and welfare, exists in this State and that persons afflicted with said disease are permitted to be at large thus endangering public health,

SEC. 2.—*Be it further enacted, etc.,* That all persons afflicted or suffering with said disease of leprosy shall be confined in an institution isolated and used for the treatment of said disease. And it shall be a misdemeanor for any one to harbor a leper or lepers and the penalty to be imposed upon any one harboring said leper or lepers and refusing to commit them to the care of said institution shall on conviction before any committing magistrate in this State, be subject to a fine of not less than \$5 nor more than \$25 or imprisonment for a term not exceeding thirty days. Said fine shall go to the support of said institution and said party so found to be a leper, shall be committed to said institution. That whenever it shall be made known to the judge of the district court by the petition and oath of any individual, that any person afflicted with leprosy within his district ought to be sent or confined in said institution, it shall be the duty of said judge to issue a warrant to bring before him, in chamber, said person so afflicted with leprosy, and after proper inquiry into all the facts and circumstances of the case, if in his opinion, he ought to be sent to or confined in said institution, he shall make out his warrant to the sheriff of the parish, commanding him to convey said leper to said institution: for which duty the sheriff shall be liable and have the right to demand the same fees as are now allowed by law for the conveyance of insane persons to the State Insane Asylum, which shall be paid out of the parish treasury upon the order of the district judge, and likewise all other expenses previously incurred in bringing said person before the district judge.

SEC. 3.—*Be it further enacted, etc.,* That the buildings and institution situated in the city of New Orleans in this State now used, or that may hereafter be used, selected, or directed to be used for the care of and treatment of leprosy, under a contract with the city of New Orleans, by virtue of an ordinance No. 5785, passed and adopted on March 31, 1891, shall be the institution to which lepers shall be sent and committed under the penalties provided for in Section 2, of this Act.

A number of lepers have been gathered into a hospital at New Orleans, where they are maintained on a contract with a certain physician at a charge of \$25 per month.

At the date of my information (January, 1894,) this number was only ten, and this arrangement could not be regarded as a successful mode of dealing with the case.

In California, several unsuccessful efforts have been made to obtain an appropriation from our Legislature for a State leper hospital. The law requires lepers to be kept apart from the other population, and the burden of their maintenance falls on the counties. No one of the counties or cities has a special hospital which deserves such a name.

Most of the known lepers in the State are kept in a hovel which stands on the same grounds as the smallpox pesthouse in San Francisco, and the two classes of patients intermingle at will, whenever cases of smallpox are sent there.

This method (if method it be) of dealing with these two loathsome diseases in our metropolis, is in the highest degree discreditable to a great and wealthy city.

Whenever it is found practicable, the Chinese and Hawaiian lepers are shipped back to their native countries, as the easiest method of disposal of troublesome subjects. At present there are fourteen inmates of the leper quarter.

As to the control of leprosy, therapeutics still affords us no hope. Segregation has succeeded in the past, and will succeed again, though it involves individual hardship.

It seems probable that contagion is to be apprehended only from cases of the tubercular type at a stage when open sores exist, and that others need not be deprived of their liberty.

In my judgment, however, all lepers should be legally registered and kept under surveillance by the sanitary authorities, so that they may be isolated whenever necessity occurs. The law might provide for periodical inspection, and certificates of the same to those allowed to be at large.

RESTRICTION OF TUBERCULOSIS.

Read in the Section on State Medicine, at the Forty fifth Annual Meeting of the American Medical Association held at San Francisco, June 5-8, 1894.

BY J. H. DAVISSON, M.D.

MEMBER OF CALIFORNIA STATE BOARD OF HEALTH; MEMBER AMERICAN PUBLIC HEALTH ASSOCIATION, ETC.

Tuberculosis is the great enemy of the human race,—one-seventh of the entire human family die of tuberculosis.—(Koch). But little progress had been made in prophylaxis or treatment until the discovery by Koch of the pathogenic germ, the bacillus tuberculosis, which he announced to the world in 1882.

The bacillus tuberculosis is "parasitic, aerobic, non-motile, and only grows at 37 degrees C."—(Sternberg); though certain bacteriologists of the French school say it thrives even better at 39 degrees C. The thermal death point of the bacillus tuberculosis is about 70 degrees C.—moist heat—but it was formerly believed to be much higher, even 100 degrees C. The unstained spaces in the preparations of the bacilli under the microscope are generally believed to be spores, but the question of sporulation remains unsettled as the non-resistance of the bacillus to chemical agents, and having such a low thermal death point, would not indicate the existence of spores.

The bacillus being strictly a parasite does not grow or propagate outside of animal bodies, though certain animals, indeed a large number of the mammalia are immune. The human species, bovines and monkeys are more susceptible to the action of the bacillus tuberculosis than other animals. The period of viability or potential period of the bacillus tuberculosis, as it is found in dried sputum in residences, public buildings, and thoroughfares, where hidden from the sunlight, is about three months. De Tonia and others have found it potential after nine or ten months.

It is needless to say that it is now definitely settled that every case of tuberculosis in man or other animal, like every case of typhoid fever or Asiatic cholera, is due solely to its own pathogenic germ, and derived from a previous case. No one now believes in heterogenesis, as every circumstance connected

with origin, development and progress of tuberculosis goes to prove the correctness of pathogenesis, as in typhoid fever, Asiatic cholera, and other infectious and contagious diseases. Dr. Flick's analysis of the mortality of the Fifth Ward in Philadelphia constitutes a most striking example of the infectiousness of tuberculosis.

Tuberculosis has always been regarded an hereditary disease, but since the discovery of the specific bacillus we have learned that tuberculosis is not inherited but is due to infection. That peculiar condition of the organism which lacks immunity to tuberculosis and renders one susceptible is inherited. While the greater number of individuals are born immune, many conditions of ill health and traumatism lower vitality, and render many others susceptible to tubercular infection by destroying native or innate immunity.

Human tuberculosis of every form then is directly due to inhalation, ingestion or inoculation of bacilli derived from mammals, either taken in with the air we breathe, or with food or drink, or by kissing, or by handling infected articles, as money, toilet articles, furniture, etc., or being otherwise inoculated with tubercular bacilli. Probably the larger proportion of cases of tuberculosis originate from the inhalation of the bacilli in desiccated and pulverized sputum which floats in the air as impalpable dust, in apartments and in the open air, producing pulmonary phthisis generally.

Next in order of frequency comes the immense number of cases of the numerous forms of tuberculosis from ingestion of infected food and drink—especially milk. Among this class are to be found most of the tubercular infants and children with tubercular meningitis, tuberculosis of glands, joints, bones, etc., the direct result of infected milk.

The third class, and probably the smallest number, in the light of existing knowledge on the subject, includes all cases otherwise infected or inoculated.

Many people look upon the restriction of tuberculosis by legal methods as tyranny and not consonant with our highest civilization; but this first thought or impression is soon dispelled by an understanding of the *rationale* of infection and correct methods of sanitation and its results. The restriction of tuberculosis by offensive legislative enactments being placed upon the subjects of this chronic, infectious, and eventually fatal malady is erroneous. Certain reasonable legal restrictions should be placed upon tubercular patients, but principally upon others with whom they have to do. A strict quarantine should not be placed upon intelligent, rational and cleanly patients who willingly conform to the demands of sanitation which offers the surest means of preventing auto-infection, and security to the family and the country at large. It is a mistake to think that society is not ready for restriction. Society has long since been educated up to the point of absolute quarantine against all other infectious diseases, as smallpox, cholera, yellow fever, etc., diseases comparatively less fatal and by far less frequent—indeed society clamors for restriction of all such preventable diseases; but the legal restriction of a disease as surely preventable, so universal and so fatal, confronts the sanitarian with many difficulties, chiefly imaginary, that thorough education of the masses by official bulletins and other literature, by boards of health, can remove in a little time. Legal re-

strictions should be placed upon hotels, lodging houses, dwellings, public buildings and public thoroughfares, as railway coaches, sleepers, steamships, sailing vessels, omnibuses and other public conveyances. All such apartments and common carriers should be so furnished that under rigid sanitary rules they should be thoroughly disinfected immediately after occupancy by tubercular patients. Tuberculosis is not infectious until it is apparent—as during the third stage of pulmonary tuberculosis, or when breaking down and ulcerating and discharging, in affections of the glands or bones—and is not communicated by the breath of patients. Notification, registration and disinfection after death, removal, or recovery, should not be deemed hardships in the face of so much danger, even to members of the household.

If patients in the third stage of pulmonary tuberculosis will persist in traveling, it should be unlawful to infect highways, public buildings and thoroughfares, etc., by spitting broadcast, as is usually done, but such patients should be provided with suitable sanitary cuspidors, or they should be supplied with handkerchiefs of cheap and suitable material, to be used but once and then rolled up and burned at the first opportunity. The roving of such patients in the vain hope of regaining their health—often by the advice of a physician, but generally at the suggestion of some would-be friend who knows absolutely nothing of the case and generally less of the country or climate to which he presumes to direct the sufferer, is to be condemned as dangerous to the public health, and bad treatment for the patient. Many of these unfortunates, in the third stage of consumption, and beyond all hope of recovery, roam the country over, planting germs of disease and death in their tracks, and subjecting themselves to all manner of hardships and unscientific treatment at the hands of unscrupulous advertising charlatans, to die away from home and among strangers. Keep such patients at home for their own sakes and keep them at home for the sake of others.

The segregation of tubercular patients in hospitals, both private and public, is to be encouraged. While it is true that with perfect sanitation tubercular patients do not spread infection, even though they are intimately associated with others, yet segregation in hospitals, hotels, restaurants, lodging houses, asylums, prisons, dwellings, and in common carriers, is necessary until the masses are thoroughly schooled in the technique of sanitation.

"A person suffering from tuberculosis can be made entirely harmless to those about him by thorough sterilization of all broken down tissue immediately upon its being given off. With proper precautions it is therefore possible to live in the closest relation and upon the most intimate terms with consumptives without contracting the disease."—(Report of Committee American Public Health Association, 1893.)

I am in full accord with Dr. Baker, the efficient Secretary of the Michigan State Board of Health, in the idea that no State charity can accomplish more good results to mankind than a State hospital for the care, treatment and prevention of tuberculosis. By it the indigent consumptive can be infinitely better cared for and at less expense than now done, and all classes of society protected from this prolific source of infection. Private hospitals for the care and treatment of cases among the well-to-do, rather

than sending them to the numerous health and pleasure resorts, would give much better results, as far as the patient is concerned, and restriction would be accomplished without objectionable features. Such institutions would have every facility for treatment and the perfect sanitation of such places would lessen auto-infection, so common among tubercular patients. These sanatoria should be located in climates and localities adapted to the purpose, and in the country in mountainous regions and at altitudes of about 2,000 feet, since the best results have been attained in climatic treatment by Loomis, America's greatest climatologist, at 1,800 to 2,000 feet in this country.

The question of altitude, in the treatment of tubercular consumption is in great part determined by locality or country and peculiarities of topography, meteorological conditions and climate. Tranquillity of the nervous centers, with consequent refreshing sleep, together with absence of cardiac disturbances and lessened tendency to hemorrhages, commend the relatively lower altitudes in California and many other climates in this country, barring the disturbances of the nervous and circulatory systems, the higher altitudes of the Rocky Mountains, so ably set forth by Dr. Denison, of Denver, in many articles and reports, form notable exceptions to this rule. While in Europe many of the best climatologists regard altitudes below 4,000 feet as only preparatory to higher altitudes—as does Dr. Denison—and secure the best results at from 4,000 to 6,000 feet, or more.

In corroboration allow me to quote from Dr. S. Jaccoud's original article in the *Medical Week*, March 9, 1894, as follows: "Undoubtedly by reason of its location both toward the north and east, the climatic conditions of Görbersdorf, Brehmer's admirable creation in Silesia, in spite of its low elevation (1,827 feet), are closely analogous to the conditions prevailing in Switzerland at a height of 4,200 to 4,600 feet, and the tonic action is in every respect similar."

The dairy is now known to be one of the prolific sources of tubercular infection and Dr. Salmon, Chief of the Bureau of Animal Industry, states that about 3 per cent. of dairy cows near our large cities are tubercular. In a report to the Provincial Board of Health, Toronto, Dr. Brice, the Secretary, says that 4.5 per cent. of cattle slaughtered in Berlin were tubercular; 9.5 per cent. of those in Upper Silesia; and 12.22 per cent. of 12,000 cattle killed in England under the Pleuro-Pneumonia Act of October, 1890, as determined post-mortem.—(JOURNAL AMERICAN MEDICAL ASSOCIATION, May 12, 1894.)

That milk is often filled with tubercular bacilli, with no apparent disease of the udder, is the dictum of many authorities, hence we should have thorough inspection of cattle and dairy cows by competent veterinarians, and in addition to the usual methods of investigation the use of tuberculin as a diagnostic agent is now indispensable.

Dr. Legay stated to the Congress de la Tuberculose that he had added desiccated and powdered tubercular sputum to milk which he then boiled and then injected into rabbits and produced tuberculosis.—(*National Popular Review*). This teaches another lesson in the important process of sterilization of this most important food product.

The Committee on Restriction and Prevention of Tuberculosis, of the American Public Health Association at Chicago, in October, recommended the follow-

ing resolutions relating to restriction, which were adopted, viz:

"1. The notification and registration by health authorities of all cases of tuberculosis which have arrived at the infectious stage.

"2. The thorough disinfection of all houses in which tuberculosis has occurred, and the recording of such action in an open record.

"3. The establishment of special hospitals for the prevention of tuberculosis.

"4. The organization of societies for the prevention of tuberculosis.

"5. Government inspection of dairies and slaughter houses, and the extermination of tuberculosis among dairy cattle.

"6. Appropriate legislation against spitting into places where the sputum is liable to infect others, and against the sale or donation of objects which have been in use by consumptives, unless they have been thoroughly disinfected.

"7. Compulsory disinfection of hotel rooms, sleeping-car berths and steamer cabins which have been occupied by consumptives, before other persons are allowed to occupy them."

A practical means of limitation of tuberculosis or prophylaxis is thorough drill of the patient, friends and attendants by the physician in charge, and ample rules of technique and literature relating to the disease should be furnished gratis to physicians and nurses by boards of health. The plan of the New York Board of Health, of making bacteriologic examinations gratis for medical attendants, in suspected cases, should not only be generally adopted, but should include other infectious diseases as well.

When we contemplate an annual death rate of 163,500 in the United States from the various forms of tuberculosis, without efficient restrictive measures, we should take courage at reading the following extract from an editorial in our official JOURNAL: "The indisputable fact that its death rate (meaning tuberculosis) has been reduced to one-fifth of its former proportions by rigid enforcement of simple and practicable measures of disinfection, of excretions and discharges of every tubercular patient, and of every material thing liable to be contaminated by such excretions and discharges, is a rift in the cloud through which may be discerned the time when tuberculosis like leprosy and the black death, shall, be of interest merely to the historian of human progress,"—(Rohé).

In a recent presidential address before the Medical and Chirurgical Faculty of Maryland, Dr. Rohé says: "The isolation of patients is unnecessary; when the material containing the tubercle bacilli—in these cases the sputa—is destroyed, the consumptive is no longer dangerous to his most intimate associates." Such positive statements by these and many other most competent sanitarians should inspire the consumptive and his friends to the strictest sanitation as a means of self-defense.

Restriction of tuberculosis is not only justified from the standpoint of sociology but it is also justified from a business standpoint. When tuberculosis is viewed in the light of financial losses to the country and the nation, the logic of results of restriction demonstrates the correctness of restriction as a business proposition. It is rather difficult to understand why no material advancement in prophylaxis has been made, as the contagiousness of tuberculosis has had its believers for centuries. It is also a matter of wonder that after the thorough restrictive decrees of the King of Naples more than a century ago, which seemed to be based upon correct

views of infection, and so effectual—though in some respects overdone—that the medical world did not take up the cue and that the dictum of the Neapolitan Kingdom did not mark an important era in the prevention of tuberculosis; to be rapidly followed with more general restriction.

As announced in a circular letter in November, Dr. J. R. Laine, Secretary of the California State Board of Health, at the second annual State Sanitary Convention, held at San Jose, April 16, 1894, (under the auspices of the State Board), offered the following resolution, which was adopted:

"Resolved, That hereafter consumption (and other diseases due to the bacillus tuberculosis) should be included in the list of diseases dangerous to public health, requiring notice by householders and physicians to the local health officer as soon as such disease is recognized."

Advanced grounds are now being taken in the prevention of tuberculosis in many countries in Europe, and in our own country by various State Boards of Health, and by many cities and towns.

In conclusion, permit me to say that the difficulties of restriction of tuberculosis are in fact chiefly imaginary and pessimistic and will soon give place to reason and thorough sanitation.

TUBERCULOSIS AND ITS PREVENTION.

Read in the Section on State Medicine, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY WINSLOW ANDERSON, A.M., M.D., M.R.C.P., LOND.

ADJUNCT TO CHAIR PRINCIPLES AND PRACTICE OF MEDICINE
UNIVERSITY OF CALIFORNIA; MEMBER STATE
BOARD OF HEALTH, CAL.

Quarantine regulations are enacted and rigorously enforced in cases of cholera, smallpox and other contagious and infectious diseases, while the most dreadful scourge the human race has ever known—a disease which causes the death of more human lives than any and all other infectious and contagious diseases combined—is permitted to spread its frightful ravages without the slightest interference from medical, municipal, State or national authorities, and that disease is tuberculosis. Quarantine is declared against epidemics of a hundred or a thousand cases of cholera or yellow fever, and yet no laws reach consumption, although over 150,000 deaths occur annually in the United States from this disease alone. If this enormous death rate from any one disease does not constitute an epidemic, I should like to know what it might be termed.

To indicate how it is contracted—for it is never inherited—it is only necessary to quote such high authority as Prof. Wm. H. Walsh, of Johns Hopkins University, who states that the bacilli of tuberculosis, among other infectious diseases are found in the sputum. This sputum is dried, pulverized and inhaled. The breath itself is seldom contagious so long as it remains moist, but when it becomes dry it is competent to infect those who breathe it. Tuberculosis is also contracted by contact and absorption as well as by food and drink which has been contaminated by the bacilli.

EARLY HISTORY.

In 1810 Bayle demonstrated that persons having died of consumption exhibited peculiar grayish nodules in various organs of their bodies. Laennec considered these nodules specific of tuberculosis.

Virchow named these tubercular deposits "cheesy infiltration or caseation." Scrofulous enlargements such as glands, were later on considered tubercular. In 1865, Villemin discovered that these cheesy, tubercular deposits would, by inoculation, produce tuberculosis in healthy animals. Somewhat later, Klebs and Cohenheim declared that tuberculosis was a specific infectious disease, contrary to the generally accepted theory of Niemeyer, that consumption, in the main, was a chronic non-specific inflammation of the lungs. Afterwards, Koch in 1881 isolated the microorganism which is now proven and accepted by the scientific world as the specific pathogenic microorganism of tuberculosis.

All wasting diseases of the lungs are not necessarily tubercular. We have chronic bronchitis, bronchorrhoea, chronic cirrhosis of the lungs, etc., with more or less expectoration, fever, sweating and emaciation, which are not due to the bacilli tuberculosis, but the vast majority of cases of consumption must be looked upon as tubercular; and if you will look for the bacillus you will nearly always find it.

The tubercle bacilli, as you all know, are small rod-like bodies having a length of about one-fourth to one-half the diameter of the red blood corpuscle, so that it requires from 7,000 to 15,000 of these rod-like vegetable bodies, if placed end to end, and from 50,000 to 75,000 of them, if placed side by side, to measure one inch. The interior of these rods may frequently be observed to contain very minute colorless spots—spots which do not take up the coloring matter usually employed in staining the bacilli. These are the spores, the most dangerous part, as they are exceedingly difficult to destroy. It is more than probable that the bacilli which we discover under the microscope in the sputum of a phthisical patient, are merely the dead shells or carcasses holding the living spores. The staining of these bacilli is exceedingly simple. Any physician having the slightest doubt of his diagnosis should at once resort to the microscope, as the disease can be arrested in its early stages.

The tubercle bacilli will be found in tubercular sputum, lungs, brain, intestines, spleen, liver, kidneys, glands, scrofulous or tuberculous bones, and in the so-called "lupus," which is in fact nothing but a tuberculous skin. The bacilli are frequently found in chickens, dogs, monkeys, guinea pigs and cattle. "Pearly distemper" of cows is now definitely known to be tuberculosis.

HOW DOES TUBERCULOSIS AFFECT MAN?

It is now agreed that tuberculosis can not, like syphilis, be born in the infant. It must be acquired. Therefore, if acquired, it can and should be prevented. Dr. Billings says that in consumption the specific germ is very rarely, if ever, transmitted; inheritance giving only a special susceptibility to its action. The effect of occupation and bodily condition also plays an important part. This is proven by Dr. Biggs, who shows that out of every 1,000 deaths among farmers only 103 die of tuberculosis, while out of the same number of deaths among printers, 460 die of the disease. According to a report recently sent into the Academie de Medicine, in Paris, giving the statistics of 662 towns in France it is shown that consumption increases in proportion to the size of the towns, viz:

| INHABITANTS. | MORTALITY FROM PHTHISIS. |
|-----------------|--------------------------|
| 5,000- (less) | 2.00 to 1,000 |
| 5,000- 10,000 | 2.16 " " |
| 10,000- 20,000 | 2.71 " " |
| 20,000- 30,000 | 2.88 " " |
| 30,000-100,000 | 3.05 " " |
| 100,000-430,000 | 3.63 " " |
| Paris | 5.00 " " |

Fourteen per cent. of all deaths is from tuberculosis. Tubercular diseases play sad havoc in every civilized country in the world. Statistics show that about *one-seventh* of all deaths from all causes, is due to this same tubercle bacillus. This fact should be firmly impressed upon the mind of every physician and sanitarian, also that an acquired disease must be a preventable one. One-quarter of all deaths occurring between the ages of 15 and 30 years, according to Dr. Biggs, is due to tuberculosis. This would seem to increase the percentage even more, for many children die in infancy and many people die in old age of causes other than tubercular. During the twenty-five years ending 1886, the average annual deaths in England from consumption reached the enormous number of 50,000. During any one year in the United States over 150,000 people die of this disease. And yet we are bound to admit that the disease is a preventable one. Over 30,000 deaths from tuberculosis occurred in New York city during the five years ending Jan. 1, 1893, while all the other contagious and infectious diseases combined, including smallpox, typhus, typhoid, scarlatina, diphtheria, measles and whooping cough, only caused the death of 21,000 during the same period.

The vast majority of cases of phthisis occur in the lungs—why? Because the germs are drawn in during inspiration. Inoculation experiments prove that the first expression of the disease takes place at the site of its inoculation. Extension may then be rapid or slow and become general or remain localized. If inoculation be practiced in the anterior chamber of the eye, the first tubercular nodule will appear on the iris. If it be in the abdominal cavity, there is first a tuberculosis of the abdominal glands and peritoneum. Should the bacilli enter a wound or a scratch on the hand, the first manifestation of tuberculosis will be seen in the nearest lymphatic gland. Consequently, if the germs are breathed into the lungs we have first a tuberculosis of the bronchial glands and lungs.

For several years, Tappeneiner and others, powdered tubercular sputum in the Pathological Institute in Munich and had different animals inhale it. In every case the animal experimented upon became tuberculous. Domestic animals also play an important part in the production of tuberculosis in man. Chickens will eat the sputum of phthisical patients and contract the disease. By eating under-cooked chickens, tuberculosis may be communicated to man, although the disease is claimed to be slightly different. Dogs in like manner become consumptive and may readily communicate the disease by licking the mouth. Fissures and excoriations of the skin may also become infected. The wearing of clothing, earrings, etc., previously worn by consumptives may spread the disease. Laundrywomen have been known to contract the disease from washing infected clothing. Consumptives occupying public positions, such as clerks in post-offices, banks and the like, are dangerous to public health. Clerks in grocery stores and dry goods establishments should not be con-

sumptive, as the dry sputum might easily infect the food and the wearing apparel which they handle. Meat and milk often spread the disease. Cattle frequently become consumptive as manifested in the "pearly distemper," which, it is estimated, affects at least 3 per cent. of all cows. Their meat, as has been proven by Strümpell, is capable of communicating tuberculosis by infecting the intestinal glands with the uncooked bacilli. Billings assures us that one-half to 1 per cent. of all meat sold for food is tuberculous. More frequently, however, the communication is produced by diseased milk. Pallaske in *Virchow's Archiv.*, concludes from a series of experiments that microorganisms are found in 50 per cent. of human milk. Cow's milk frequently contains bacilli tuberculosis and nearly always when the udder presents pearly nodules. This will no doubt explain why so many children die of tubercular meningitis and consumption of the bowels, and yet we have no systematic scientific examination of milk in any part of California. For that matter we have no scientific inspection of any article of food that we consume. Is it any wonder that one-seventh of our deaths is from tuberculosis? One sometimes wonders how it is so many escape! It can readily be seen how easily persons having weakly strumous tendency or diathesis inherited from sickly or drunken parents may become tuberculous. They are certain to breathe in the germs, if not at home from some member of the family, then from the air in the street cars, railway carriages, churches, theaters, the streets and public highways which are sure to contain the bacilli, so long as that filthy habit of spitting is permitted. Our modern sweeping machines are excellent microbe disseminators. Those in San Francisco can be particularly recommended for that purpose.

There is every reason to believe that man becomes infected principally from the sputum of phthisical patients which dries upon the ground, on the floor, linen and other objects. It becomes powdered, and with the dust particles the bacilli float about in the air. Thus we see how easy it is for infection to take place. Sternberg says there can be no doubt that a large proportion of cases of tuberculosis in man results from the respiration, by susceptible individuals, of air containing the bacilli in suspension in a desiccated condition. He also asserts that the germs of tuberculosis may remain in the air for many months and retain their vitality until they find a favorable nidus for multiplication.

BACILLI IN AIR AND EARTH.

According to Billings, bacteria are persistently present in the lower stratum of the atmosphere we breathe, just as they are nearly always found in the upper stratum of the earth. These statements hold good with the exception of high altitudes, mid-ocean and polar regions. Tuberculosis is rare over 10,000 feet and never found over 16,000 feet elevation.

The bacilli most frequently found in the air and in the earth are those of tuberculosis, malignant edema, tetanus, summer diarrhea, anthrax, malaria, diphtheria and cholera. Dr. Osler has estimated that from one and one-half to four billions of bacilli are expectorated daily by every well marked case of phthisis. Carnet examined the dust on the floor, on the walls, in the curtains, etc., in houses previously occupied by phthisical patients, and found it teeming with bacilli. When these were injected into guinea-

pigs, consumption was rapidly established. This is about what we should expect. How could it be otherwise? And yet we move into these houses and occupy the very rooms without knowing or caring who occupied them previously. In prisons the mortality from consumption often reaches as high as 50 per cent. of the total number of deaths. This is easily explained when we remember that the rooms are infected with the deadly germs.

The Imperial Board of Health of Germany have been conducting experiments with dust taken from the floors, walls and seats of passenger cars. They examined forty-five compartments of twenty-one cars and inoculated with the dust so obtained one hundred and seventeen animals. Some of these died within a few days of various contagious diseases, before there was sufficient time to develop phthisis; three of those remaining had tuberculosis when killed five or six weeks after the inoculation; 78,000 bacteria *per square inch* were found on the floor of a fourth class car, and from 16,500 to 34,400 for the same space on the first, second and third class.

INTERMARRIAGE.

Intermarriage of consumptives is one of the most baneful practices modern civilization countenances. Hundreds of deaths occur annually from this cause alone. Not only is the offspring weakly, puny and prone to contract tuberculosis from one or both parents soon after birth, but the husband or wife even if perfectly healthy, will contract the disease from the sick one. I recently saw this exemplified in my own practice.

In 1874 Dr. Herman Weber furnished some startling statistics regarding the transmission of consumption between husbands and wives. He records thirty-nine husbands more or less tainted with the disease who had married healthy wives, nine of whom died with consumption. These nine husbands lost eighteen wives among them, viz: three lost one each; four lost two each; one lost three and one lost four; all of these women were healthy previous to their marriage and died within two years thereafter of consumption.

Ten years later the British Medical Association, wishing definite information on the subject, communicated with medical men in various parts of the world, and received returns to the effect that in the majority of cases the husbands imparted the contagion to their wives, but occasionally the rule was reversed. Servants and nurses contracted the disease from their mistresses and from each other. One case was cited of a consumptive dressmaker who had three apprentice girls from different villages and without any consumptive diatheses, who took turns in sleeping with her. In less than two years these three girls died of consumption.

Compare the foregoing conditions with the care we take in breeding horses and dogs. We go to any expense and trouble to breed healthy full-blooded horses. Stables of palatial pretensions are erected for them in the most salubrious climates. A veterinary surgeon visits them frequently, inspects their food and directs their exercise and the hygienic conditions under which they live. Dogs are similarly cared for and tended and yet, sad to relate, no such care, attention nor prophylaxis is attempted in regard to the human race. It is indeed a sad commentary on the value we place on one of God's noblest creations

when we have to chronicle the fact that more care and more thousands of dollars are expended on a horse or a dog than on the life of a human being. The horse and the dog are carefully mated and cared for during gestation, while man, in any condition, is permitted to marry whom he pleases although loved ones are carried to the grave by the hundreds, and the soil for scrofula and tuberculosis is prepared for generations yet unborn by such unwise, unjust and unjustifiable marriages.

IMPURE FOOD.

Fully as dangerous as the foregoing is the matter of impure food. Last year I had the honor of pointing out, in a paper read before the Sanitary Convention of the State of California, that much of our food supply was unfit for use, as it had not been properly examined. A still greater evil exists in our milk supply of this and many other cities. I have examined many samples of milk, and I am bound to confess that very few of them came anywhere near the standard prescribed in England or Germany, or the standard for pure milk in our own country. But the most dangerous consideration is that of tuberculous milk. Of this I found more than one sample. Several other investigators have corroborated my researches. It is now conceded and capable of demonstration that from three to five cows in every one, are suffering with tuberculosis.

Dr. P. H. Bryce in his report presented to the Provincial Board of Health Feb. 15, 1894, says that from 2 to 3 per cent. of the cattle in the State of New York are afflicted with tuberculosis. This means that there are over 1,200,000 head of cattle in the United States which should be killed. Dr. Bryce further states the relative prevalence of tuberculosis in cattle in different countries to be 4.5 per cent. in Berlin, 9.5 per cent. in Upper Siberia, and 12.22 per cent. of those slaughtered in England under the Pleuro-Pneumonia Act of 1890.

The State Board of Health of California under its distinguished President, Dr. C. A. Ruggles, found more than 50 per cent. of the cows used at the Stockton Insane Asylum infected with tuberculosis in 1894.

Their milk contains the bacilli of the most dreadful foe the human race has to contend against, and yet we have no scientific milk inspection. Butter may also contain the germs as we all know meat does. Who can tell how many cases of *tabes abdominalis* are due to the bacilli-laden milk the infant drinks? Consumption of the bowels is not an infrequent disease in San Francisco, and it has been fully demonstrated that tuberculous milk produces the fatal disease. Not only is this the case with infants but also with grown people. Dr. Olliver reports an instance requiring more than a passing notice. It was in a boarding school for young ladies. In the course of some little time several of the scholars were taken ill with tuberculosis and removed to their homes. Sanitarians inspected the premises. The plumbing was good, the air salubrious and the buildings were properly ventilated. The food and water were found to be wholesome and no cause could be assigned for the disease. Still one after another came down with abdominal or pulmonary tuberculosis until the number had reached twelve. Everything had been examined excepting the milk. This was the last article of food thought of, as it was produced from a large dairy not far away. However, upon investigation the

milk was found to contain tuberculous germs, and as milk was cheap and presumably healthy, the young ladies of the school had been fed upon it *ad libitum*. The cows were next inspected and many of them were found to have "pearly distemper" or consumption. The owner of the herd was forced to withdraw his milk from the market, and not knowing what to do with it he fed it to his pigs. The records show that even the pigs could not withstand the bacilli tuberculosis, as all died from the disease within a year. Suffice it to say that as soon as healthy or boiled milk was supplied to the young ladies' school there was no more consumption. It is asserted, and rightly so, that if bacilli are introduced into the stomach of a healthy individual, they are usually digested or rendered inert by the gastric juice, but how many infants who drink milk are *not healthy*? How many have the necessary resisting power? We all know that there are thousands upon thousands of susceptible cases in every large city, and these are the first to succumb. It is all wrong, it is unscientific, nay more, it is absolutely criminal to allow such matters to go unchecked. We owe it to ourselves, our friends, and to the community at large to enter our solemn protest against the consumption of articles of food, and especially of milk, until they have been carefully examined by competent authorities. Every Board of Health should have the power to appoint competent chemists and bacteriologists to investigate this matter, and thus lessen the mortality from tuberculosis.

ISOLATION OF TUBERCULOUS PATIENTS.

A hundred years ago a law was enacted in Naples which compelled physicians to report all cases of consumption to the Health Department under penalty of a fine of three hundred ducats; a second offense being punishable by ten years' imprisonment. In this way Naples has reduced her mortality of consumption 90 per cent. Improved hygienic conditions and isolation of tuberculous patients in England, has reduced the mortality 50 per cent. within the last few years. Philadelphia, during the eight years just passed, has reduced her mortality from phthisis 20 per cent.

The disposal of consumptives both living and dead is another subject of considerable importance. There can not be the slightest doubt that consumption is communicable from one person to another in the various ways indicated. It can not, therefore, be denied that every consumptive becomes a danger to those around him—a danger to public health. What shall be done with him? Shall we, as intelligent physicians, fully aware of the danger, prostrate ourselves before Allah as do the good Mohammedans in times of cholera epidemic and say: "Let thy will be done; there is no God but Allah?" or shall we stand calmly by with our hands folded and our face to the sun, as do the people of India, imploring protection from Brahma and Vishnu the creator and preserver, that Shiva—the destroyer—does not annihilate us? Rather, shall we not as men, imbued with Western thought and civilization and freed from the trammels of oriental and occidental superstitions, assert our rights as teachers of the healing art, determine what had best be done with the unfortunates who become consumptive? I say, yes, we must protect the public health. In that event we are bound to isolate and care for consumptives so that the disease does not

spread. California is rapidly becoming a great sanitarium for these unfortunates. If we allow them to come to our shores to seek health, is it not proper that we should protect the healthy? Should we not protect our fair sunny shore with its balmy atmosphere from becoming a cesspool of contagion and infection? How can this be accomplished? Not by denying consumptives to come to our fair land to be cured. No; but by proper isolation; by proper regulated sanitarium, giving them all the advantages of climate and hygienic surroundings, rationally constructed buildings and scientific medication.

CREMATION OF CONSUMPTIVES.

What shall be done with the bodies of those who die of tuberculosis? It is estimated that 32,000 persons die annually to every million that are living. This means that 48,000,000 people die annually, of which one-seventh, or about 7,000,000, die of tuberculosis. These figures are almost incomprehensible. Estimating seventy-five pounds to each consumptive's body there are about 300,000 tons of bodies for burial annually. Fortunately they are not all buried; many of them are, as they should be, cremated. The bacilli of tuberculosis have been found in old cemeteries in which no inhumation had been practiced for over twenty-five years. Pasteur and others have proven that the earthworms bring the bacilli to the surface of the soil where they can be found in all cemeteries. It takes from five to twenty years for human bodies to decay, and as millions upon millions of consumptive bodies are continually being added to those already buried, the result must be self-evident, and instead of one seventh of our population dying—as they do now—of tuberculosis, it must of necessity increase. Something must be done, and that before it is too late.

The Mosaic laws direct that all lepers be driven out of their houses and their effects burned. What leprosy was to Moses and his people, and is to-day to the Hawaiians, tuberculosis is to the American people—the greatest scourge the human race has ever encountered.

RULES FOR THE PREVENTION OF TUBERCULOSIS.

Comprehensive and efficient means should be adopted for the prevention of tuberculosis. I will recommend the following:

1. Educate the public to a proper understanding of the communicable character of tuberculosis. Teach the people how they can avoid contracting the disease themselves and how they can prevent transmitting it to others.

2. The promiscuous expectoration of consumptives should be prohibited. The sputum should be received into a 10 per cent. solution of carbolic acid, or an acid solution of bichlorid of mercury, 1 to 1000. If at any time this be impracticable, the sputum may be collected on paper napkins or handkerchiefs which must be burned before they become dry. Under no circumstances should a phthisical patient be allowed to spit on the floor or on the streets.

3. Let every physician employ systematic bacteriologic examination for the early diagnosis of the disease, and let us inaugurate compulsory registration of all cases of tuberculosis.

4. It should be made compulsory to have careful and thorough disinfection of all houses, apartments,

penal and reformatory institutions, carriages, street and railway cars, steamships, theaters, churches, etc., which have been exposed to infection from phthisical patients.

For disinfection of rooms I would recommend sulphur acid gas obtained by burning one ounce of sulphur to every ten cubic feet of space, or chlorin gas to saturation. Shut all doors, windows and crevices for four hours, then let in the fresh air and scrub the walls, floor and articles of furniture with the acid bichlorid solution (bichlorid of mercury 3ij, tartaric acid ʒii to the gallon of water, or ʒij each of HgCl₂ and permanganate of potassium to the gallon). Remove all wall paper if it can not be washed or painted. Thoroughly boil or steam all bedding, carpets, curtains, etc., for at least one hour.

5. Under no circumstances should the stools of tuberculous patients be emptied into the sewers until they have been thoroughly disinfected. The intestinal glands are frequently implicated in tuberculosis, and the dejecta often teem with bacilli; therefore all discharges should be received into a solution of eight ounces of carbolic acid to the gallon, or four ounces of chlorid of lime to the gallon of water.

6. Enact regulations prohibiting tuberculous individuals from following vocations that may expose others to the danger of infection. The sputum may dry on their beards or clothing and then be disseminated. For the same reason, consumptives should avoid kissing and even hand shaking to protect those near and dear to them. All dishes and drinking cups should be used by the patient exclusively and should never be mingled with those in use by other members of the family. The promiscuous use of public drinking cups in schools, cars, streets and churches, can not be too severely condemned, as contagion is possible from this practice.

7. Tuberculous mothers should not nurse their children. In fact, consumptive people should not be permitted to marry.

8. There should be established careful scientific examinations under city and State control, of all milk, meat and other articles of food sold. All animals suffering from tuberculosis, anthrax, septicemia, glanders, cattle plague, sheep-pox, swine plague, foot and mouth disease, acute pneumonia, actinomycosis, drosy and rabies, should be killed and at once cremated.

9. Consumptives should always be isolated, and there should be established under State control public hospitals and sanitarium for the segregation and isolation of the consumptive poor, where they could live under the best hygienic laws, receive proper food and judicious medication.

10. All persons having died of tuberculosis should be at once wrapped in sheets wrung out of bichlorid solution, and cremated as soon as practicable. If this be not possible, then they should be buried with quick-lime, as the bacilli do not die with their host, but have been found in cemeteries from two to twenty-five years after inhumation.

Is it not our duty to prevent the ravages of tuberculosis and thereby save over 150,000 lives annually in the United States? Are we not bound by our obligations to ameliorate suffering and prevent loss of life, and this can be accomplished by isolation, proper hygiene and disinfection. That tuberculosis is contagious—even from man to wife, no one but the ancient, non-progressive physician will deny—preven-

tion is not only possible, but comparatively easy, and it is *demande*d of us as physicians and sanitarians guarding the public health.

CLEANLINESS THE CHIEF ANTISEPTIC.

Read in the Section on State Medicine at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY C. F. ULRICH, A.M., M.D.
WHEELING, W. VA.

In these days of bacteriologic investigations much time and study is necessarily devoted to the prevention of disease by destroying the bacilli that have entered the human body or preventing their entrance. The latter of these methods is to be preferred where it can be done, and it is the province of this paper to show that this may be accomplished much more thoroughly and satisfactorily by perfect cleanliness than by the use of so-called antiseptics. First, a few words regarding the physician and surgeon in whose practice cleanliness is an absolute necessity. This branch of my subject, although not precisely to be classed with State Medicine has nevertheless a bearing on it, and will form a suitable introduction to the main theme. Let us first speak of the surgeon and his work, in which the necessity of cleanliness is most apparent. If the surgeon will see that his hands, his person and his clothing are clean, that his instruments have always been thoroughly cleansed immediately after using them and are then cleansed again just before using, much difficulty will be avoided. Drenching the body and its exposed cavities with antiseptic fluids is not always the best thing to do, as injury is sometimes done by the absorption of the poisonous articles used as antiseptics. When a laparotomy is performed in which the interior of the abdomen is exposed to the outer air; when the interior organs are handled by the surgeon or his assistants: when instruments and sponges are introduced into the cavity and come in contact with healthy organs, the necessity of perfect cleanliness becomes apparent even to an inexperienced observer. I have seen surgeons who prided themselves on their extreme care in preserving antiseptics, make lamentable blunders by allowing sponges that had been in contact with diseased parts, removed from the abdominal cavity, to be used again in cleansing the cavity after the operation, preparatory to closing it up. Many little errors of that kind, escaping observation at the time, contribute to unfortunate results which are then ascribed to something else. A few words about the physician before referring to the main topic. Here cleanliness is just as important as in the case of the surgeon, although not always so carefully observed. See the number of cases of puerperal peritonitis caused by the carelessness of the accoucheur in handling the puerperal woman with unclean hands or with imperfectly cleansed instruments. I knew a case of a physician who was skilful, amiable and generally beloved, compelled to abandon the practice of medicine because, during one season, almost every case of obstetrics he attended was followed by puerperal fever, fifteen of which died within the space of a few months. Now there is no doubt in my mind that he carried the disease from one patient to another by a want of proper attention to cleanliness. He either failed to clean his instruments thoroughly when he used them,

or carried some of the contagion on his hands. There are many places on the hands that escape the scrutiny of the owner, even when he employs frequent lavations; as under and around the nails, between the fingers, etc. The thermometer may carry disease when used in the mouth, if it is not carefully cleansed before and after using. In treating contagious and infectious diseases absolutely perfect cleanliness will do much toward preventing infection of the patients who are seen afterwards; the hands, the clothing, the hair and beard of the doctor may do much mischief if not kept perfectly clean.

We will now approach our main subject, the prevention of disease by cleanliness, so far as this can be controlled by the public authorities. Disease is undoubtedly propagated by germs, bacteria, micrococci, bacilli, or whatever they may be called. These germs may be conveyed into the body by the air passages or by the alimentary canal. In regard to the former, many would say that legislation can do nothing to purify the air. This, however, is not true. Consider the sewer gas, the exhalations from manure piles, the foul smells from shallow or full privy vaults, the odors from reeking back yards and alleys, and you will find them filling the air with all kinds of disease germs. When there is any talk of a prospective invasion of cholera, how all the papers teem with cries for a general cleaning up! How the health officers and inspectors begin to bestir themselves, ordering the people to clean up their premises, throwing copperas and other alleged antiseptics into holes from which issue foul smells, not knowing, perhaps that about all the effect these so-called antiseptics have on the bad air is to substitute another smell, so that the original one is not perceived. If the health officers and the health boards under whose authority they serve, instead of getting spasmodic fits of cleaning up, would exercise eternal vigilance to prevent the accumulation of filth, would have the plumbing of houses, the sewer system leading from the dwellings to the streets regularly inspected; if they would devote time and labor to the proper construction and maintenance of the sewer system in the streets of their cities; if they would appoint men to attend to this business who have made this work a special study, instead of making their appointment a means of bestowing political patronage upon their favorites, there would be infinitely better results.

In a paper I read before the Wheeling Medical Society, I spoke of the air as one of the media through which the bacillus of typhoid fever is conveyed into the system. This was controverted by several members who have had a bacteriologic training, on the ground that the bacillus of this disease can only be propagated in the alimentary canal. Admitting this hypothesis I still maintain my position. We will suppose that the excreta from a fever patient have been deposited upon the surface of the ground, or have found their way there from an imperfect receptacle, what becomes of it? It mingles with the soil and much of it is converted into dust. This dust pervades the atmosphere and is inhaled by people who move about in the air thus polluted. "But," says the objector, "the lungs do not form a suitable nidus for the bacillus of typhoid fever." Granted. But what becomes of the dust that clings to the cavity of the mouth, the palate, the pharynx, the upper part of the esophagus? By the next drink of water or any other fluid that is swallowed, the whole of it

is washed into the stomach where it does precisely the same work as that performed by the polluted drinking water. From this we see that impure air may even be instrumental in propagating diseases that do not develop in the air passages.

Much can be done by legislation and continual vigilance to purify the air of disease germs, in the way of proper attention to sewerage, the prompt destruction by cremation or otherwise, of the filth that is so often left rotting on the surface of the ground. The methods of doing this I do not propose to discuss here, that being a subject too extensive for a single paper.

Having spoken of the air which enters the mouth and nostrils, we will take up the substances that are taken into the stomach for nutrition, *i. e.*, food and drink. I will endeavor to show that much can be done here by being clean and by using our utmost endeavors to prevent anything that is unclean from entering the great work-shop of the body, the alimentary canal. When I speak of clean food I do not mean only the absence of that which is generally known as dirt or filth; for the average housewife will see that such impurities are not permitted to defile the food she prepares for the use of her family. I mean by impurity everything that is not a natural constituent of the article of food that is to be prepared for the table. All sorts of adulterations may be characterized as impurities. Some of these are of the grossest kind. For instance, the various ground spices that are sold by the grocer for family consumption. Who can tell what filth and what bacteria-laden substances are added to pepper and other spices to make them more profitable to the dealer, but deleterious to the consumer? The adulterations of butter, lard and other fatty substances are sometimes of a character that is injurious to health and dangerous to life. Meat can not be adulterated but it may come from diseased cattle, sheep or hogs. I know a man whose cow died of some unknown disease when she was near calving. The owner being a butcher, dressed the meat for market and sold it. He also prepared the unborn calf in the same way and sold it for first class veal. You might suppose that vegetables at least must be pure. Even here much filth may be found. Take radishes, lettuce, etc., which are raised in hot-beds for early use and in highly manured ground for later consumption. What is used as a fertilizer to hasten and render more luxuriant the growth of these vegetables? It is the manure taken from stables where may be diseased horses or cattle; or from privy vaults of the city where may have been deposited the dejecta of patients suffering from typhoid fever or other infectious diseases. This manure is not prepared by a chemical process which would destroy the life and activity of the germs that might be contained in it; but it is put on fresh just as it comes from the reeking receptacle. These vegetables are eaten raw and even if the sap going into them is purged of all germs, yet the outside of them is in close contact with the soil enriched by the manure which teems with all sorts of bacteria and may be, in some instances, a deadly poison. All these sources of impurity can and should be prevented; and it is the duty of every conscientious sanitarian to do all in his power to render the food we eat as clean as human care and watchfulness can make it.

What we drink forms a much more abundant and

deleterious source of disease than anything else. The effects of spirituous, vinous and malt beverages do not come under my consideration unless they are adulterated with poisonous substances. I will leave the discussion of these articles to the tender mercies of the temperance lecturer, prohibitionist, etc. Although water forms by far the largest constituent of the human body, and must be constantly consumed in order to keep us alive, it is nevertheless the most prolific source of disease. It is not necessary to explain here how the germs of disease find their way into the water; for that is known to every intelligent and well read physician, and most certainly to every one who pays any attention to sanitation. To keep the water used for drinking clean, *i. e.*, free from bacteria, is one of the great problems of the hour.

In most of the cities of our land the water is pumped from running streams into reservoirs and thence sent through a system of pipes into the dwellings of the inhabitants. Now let us look into the character and qualities of this water and see whether it is clean and fit for use as a beverage. In order to make a test case by which all other localities may be judged, I will select my home, Wheeling, W. Va., situated on the Ohio River, ninety miles below Pittsburg, Pa. What an amount of filth is poured into this stream by the two great rivers, the Allegheny and Monongahela, one of which, at least, passes through a densely populated region, I shall not endeavor to portray. But let us look at the stream from which our water supply is taken and let those who hear or read this paper judge if it is clean. Between Pittsburg and Wheeling are about twenty-eight towns and cities situated on both banks of the river. Besides there are numerous small tributaries that have towns and villages on their banks. Now what becomes of all the filth and excreta that are deposited by the inhabitants, both human and animal, in these places? You all know that the greater part of them finds its way into the stream running by. Much is being done and has been done to obviate the difficulty and to remove this source of disease. But this is scarcely a drop in the bucket. Crematories are established here and there for the destruction of garbage and the contents of privy vaults. But what proportion of the disease-breeding filth is thus destroyed? Very little. Some years ago, the Legislature of West Virginia passed a law prohibiting the throwing of filth of any kind into a running stream. But who is there in the rural districts to see that the law is executed? Even if it is obeyed, where do they put their objectionable substances? If it is manure, animal or human, they spread it on the ground and the first rain that falls washes it down into the nearest stream. These streams carry the pollution into the great river, and the unfortunate people dwelling on its banks pour this polluted, disease-producing fluid into their stomachs, where it is likely to breed pestilence and cause destruction of life. The country districts, where the water supply is not obtained from the river, are not exempt from this scourge. It is often cited by those who do not believe in the theory of infection, now almost universally accepted by the profession, that epidemics of typhoid fever exist in villages far away from the great source of contamination, the river. Now let us investigate a typical farm-yard, or a home in a village in which horses and cows are kept. This

farm-yard, in a hilly country, is generally located on a gentle slope; the dwelling near the front with perhaps a moderate sized lawn. In the farm-yard is the well, an old-fashioned affair with a windlass, by means of which the "old oaken bucket, the moss covered bucket" is lowered and raised, bringing up the clear and limpid fluid of which the farmer is so proud, boasting that he has the finest water on the whole country side. In the rear, and consequently at a greater elevation are the stables, the cow sheds and the inevitable privy. This latter is generally shallow, liable to overflow when a heavy rain falls. This overflow runs down the slope, and much of it finds its way into the unguarded and carelessly constructed well. Now, let us suppose some visitor has come from the city; or one of the members of the family has visited a friend in the city where the river water is used, and returned. A case of typhoid fever occurs; the contents of the night vessel are emptied into the "backhouse" as they call it. The overflow comes and the well is polluted, the water being charged with bacilli. The inevitable consequence is that other members of the family become infected by drinking the water. Should neighboring families use out of the same well, as is often the case, they take in the contagion, and an epidemic on a small scale is the result. Now what is to be done here? We can not put antiseptics into the water to kill the bacilli for two good reasons: 1, it would render the water unfit for drinking; 2, it would not destroy the poison.

Antiseptics have by no means the powers that have been attributed to them. It was suggested some years ago to administer antiseptics, such as iodine and carbolic acid to fever patients for the purpose of destroying or neutralizing the ptomaines which cause the disease. I paid some attention to that practice, observing that all the young physicians employed it. I also tried it in some cases myself, although I had but little faith in its efficacy. I discovered that the death rate was not diminished by that method of treatment. Much preferable would be the treatment first proposed by Debove; subsequently experimented on by Lichteim and lately adopted with great success by Maillart, of Geneva, called the drinking treatment; in which large quantities of water are administered to the patient for the purpose of diluting and washing out the toxic substances in the alimentary canal and the blood. So we see that neither in nor out of the body is much gained by piling in antiseptic substances. The best thing to do is to see that everything that enters the body is clean, *i. e.*, free from deleterious ingredients, whether disease germs or irritating substances. It is utterly impossible to do this with absolute perfection; but we can at least approximate to a perfect standard of cleanliness.

I might go on ramifying this topic and speak of the necessity of giving none but pure uncontaminated water to the cattle, as much has been said lately concerning the communication of typhoid and other fevers through the milk, many cases of which have been proved beyond a doubt. It has long been known that certain diseases are communicated to persons using the milk from cows that are not themselves affected by these diseases; and this is sometimes plainly traced to the water that the cows drink. But my paper is already assuming an unwarrantable length and I will not discuss that here. If the phy-

sician is always clean in his person and clothing; if he takes care that his thermometer, or any other instrument he may have occasion to use, is thoroughly cleansed before and after using; if he insists on cleanliness in the sick room and of the patient as well as of the attendants, much trouble will be avoided and the death rate greatly diminished. If the authorities will use their utmost endeavors to purify the atmosphere, not by distributing antiseptic vapors, but by seeing that the least possible filth goes into it; if they will adopt the necessary precautions to prevent the sale of impure food; and if they will not only make laws but exercise eternal vigilance in their execution, to render the water supplied to the inhabitants, clean, in the proper sense of the word; not only clear and transparent, but free from the germs of disease; the general health will be vastly improved, the death rate will be reduced to the minimum, and preventable diseases will be almost stamped out. It will be found that antiseptics will not play so important a part as they are doing now; neither will the physician's duty be as sad and somber as it is at the present time. He will constitute an advisory committee to show his clients how to avoid disease, and will be a gentle help in alleviating the sufferings of those who are afflicted with unavoidable and incurable diseases. Let us hope it may not be too long before we reach "this consummation devoutly to be wished."

COMMON CARRIERS AS DISSEMINATORS OF CONTAGION.

Read in the Section on State Medicine, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY S. S. HERRICK, M.D.
SAN FRANCISCO, CAL.

It is not necessary here to consider the part played by sea-going craft, for this, as a factor in spreading disease, is practically eliminated. The ancient method of detention for a definite period has been superseded by inspection and exclusion of infected persons and things at the port of departure and repeated inspection, with disinfection if needed, at the port of arrival. Neither is it necessary to speak of the modern methods of inland quarantine, in which inspection with cleansing and disinfection have obviated all serious interruption of traffic. In both the measures used are reasonably efficient for the protection of the public, and at the same time generally satisfactory to carriers.

There is, however, a source of danger which so far, has attracted little attention, and no measures have been put in operation to counteract it. This is the disposal of the excretions of travelers on inland waters and on railway cars, in such manner as to prevent the contagion which they carry from reaching other persons. There are certain communicable diseases, whose contagions property is discharged from the alimentary canal, and is liable to reach the alimentary or respiratory tract of other persons, if not intercepted or destroyed. Cholera, typhoid fever, dysentery and intestinal tuberculosis are notable examples, and they are common enough among travelers by rail and by steam-vessels on inland waters to become a source of serious danger.

In some of the States there are statutes which forbid the pollution of streams by animal impurities,

having reference chiefly to the contents of sewers and to carcasses and offal of domestic animals. I am aware of no legislation thus far, which seems to take into account the pollution of rivers by travelers, nor the dangerous and indecent practice of allowing fecal matter to drop from railway coaches.

Art. 370 of the Penal Code of California reads:

"Anything which is injurious to health, or is indecent or offensive to the senses, so as to interfere with the comfortable enjoyment of life or property by an entire community or neighborhood, or by any considerable number of persons . . . is a public nuisance."

Art. 372 reads:

"Every person who maintains or commits any public nuisance, the punishment for which is not otherwise prescribed, or who willfully omits to perform any legal duty relating to the removal of a public nuisance, is guilty of a misdemeanor."

There is no reason to suppose that the authors of the above enactments had in view the prohibition of the special nuisances herein considered, and it is rather doubtful whether courts would now construe them as applicable to the same, for want of precedent; but it would be practicable to amend these articles so as to make them apply to this offense, or to frame new statutes which would cover the ground.

Obviously, travelers themselves should not be held responsible for committing a nuisance, so long as transportation companies provide no facilities for obviating the same; and legislation should be aimed directly at these companies, holding them responsible and requiring them to provide an adequate remedy.

It is well understood that the law must not ordain what is impracticable, and equally plain that no serious difficulty and expense would be involved in abating such nuisances. No mechanical difficulty exists for a steamboat or railway coach to have its closet provided with a closed receptacle, having suitable means for deodorizing, disinfecting and ventilating, and for discharging the contents into some proper place at short intervals. The details of a contrivance suited to such a purpose need not here be entered into; they belong to the inventor and mechanic rather than to the sanitarian as such.

Aside from considerations of health, it seems strange that respect for common decency has not abolished a practice in travel by land which would have brought a blush to common carriers in the good old days of slow coaches. While inventors and builders of palace cars are doing so much for the comfort and convenience of passengers in other respects, they adhere to a form of closet from which travelers must be excluded at the time when it would be most acceptable (halting at large stations) and which scatters filth and disease along the route. It is to be noted that cholera still lingers in Europe, and meanwhile we must not consider ourselves safe here within two weeks' travel by steam; while the other filth diseases, like the poor, are always with us.

In my judgment the time has come for sanitarians to speak plainly and forcibly on the subject, and to demand of legislators a specific remedy which courts will be bound to apply to this class of offenses against health.

VACCINATION AND RE-VACCINATION.

Read in the Section on State Medicine at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY EZRA M. HUNT, M.D., LL.D.

SECRETARY OF STATE BOARD OF HEALTH OF NEW JERSEY.

Vaccination for the prevention of smallpox was the first indication that an animal disease could supervene a human disease; that one disease could modify or prevent another, and that a great plague could possibly be abolished from the earth.

It is not our plan just now to outline, even in brief, the marvelous historical record, or the clinical facts as to it for the last hundred years, but only to specify and briefly note changes of view that have modified what we may call the Jenner impression as to it.

1. We have probably come to know that more than one animal disease has the power by inoculation of modifying smallpox. Jenner thought that it was the disease known as "grease" in horses, modified by passage through the cow, and again in man so as to prevent smallpox. Now it is probable that there are two or three forms of disease that may supplant variola in man, such as horsepox, sheeppox and cowpox of which some claim that there is more than one effective variety. Dr. Flemming (see paper referred to, *Lancet*, Aug. 2, 1890,) favors the conclusion that these three variolous diseases in the horse, cow and man are distinct, yet the inoculation of the virus of either of these affections protects from smallpox in man.

2. It is more than probable that kinpox is the smallpox of man which passing through animals is attenuated so as to give a virus which supplants the "caught" smallpox of man and so prevents it. This, in the view of Badcock and Ceely, is the real source of all the varieties of vaccine lymph in use for the prevention of smallpox. It is still, however, disputed by Flemming and various other authorities, the latter calling it a dangerous and fallacious doctrine. It has too many facts as to it, to be so regarded.

Besides various foreign papers, some confirmatory facts in the United States are presented in a paper in the *Philadelphia Medical News*, March 31, 1883, entitled "Notes on Variola and Vaccina." We think this view has been strengthened the last few years. Dr. McVail in his recent classical essay says: "The whole tendency of the evidence is to show this." (See *Treatise on Hygiene and Public Health*, Stevenson and Murphy, Vol. ii).

3. Though the identity of the disease is unchanged it has not a uniform type of severity. So far as we can trace in the period before inoculation, and far more before vaccination, the type was uniformly severe and the death rate uniformly high. This is not, as many affirm, so much the case now, independent of vaccination. Leicester and the anti-vaccinationists of England have been in the habit of giving many facts bearing on this point and some are added by Dr. B. A. Whitelegge in his Milroy lectures, London, 1893, "On Changes in Type in Epidemic Diseases," (See Lecture 2 especially. February, 1893). We quote as follows: "Vaccination has profoundly affected the epidemic course of smallpox, but changes of type are evident. In the latter part of the last century smallpox contributed on an average about one-tenth of the whole death rate of London, and in

1796 no less than 18.3 per cent. After this and coincidentally with the introduction of vaccination, its ravages lessened until 1830. From 1830 to 1838 the records are missing, but in 1838 the mortality was again comparatively high, though below even the average which prevailed half a century before. After 1838 we can measure its course by actual death rates, and a considerable degree of order and even rhythm becomes apparent. Every few years—usually four or five, but sometimes two or three only—it recurred as an epidemic, but with somewhat reduced destructiveness each time until 1855, which happened to be halfway between 1838 and 1871. After 1855 minor epidemics continued to recur at about the same interval, but the loss of life on each occasion increased rather than otherwise. Then came the great epidemic or pandemic of 1871, killing a larger proportion of the population than in 1838. The course of events for twenty years after 1871 was not unlike that which followed the 1838 epidemic—successive outbreaks at intervals of four or five years, decreasing in mortality and subsiding after 1885 to a much lower level than was ever before reached.”

4. Protection depends upon the quality and quantity of lymph and is often not permanent, so as to need repetition. It is now fully conceded that there is significance in the character and number of the marks, such as quite justifies a plan of vaccination in use on the continent which repeats the process from week to week until no effect is produced. The English habit is to have four insertions within an area equal to a half inch square and to insist that at least three must be effective in order to have the cicatrix or marks satisfactory. Re-vaccination is now insisted upon as always necessary after a few years.

5. Through modification of type and through vaccination and re-vaccination we are far more apt than formerly to have mild and walking cases of the disease, so that by reason of this, far greater numbers are exposed to the contagion. In other words, unless vaccination and re-vaccination in all their details are followed up and become the universal habit of the people, smallpox or varioloid will be more largely diffused and more frequent. So that a real remedy becomes the means of extending the disease.

As to this point we note some cases which have quite recently come under our observation:

Within the past year there occurred at Red Bank, in this State, an outbreak of smallpox which seemed singularly persistent. We can generally leave sporadic cases, especially in cities, to local health boards and local physicians. In this case the endemic seemed persistent notwithstanding the ordinary precautions. It even happened that there was doubt between smallpox and chickenpox in early stages, by those of tact and experience.

How this can be is something of a mystery to the physician who has only seen typical cases of each disease and regards the distinction between a vesicle and a pustule as definite. A recent case presented in letters to the *London Lancet*, Dec. 9 and Dec. 23, 1893, by Dr. J. B. H. Smyth, of London, is illustrative. The writer could not conceive how any such doubt could exist until he met with a sporadic case of varicella, (chickenpox) studding every part of the body, and confluent at parts, and attended two patients in one family with varicella which an able neighboring practitioner had pronounced variola

(smallpox) but which had been attended for that disease by myself only a few months ago. So late and so good an authority as Hebra regards them as very closely allied. In the epidemic referred to, some of the lighter cases were thus mistaken for varicella. In one case vesicles could only be found in the hair of the head.

Inquiry showed that many cases were so mild in this epidemic at Red Bank, that persons who had the disease were not confined to the house and so exposed others to the disease. The president of the health board there writes us: “One of our greatest difficulties has lain in the fact that a number of cases have been so mild that neither the persons themselves nor their physicians have known they were suffering with the disease. Only after other cases have occurred and they were traced to these people, have we been able to discover by their description of their symptoms, that they have had a mild form of varioloid. These cases while not sufficiently severe to confine the patients to the bed, or even to the house, have still been sufficient to cause the spread of the disease and it has been in this way, we think, that the disease sprang up so unexpectedly in different parts of the town. Other similar cases were reported and as re-vaccinations were made when numbers had been exposed, it was evident that in some cases the influence of the contagion was enough to cause some symptoms. It became apparent that important as re-vaccination is, it was incidentally becoming an occasion for the spread of the disease so that stricter inquiry and isolation were necessary.”

A few weeks after, similar facts were found at Carteret, a small village in Middlesex County, in this State. Here one of the men traveled to Bayonne, Hudson County, with but little feeling of ill health. One woman examined had no evidence of the disease except two small pustules in the hair. All the cases were mild.

It is a strange record that we have also from the city of Reading, Berks County, Pennsylvania. A late bulletin, January, 1894, announced 710 cases with only 18 deaths and 29 cases remaining under treatment, and several fresh cases up to February, 1894.

Another point for us to note is, that some recent movements in England and some contributions to the literature of smallpox are such as make it essential that the study of the disease, and of vaccination as related thereto, be pursued with new zeal and with minute attention to all details and all facts bearing upon it.

Opposition in England to the law of compulsory vaccination is too formidable to be ignored. It has arrayed against it a strong constituency and has given rise to a most important parliamentary commission, already spending two years in its inquiries. It has shown, as in the case of Leicester, that quick isolation, disinfection, quarantine of exposed healthy persons and thorough sanitary police are very effective in dealing with the disease, although, especially in view of the more recent epidemic in that city, it is plain that the need of vaccination, as an additional protection there, has been greatly underrated. Although it is hard to have patience with some of the wild utterances of the anti-vaccinationists, we do well to review their facts and statements in a judicial spirit.

For a time they had no strong medical support,

but the various writings of so noted a pathologist and authority as Prof. C. Creighton, of Cambridge, (see his treatise on "Cowpox and Vaccinal Syphilis" and on "Jenner and Vaccination," and especially his article on "Vaccination" in the new Encyclopædia Britannica,) has contributed much to the apparent argument against vaccination. Still more serious became the scientific position when the learned bacteriologist, Prof. Edgar M. Crookshank, M.B., of University College, London, published 1889-90, two volumes on "The History and Pathology of Vaccination." His work is a sample of great research, is executed with accuracy and is learned and ingenious in its facts and arguments. He concludes that "the inoculation of cowpox does not exercise any specific protective power against human smallpox," and that it is destined to be replaced by the "more rational and comprehensible procedures of the compulsory notification of smallpox and the isolation of all cases of this disease."

"This in the face of the almost concurrent testimony of all nations and the testimony of the great mass of the medical profession, that it is the one great prophylactic that has interrupted what was once the most serious of human contagions, has immensely limited its frequency and fatality and has shown its capacity, when fully applied, for well nigh driving this great pest from the earth."

Dr. Creighton, too, in his more recent work, a "History of Epidemics in Great Britain," shows no change of view. We have in these high authorities and in the minority of persons agreeing with them, a remarkable disregard of clinical experience and no explanation of the accumulated facts as to the mitigation and prevention of this disease.

We regard "such statements as entirely opposed to universal experience; to experiences both of prevention of smallpox and of mitigation of its attacks; to experiences which belong to every quarter of the globe and which are far more to be trusted than the theories of comparative pathology, however suggestive and however interesting these may be."

Yet it will not do, amid such contentions and such opposition, to rest upon the facts of the past and the loyal declaration of our faith.

a. We must sift and weigh in full our evidences as the years go on, increase the number and accuracy of classified experiences. We must seek to adjust and harmonize the testimony of the clinician and the biologic pathologist. We must reexamine sources of lymph supply, account for variations in effect, explain the greater apparent need of re-vaccination and so eliminate errors and fortify the truth in the spirit of scientific investigators and skilled practitioners. In the meantime we must rest boldly and strongly upon the present accepted practice and see to it that the people at large from childhood to age have protection from this marauding pestilence. As an instance of one of these cautions, at a recent meeting of the Society of Medical Officers of Health in London, Feb. 19, 1894, the President, Dr. W. T. G. Woodforde, insisted that "certificates of successful vaccination should specify the number and area of well marked cicatrices."

b. More systematic methods need to be instituted for the production and furnishing of vaccine lymph. At present the whole matter is left in the charge of single individuals, or firms, and it is often retailed by druggists, like any other commodity. This in the

face of the fact that there are many different sources of lymph, that they are not of equal reliability, that there is much variation as to freshness of material and that the question whether a person shall have smallpox, or whether there shall be an epidemic thereof, often depends upon the potency of the single point used. The case is not at all analogous to that of the sale of an ordinary drug.

Dr. Snow, so long the Health Officer of Providence, Rhode Island, was so impressed with the ultimate results of this kind of merchandize dependence, that he kept and distributed through the country a supply of what is usually spoken of as the Jenner lymph, and favored the old method of arm-to-arm vaccination. This was not because he opposed bovine lymph, but because he thought this the safer method for permanent reliance.

It has already come to pass that some of our best health officers, notably Dr. C. N. Hewitt of Minnesota, are advocating a return to arm-to-arm vaccination, the bovine lymph being used to start new supplies. It is thus not meant to supersede, or to contend with bovine lymph, but while maintaining the old source to secure also a more reliable and ready supply of virus.

If the present method is carried out we believe that vaccination will be less certain in its effects, that re-vaccination will be more frequently needed and that walking cases will so multiply as to constitute a grave source of epidemic influence.

If this plan is not adopted, bovine lymph should be produced and distributed under national or legal methods and with strict oversight as to details. Never was so much loose vaccination done as now. We hear of 200,000 vaccinations in New York city without charge and many not returning to see if the result is complete.

On the other hand, in London, return is secured and the vaccination must be authenticated. Adopting this plan and having skilled vaccinators, we have the record last year, that of primary vaccinations at the central London station, 7,529 returned, and 7,448 had been successfully vaccinated. The 81 that failed were all successful on a second vaccination. On this plan vaccination will be found to be no failure. The recent article of Dr. McVail, in the second volume of Stevenson and Murphy's "Treatise on Hygiene," together with the constant results of skilful systems of vaccination furnish a complete answer to the contentions of a few biologists and to the charges of anti-vaccination societies.

Yet we sound not too soon this note of warning, for we believe that if the present loose methods are permitted to continue, vaccination will become less and less a preventive of smallpox and its enormous value be greatly impaired.

c. Local health boards and physicians, on the basis of large series of classified facts by competent observers, need to be more in unison as to the necessity for and frequency of re-vaccination. Layet of Bordeaux, a skilled authority, was successful in about 40 per cent. of his re-vaccinations after nine years, but we have no particulars as to various points, such as number of marks, etc.

The Pennsylvania Health Board hand bill, or poster, proclamation says there should be repetition in seven years. One, who represents the New York City Board, says ten years. The Local Government Board, Great Britain, names the age of 12. Many authori-

ties name 14, or in general the age of puberty. This vagueness we believe comes largely from imperfect vaccination at the start.

Dr. McVail says that "the rule, that re-vaccination should be performed at 10 to 12 years of age, is not founded on any theory that primary vaccination has then lost its protective power. The power of infantile vaccination against attack by smallpox remains to perhaps at least one-half of its original extent at 20 years of age, and its power against death exists to very considerable extent all through life, as abundantly shown by the statistics of the great smallpox hospitals." This certainly justifies the early vaccination, but is too indefinite for us to rest upon. A series of collective investigations should be made on these points.

The cities of New York and Philadelphia, with adjacent sections of their respective States and of New Jersey, still have outbreaks of the disease. It is occurring, and likely to occur, more than usual in various sections, by reason of the great increase in the number of nationalities that choose their nests in every city and there abide.

There must be more thorough work and more exact discipline as to this whole matter of vaccination, or else the disease will stalk abroad here and there much oftener than heretofore, the number of cases in proportion to deaths will increase, and now and then a severe epidemic remind us of its previous more fatal history.

We present a few of the questions which seem to us to stand in need of such authoritative answer as comes from series of closely studied facts and not as the mere opinions of a committee.

1. What legal or professional method should be adopted to secure a more reliable supply of bovine lymph?

2. How far is the older method of arm-to-arm vaccination still to be commended for adoption?

3. What mode of insertion of vaccine lymph is to be advised?

4. What directions should health boards and physicians give as to re-vaccination?

5. What measures are practicable in order to secure a more general primary and secondary vaccination of the population?

6. What after examination should be made, and what should be the form of vaccination certificate? Should it state number of points at which the insertion of lymph produced a distinct depression or cicatrix?

7. What quarantine or other restrictions should be placed on those who have been exposed to smallpox?

We think a committee should be appointed to furnish us facts and evidence touching each of these items, and then to outline a plan for the better securing of the results sought.

At present we name not as conclusions, but as suggestions, a few tentative answers as indicating lines of direction for inquiry.

a. There should be a National vaccine and distributing establishment for bovine vaccine at Washington.

b. Arm-to-arm vaccination should not be wholly abandoned. In our large cities, at least, physicians should arrange to have at hand certified, humanized lymph of which the sources are local and fully known.

c. Vaccination direct from a charged ivory point used for scratching, or from a needle, used but for one case, should be relied on.

d. Re-vaccination should be advised for all who have not been vaccinated within ten years, and ofener where there has been special exposure, or there is any doubt as to marks or time of first vaccination.

e. Children should not be admitted to public schools until vaccinated. Provision should be made to encourage general vaccination of infants and youth.

f. A vaccination card or certificate should be given stating time and place of vaccination or of re-vaccination, whether there was subsequent examination and at how many points the lymph had taken.

g. While time of quarantine must vary somewhat according to circumstances, persons who have been fully exposed, if not quarantined at once, should be under quarantine or watch from the ninth to the fifteenth day after exposure.

TYPHOID FEVER.

Read in the Section on Practice of Medicine, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY JOHN ELIOT WOODBRIDGE, M.D.
YOUNGSTOWN, OHIO.

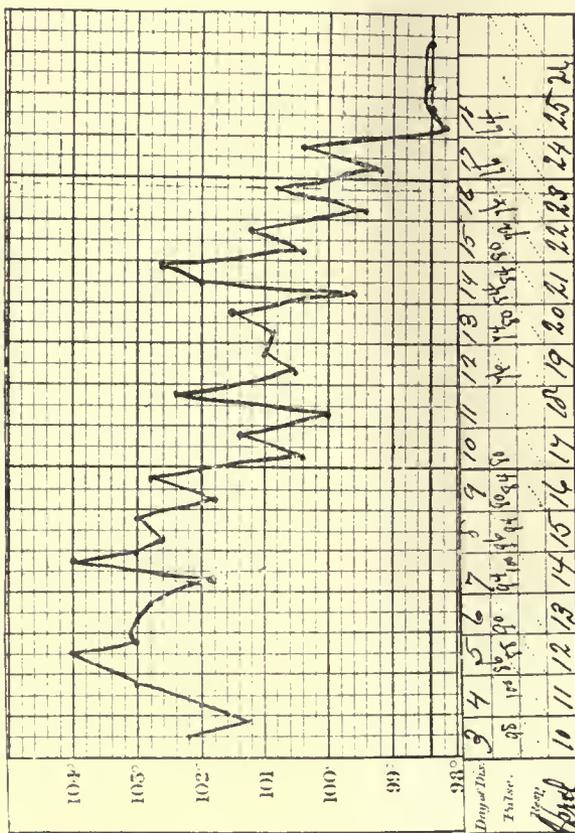

It was my intention to have made in this paper an effort to discuss from the scientist's standpoint the etiology and treatment of typhoid fever, but the positive expressions within the past few weeks of the opinions of many of the greatest thinkers of the age, that typhoid fever can not be aborted, and in fact, that the internal exhibition of drugs can have no curative effect, warns me that I have essayed enough and that this paper had better be devoted to strengthening the evidence that the claims already made are valid, and avoid as much as possible enlarging the territory which I shall have to defend. I feel that I do not owe the Section any apology for this change, because this is a disease that according to eminent authority "destroys annually the lives of 50,000 of our people, leads to the very brink of the grave more than half a million more, which during the next twelve months will inflict upon us more injury, suffering and death than any foreign foe could possibly do," and which, I believe, is rapidly increasing. A disease whose geographical distribution is limited by no boundary lines, whose germs may live indefinitely in the icebergs of the frozen North, and thrive in the torrid heat of the equator, can not be accorded too much attention by this Association, especially as the medical literature is in such a chaotic state as to be exceedingly confusing to those who place any trust in it. A literature which is not at all creditable to the medical profession as long as its recommendations for treatment form such a medley of contradictions, from "armed expectancy" to the most heroic exhibition of the most dangerous therapeutic agents, from corrosive sublimate to the coal-tar derivatives, including almost every known poison, and all having most enthusiastic devotees until finally, the *materia medica* having been taxed to the limit of endurance, a new class of enthusiasts has arisen, and now the bath-tub and sponge and the cold pack have their advocates who can see nothing but dire disaster in the use of any

therapeutic agents except cold water. And the most amusing, were it not the most tragical publication that has ever issued from any press, is the Johns Hopkins Hospital Report, Vol. iv, No. 1, on "Typhoid Fever," which I have just received, in which the learned Professor of the Principles and Practice of Medicine of the Johns Hopkins University asserts, and I quote him literally: "Since typhoid fever like a majority of the specific infections runs a course uninfluenced by any known medicines, the duty of the physician is to see that the patient is properly nursed and fed and that dangerous symptoms should they arise are combated by appropriate remedies. In hygienic and dietetic measures his activity is incessant; so far as drugs are concerned his attitude is best expressed in the term 'armed expectancy,' giving no medicine simply because the patient has a fever; nursing and diet are the supports in which we

ation in an unhonored grave, and his widow had lived long in poverty and, I fear, even in want; and which in the most enlightened capital of the Old World made the life of the discoverer of vaccination immeasurably burdensome.

These papers show that after having had, during the ten years from 1866 to 1876, about thirty deaths from typhoid fever, with an average duration of illness of those who recovered of about thirty-five days, I abandoned the symptomatic treatment now advocated by some learned professors and began in 1876 with extreme caution to treat typhoid fever under the same general principles which crudely govern my practice to-day. That after having had unusually favorable results for four years, in 1880 in my local society I condemned all known methods of treating typhoid fever and foreshadowed the brilliant results I have since obtained from the principles of treatment then laid down. That in 1882 I declared hemorrhage of the bowels would be unknown if the disease were properly treated, saying I believed that a law sending to State prison a physician having such a result would be wise and beneficent. That in 1890, to emphasize my statement that typhoid fever could be aborted, I offered to compensate any member of my society for every visit made to a patient after the tenth day of treatment. That for several years I had invariably given a favorable prognosis, and that for more than thirteen years I have had no death from typhoid, malarial or any continued fever. With each of these papers I presented up to the date of its reading the histories of the most interesting and characteristic cases, exhibiting the bedside charts of all the cases treated since June 25, 1893, when I first began to keep accurate bedside records. They were all freely discussed by many of the ablest members of both my local and State societies. The charts were verified by the members who had seen the patients and my statements were endorsed.

The criticism of my paper read recently before the Ohio State Medical Society was highly gratifying to me. The discussion was opened by Dr. Collamore in his happiest vein. The general tenor of the remarks were in favor of giving progressive ideas a warm welcome and a fair trial. There was present but one member from Youngstown—Dr. J. E. Cone—who said: "Being from Dr. Woodbridge's town and society, I wish to say that we have had several 'fights' on this subject and we have been watching his cases for several years to see if he could make his pledges good, but so far we have been unable to discover that he has made any failures or had a death from typhoid fever. And we intend to continue watching his cases in the future, and if he has a death we will report it." A little speech which read between the lines speaks volumes. Prof. Murphy, however, spoke eloquently in adverse criticism, saying in substance that there could be no curative treatment for typhoid fever and he doubted the correctness of the diagnosis and observation of any physician who asserted he was able to abort the disease. He said I shocked him when I said I allowed my patients to sit up, walk about, and even to eat solid food. I shall not attempt to quote Dr. Murphy's words or essay the hopeless task of reproducing or even describing his eloquent speech, but as I sat spell-bound listening with admiration to his brilliant oratory, I could not help wishing that he could see the subject as I see it, and were speaking for, instead of against the right; and not long since

Case No. 67.

trust, the essentials under all circumstances to which is added the cold bath, when possible, or cold sponging for the antipyretic action and stimulating effect. Medicines are not as a rule indicated. No known drug shortens by a day the course of the fever. No method of specific treatment or of antisepsis of the bowel has yet passed beyond the stage of primary laudation."

During the past year I have written papers under the title "Can Typhoid Fever be Aborted?" for the Mississippi Valley Medical Association, the Mahoning County and the Ohio State Medical Societies, in which I presented evidence that typhoid fever can be and has been aborted, which would have been accepted as absolutely conclusive in any profession save that which in America's most cultured city failed to find the discoverer of ether until he had lain for a gener-

after having read a paper before a medical organization composed largely of the teachers in one of our boasted centers of learning, the same general expressions of opinion were made, one gentleman saying: "If there is anything in medicine that is well established, it is that the course of the disease (typhoid fever) can not be interrupted." Another gentleman who, as I judged, from his special learning and ability had been given the closing argument against my theories, criticised these charts very severely, saying: "With four or five possible exceptions there was not a typhoid fever case among them;" evidently forgetting that they are presented to show the modification of the "curve" by antiseptic treatment; that most of the patients were examined and the diagnosis verified by physicians quite as cautious as himself, and that if the "curve" had remained unmodified the treatment would have been a failure.

These oracular assertions (they can not be called arguments) should never have been made. We know too little of the action of antiseptics, too little of the bacteriologic world, of the antagonisms existing between these minute denizens to warrant any gentleman, however learned, in placing his individual opinion above the evidence of years of experience, and the testimony of a score of physicians quite as competent as himself to make careful observations and exact diagnoses, especially when among these observers are included several ex-Presidents of our local Society and at least one ex-President of our State Society, or in placing himself as a stumbling block in the pathway of investigation and progress. Had they anything better to offer, their opinions ought to be carefully weighed, but when they oracularly assert that a course of treatment which they have never tried and of which they have no knowledge can do no good, they are simply lending their learning and the weight of their great names to aid in retarding the day when typhoid fever shall cease to be at once the stigma and the despair of medicine.

In you accept the theory that typhoid fever is caused by a germ, you must accept its corollary, that the germ can be destroyed, and if in one receptacle, or the alimentary canal of one patient, then as a legitimate sequence in every one, and if the physician who accepts this theory sees his patient sufficiently early and treats every suspicious case on the first appearance of suspicious symptoms, he will rarely see a typical case of typhoid fever, and never a death from the disease. Now the simple fact that I have had no death from typhoid fever for more than thirteen years is alone strong presumptive evidence that the claims I make are well founded, and when taken in connection with my previous record and with the statement of the last President of our local Society, when one of my earlier papers was under discussion, that he had no doubt that I had treated more than my full share of typhoid fever, entitle the subject to careful consideration. Since the unaided efforts of one man, however faithfully he may pursue his investigations, must be long indeed in accumulating sufficient data upon which to base a scientific discussion of the subject, and longer in giving such expression to the finished work as to command the attention and the confidence of the great body of a profession peculiarly prone to look upon anything new with a great deal of suspicion; I therefore appeal to every member of the AMERICAN MEDICAL ASSOCIATION, and to every physician who treats a case

of the disease, to aid me in the accumulation of such data as shall lead to a better knowledge of typhoid fever, and especially of the action of antiseptics in its treatment. For this purpose, and because I have been unable to find a clinical chart so arranged as to make the collection of necessary data practical and easy, I have devised one that will enable the busy practitioner to make his record valuable with the least possible loss of time.

In conclusion, I wish to call attention briefly to the treatment which has already been published, and to say that with wider experience I hope to be able to eliminate some of the ingredients which give the formula such a complex and unscientific appearance. I am still using the formula as already published, viz.:

| | |
|------------------------------|--------|
| R Podophyllin | gr. i. |
| Hydrarg. chlor. nit. | i. |
| Guaiacol carb. | vi. |
| Thymol | v. |
| Menthol. | i. |
| Sacch alb. | ʒ ii. |

alternated with the

| | |
|----------------------|-----------|
| Eucalyptol | 5 x 10 m. |
| Guaiacol | 2 x 5 m. |

No pretense is made that this is the *only* preparation which will cure typhoid fever, nor that all or any of its ingredients are necessarily essential, but because thus far it has not failed me,¹ and crude and unscientific as the mixture appears I know of nothing better, and I hope no gentleman will say he has given my treatment a trial and failed, who has not exhibited these identical mixtures, alternated as directed; nor must he interject anything calculated to interfere with their effect. As the mixture is practically harmless it may be exhibited in almost unlimited quantities. I, however, advise beginning with exceedingly small doses and thus avoid early catharsis.

As I stated in a former paper, I am ready to go wherever in the wide world typhoid fever claims a victim, whether it be across the continent or over the ocean's broad expanse, and I challenge the publication of any failure.

DISCUSSION.

THE CHAIRMAN—This is a paper upon a well-known subject, one in which you have all have had cases, and I hope it will be thoroughly discussed. It is somewhat unique in character and much can be said upon it.

DR. WASHINGTON AYER—The paper certainly commends itself to this Section as being upon a subject of great interest. That the gentleman should have been so very fortunate in the treatment of his cases is certainly noteworthy. I understand that he does not treat the disease, but rather the symptoms. Is that so? that you do not confine yourself to the treatment of the disease especially, but rather the symptoms, as they present themselves, of typhoid fever?

DR. WOODBRIDGE—I would say that the symptoms of typhoid fever could not be treated; that I pay no attention to the symptoms for that treatment, but as an evidence of the result of past treatment.

DR. AYER—In case of severe diarrhea, as the fever sometimes begins with that as one of the prominent symptoms, I suppose that a little opium or Dover's powders, or something of that kind would be admissible and not interfere with the general treatment? I have had considerable experience myself in the treatment of typhoid fever, some in

¹The accompanying chart, No. 67, shows the need of more exact knowledge in the use of antiseptics, since I twice discontinued the use of formula No. 1, only to find the temperature again going up, and to be forced again to resume it.

my very early practice, and some in California, having been practicing here for nearly forty-five years. I must say, however, that my cases in California have not been of that severe type, as a general thing, that occur in the East, and that I have been treating my cases more upon a hopeful than perhaps a thoroughly prescribed course of treatment. I would like to hear any explanation upon the matter by the author, if I have not properly understood the paper. A fever that has caused so much anxiety among physicians, and especially in districts where it has prevailed as an epidemic—with such a disease, a treatment by which it may be cut short and the terror removed from the household is certainly deserving of the most careful consideration, whether it be looked upon as a combination of remedies strictly scientific or otherwise. The treatment is certainly new to me, and I hope the gentlemen here will feel at liberty to give a careful expression of their sentiments upon this so important question. I understood the author of the paper to say he never had any hemorrhage of the bowels in typhoid fever. No appearance of blood in any of the evacuations, I would ask, or do you confine it to the more strict interpretation of a hemorrhage? In many of the severe types of typhoid fever, those which approximate that, we formerly made a distinction between typhoid and typhus fever; the type of that fever in the early days came from the ships that brought passengers from Panama here—in those more severe types, I say, that was a very severe test upon the skill of the physician, and of the effect of the remedies. A very large percentage of the cases that were treated by the physicians here at that early time were fatal. Yet, I must say, my treatment, even in those grave forms of the disease, was not formulated exactly according to the prescribed rules for treating the disease, for I used towels wrung from cold water, applied frequently over the region of the heart, and found great benefit from that method. The application of cold water afforded great relief to the patients, reducing the temperature of the body and the action of the heart; if the heart is stimulated by the decomposition of foods in the stomach, or from whatever other cause we might say, the friction, as the cold blood is thrown through the arterial system, increases the heat at the surface. My theory was that the application of cold lessened the heat of the blood, and thus afforded relief to the patient and hastened convalescence.

DR. A. W. PERRY—I have listened to this paper with a great deal of attention, and although I have been putting into practice some of the principles that the author has given in his paper, yet this paper has convinced me that my former action was to a certain extent correct, and it has given me the reason for what I have done. My experience has been, like that of Dr. Ayer, considerably in California, and here the disease is not of the severe type that it is in the East. My cases have been cases where the patient has very generally recovered from the fever within twenty days. The treatment that I adopt is principally an antiseptic treatment, although I do not use the antiseptics that are mentioned in the paper. The antiseptics that I use are hydrochloric acid, about two drops every two hours, and carbolic acid given with it, and sometimes iodine. We know that the intestinal canal is full of bacteria in health, and what keeps them from multiplying here is the germicidal action of hydrochloric acid, and by keeping the stomach in an acid condition we not only prevent the multiplication of these bacteria but we destroy their activity as well. The carbolic acid that I give has about the same effect, I suppose of the guaiacol that is in this mixture of the author's. I also use the eliminatory treatment to some extent, begin with a dose of calomel, and I have no trouble with diarrhea. I have rarely had occasion to give a remedy to stop the

bowels; I think it would be poor treatment. I pursue this antiseptic treatment steadily throughout the disease unless the temperature rises very high, and whenever the temperature rises about 103.5 in the rectum I give frequent cold baths, baths of about 80 degrees every two hours until the temperature comes down. This paper has shown me that I have been on the right track, but have not gone far enough and I shall in future use antiseptics more thoroughly.

THE CHAIRMAN—I would like to ask the author, have you in any case aborted an attack of typhoid fever?

DR. WOODBRIDGE—I have, yes. I have had cases that seemed to be typhoid fever, and that I was sure from every symptom were typhoid fever, and the fever was broken down in nine or ten days. I was rather disposed to doubt my diagnosis at first. Future investigations, however, led me to believe that I have aborted the fever, and that the cases were typhoid fever.

THE CHAIRMAN—The generally accepted doctrine as has been often stated is that we can guide the patient through the fever, but can not abort it. That has been my experience. I have had cases where for nearly a week the temperature would range from 105 to 106, but I never saw a case that I thought I had aborted. I have had one case within a year with three relapses. The patient was confined to her bed for over seventeen weeks, and I failed to make any appreciable effect upon the fever with any remedy used.

DR. COLLINS—I would like to ask the author of the paper upon what basis he diagnosed the typhoid fever in those cases reported cured in seven or eight days. In my cases the diagnosis has been based largely upon the length, the duration of the fever. I think many of us have had cases which resemble typhoid fever very closely, but in my opinion, until we have had results, we have no basis upon which we can say surely that the patient has suffered from typhoid fever. Many of us have had cases which have recovered at the end of seven or eight days, which I have always looked upon as infection cases, where we have had poisoning of the patients, where these symptoms, and symptoms very much like typhoid fever appear at the beginning. It is only after a course of three or four weeks that we are able to say at our post-mortem absolutely that it has been a case of typhoid fever. Therefore, I ask the Doctor upon what he bases his diagnosis in these cases where the fever is arrested so early.

DR. KENT—I would like to say that in the mountainous region of this State there are quite a large number of these continuous fevers which are put down very often as typhoid fever; they run a course of anywhere from three to ten weeks. I believe the only symptom upon which they make diagnosis is the temperature and the peculiar feeling of the legs that accompanies them. I believe that a great many of these cases can be cured by almost any good treatment, and I believe a great many are put down as cured of typhoid fever when they have not suffered from typhoid fever at all. Some gentleman in Colorado—Leadville, I believe it was, published in the *Philadelphia Medical News* a series of these cases in which he took the ground that these cases of continuous fever were not typhoid fever, and that with a little proper alimentation and a little common sense the patients recover in from six to seven weeks.

MR. WEIR—I was so unfortunate as not to hear the paper under discussion read. Having been only ten years in the practice of medicine I have some timidity in rising here, where I shall put myself on record as one of the profession who has faith in the abortive treatment of typhoid fever. I have been called to cases in which there was a muffled sound of the heart, in which there was a rise in temperature from the morning to the afternoon, and where all the other symptoms common to typhoid fever have existed, and my diag-

nosis was incipient typhoid fever. And I hastened at once to begin the use of intestinal antiseptics. I used the hypsulphite of soda and muriatic acid. I clear out all of the organs of elimination. And I will have to take issue with one gentleman when I say that in my experience in one or two cases I have found constipation; the rest of the cases were decidedly diarrhetic. I was then confronted by members of the profession who said: "Doctor, there is an error in your diagnosis; it is not typhoid fever in the patient, but the trouble is professional cerebral inaptitude." Mr. President, that put me on my mettle. I got down my Flint, I got down my Costa, and my Guttman, and my reference note-book, and other works, and I began the study of the abortive treatment of typhoid fever. What I discovered there was truly surprising. There were statements made by men of eminence, whose diagnostic powers have never been questioned, that I would not have believed had they not been matters of record, had they not been in black and white, and, to my knowledge never refuted. I was told there that there had been cases of typhoid fever that had been aborted that were of only three days' duration. I was told in these references that there were cases of typhoid fever that had been aborted in seven days, in nine days, in fourteen days, in twenty-one days. I was told that there were cases of typhoid fever in which there had never been a rise of temperature. Now, I didn't know I was going to get on the floor here, or I would have had my references tabulated, and give you the pages, and the statements.

Now, gentlemen of this Section, you know nothing of me; I am an entire stranger to you. Just to show you to what lengths I have gone in typhoid fever, I will state that in one case I had a condition of relapse of seventy-two hours. In that time I gave four hundred injections of brandy hypodermically; I gave one and a half ounces of carbonate of ammonia, in doses of 1 to 10 grains at a time. I rendered his blood in such a condition that he became just one entire mass of erythema. But I would rather have a live typhoid recovery than a dead therapeutic failure.

And I take my place on the floor to state emphatically, that I am an absolute believer in the efficacy of the abortive treatment of typhoid fever.

DR. WOODBRIDGE—These gentlemen will get so much for me to answer if they speak much longer that I will not remember more than half of what they say. The gentleman who has just spoken is right; that the time has already come when the profession must recognize that typhoid fever can be aborted. And I say that the time will come when it will be more of a disgrace to any member of the profession to have a death from typhoid fever than it is to-day to have a death from measles. The evidence has been before you since typhoid fever was first known. It has been a matter of record through all time that there are a very large number of cases of so-called aborted typhoid fever. They were simply cases in which the physician, unwittingly, perhaps, placed something in the stomach or alimentary canal that destroyed the germ. And, if that is the case, why not take it a step farther and use it in all cases? It seems to me that if you accept, as I say in my paper, the theory that the germ itself is present, you must accept the corollary that the germ can be destroyed. If it can be destroyed in one alimentary canal, why not universally? You do not treat typhoid fever. The physician who practices the methods of the past will not treat the patient at all. The gentleman who first spoke asked me if I would administer opium if the patient had diarrhea. I say most emphatically, no; no astringent whatever. Don't interrupt nature in her good work, but rather, if your patient has diarrhea, give him a dose of salts. But I wish to give the effect of my antiseptic. I am not a stickler for this particular formula; I only give that because it is the one that seemed to me the most useful. There are probably hundreds of others just as good; anything that will thoroughly cleanse the alimentary canal is good; plenty of hot water might do it. Even though your patient has diarrhea at the beginning, administer this preparation, which is a cathartic in large doses, and you will stop the diarrhea. One gentleman said that when the temperature got to be 103.5, he gave cold baths or sponges. I think that is wrong. I think that anything that reduces the temperature is detrimental, except as you have seen that I use euca-lyptol. I was called to one case on the sixteenth day when the temperature was 105, the abdomen was greatly distended, and when the lips were glued to the gums—and right here I wish to say that the gentleman didn't understand me rightly when he understood that I never had hemorrhage of

the bowels. I have had two. What I say is this: If the patient is properly treated from the beginning, he will never have a hemorrhage of the bowels, and I mean, too, the slightest seepage of the blood. I mean that the result of the treatment will be that there will be no hemorrhage; if you administer this or some other antiseptic the symptom will not appear, and the evidence that the germ is performing its work upon the glands will be conclusive that he is no longer doing any such work. Although I may be wrong I believe this: That the germ of typhoid fever as a germ, as a living germ, although he may have been living buried in the glands of Peyer, is harmless; the idea that he throws off a germ that produces all this is, I think, an error.

Now, it took me eight or ten years to believe that to be typhoid fever. There is no man living so learned that I would have accepted his statement fifteen years ago, that typhoid fever could be aborted. I was so strongly convinced in the matter that when a man told me he could abort typhoid fever, I would have said he has either made a mistake in diagnosis or he has not given a statement of fact. But some of my grievous mistakes taught me that typhoid fever can be aborted. I don't mean to say that because I have taken cases at the eighth or tenth day and aborted or cured the disease, that every case at that stage can be aborted; but I do say that if you will regard it as a case of typhoid fever and treat it by this method from the very start it can be cured, can be aborted. And this treatment is not only the best treatment for typhoid fever, but it is the best for any disease that is taken for typhoid fever—for diphtheria or pneumonia. I know of no better treatment for diphtheria than the use of some of these antiseptics. And I say that for the purposes of this treatment, make the diagnosis not when the rose spots appear, not when the bowels are intensely distended, but when you see the very first indications. Let not one moment of time pass.

I want to answer one question by a gentleman as to how I could diagnose a case as typhoid fever where the fever was aborted on the eighth day. If you treat typhoid fever you will often see cases where you can make a positive diagnosis. As a general thing on the charts you will find a little figure in the left hand corner, showing the number of physicians, one, two, three or four, who have confirmed the diagnosis. I would never have dared to go before the profession and state what I have here if I had not the statement of a score of physicians, and men as able as any one; men of high reputation as diagnosticians. It is one of the worst statements that was ever made that typhoid fever can not be aborted, the many men of high standing to the contrary notwithstanding, though no man appreciates more than I do the great learning and ability of many of them; they have been stumbling blocks in the way of progress in this direction beyond a doubt. But to return to the gentleman's question as to how I would make a diagnosis when the disease was aborted on the eighth day. I have in several instances had patients eating beefsteak when they were yet covered with rose spots, the other symptoms having disappeared before that. In order to reach that it is necessary that the patient should be properly treated from the beginning. I do not mean that it is wise to let every patient eat beefsteak, but, to repeat, if you will treat them as I say, they may walk and eat beefsteak, and it will do them no harm.

THE LAW OF EQUIVALENCE IN MEDICAL SCIENCE.

Read in the Section on Practice of Medicine, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY R. W. MURPHY, M.D.
SAN FRANCISCO, CAL.

There is a law of exact equivalence which pervades all nature. This law while perhaps most emphatic in mathematics, in music and in chemistry, is none the less true in the evolution of mineral, vegetable and animal development. The same is also true of all the various diseases when considered in relation to their antecedents.

It was not until the germ theory attracted the attention of scientists or rather was brought to light by scientists that much attention was paid to the antecedent of diseases; the effect was only considered

and treated by our physicians. Each separate disease or ailment must be the equivalent of the producing cause, and any remedial agent that cancels or cures the disease must stand as the equivalent of the antecedent producing it. This proposition being correct, would lead us to first consider the importance and value of a prophylactic.

We all know that vaccination with a specific virus will prevent smallpox. This being true, vaccination must stand as the equivalent of the antecedent that produces it.

The French scientist, Pasteur, has given to the world a prophylactic for hydrophobia which must ever stand as the equivalent of that much dreaded malady. The world renowned Prof. Koch, of Berlin, thought he had not only found a cure but also a prophylactic for phthisis, but as yet his feet do not rest upon the sure foundation of scientific truth where he can unfurl his banner with Eureka written upon its folds. But we predict the time is near at hand when medical science will not only find a cure but a prophylactic not only for phthisis, but also for cancer, for Bright's disease, and other diseases now considered incurable which are known to be hereditary.

Examine minutely, with the best glasses, the germ cells in the broad field of biology and you detect no difference in them, but let the life germ become vitalized and development take place, as evolution proceeds we find that at a certain point a weakness, a lack of the normal strength and vitality is shown, and if not checked will soon get beyond our control, but if medical science can furnish a prophylactic, and the rising generation liable to hereditary disease receives timely treatment, we may not only ward off but soon render the lineage immune, so that heredity will not be known.

The diversity in the type of disease must ever be in strict accordance with this law of equivalence. We may not be able to tell how many bacilli are necessary to produce typhoid fever or scarlet fever or diphtheria, but as we have the mild and the severe or malignant types, everything being equal they must ever be in a ratio of exact equivalence to the antecedent.

But what claims our attention more particularly at present is the great diversity in the treatment of the same disease by our physicians.

In the January issue of the *New York Medical Times*, on page 17, the editor says: "That at present a large part of the effort at teaching materia medica is thrown away because it has no practical application in the treatment of diseases. Graduates of medicine are turned out with little idea of what to do with drugs in treating the sick, and many even doubt whether they are of any use whatever, because teachers and students are all at sea respecting their adaptation. It is time that we should have more practical text-books from which students may individualize the action of drugs according to effects produced by maximum and minimum doses, for this is the only basis upon which a decision can be reached in regard to the selection.

The primary and secondary symptoms furnish no reliable data in this direction as claimed by some. The physician in the future will be a man who recognizes the dual action of medicine and governs his practice accordingly.

The dual action of medicine upon the system,

closely observed, may lead to the dose which will be the equivalent for the error to be corrected, neither too small nor too great.

Our text-books and our teachers in medicine do not agree as to the dose of medicine to be given even in the same disease; the great range of latitude so marked among our doctors has led some to place the practice of medicine outside the pale of science.

I knew a doctor to give a patient 40 grains of calomel at one dose and in three hours repeated it; while one of our leading physicians tells me he gets very satisfactory results from one-twentieth of a grain in adults and one-fiftieth of a grain in children, given every hour or every two hours. In hepatic trouble 10 or 15 grains is very frequently given to be repeated once in four or six hours.

In the use of quinin we also find the range from the minimum to the maximum to be very great. Some will advise 2 grains, others will advise 4, others 6, and others 10 grains once in three hours. Some will advise 30 grains at a dose, to be repeated every three or four hours. We are told, in Japan and in Southern malarious districts they often give 40 and 50 grains at a dose.

Several years ago a very wealthy man in St. Louis was taken with a severe congestive chill. Three or four doctors were called, Prof. McDowell among others. The patient's jaws were set so they could not administer anything by the mouth. Dr. McDowell put an ounce of quinin into a pint of warm water, stirred it up and gave it all by enema at once. This case was reported to me by Dr. A. C. Donaldson, who was present at the time. The patient recovered but his eye-sight was not so good as it was before the attack. Whether it was due to the large dose of quinin or to the excessive congestion they could not tell.

But it is not in quinin or calomel alone, but in nearly all the drugs in use do we find this diversity of doses among our professors and teachers and doctors; until one is ready to ask the question, Do we all belong to the same school?

Should we not study the dual action of all the various medicines until we find the equivalent doses to give?

But another remedial agent of great value that is used without the slightest regard to the law of equivalence is electricity. Many of our doctors use batteries without any indicator to determine the strength or quantity given, and but few study the temperament and vitality of the patient, but place them all in the same class. Many are benefited by the treatment while others are made worse. If there is any agent that should be studied and used in strict accordance with a law of equivalence it is electricity.

It must be apparent to all that there is a lack of practical scientific unity in the medical profession. The day of experiments upon our patients should be a thing of the past. It is the scientific discoveries of our profession and their application in the healing art that has drawn the lines so sharply between the regular and irregular schools of medicine. We should not be satisfied simply because we excel all other schools of medicine; we should not be satisfied or stop short of absolute scientific perfection in all the various branches belonging to our noble profession, and with the pages thus illuminated by science our young physicians will be able to trace clearly the lines of equivalence from antecedent to subsequent, and treat their patients accordingly.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

SATURDAY, AUGUST 25, 1894.

MALIGNANT GROWTHS AND THEIR TREATMENT
BY THE ANTAGONISTIC PRINCIPLE OF
ERYSIPELAS.

Of the questions that have been brought to the attention of the medical profession within the last year, decidedly one of the most interesting is that of the effect of erysipelas and the toxic products of erysipelas upon malignant growths. We have had for many years sporadic observations and suggestions as to a remarkable effect of intercurrent attacks of erysipelas upon malignant growths; but these have been for the most part vague and uncertain, and, perhaps from lack of convincing scientific verification, have not been regarded as more than doubtful clinical curiosities. Recently, however, under careful and systematic investigation in various quarters the subject has developed unexpected interest, and equally unexpected importance. The results, indeed, of this investigation which are being published from time to time, would seem to indicate that the subject merits the wide attention that it is unquestionably receiving.

The most extensive study of the subject that has been presented is that by DR. WM. B. COLEY, of New York City, who has embodied his experience in two papers published in the *American Journal of the Medical Sciences*, the first in May, 1893, the second in July of this year. These two papers present the record of forty-four cases of malignant growth, treated either by inoculation with erysipelas or injection of its toxic products. In the first paper DR. COLEY reported ten cases—six of sarcoma and four of carcinoma—treated by inoculation with pure cultures of the streptococcus of erysipelas. Leaving out of consideration for the moment the effect of the treatment on the tumors, the immediate result of his experience was to show that the production of erysipelas by direct inoculation was an uncertain procedure and one not free from danger. More

important than this, he found that in cases in which erysipelas was not produced a definite group of symptoms followed the injection of the pure cultures, consisting of severe chill, rapid rise of temperature to 103 or 104 degrees, nausea and prostration—a group of symptoms, in fact, exactly representing the stage of invasion of erysipelas and further, he found that this constitutional reaction was accompanied by changes in the malignant growths which resembled in all essential particulars the changes produced by true attacks of erysipelas. From this he was led to the interesting inference that the active principle in the process was the toxic products of erysipelas and, following that, that in all probability the beneficial effects of the treatment could be obtained by injecting the toxic products alone, without subjecting the patients to the risks attendant upon true attacks of erysipelas. Subsequent experience has established that this is true; so that the method has now resolved itself into the injection of toxic products.

His second paper, therefore, presents us with a series of cases treated, all except one, by the injection of the toxic products of erysipelas. Some of these were treated by the injection of the toxic products of erysipelas alone, but in most of the cases these were combined with a lesser quantity of the toxins of the bacillus prodigiosus. This modification was suggested to COLEY by the experiments of ROGER in BLOUCHARD'S laboratory in Paris, who found that the presence of the bacillus prodigiosus in cultures of the erysipelas streptococcus markedly increased the latter's virulence; and the combination, by increasing the effects of the erysipelas toxins, has proven a distinct advance in the technique of treatment.

In the second paper there are recorded the histories of thirty-five cases (which includes one case counted in the first paper)—twenty-four of sarcoma, eight of carcinoma, and three of sarcoma or carcinoma; we have, therefore, including the ten cases in the first paper, a series of forty-four cases of malignant growths treated by this method. As to the carcinomata and the three cases of uncertain character perhaps, for the sake of clearness as well as brevity, we had better omit them at once from consideration; for while the effects of the erysipelas toxins upon carcinomata have been of a very favorable character, the results thus far are not conclusive.

With the sarcomata, however, the facts presented are worthy of careful consideration. Twenty-nine cases are reported that have been treated by this method; and the results in these twenty-nine cases may be put briefly as follows:

One case of recurrent sarcoma of the neck and tonsil, which had been operated on by DURANTE, of Rome, and afterwards by BULL, of New York, and

which had passed beyond the hope of successful surgical interference is well, with only a trace of tumor left and no indication of recurrence of malignancy three years since cessation of treatment.

One case, equally as desperate as the foregoing is well, with no indication of recurrence fourteen months since leaving off treatment.

Two cases are well with no indication of recurrence, twelve months and three months, respectively, since leaving off treatment.

One case, a sarcoma of iliac fossa, is well one year since beginning treatment, with the tumor one-third its original size, and with all traces of malignancy destroyed.

These cases, it may be remarked parenthetically, are not offered as inoperable sarcomata on COLEY'S own authority, but all of them have passed under the critical observation of expert pathologists and surgeons, who have decided as to their character.

Of the twenty-four cases making up the rest of the series, eleven cases, some of which are still under treatment, showed marked improvement; ten slight temporary improvement; three no effect. Of the eleven cases classed as showing marked improvement much more could be made, were it not desirable in dealing with so treacherous a subject as the curative treatment of sarcoma, to exclude as far as possible all uncertain data. But it would seem that their aid is not necessary to give interest to the subject. Five cures in thirty cases is not a high record as percentages go, but when one remembers what "inoperable sarcoma" means, is it too much to say that these results are startling? What else, besides death, has ever been known to check the course of inoperable sarcoma before?

Finally, it remains to be said that other observers are confirming in their own experience the remarkable results reported by COLEY.

QUININ IN CHOLERA.

Although it might have been reasonably hoped that the remedial treatment of Asiatic cholera had lost practical interest for the profession in this country, the steady western extension of the epidemic in Europe and the recent disturbing appearance of cases in the Thames, hint at a contingency when it may become necessary to begin again the hitherto almost fruitless task of therapeutic experiment with this disease. Such a consideration lends especial importance and timeliness to the results of the researches of DR. FULLERTON, as set forth in his paper¹ read before the Ohio State Medical Society at its meeting of May 16, ult., and in which he arrives at the conclusion that, "If there is any reasoning in therapeutics—either by analysis or by synthesis, the American method that has done so much, or the

Continental, that has promised so much—with vigilance, activity and bravery, the mortality from cholera should not in the United States exceed 5 per cent."

These be brave words to use with respect to a disease which, according to HIRSCH, levied an average toll of 54.74 per cent. in the epidemics between 1852 and 1873—the lowest mortality (Pesth, 47.15) and the highest (Bengal, 64.85) for the period, being in the latest year, 1873, thus conclusively showing no gain in its therapeutic treatment during that period. And the showing is no better since HIRSCH. Our epidemic of 1873 gave a mortality of 51.65 per cent., that of the recent epidemic in Western Europe, 52.38 per cent.

Though DR. FULLERTON begins his argument deductively, on data furnished from the laboratory of PROF. KOCH—the results of experiments to determine the agents which kill, and those that only inhibit, the growth of the cholera spirillum—the bulk of his paper is made up of empiric observations on the use of quinin in the treatment of cholera by a number of authorities between 1831 and 1873, and these are by far the most convincing and the most valuable in support of his advocacy of the salt. Reference must be made by those interested to the original paper for these details, but space is here given for the following practical conclusions:

"Ten grains (of quinin) in powder, diffused through a small quantity of water, or in acid solution, at hourly intervals, until twenty to forty grains have been given, afterward *pro re nata*, should be the ordinary instructions; the same dose at half-hourly intervals for a sufficient time in collapsed or in *foudroyant* cases; smaller doses, perhaps, at longer intervals in choleraic diarrhea. There should certainly be retained, of other treatment, appliances for the restoration of heat; saline hypodermoclyses to supply lacking serum to the blood; morphin hypodermics to allay pain and cramps, with enteroclyses of quinin where, as past experience shows rarely to have been the case, the remedy is vomited; and in the sequent enteritis or otherwise persistent diarrhea, calomel in small doses should not be lost sight of. That by so treating our patients we may hope for a mortality in collapsed and collapsing cases of about 14 to 25 per cent. only; that by earlier administration of the remedy, instead of the use of other agents that have heretofore permitted so many cases to run on into collapse and death, we may reduce the mortality in such cases to 2 to 5 per cent. only, seems a fair assumption for the best of reasons—*i.e.*, it should be so, and so far it always has been so."

CORRESPONDENCE.

LETTER FROM EUROPE.

No. IV.

MUNICH, July 21, 1894.

To the Editor:—In my last letter written several days ago, I promised to say a word concerning the work in obstetrics, gynecology and diseases of children, in Prag. I will be very brief indeed and speak only of a few points that seemed to me of special interest.

The obstetrical and gynecological department is presided over by Rosthorn, a young man in his thirties, who was called, I believe, from the position of privat-docent in Vienna

¹ Is There a Better Remedy in Cholera? By Erskine B. Fullerton, A.M., M.D., Columbus, Ohio. N. Y. Med. Jour., Aug. 18, 1894.

to a full professorship in Prag, an unusual honor, especially in the case of so young a man. He is looked upon as a man of unusual promise. His gynecological clinics and his didactic lectures are always well attended. The obstetrical cases are divided evenly between the German school, the Czechish and the school for midwives. This gives to each department about eleven hundred cases a year, as in the lying-in-hospital there are yearly about thirty-two hundred patients. I had remarked before making a visit to the maternity hospital that I had, in my three months with Chiari, seen no autopsy on a case of puerperal septicemia. On referring to this fact in my conversation with one of Rosthorn's assistants, who showed me through the wards, I was informed that in the past year, from July 1, 1893, to July 1, 1894, there had been no death from puerperal septicemia in over one thousand cases. A more practical illustration of the advantages of antiseptic midwifery could not be asked. This category of cases does not include any case entering the hospital with an already developed sepsis, or any case in labor where a vaginal examination has been made outside the hospital. Such cases known to be infected, or to be looked upon as possibly infected, are carefully isolated and kept apart from the aseptic cases. The year before there was one death from sepsis.

Students are present at all cases of labor and have the privilege of examining the patient. They come in small sections. For a week before they are to witness a childbirth, they are required to keep entirely away from the anatomic and pathologic anatomic rooms. That their presence and even their contact with the patients, where careful preparation of the hands, etc., is attended to, is not detrimental, is proven by the perfect result of last year in an experience with a thousand cases. The details of the aseptic and antiseptic precautions need not be gone into. Suffice it to say that all that modern knowledge concerning a sepsis demands, is here rigidly complied with.

The Children's Hospital is really made up of two sections, one under Epstein, really an infants' or foundlings' hospital, where there is excellent opportunity for studying the diseases of the new born and the important question of infant feeding; the other the hospital for older children, under Ganghofner.

I was interested in listening to Ganghofner's remarks on diphtheria, in which disease he has had a wide experience in this hospital. No suspicious or questionable case is pronounced diphtheria without bacteriologic examination. Naturally most cases are quite readily recognized but here a bacteriologic examination is always made. All questionable cases are kept in observation rooms until the examination of the cultures reveals the presence of the Löffler bacillus or *vice versa*. This quarantine of about twenty-four hours works as can be readily seen with a double advantage. A child with a mild, unrecognized diphtheria does not come into a ward and infect other children free from the disease, nor does a child with a simple angina, a follicular tonsillitis so-called, become exposed to diphtheria by being placed in a ward with genuine diphtheritic angina. It is certainly time that all our modern hospitals had such observation rooms for suspected diphtherias. They would prevent much harm from being wrought to innocent and comparatively healthy patients.

Ganghofner's treatment of diphtheria may be briefly summed up as follows: Locally, a strong solution of corrosive sublimate or carbolic acid or tincture of the chlorid of iron applied with a brush. If gargles are used, or if there is any possibility of the solution being swallowed much weaker solutions are necessary. He also injects a few drops of a 5 per cent. solution of carbolic acid into the tonsil. He believes that this local treatment while not checking the dis-

ease *in toto*, does modify it in that the number of virile organisms is lessened, and therefore a smaller amount of toxine produced. He is extremely cautious about the local treatment of the nose by sprays, and particularly by douches, believing that he has seen several cases in which diphtheritic otitis media has been caused by the irritation of the Eustachian tube thus produced, and the extension of the inflammation up this canal to the ear. Iron, plenty of nourishment, alcohol in moderation, are recommended internally. Blood serum he has tried and with favorable results, though not in any great number of cases. In a case of impending laryngeal and tracheal stenosis through spread and growth of the membrane downwards, the disappearance of the membrane after the blood serum injections was little short of marvelous. The patient, however, died of cardiac failure. The autopsy revealed no remnants of the laryngeal membrane but a heart markedly fatty. The cardiac failure was looked upon as the result of the disease, and as brought about in no particular by the antitoxin. Mercurial ointment is regarded favorably in cases where the glands are much enlarged.

Intubation is the common procedure in cases of laryngeal diphtheria where stenosis is imminent. In private practice, however, Ganghofner does not consider it as applicable, because of the sudden emergencies that often arise through the coughing up of the tube or the blocking of the tube, by membrane or secretion, necessitating the prompt attendance of the physician. For hospital he regards this operation as preferable to tracheotomy.

I may say that while in Berlin I went through Bergmann's hospital in company with Dr. Murphy, of Chicago. We were shown the tracheotomy room and were told that the operation was one of daily occurrence there, and that for the past two years Bergmann had not allowed intubation in cases of diphtheritic laryngitis. Just the reasons for abandoning the intubation I do not know. The assistant told us that he himself had done in two months between sixty and ninety tracheotomies. Dr. Murphy remarked that we did not see in Chicago so many cases of diphtheria demanding operative interference as ten or fifteen years ago, either because the type of the disease had changed, or because it was better treated and laryngeal complications avoided. Certainly no such number of these cases as is met with in Berlin is seen in Chicago, either in private or in hospital practice.

Saturday, a week ago, I left Prag for Carlsbad, having a great desire to see this famous watering-place. It is a beautiful spot as regards its natural surroundings and has all that could be desired in the way of delightful walks, mountain climbs, drives, etc. Twenty-five thousand patients have already visited the place this summer and among them a large number of Americans. It is really a wonderful sight to watch the crowd at one of the popular springs, such as the Sprüdel or the Mühlbrunn. From 6 A. M. to 8 A. M. there is one constant stream of people. At 7, Sunday morning I saw a double line about two blocks long waiting patiently at the Mühlbrunn.

The efficacy of the Carlsbad waters in troubles of hepatic origin and in diabetes is attested by all German physicians with whom I have spoken. The manner in which the waters work is not clearly understood. One of the Carlsbad doctors told me that absolutely nothing was known as to how the amount of sugar was lessened by the Carlsbad treatment, in cases of diabetes. But he assured me that it was the rule for diabetes to be materially improved and for the sugar to lessen or even totally disappear in the course of a few weeks' treatment. That the change is not brought about by diet alone, is proven by the fact that a rigid dietary is not prescribed and, in many instances, the patient is allowed to eat what he wishes. Permanent cure of diabetes is not claimed

by the Carlsbad physicians. In cholelithiasis the good results are attributed, not to any chemic reaction causing the absorption of the stones, but to their mechanical expulsion through the common bile-duct into the duodenum. Patients suffering from gall-stones who have had perhaps occasional attacks of hepatic colic are almost sure, when drinking the Carlsbad waters and taking the baths, to have frequent, even weekly, attacks of gall-stone colic. Some, or all of the stones may, as the result of the increased peristalsis be expelled.

The physician from whom I learned these facts criticised quite sharply the too common practice of sending absolutely incurable cases to Carlsbad, cases that should be cared for at home. This, he said, was particularly true of carcinoma. Let a patient have carcinoma of the stomach, the liver or the pancreas and, if jaundice were present, he was promptly shipped to Carlsbad because, forsooth, Carlsbad was good for jaundice. From personal observation I know this to be true, for I saw a patient who had but a few hours to live, whose physician had sent him to seek the benefit of the waters for his jaundice, and whose Carlsbad attending physician had told the family of the malignant and incurable nature of the malady, too late for the poor man to be removed to his home, about one hundred miles distant.

While stopping at Nuremberg I made an excursion to Erlangen, fifteen miles out from the city and spent a most delightful forenoon with Strümpell. I found him a most charming man, affable, and very cordial in his reception of me, a total stranger who had naught save a visiting card by way of introduction. In his clinic his evident aim is to be a teacher. There is no attempt at display of great erudition, no dramatic presentation of cases. In the clinic which I had the pleasure of attending, he exhibited a case of cardiac valvular disease, peculiar in that, while the lesion was apparently a mitral insufficiency, the consequent hypertrophy was almost exclusively of the right heart. The questions of congenital lesions and of pulmonary stenosis were discussed and the diagnosis of mitral insufficiency was guardedly made.

The second case was one of myoclonus multiplex. The patient, a young adult male, strong, well developed, had for three years, been annoyed but in no way incapacitated for work, by the involuntary contractions of various muscles or parts of muscles. The case resembled those first accurately described by Friedreich as paramyoclonus multiplex. The pathology of the disease, so Strümpell said, was still unknown, though the seat of the lesion was probably, according to his view, in the cord or its cells. The case in hand was only unusual in that the muscles of the tongue were involved. The case was made useful to bring out the differential diagnosis between this disease and chorea in its various forms, multiple sclerosis, paralysis agitans and particularly hysteria. This latter condition Strümpell believed, explained some of the remarkable reported cases of myoclonus multiplex, especially those where there had been a sudden onset or a sudden cure.

After the clinic I spent a most enjoyable two or three hours in the wards with Strümpell. His rooms are old and he is obliged to treat some cases, *e. g.* gonorrhoea, that he would probably gladly transfer to other departments. But in over one hundred beds, he always finds enough material that is interesting and instructive, and particularly as many cases of nervous diseases are sent to him from a distance. He had two cases of brain tumor in his wards, one a child *in articulo mortis*, and the other an adult where partial monoplegia with occasional spasm, headache, and choked disc were the main factors in leading to a diagnosis. In this case operation was advised. A case of Basedow's disease in which the enlarged thyroid gland had been removed, seemed at

the end of a week slightly improved as regarded tremor and exophthalmus. That permanent good in this instance, or in similar cases, would result from thyroid extirpation, Strümpell was not prepared to say. Cases of multiple sclerosis, of carcinoma of the liver, biliary cirrhosis of the liver, amyloid kidney, etc., were shown, and I left Erlangen feeling that I had spent a most pleasant and profitable day in intercourse with one of the brightest medical minds of Europe. My day with Strümpell only served to enhance in my eyes the value of his text-book which I had already regarded as surpassed by no other book of the same scope.

I have seen here in Munich, Ziemssen, Bauer, Winckel and Bollinger, and hope in Heidelberg to witness the work of Erb and of Vierordt. If I can find time to spare from my clinical work and sight-seeing I will describe in my next letter my impressions of these men.

I may say here that Winckel retains pleasant memories of his stay in Chicago last year. He was particularly shocked and surprised to learn of the death of Dr. Charles Warrington Earle, and referred especially to the jolly time they had together at the banquet given by the Chicago gynecologists to Prof. Winckel, where Dr. Earle sat by the side of the guest.

It is, I believe, true of Winckel that his reputation as a specialist is as great in his own city as it is abroad. This certainly speaks well for him. For I have observed in not a few cases, that the names known favorably abroad are not those of the men with the greatest reputation at home. "A prophet is not without honor," etc.

JAMES B. HERRICK, M.D.

Etiology of Pneumonia.

CHICAGO, Aug. 8, 1894.

To the Editor:—The elaborate and valuable paper of Dr. Richter on the "Influence of Atmospheric Pressure on the Prevalence of Pneumonia," published in the *JOURNAL* for Aug. 4, 1894, I have read with great interest. One of the statements made by this writer requires explanation, that error may not be promulgated. I refer to that on page 189, second column, where it is stated that "Wells and Hirsch and every other writer on the subject discards air pressure as a causative factor." This would lead the reader to infer that the subject had been carefully investigated by these authors and that they had arrived at the conclusion that atmospheric pressure was not a factor in the etiology of pneumonic fever. Speaking only for myself I will say that in the series of articles to which Dr. Richter refers, expression has been given to the following opinion: "It may be affirmed, as a general proposition (to which there are many exceptions), that pneumonic fever will be found to prevail to a greater extent than ordinarily, the influence of season and epidemics excepted, when the daily range of temperature, humidity of the atmosphere, velocity of the wind, range of barometer, amount of atmospheric pressure and amount of ozone present in the air are greater than the average, and that it will be less prevalent when opposite conditions prevail. Again, it will be found that an excess of cases will be met with when the range of temperature is low, the barometer falling and the ground water low."

These general and, it must be freely confessed, unsatisfactory statements are the conclusions derived, in so far as the italicized portions are concerned, from a study of the papers of Baker, Biach, Sanders, Juergensen, Purjesz, Seibert, Stortz and others and of a great mass of facts collected by myself. This last material it was found impracticable to analyze on account of its diffuse and contradictory nature and its bewildering extent. From it, therefore, only the impression above given could be extracted. It must be

clear, therefore that the influence of atmospheric pressure in the causation of the malady in question has not been totally discarded by me and that the meager consideration given it was due to a lack of knowledge rather than a lack of appreciation of the importance of the subject. On the contrary, my investigations were sufficiently extensive to profoundly impress me with the far reaching importance of the rôle played by this and other meteorological factors in the production of pneumonic fever.

Dr. Richter is to be complimented upon the general excellence of his paper and upon the industry displayed in its preparation.

EDWARD F. WELLS, M.D.

ASSOCIATION NEWS.

Section on Neurology and Medical Jurisprudence.

At a meeting of this Section during the forty-fifth annual session of the AMERICAN MEDICAL ASSOCIATION the following preamble and resolutions were introduced:

DR. CROTHERS—Now, Mr. Chairman, I have here a resolution which reads as follows:

"WHEREAS, In view of the fact that the problems concerning the care and treatment of inebriates, have become of practical interest in every part of the country; therefore

"Be it Resolved, That we earnestly wish and advise the erection of a special asylum for the care and treatment of habitual drunkards in each State of the Union; also

"Resolved, That such asylums be organized as industrial homes where each person can be placed under restraint, treatment and medical care for a sufficient length of time to promise full restoration."

DR. GAVIGAN—I thought that there would be room for such an institution, and if it was advised by this Section, those who think well of such a movement would have some support in going before a legislative body asking for the appropriation of moneys for the purchase of a site, etc. It is hardly probable though that it would materialize in this State in the next year, or the year after, or the year after that, but still it might, in time, and there is nothing like agitation.

THE CHAIRMAN—The trouble with many of the public institutions we have now is the same as with the Washingtonian Home, located in Chicago. It is not a public place or home, and there is now litigation over the funds. In that institution they take the patients and give them a few wholesome lectures and then send them out, but there is no authority sufficient to keep them there long enough to correct their neurologic or neuropathic tendencies.

DR. HEISHOLT—That is where the trouble comes in, in regard to their incorporation. Generally speaking it is necessary to have laws regulating the detention of such people in any place of restraint. So with criminals. It is a farce here, looking at it from a legal standpoint. The criminal is adjudged insane, sent to an asylum and if he is considered well at the end of three or six months, the superintendent can not keep him; and if the superintendent wants to do what is right and keep him as long as necessary, the individual will have some friends who will get him out on *habeas corpus*. In New York there is a law, I believe, requiring that they should not be kept less than a definite period. There are not many States who have such laws, but there ought to be. With regard to asylums of this kind, I think the time is ripe for it here in California. We have a home for inebriates—I don't know whether you have read much about it—but it has been discussed in the papers here and criticised severely—I see patients from there every now and then; they are kept there one or two or three days or a week, and certainly the treatment is not right or proper.

THE CHAIRMAN—We have in the State of Illinois, in our State Medical Society, a committee on legislation. We have had that committee for a good many years and we are getting the people educated up to some pretty good laws. We have had some improvement in our legislation governing the commitment of the insane and we are getting little improvements every time the Legislature meets. We are working away at it vigorously and are quite satisfied with the results. But the doctors have to do it; the lawyers never will improve the laws. The more complicated the laws are, the better it is for the lawyers. As long as a lawyer can get a fee for *habeas corpus* in the case of an insane person in an asylum the laws will be continued. You must educate the people up to the proper standard.

DR. GAVIGAN—My idea in having this presented is that although we are a small body here this morning, yet at the same time the resolution adopted by this body is official and can be embodied in a petition to the next Legislature which will assemble in January. Now by going before that body, and having a bill properly presented and introduced—accompanying that bill would be a bill amending the laws to conform to the detention of inmates or proposed inmates in insane asylums—by agitation probably, as Dr. Heisholt says, we will get it in a couple of years or three or four years. As the Doctor says, there has been considerable in the newspapers about our local home. The question has been raised as to who owns it. Nobody can tell, and it is thought by some good lawyers that if a suit were brought it would escheat to the State. It was formerly originated by a Society organized here some years ago, and well known as the Dashaway Society. That society has disincorporated and there is no head. The directors seem to be supreme, the public has lost interest in it, and it brings ridicule upon the question of inebriety—people seem to ridicule and criticize it unfavorably. So I think if we have in this State an institution under the care of the State and looked after by the State officers, as our insane asylums are, it would be advantageous to the poor inebriates within the State and would probably lead to like establishments in other States. They have an institution of that kind in Massachusetts, I believe.

DR. CROTHERS—Yes. Patients are sent there for three years. It is an industrial asylum, working on five hundred acres of land. They have 150 people there now; every one is placed there for three years, and if they run away they are obliged to return. We have in our State (Connecticut) a law by which a man can come to my institution or any other, and commit himself for four months, by simply going in and asking to be received, and we hold him the same as a man in an insane asylum; if he runs away we have simply to ask the police force of the State to arrest him and return him, but within four months he has his liberty. But if the laws or the courts choose to examine into his condition as to habitual drunkenness, and determine that he is a habitual drunkard they can send him for three years, one at the institution and two years on parole. And supposing he goes out at the end of a year and relapses in the course of a month or two. He is returned at once, and then the three years continue from the time of the last lapse, so that some men may be under the control of the law forever.

DR. GAVIGAN—In England they have something equivalent to that.

DR. CROTHERS—Yes, but you have to go before a magistrate and certify that you do this of your own free will, and there is so much voluntary requisition on the part of the patient that they rarely ever do it. However, that is to be amended very soon. The Massachusetts law is a very good one and the institution is a valuable one and has a great future before it; and the intention of that institution and of

some of these others is to take up the men who are now repeaters in jails and prisons and under sentence for a short or long period and save the expense of repeatedly sentencing them. It costs from \$25 to \$50 every sentence—court fees and admission fees, and all that sort of thing. The idea is to sentence them once for such a length of time that they are not likely to get out and repeat the offense again. In our State we have a law and an institution organized but there is no public institution—no public industrial hospital, simply because we have been opposed by the temperance people. They deny the possibility of those people being sick and diseased and say it is a moral trouble entirely.

DR. HEISHOLT—There are two classes of people who are insane; epileptics and alcoholics, and in regard to the former a great deal has been done. There is an institution in Ohio, established about two years ago, a colony so-called—an epileptic colony. And now in New York it seems the scheme of Dr. Paterson is going to be realized. Now if that has been done for epileptics why couldn't the same be done for alcoholics? The trouble is that alcoholics while in the asylum have considerable control of their faculties, and they are so restless on account of their nervous condition that they bring about a similar restlessness in the others.

THE CHAIRMAN—We are getting things in shape in Illinois for the establishing and founding of an epileptic colony, and I should not be surprised if our next Legislature would do something towards the establishment of such a colony.

DR. HEISHOLT—I think I have over fifty epileptics in our institution, and I would say that 90 percent. of all the fights are brought on by epileptics. Just as you say there is always a woman at the bottom of a scandal on the outside, there is always an epileptic at the bottom of those fights in the asylum.

DR. GAVIGAN—I suppose that if you have that many in Stockton, Napa has probably a good many also.

DR. HEISHOLT—Yes, about the same proportion but they have two hundred people less. They should have about thirty I should judge, and Agnews probably would have twenty. That would be one hundred in all.

THE CHAIRMAN—Our object for establishing this colony for epileptics in Illinois is not only to take epileptics who are called insane, but to take independent epileptics generally and see if we can not do something towards improving their condition, to take those who are in the almshouse and elsewhere throughout the State and those who are cared for in their own homes, and see if something can not be done towards their cure as well as their care. That is the idea we are to take up, and I wouldn't be surprised if your Legislature did something this winter. We are getting our people educated up towards the proper appreciation of this thing.

DR. HEISHOLT—We have an institution in this State known as the Home for Feeble-Minded Children, in Glen Ellyn. The institution there is not an epileptic colony in the proper sense, because idiots and such cases are in there, but still it is better than nothing, only that the institution is a small one. You see we have at least one hundred in our State asylums that should be up there but they haven't room for them.

DR. CROTHERS—There is one pleasant feature about this whole thing. To push a theory is one thing and to push it against public sentiment is another. Here is the fact of the tremendous losses that follow from the alcoholic habit; and the fact that the railroad companies refuse to employ a man who is a moderate drinker is doing immensely more for us than all the preachers. We are just now on the verge of a great revolution in that way, a revolution that is founded on absolute necessity. Men refuse to employ alcoholics in their business, no matter how much genius there is, and the public recognize the tremendous losses they suffer, and hence

they are going to urge that a new method or a new means be employed to restrain that terrible evil.

THE CHAIRMAN—It was that public sentiment that made Keeley's institute a success—reaching out for something to check this evil. Keeley could not have been a possibility ten years ago.

DR. HEISHOLT—Speaking about railroad companies you might speak of life insurance companies. Life insurance companies within the last few years have made a clause as to that. I insured myself in a company here recently and a friend of mine did the same. Well, I rarely touch liquor. If I do, it is once in two or three months when I am in company with some one; but I could just as well abstain altogether. But my friend is a little different, and he was going to give up the life insurance policy on account of this clause, which is that if the policy holder should at any time take to drinking and that his death should have some connection with this habit that may develop, he would lose his claim to that policy.

DR. GAVIGAN—This State in 1882 by an overwhelming vote voted against what was known as sumptuary legislation, and in the last gubernatorial contest the prohibition party got about ten thousand votes. There is something behind that. Look at the next prohibition vote and see what will be the increase of votes. It is not prohibition which is doing it, but it is the wreck of alcoholism that is doing it. They had a temperance congress here some time ago, in connection with the Midwinter Fair, and two days afterward the liquor men of the whole State met for protection.

DR. CROTHERS—I had an article in the *Public Science Monthly* for June. Dr. Appleton Morgan wrote an article in the March number entitled, "Does Prohibition Prohibit?" showing that prohibition did not decrease but rather increase the drinkers. My article was in reply. He is a very good man but evidently under the influence of the beer men. It is most extraordinary the statements he has made; for instance, that there was no prohibition until 1832. The fact is, prohibition has been going on in the country since 1640, soon after the settlement of this country, when they began the prohibition of the sale of liquor to Indians and minors, and on Sundays. I have made clear the idea that if it is true, our theories concerning alcohol are true, and are borne out by future experiments, that alcohol is a depressing agent, prohibition is bound to come whether it is urged by a party or anything else. And it won't be a question whether prohibition prohibits or anything of that kind, but we will take up the alcoholic question the same as we take up the question of polluted springs, or any other such question of public importance, and we will abolish saloons the same as we do pest-houses.

BOOK NOTICES.

Transactions of the Association of American Physicians. Ninth Session, held at Washington, D. C., May 29-30, 31 and June 1, 1894. Vol. ix. Philadelphia. Printed for the Association. 1894.

This volume, which has been issued with commendable promptness, contains the minutes of the meeting, list of officers, honorary members, and members; the constitution, and twenty-four papers read at the meeting. We learn from the minutes that there were seventy-two members present, and we are pleased to note that an examination of the list shows that about one-half of them are active members of the AMERICAN MEDICAL ASSOCIATION. The papers have, we believe, all been printed in the several medical journals during the year.

The interesting address of the President was published in this JOURNAL with editorial comments June 9, 1894.

The volume is an instructive one. Many of the papers are contributions of permanent value to the medical literature of the period, and it is a great pity they were not read to the larger audience of the great ASSOCIATION.

PUBLIC HEALTH.

A Notable Precedent.—The Toronto courts have recently had the question of the contagiousness of consumption before them. A health officer had demanded the exclusion from school of a child suffering from tuberculosis and his action led to legal proceedings. The judge sustained the action of the health officer, deciding that the disease is contagious.

Smallpox in Milwaukee.—Under date of August 18, Dr. U. O. B. Wingate, Secretary of the Wisconsin State Board of Health, thus summarizes the smallpox situation in Milwaukee: "At present the city is orderly and everything is being done that can be done to control the outbreak. There are at present about fifty-five cases in the city. There have been 31 deaths out of 121 cases reported up to this date. A large corps of physicians are vaccinating from house to house, extra barracks are being erected, in order to relieve the hospital which is now full. Two sets of inspectors are on at the depots, one for day and one for night service; also at the steamboat wharves, doing everything possible to prevent suspects, or those coming from infected districts, from leaving the city. The railroad authorities and boards of health in the adjoining towns to the city are coöperating to prevent all such persons from boarding the trains at those points."

Need of Sanitary Organization.—In a recent address before the Cleveland, Ohio, Medical Society, Prof. William Pepper recalled that when the International Medical Congress met in Philadelphia in 1876, the address on "Hygiene and Preventive Medicine," delivered by the distinguished Bowditch, himself a pioneer in sanitary science, was one of the most impressive utterances on that important occasion. The review he gave of the work of the previous century in this country in sanitary science was not flattering; but with the fine enthusiasm which marked that gifted man he predicted the immediate opening of the grandest epoch yet seen in the history of medicine. His closing appeal must be quoted: "Our present duty is organization, national, State, municipal and village. From the highest place in the national council down to the smallest village board of health we need organization. With these organizations we can study and often prevent disease." Much had been accomplished, it is true, in preventive medicine before 1876, when Bowditch spoke; but it is scarcely an exaggeration to say that the progress in the past twenty years has been greater than in the preceding twenty centuries. And yet the need of sanitary organization and of adequate sanitary legislation is still a pressing one. Sanitation by "bluff," or by tolerance, or at best by individual effort, is still too frequently the rule in many communities and commonwealths. Only thorough organization can secure the legislation necessary to make public hygiene really a science and not an intermittent and unreliable rule-o'-thumb procedure.

A Minister of Public Health.—There is a demand on the other side of the water, also, for a more signal recognition of the transcendent importance of public hygiene and State medicine, by the creation of the office of Secretary or Minister of Public Health. In his address at the recent meeting of the British Medical Association, on "Sanitary Science and the Prevention of Zymotic Disease," the veteran sanitarian, Sir Charles Alexander Cameron, regretted that medical men, even from a public health point of view, play a very subordinate part in the functions of government in Great Britain—only one, Sir Walter Foster, occupying a position which gives him a direct share in the administration of any great department; and only two of the 250 Privy Counsellors having medical qualifications, Lord Playfair and Prof.

Huxley. Prof. Cameron points out that in Germany medical men are constantly appointed Privy Counsellors; that the government of that empire is largely in the hands of those who possess the highly prized titles of Professor and Doctor; that the Prime Minister of Hungary is Dr. Alexander Wekerle; and adds that: "As the present tendency in the social world is the upheaval of the lower strata of society towards its 'upper crust'; as the working man has become a senator, and mechanics are being metamorphosed into justices of the peace, we may hope soon to find some of the members of our profession following in the wake of Sir Walter Foster and taking high places in the executive government of the country. Hitherto we have only been permitted to suggest measures for the promotion of the public health; it is time that we should have a more direct influence in sanitary legislation and in the administration of the sanitary laws. There are many medical men eminently fitted by their culture, experience, and ability to hold the office of Minister of Public Health—aye, even with a seat in the Cabinet!"

Extension of Cholera.—Recent advices of the western extension of cholera in Europe are less reassuring. There are conflicting reports as to the situation in Russia, but in the other infected countries, from which information is less trammelled and more trustworthy, the disease is known to be spreading. North-eastern Austria is completely in the grip of the epidemic and the German Cholera Commission has been again convened in order to consider the serious news that the scourge has not only spread to East and West Prussia, but that genuine cases have been found at Cologne. In East Prussia the new towns affected are Johannisburg, where there have been over fifty deaths, and Lyck and Allenstein; in West Prussia, Althof and Thorn are among the towns where cholera now exists. In the Low Countries, Holland and Belgium, the infected area is undoubtedly increasing, but the disease appears to have died out in the localities hitherto reported infected in France. Following upon Dr. Klein's confirmation of the diagnosis of Asiatic cholera on the *Balmore*, which arrived from St. Petersburg at Gravesend on the 7th, with one fatal and four other cases on board, came the discovery of the disease in London itself—eleven cases, with two deaths, being announced on the 20th in the Battersea district on the Surrey or south side of the Thames. It is learned that the disease was brought from Amsterdam by seafaring men who had arrived within the fortnight, but some of the victims were natives of the district. The Local Government Board and port sanitary authorities, it is reported, though not taken by surprise, confess to some chagrin and are exercising every precaution at exposed points. The restriction of cholera by purely sanitary preventive measures is likely to be as severely tested again in England as at any time within the previous years of the present pandemic.

Startling Propositions.—The full bench of the Massachusetts Supreme Court, in a decision rendered June 20, ult., announces certain propositions which imply a condition of statute law which can not be too soon remedied in the interest of individual and of public health. These propositions are, in effect, that a landlord is not legally bound to inform his tenants at will of sanitary defects in the drain of the house; neither is he liable to the tenant at will in a suit for damages for negligence in not acquainting such tenant of defects in the drain which arose during the course of the tenancy, even where the condition of the drain caused one of the occupants to take typhoid fever and die. The suit which developed these monstrous propositions was brought by Mrs. Julia Bertie, administratrix of the estate of John Bertie, intestate, against Hiram P. Flagg. She alleged that

the defendant was the owner of the house 76 Poplar Street, and her intestate was a tenant at will of the premises; that in the course of making other repairs the defendant discovered that the drain was in bad condition and needed certain repairs; that he neglected to repair it, covered it up, and did not inform her intestate, and that "by reason of said negligence . . . the plaintiff's intestate, being ignorant of the condition of said drain, contracted typhoid fever" from it. The Court says that "this defect was an ordinary defect in the drain in use on the premises, and the danger was the ordinary danger from that source. It was discovered in the course of a tenancy at will. We are of the opinion that the landlord was under no obligation to repair it, and if we are to take it that the plaintiff was ignorant of the defect as well as of the failure to repair it, notwithstanding the allegation that the defendant refused to make the necessary repairs, we are of the opinion that he was under no obligation to disclose it." If this be the law in Massachusetts, or elsewhere, it behooves State Boards of Health to secure prompt correction of such legal condonation of crime against the sanitary interests of tenants.

NECROLOGY.

JOHN SEATON, M.D., of Fort Wayne, Ind., August 17. He was a member of the G. A. R. and Union Veteran Legion. He was a prominent Mason and Knight of Pythias.—W. P. Foster, M.D., of Warsaw, Ind., August 17. Aged 50.—David F. Urmy, M.D., of Gowanda, N. Y., August 17. He was formerly Attorney-General for the State of Colorado.—Stephen G. Risley, M.D., of Rockville, Conn., August 2. Aged 74.

MISCELLANY.

Should be Elected.—Dr. Charles A. Wells, of Hyattsville, Md., is spoken of as a candidate for Congress to fill the unexpired term of the Hon. Barnes Compton.

Death of the Leprologist, Danielssen.—The death is announced of Dr. Daniel Cornelius Danielssen, Chief Physician to the Bergen Leper Hospital, eminent for his lifelong researches on leprosy.

Ills of Body vs. Faults of Soul.—The following ingenious illustration tends to show how more important medicine is than psychology:

"Some man says that when one reads a medical book he fancies he has every disease described, but when he reads the work of a moralist he discovers all the faults it points out in others."—*Montreal Star*.

Inexpert Dentistry.—The Dental Society of New York City has recently undertaken to prosecute an amateur dentist. A compounder of patent medicines advertised a remedy for toothache. He was consulted by a poor woman. Instead of applying his drops, Johnson undertook to extract her aching tooth and in so doing broke off two teeth. These broken teeth have been the source of much suffering to the woman. The facts in the case were not long after brought to the notice of the Society above referred to, and the counsel of that organization has been ordered to proceed against the inexpert dentist, for a violation of the laws governing dental practice.

Hygiene of Sports.—The schematic program of the division of Hygiene in the Buda-Pest Congress of Hygiene and Demography, which begins next Saturday, is very elaborate. It embraces the following sections: 1. Etiology of Infectious Diseases. 2. Prophylaxis in Epidemics. 3. Hygiene of the Tropics. 4. Hygiene of Trades and Agriculture. 5. Hygiene of Children. 6. Hygiene of Schools. 7. Articles of Food. 8. Hygiene of Towns. 9. Hygiene of Public Buildings. 10. Hygiene of Dwellings. 11. Hygiene of Communication. 12. Military Hygiene. 13. Red Cross. 14. Saving

of Life. 15. State Hygiene. 16. Hygiene of Sports. 17. Hygiene of Baths. 18. Veterinary. 19. Pharmacology. The first topic under "16. Hygiene of Sports," reads as follows: "Different kinds of traveling and their influence upon the nerves and the formation of blood. Wedding tours."

Prophylaxis of Suicide.—Are gouty and rheumatic subjects less frequently the victims of suicide than those of the opposite diathesis? Statistics on this point are needed to complement the theory that the relation of mental depression and suicide to temperature is that of the effect of temperature on urate excretion. Alexander Haig, who has devoted much time to the study of this subject, now claims that his researches show an annual fluctuation in the excretion of uric acid, with its maximum in the warm months, April to July, and its minimum in the cold months, November to March; and he had previously demonstrated that an excess of uric acid in the blood causes high arterial tension profoundly affecting the intra-cranial circulation. Applying these deductions to the recent epidemic of suicide in France, coincident with the onset of hot weather, he finds the relation very interesting—"because it is just with the onset of the heat and the first great fall in the acidity of the urine that the great rush of stored uric acid into the blood will take place. Then, again, 6 A.M. to 12 noon—the most frequent time for the fatal act—is also just the time of the largest daily excretion of uric acid—i.e., the time when there is most of it passing through the blood—and the facts I have collected will, I think, fully bear out this observation." The prophylactic lesson of which is, to those of suicidal tendencies: Keep the renal secretion acid and the blood alkaline.

Reminiscences of Hyrtl.—A correspondent of the *Lancet* furnishes some reminiscences of the late Prof. Hyrtl the famous anatomist who has just died in Vienna. His sympathy with student life is well known, and many stories in this connection are told of him. A Jewish medical student named Jerusalem was being examined, and in the hall there was waiting a small crowd of his co-religionists, when Hyrtl came out from the examination chamber. He was immediately surrounded by the crowd of young students, who asked him the fate of their comrade Jerusalem. Hyrtl, with a plaintive voice and sympathetically shaking his head, said, "Weep, O Israel; Jerusalem has fallen." Once a student was unable to reply to one single question at his examination. Hyrtl then asked him, "Perhaps you can tell me where you live?" The student named the street, of which Hyrtl professed his ignorance, and said: "You see how science is divided; you know nothing of anatomy and I do not know the locality where you live." An anecdote respecting his marriage is worth repeating. It was in the year 1866, when one day Hyrtl approached the porter of the Anatomical Institute, Andrew Swetlin by name. "Andrew, have you a prayer-book handy?" asked Prof. Hyrtl. Andrew fetched the book, and Hyrtl went away. An hour later he returned and handed to the porter the prayer-book. The porter, unable to suppress his curiosity, asked: "You do not need it any more, Sir?" Whereupon Hyrtl replied: "No, thanks; I only needed it for a moment. I have just been at my own wedding."

Man Growing Lazier.—Man grows more and more lazy every year. He is living in a machine age, when his walking and his climbing, if not his eating, are done for him by some mechanical invention too obvious to be recorded. If it were not for the athletics and gymnasiums, it is believed the race would lose the use of its legs, as scientists say it is losing its jaws and its teeth from too much civilization. Men who used to skip up the long flights of stairs of downtown buildings without a murmur now complain if they are asked to walk up one. And it isn't age, either, for boys in their teens will "wait for the elevator" an hour rather than give their legs needful exercise. The result of so much level action would be horrid was there no bicycle in existence. But the wheelman goes "up-stairs" for hours and says not a word when there is a saddle under him. It may be this universal wheel is the real cause of the present indolence. On some new principle developed by this popular motion

otherwise able-bodied citizens now refuse to live in houses with high stories and no "lifts," and kick at any "steps" over or under any railroad tracks. In short, there are people who would rather risk their lives than have the grade changed on a road they would be in the habit of crossing.—*Boston Herald.*

Non-Expert Opinions on Questions of Health.—There are many cases, says the Supreme Court of California, in the recently decided case of *Robinson v. Exempt Fire Co.*, where a witness, though not an expert, may be permitted to state the result of his observation, notwithstanding it involve in a sense his opinion or judgment, such as the apparent state of health of a person, whether a person is drunk or sober, or other characteristic or state which manifests itself to the apprehension of the common observer. It is sometimes difficult to distinguish between that which is purely matter of opinion, and so not admissible, and that which partakes of the nature of a fact by reason of being the result of personal contact and observation by the witness, but this difficulty does not in any sense militate against the rule. There are many matters of importance to the investigation of truth that could not be established or presented to the jury if this were not the rule. Here, a witness, who knew a certain person quite intimately, and saw him frequently, and had conversations with him about his health during a period when it was in question, was asked this question: "Well, now, when you saw him on these occasions walk along, when he noticed you, was he or was he not apparently well?" This the court holds was competent. True, it says, the question tended to elicit the opinion of the witness, who was not an expert; but it called at the same time for the fact of the physical appearance of the person referred to, as a result of the witness' observation, and that fact the party was entitled to lay before the jury.

Abatement of Nuisances by Boards of Health.—The Court of Chancery of New Jersey holds, in the case of *Board of Health of North Brunswick Township v. Lederer*, decided June 5, 1894, that where it appears that the odors and gases from an establishment, of the nature of one for fat-rendering, produce headache, nausea, vomiting, and compel citizens to close their doors and windows, both by day and at night, and interfere with them in the enjoyment of their meals and of sleep, such establishment is a nuisance; and it is the duty of the boards of health, in such cases, to take proper measures for their abatement. Furthermore, the board of health in the township in which a nuisance exists, or is carried on, has the authority, and it is its duty, to abate such nuisance, either on its own motion, or by the aid of the court, though it is only hazardous to the health of individuals residing in another township. Carrying on an offensive trade for twenty years in the same place, remote from buildings and public roads, does not entitle the owner to continue it in the same place after houses have been built and roads laid out in the neighborhood, to the occupants and travelers upon which it is a nuisance. In such cases, prescription, whatever the length of time, has no application. Every day's continuance is a new offense, and it is no justification that the party complaining came voluntarily within its reach. It was earnestly insisted in this case that the persons affected by the odors emitting from the establishment in question were in feeble condition of health by nature, or of abnormal physical characteristics; in other words, possessed of some idiosyncrasy which cast them beyond the protection of all laws of a general nature, or which are enacted for the public welfare. With regard to this, the judge, who delivers the opinion of the court, says that he thinks that the utmost use which can be made of this argument is in reference to persons that are peculiarly sensitive to odors or sounds, and

which affect them seriously, and in a radically different manner from which they do the great mass of individuals; it being quite difficult, if not impossible, for the law to provide adequate safeguards against all the imaginary ills which arise in the minds of eccentric or those of morbid habits or tastes. But this condition of mind or body must be established by clear proof. It can not possibly have reference to that large class, in every community, that are less robust, or are more feeble in body, or less capable of resisting deleterious influences from without, than many, or, it may be, a majority, of their neighbors. All citizens are presumed to enjoy a normal condition of mind and body, until the contrary is clearly shown.

Korean Native Medicine Atrociously Harsh.—Dr. R. S. Hall, of Séoul, has written to the *Chinese Recorder* some instances of the atrocities practiced in Korea by the native medicine man. Some of these cases have fallen directly under the writer's observation, and are not taken at "second-hand." The following is a part of Dr. Hall's statement:

"This year, for the first time, I saw one of them at his work, and I will try to tell you about it. I was called one day to the house of one of the higher class to see a child who had become very sick two or three days before, after being carried a long distance, strapped to the back of his nurse, as is their custom, his bare head and the nape of his neck exposed to the fierce heat of a July sun. I found him in convulsions, and after careful examination I told the father I feared there was little or no hope of his recovery. Both father and mother bowed before me and begged me to 'give life,' as they express it here. I told them only God could do that, but we would do all that we could, and I left them medicine and the necessary directions, with the promise to return in the morning. Now this child was the only son of these people, and their love for him was just as strong as that of fond American or English parents, and like them they wanted to leave nothing undone that could be done for their darling. They had sent for the Korean doctor before they called me, and when they saw the child surely growing worse they thought they would try the foreign doctor, but now as morning dawned and no improvement was visible they again sent for the Korean doctor, who arrived shortly after I did. It was evident that the child was moribund, and I so told the father. Then the father bade the Korean doctor to again try his skill. The first thing this doctor did was to make a little pyramid of a brownish-looking powder upon each breast of the child, and then to set it on fire; as it began to burn the tender skin I begged the father to have it removed and I said to the doctor, 'You know it can do no good,' but he only calmly smiled, as he obeyed the now almost frantic father to go on with his treatment. He then took out from its sheath a needle halfway between a darning-needle and a surgeon's probe in appearance, and this he proceeded to stick through each little foot, through the palms of the hands, the thumb joints, and through the lip into the jaw just beneath the nose. Again I tried to make him stop, but he said it was 'Korean custom.' I replied, 'It is a very bad custom,' and that though in this case it would result in no further harm, as the child was dying, yet it was exceedingly cruel, and in cases where recovery from the disease might occur inflammations of these punctured joints were sure to follow, and often supuration with death of the bones, so that amputation of the foot or hand is the only radical cure—that many such cases had come to me at the hospital. The child died not long afterwards."

Strawberries as Food and Medicine.—In *Medical Classics* we find a condensation of the wisdom of the ages, in regard to this luscious berry, the *avant courier* of all the summer fruits.

"Those persons are easily numbered who disagree with the opinion of Dr. William Butler of Suffolk, England, who stated long ago that 'doubtless God could have made a better berry than the strawberry, but doubtless God never did!' The saying is found in Walton's 'Angler,' quoted from Dr. 'Boteler' or Butler. It made the Doctor famous, and early in this century, the head of the author was painted upon the signboards of English inns.

"In the Privy Purse Expenses of Henry VII., under June 30, 1493, a woman receives *1s. 8d.* for bringing the King cherries and strawberries.

"In the time of Henry VIII. (1530) we read of the King buying a pottle of strawberries for *10d.* The pottle, in which

strawberries used to be sold, goes back to the fifteenth or even the fourteenth century.

"The great philosopher Bacon, in his 'Sylva Sylvarum' (1627), seems to prefer the white strawberry to the red, just as he does the white currant, white raspberry, and white grape. The white, or rather pink, strawberry is very common in Ireland.

"The strawberry and raspberry, the latter under the name of the hindberry, occur in the eleventh century vocabulary as an herb.

"The common word strawberry (*fragaria vesca*) is indigenous in almost all temperate climates. It grows in woods and thickets, and the fruit is small, but of a delicious flavor. The products which have been obtained by cultivation rank among the choicest and most tempting summer fruits, and afford an example of one of the greatest triumphs of the gardener's art.

"Jolly old Dr. Butler would now view with astonishment the large brilliant specimens that are produced. The wonder would not be less should he test the quality of the splendid fruit, and he might be led to exclaim: 'O delicious sweetness, where hast thou fled!' But we are not disposed to quarrel with the grower who has enlarged the proportions at the expense of the saccharin element. The whiteness of the sugar granules is a pleasing contrast to the color of the fruit, and the loss to the palate is a gain to the organs of vision, as well as the sugar trust. The flavor is diffused through a larger mass, and is not so pronounced as formerly, but, with cream, the berries are delectable enough to render their mastication a pleasure, however so many times the fruit is presented. While contour, color and aroma are unimpaired, the globose receptacles will be held in high estimation. These are not in their best estate except when fully ripened upon the vines and eaten soon after being gathered. Sugar scattered over them is destructive to form and brightness, if the added sweetness long precedes the serving.

"No method of eating strawberries can surpass that of eating them with cream.

"The Spaniards have another noble combination—moistening the strawberries with the juice of a sweet orange. There are gastronomers who go further and say that with the addition of orange-peel (by grating), the flavor with a lump of sugar is an immense improvement; and that it must have been in this fashion that the fruit was served in the banquets of Mount Ida.

"A century and a half ago the strawberry had quite a place in the *Materia Medica*. Even in more recent times it held some of its earlier prestige as a remedial agent. Abercrombie says:

"Physicians concur in placing strawberries in their small catalogue of pleasant remedies. They dissolve the tartarous incrustations of the teeth; they promote perspiration. Persons afflicted with the gout have found relief from using them; so have patients in cases of the stone; and Hoffman states that he has known consumptive people cured by them."

"The illustrious Cullen (1789), however, takes issue with the claim that they are curative in gout. He says:

"If the large annual sale of strawberries could preserve from the gout, we should seldom find the inhabitants of Edinburgh affected by that disease; but, though they use that supposed preservative very largely, we find them as often and as severely affected with the gout as the inhabitants of other places who do not use the same."

"In 'The Complete English Dispensatory' of 1729, we read that 'this plant is too well known to want description; the leaves are frequently used in gargarisms for sore mouths, quinies, and ulcers of the throat, and the fruit is moderately cooling and cleansing, chiefly by urine.'

"According to the 'Edinburgh Dispensatory' of 1769, 'The leaves are somewhat styptic and bitterish; and hence may be of service in debility and laxity of the viscera; and immoderate secretions, or a suppression of the natural evacuations, depending thereon. They are recommended in hemorrhages and fluxes; and likewise as aperients in suppression of urine, obstructions of the viscera, in the jaundice, etc. The fruit is in general very grateful both to the palate and stomach; like other fruits of the dulco-acid kind, they abate heat, general thirst, loosen the belly and promote the flow of water.'"

Hospital Notes.

REQUESTS TO HOSPITALS IN NEW YORK CITY.—Under the will of Mrs. Mary Stuart, the Presbyterian Hospital has received the sum of \$220,000. Other hospitals, dispensaries

and societies having a medical dependency receive a total sum of over one and one-half million dollars. The entire value of the estate is not far from five millions, of which four-fifths are devoted to charitable and educational objects.

HOSPITAL OF SISTERS OF MERCY, ST. LOUIS.—The Sisters of Mercy, of St. Louis, Mo., are to enlarge their hospital with a three story brick structure to cost \$15,000.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from August 11, 1894, to August 17, 1894.

Capt. WILLIAM J. WAKEMAN, Asst. Surgeon, is granted leave of absence for one month, to take effect upon the completion of his present duty at the Ft. Thomas Rifle Range, Ky.

Capt. EDGAR A. MEARNS, Asst. Surgeon, will be relieved from duty with the commission appointed for the location and marking of the boundary between Mexico and the United States, and ordered to Ft. Myer, Va., for duty, relieving Capt. JOHN L. PHILLIPS, Asst. Surgeon. Capt. PHILLIPS, on being thus relieved, is ordered to Ft. McKinney, Wyo., for duty at that post, relieving Capt. GEORGE E. BUSHNELL, Asst. Surgeon. Capt. BUSHNELL, on being thus relieved, ordered to David's Island, N. Y., for duty, relieving Capt. SAMUEL Q. ROBINSON, Asst. Surgeon. Capt. ROBINSON, on being thus relieved, ordered to Philadelphia, Pa., for duty as attending surgeon and examiner of recruits.

Major CURTIS E. PRICE, Surgeon, upon the expiration of his present leave of absence, is ordered to Ft. Supply, Oklahoma Ter., for duty at that station, relieving Capt. WILLIAM H. CORBUSIER, Asst. Surgeon. Capt. CORBUSIER, on being relieved by Major PRICE, is ordered to New York City, for duty as attending surgeon and examiner of recruits, relieving Capt. WILLIAM C. SHANNON, Asst. Surgeon. Capt. SHANNON, on being thus relieved, will report in person to Col. G. H. ALDEN, Asst. Surgeon-General, President of examining board, for examination for promotion.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 18, 1894.

Medical Inspector EDWARD KERSHNER, ordered as fleet surgeon, North Atlantic Station.

Surgeon L. G. HENEBERGER, ordered to Marine Rendezvous, New York. Surgeon N. H. DRAKE, from Marine Rendezvous, and to receiving ship "Franklin."

Surgeon B. S. MACKIE, from the "Franklin," and as fleet surgeon, European Station.

Asst. Surgeon C. T. KINDLEBERGER, ordered to Naval Laboratory and Department of Instruction.

Medical Inspector T. N. PENROSE, from Norfolk Hospital, and to special duty repairing and renovating New York Hospital.

Medical Director C. J. CLEBORNE, from Naval Hospital, Chelsea, and to Naval Hospital, Norfolk.

Medical Director A. A. HOCHLING, from special duty, Washington, D. C., and to Naval Hospital, Chelsea, Mass.

Medical Director B. H. KIDDER, ordered to report to chairman of Senate Committee investigating Ford Theater disaster.

LETTERS RECEIVED.

(A) Atkinson, Wm. B., Philadelphia, Pa.

PAMPHLETS RECEIVED

Abdominal Surgery on the Battle-field. By N. Senn, M.D., Ph.D., LL.D., Chicago.

The Bristol (England) Medical Society. Annual Meeting, 1894.

Two Cases of Unclassified Infection. By W. F. Arnold, M.D., P. A. S., U. S. N., Sacramento.

Some Observations on Gonorrhoea in the Male. By W. F. Arnold, M.D., P. A. S., U. S. N., Sacramento.

Cremation as the only Sanitary Method of Disposing of the Dead. By W. F. McNutt, M.D., San Francisco.

The Journal of the American Medical Association

VOL. XXIII.

CHICAGO, SEPTEMBER 1, 1894.

No. 9.

ADDRESS.

CHAIRMAN'S ADDRESS.

Read in the Section on Ophthalmology at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY ALBERT R. BAKER, M.D.

PROFESSOR OF OPHTHALMOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF WOOSTER, CLEVELAND, OHIO.

One of the great faults of our medical societies is the occupation of the time in reading papers and participating in discussions which, for the most part, are the mere quoting of authorities and presenting of views that are not new.

The chairman is, however, a privileged individual in this respect, as he is either expected to present a *résumé* of the present status of our science, or make a few general platitudes that may serve to open the meeting of the Section, and if possible put us in good humor with ourselves and our profession. It would be fortunate if all of our old straw could be threshed out in this one address, so that the remainder of our time could be profitably spent in the presentation of original observations and participating in discussions that might prove of permanent value to each of us. And yet an occasional review of what has been done by our predecessors often proves of inestimable value, and nothing like an extensive acquaintance with the literature of the subject so effectually prevents the presentation of poorly prepared and incomplete observations as "new truths." I have had occasion to remark that it is much easier for me to prepare a paper on some other subject than those pertaining to the eye, and I suspect the reason is because I know less about what has been done in other directions. Because the thing is new to me I am tempted to present it as new to others.

A few years since when the treatment of granulated lids by "grattage" was proposed, I was reminded of the treatment recommended by St. Yves¹ for a similar condition nearly two hundred years ago. He says: "It is to be noticed that the *Spots*, the *Ulcers*, and certain *Abscesses* of the Cornea Transparent, attended with an Inflammation of the Conjunctiva are more speedily cured by Bleeding of the *Eye*, than by any other Means. Notwithstanding in some cases it is not proper as Practice evinces. This Bleeding of the *Eye* is performed in different Manners. Some take a Bundle of Beards of *Oat-blades* and make a kind of Brush with which they scrape the Conjunctiva and so scarify it: [Grattage]. Others pass a covered lancet between the Globe and the Eye-lid and scarify the Cornea [Sclerotic] with it. Others glide a *Crooked Needle* under the varicous Vessels which communicate with the *Spot*, *Ulcer* or *Abscess* and cut the Vessels which creep on the *Conjunctiva*. This last operation is the surest and least painful." Have we anything better to propose to-day?

Since Richard Banister, Master of Surgery, Oculist

and Practitioner of Physic, published his little book of twenty-three pages on the preservation of the "Eye-sight" three hundred years ago, in which our illustrious predecessor gave the *regime* he thought necessary to preserve the sight, together with the chief lotions, syrups and juices that should be applied to eye diseases, we have made wonderful progress; and yet we must confess there are many points needing elucidation, that will require the most patient study on the part of the anatomist, histologist, physiologist, pathologist and clinical observer.

Who will give us a clear and rational description of the course and termination of the intra-cerebral fibers of the optic nerve? Who will explain to us the cause of sympathetic ophthalmia? What are the relative functions of the rods and cones? Who will give us a good working theory of color perception? one that will explain color blindness. Why is it that after the canaliculus is slit and large probes passed that the tears continue to overflow? What operation for cataract extraction is the best? The last word has not been said on heterophoria and errors of refraction, as we shall doubtless learn before the close of this meeting. These and numerous other important problems require our most careful consideration. In order to solve these questions we can not be guided entirely by our own experience. Many of them can not be answered by one generation, and need not only the experience of ophthalmologists of the present, as well as the past, but that of the entire profession, including the labors of chemists, physiologists, physicists and men engaged in every department of scientific research. It will be a most unfortunate step backward if we, as ophthalmologists should permit ourselves to be segregated from the great body of the medical profession as the oculists have been in ages past, or as the dentists are now.

One of the most interesting chapters in Richard Banister's book² is devoted to the exposure of what he calls "proud quack-salving mountebanks, that would undertake all cures, and perform few." He says further: "In the methodical practice and cure of blind people, by couching of cataracts, our English oculists have always had an especial care, according to arts, to couch them within doores, out of the open aire, to prevent further danger. Yet some of these mountebanks take their patients into open markets, and there, for vain-glories sake, make them see, hurting the patient, only to make the people wonder at their rare skill. Some others make scaffolds, on purpose to execute their skill vpon, as the Frenchmen and the Irishmen did in the Strand, making a trumpet to be blown before they went about their work."

Much of the prejudice (and with justice) against oculists who treated diseases of the eye exclusively, has been handed down almost to our own day. Only a few years ago a most bitter fight was made against

¹ A New Treatise of Diseases of the Eyes by M. De St. Yves, translated from the original French by J. Stockton, M.D., London, 1741.

² A treatise of 113 Diseases of the Eyes and Eye-lids, by Richard Banister, Mr. in Chyrurgery, Oculist and Practitioner in Physicke, published for the second time in 1622.

Dr. Nettleship's appointment on the staff of the Royal London (Moorfields) Ophthalmic Hospital. The only objection of any weight urged against his appointment was that he is not a general surgeon.

An interesting parallel between the separation of the oculists from the general profession of old, and the present tendency in that direction might be drawn. The tendency at present is to make expert opticians but poor oculists. We must be something more than spectacle peddlers. We must keep in touch with the general profession. In order to do this, we must not only have an extensive knowledge of general medicine and surgery, but we must insist upon better education of medical students in eye diseases.

Because the ophthalmologist fails to relieve a headache by the use of spectacles, or a tenotomy, he has not exhausted all the resources of his art. And even though he refer the case to the general practitioner he should be able to make intelligent suggestions as to the future management of the case. It is possible to have reflex troubles originating in the eye not due to refractive errors, muscular insufficiencies and possibly not manifested by gross pathologic changes in the eye itself. On the other hand it is possible to have pain referred to the eye as the result of some constitutional disease, or it may be of some local disease in a distant portion of the body.

The tendency to supply every town and village with one or more oculists so-called, who limit their practice to the treatment of eye diseases is not for the best interests of the patient or the profession. The helplessness of the average medical practitioner in a small town when some young gosling comes to the village with his six weeks' post-graduate instructions, brand-new trial case and ophthalmoscope is pitiful indeed. The practitioner is made to feel keenly his ignorance of the subject. He knows intuitively that he is being imposed upon by a few big sounding names, but is entirely helpless in preventing this fledgling from giving myopic lenses to hypermetropes and snipping the ocular muscles of all the bright school girls in the village.

As an example of the ingenuity of these fellows I have in my possession a pair of bifocal lenses which analyzes as follows: Right eye +.25 C. axis 90 for distance, $\ominus +25$ C. $\ominus +.50$ S. for reading. Left eye +.25 S. $\ominus +.50$ C. axis 75 for distance, and +1. S. $\ominus +.50$ C. axis 75 for reading. These lenses were given to an Oberlin student aged 18, who has a simple hyperopic astigmatism of .75 D. axis 90 in each eye.

Every practitioner should possess an ophthalmoscope and a few trial lenses, and he should be able to fit spectacles much better than the jewelers and druggists who style themselves opticians, and I see no reason why he should make such ridiculous blunders as the above. That every practitioner who knows a little more about the care of eyes than his neighbor should pose as an ophthalmologist and limit his practice to eye diseases, is almost as preposterous as the claims of the jeweler optician. After an apprenticeship of ten, twenty or thirty years the ranks of the ophthalmologists should be recruited from these practitioners who have given the eye and its diseases special study.

There is a considerable amount of work which requires especial skill and experience on the part of the ophthalmologist in the diagnosis and treatment of eye diseases. It is not possible for a man to make a skilful cataract extraction who only has the op-

portunity to make the operation once or twice a year, nor is it possible to distinguish between a case of chronic glaucoma and atrophic cupping of the disk by one who sees such cases but once or twice in a lifetime. To make skilful operators and acute diagnosticians the specialist must have had a wide experience; and this can only be secured by a long apprenticeship, with exceptional opportunities for study and practical experience, in the performing of delicate manipulations and the making of difficult operations.

The specialist is the general practitioner's most valuable assistant. He supplies him with skilled hands to do that he can not do. He furnishes him with educated eyes to see that he can not see. He gives him trained ears to hear that he can not hear. And he should supply him with a well stored mind to tell him that he does not know.

When about to select an architect to build a house, if we found him ignorant and exhibiting poor judgment in matters pertaining to religion, science, literature, art and other subjects about which we knew something, we should distrust his judgment in architecture about which we know nothing. If this is true in a general way, how much more must the physician distrust the judgment of the specialist who is ignorant of general medicine and surgery.

The promptness with which the announcement of the reading of a paper on an ophthalmic subject will empty the seats in our local and State medical societies is discreditable alike to the practitioner and to the oculist; discreditable to the physician because he does not take greater interest in ophthalmic subjects as no other special study lends so much assistance in the diagnosis, prognosis and treatment of disease remotely situated. Discreditable to the ophthalmologist because he does not make his papers so interesting as to compel attention. In order to do this he must as far as possible discard technical terms. The necessity for this is largely due to the insufficient and perfunctory manner in which ophthalmology is usually taught in our medical colleges.

A gynecologist has a great advantage in teaching his specialty, because of the simplicity of the structures, and the previous studies of the medical student in anatomy, physiology, embryology and obstetrics have prepared him for an intelligent understanding of the teaching of the gynecologist. But when the average medical student enters upon his ophthalmologic studies it is a veritable *terra incognita*; he has little knowledge of the anatomy of the eye and its appendages and less of its physiology.

The nomenclature is all new, and because the subject seems difficult it is neglected. The lectures are cut, quizzes avoided, dispensaries not utilized and the practitioner is turned out with but little knowledge of the subject.

One of the principal reasons for this unsatisfactory conditions of affairs is that there is not enough time allotted to this subject in the medical curriculum. In some schools I am informed the study of ophthalmology is not compulsory. The teacher realizing the hopelessness of instilling any useful knowledge into the mind of the student in the few hours given him, is often content to call attention to the most frequent and grave ocular diseases, make a few operations and advise the student meeting such cases not to attempt their treatment but to send them to the nearest oculist.

It does not seem to me that we ought to be content to let this indifferent method of teaching this important subject continue. The use of the ophthalmoscope is not more difficult to learn than that of the stethoscope, and of much more value to the practitioner of medicine. The teachers of ophthalmic medicine and surgery ought to decide upon some definite minimum length of time in which the average senior medical student can master a good working knowledge of this subject, and then insist upon being granted this amount of time in the medical curriculum. This would require at least 100 hours; 50 of which should be devoted to didactic lectures, clinics and recitations, and 50 to practical work in the dispensary.

My experience as a teacher of ophthalmology has been that those students who leave college with some definite knowledge of eye diseases, not only treat more intelligently the cases coming under their care, but are the first to refer suitable cases to the specialist—so that the better education of the general practitioner in eye diseases does not curtail the number of cases referred to the oculist for treatment but increases the number of his consultations.

THE PHYSIOLOGY OF CERTAIN OCULOMOTOR PHENOMENA WITH RESPECT TO SOME RECENT THEORIES OF ASTHENOPIA.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY F. B. EATON, M.D.

PROFESSOR OF OPHTHALMOLOGY, OTOTOLOGY AND RHINOLOGY MEDICAL DEPARTMENT UNIVERSITY OF OREGON; OPHTHALMIC AND AURAL SURGEON GOOD SAMARITAN HOSPITAL, PORTLAND, OREGON.

That physiology is the basis of scientific medicine is generally recognized. Medical students are taught that physiologic processes and the known laws governing them, form the foundation of our knowledge of the pathologic conditions with which we have to deal,—a criterion of the value of clinical observation; the base-line from which we are to estimate every real or apparent deviation from the normal functions of the human body. More especially is this true as regards ophthalmology, in many respects the most scientific department of medicine. Nevertheless, there have appeared in our ophthalmic literature, during the past five years, a number of theories which, when critically analyzed have little or no substantial scientific foundation.

While it is true that our knowledge of ocular physiology is incomplete, yet those physicians whose educational training has disciplined their minds to act logically; to habitually analyze the evidence presented; to refer phenomena if possible to known laws, have naturally assumed a conservative attitude toward the attractive theories and sanguine assumptions of certain authors, and it is in the ophthalmological sections of our societies and congresses that a minority of the members, possessing the courage of their convictions, have opposed them. The articles of these authors indicate that though they conduct their examinations with a degree of method as regards the use of ordinary tests and apparatus, they do not employ an equal degree of scientific

method in marshalling their facts or make correct inferences from the knowledge so acquired—in fact, they do not reason scientifically. To do so as regards the phenomena of binocular vision requires, as we know, a considerable knowledge of physics and mathematics, as well as the ability to apply it; above all it requires an intimate knowledge of ocular physiology. Instead of referring their observed facts to some known natural law, or seeking an unknown law on which to ground them, some of our authors hasten to propound an hypothesis to which an inadequate number of observed facts are made to conform, thus pursuing a *deductive* rather than an *inductive* method of reasoning.

Nevertheless, while without theoretical proof and practically more or less mischievous, some of these novel and attractive hypotheses and the therapeutics based upon them have attained, to judge from some current ophthalmic literature a wide popularity, and govern the practical work of many of our colleagues. They who have the best interests of American ophthalmology at heart should not therefore take refuge in indifferent silence.

There is, as we know, a considerable difference of opinion among ophthalmologists of to-day concerning the significance of the phenomena attendant upon the function of binocular vision, which comprehends the two associated functions of the focal and axial adjustment of the eye. Especially is there a difference of opinion as to the relative influence to be attributed to each of these functions as a cause of asthenopia.

During the past five years particular attention has been directed to the oculo-motor apparatus, largely owing to the refinement of the clinical apparatus employed for the detection of errors of muscular equilibrium, and to their classification under the various forms of heterophoria.

In the discussion of papers bearing on this subject, it appears to me that those participating have too little common ground on which to meet. As an illustration of this, I may mention the remark of Dr. Stevens in a recent paper, that the half written cases with bare statements of the results of certain tests "leave in the mind of the critical reader the impression that the writer has not himself ascertained the remaining facts necessary to a just conclusion." How rarely, for instance, do we find in the report of an asthenopic case any record of the ranges of accommodation and convergence, or more important still, a record of the relative ranges of these two functions, physiologically so closely connected with normal adjustment of the eyes.

While it is not my purpose to attempt an elaborate discussion of theories, I shall endeavor to analyze certain hypotheses concerning the origin of asthenopia, so as to demonstrate wherein they are or are not tenable as correct or incorrect doctrines, according to the established principles of physiology and the facts of clinical experience.

Let us consider first the theory of "insufficiency of the oblique muscles," the discovery of which its author states he announced in 1891 as an explanation of certain cases of eye-strain. Briefly stated, the phenomenon¹ is as follows: A horizontal line being regarded at eighteen inches and seen double by one eye before which a Maddox prism is held, a third line is seen between the two parallel ones and according to the author, "with which it should be perfectly parallel." In "insufficiency," the right end of the middle line pointing toward the bottom and the left end

toward the top line, or *vice versa* depending on the nature of the individual case. As is well known, upon this phenomenon, dignified by the term cyclophoria, the theory has been erected which is held to be explanatory of a form of asthenopia, and this is supposed to be corroborated by the relief claimed to result from the gymnastic exercise of the oblique muscles by cylindrical lenses. That this phenomenon is a physiologic one and that the eyes normally rotate outward on the axis of fixation in convergence, any one can easily verify by a few simple experiments, with or without prisms. One of the simplest is a modification by Le Conte of Meissner's original experiment for the determination of the horopter: "Hold a stretched black thread parallel with the surface of the glass of an open window, and within half an inch of it. Now, with the eyes in the primary position look, not at the thread, but at some spot on the glass. It will be seen that the double images of the thread are not parallel, but make a small angle with each other, thus— \sphericalangle ." I have found a simpler experiment can be made by taking a piece of black thread about eight inches long, tying a knot midway between the ends, moistening it and then sticking it in a horizontal position on a pane of glass at the level of the eyes. Then converging the eyes upon the knot and approaching it gradually, at a distance of from four to six inches the thread will appear double toward the ends, the knot and the thread for about one-quarter of an inch on each side of it appearing

Fig. 1.

single and the divergence of the ends increasing with the convergence. The divergence is increased by inclining the head so as to converge upwards, since in the great majority of cases the inclination of the images is that resulting from an outward rotation of the eyes on the line of fixation; this rotation is decreased by looking downward, and as Le Conte and Meissner have shown, the vertical meridians of the eyes are parallel and vertical when the plane of vision is depressed 45 degrees, so that the inclination of the middle line as seen by a Maddox double prism disappears at that inclination. In some cases the rotation is in the contrary direction and all the conditions reversed.

That this phenomenon in no way disturbs binocular vision, is owing to the habitual neglect or toleration of the necessarily incoincident positions of images outside the immediate area of fixation. Meissner, who arrived at his results indirectly while investigating the question of the horopter, attributed the phenomenon to an outward rotation of the eyes on the visual axis. By far the most refined method of proving and measuring this rotation in convergence is that described by Prof. Le Conte (*loc. cit.*, p. 180): "Prepare a plane two feet long and one foot wide. Dividing this by a middle line into two equal squares, let one of the halves be painted black and the other white. Let the whole be covered with rectangular coördinates, vertical and horizontal; on the black half the lines being white and on the white half black. Near the middle of the two square halves, and at the crossing of a vertical and horizontal line, make two small circles, *c c'*. Set up this plane on the table in a perfectly vertical position, and at a

distance of two or three feet. Rest the chin on the table immediately in front of the plane, with a book or other support under the chin, so that the root of the nose shall be exactly the same height as the circles, which in this case is about six inches. Now shutting alternately one eye and the other, bring the image of the lowest part of the root of the nose coincident with the horizontal line running through the circles. The primary plane is now perfectly horizontal, and therefore at right angles to the experimental plane. Now, finally, converge the eyes until the right eye looks directly at the left circle, and the left eye at the right circle, and of course the two circles combine. If one is practiced in such experiments and observes closely, he will see that the vertical lines of the two squares (which can be readily distinguished, because those of one are white and of the other black), as they approach and pass over one another successively, are not perfectly parallel, but make a small angle, thus— \sphericalangle ; and also that the angle increases as the convergence is pushed farther and farther, so that lines even beyond the circles are brought successively together. Similarly also the

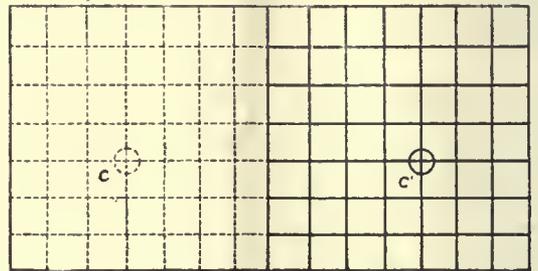

Fig. 2.—In this drawing the left half is drawn with red lines on a white background, because of the difficulty of drawing white on black background, as it should be.

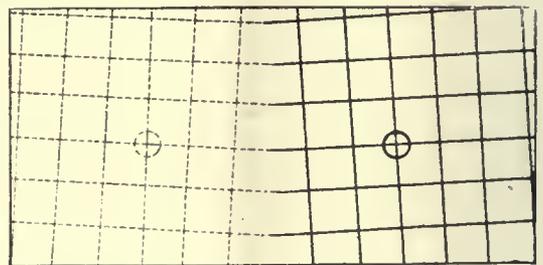

Fig. 3.—Left half should be white lines on black background.

horizontals cut each other at a small angle, but this is not so easy to observe as in the case of the verticals.

"*Experiment 3.*—A far more accurate mode of measuring the amount of rotation is by constructing diagrams on a plane similar to the one used in Experiment 1, but in which the verticals and horizontals are both inclined on the true verticals and true horizontals in a direction contrary to the rotation of the eyes, *i. e.*, inward—and then determining the degree of convergence necessary to make them come together perfectly parallel. I find that for my eyes, when the verticals are thus inclined in each square one and one-fourth degrees with the true vertical, and therefore make an angle of two and one-half degrees with each other, they come together parallel when the point of sight is seven inches from the root of the nose. When the angle of inclination in each is two and one-half degrees with the true vertical, and therefore 5 degrees with each other, the point of sight must be four inches off. When the inclination with

the true vertical is 5 degrees, and therefore 10 degrees with each other, the point of sight is two and one-fifth inches. Finally, when the inclination with the true vertical is 10 degrees, or 20 degrees with each other, then they can be brought together parallel only by the extremest convergence, the point of sight being then only a quarter of an inch in front of the root of the nose. In the diagram, Fig. 3, the lines, both vertical and horizontal, are inclined inward one and one-fourth degrees, and therefore the verticals of the two squares make an angle with each other of two and one-half degrees. It is therefore a reduced *fac simile* of the plane used. The coördinate lines coincide when the point of sight is seven inches from the root of the nose."

The evidence of Hering regarding the physiologic rotation in question is also unmistakable: "In general," he says,³ "the vertical meridians of the globe undergo, in symmetrical positions of convergence of the visual lines, a rotation in the course of the inferior oblique, so that their upper ends diverge more

careful and repeated experiments, that this outward rotation begins in some perfectly healthy eyes, free from all asthenopia, at a distance of twenty inches, when slight vertical diplopia is produced by a prism, and that an elevation of the visual plane of 20 degrees will render it appreciable when the line observed is twenty-two inches distant. The action of the oblique muscles is invoked in support of still another theory of this author, namely, that of

"The Harmonious Symmetrical Action of the Oblique Muscles in all Cases of Oblique Astigmatism." Briefly stated, this theory is based upon the assumption that the cylindrical deflection of the retinal image produced by corneal astigmatism necessarily produces a disturbing diplopia, unless this is neutralized by a compensatory rotation by the oblique muscles.

In an article published on "Binocular Metamorphosis," five years ago,⁵ Dr. J. A. Lippincott, of Pittsburg, gave a clear analysis illustrative of the action of cylindrical lens with axes oblique in deflecting the retinal image, which applies to corneal astigmatism,

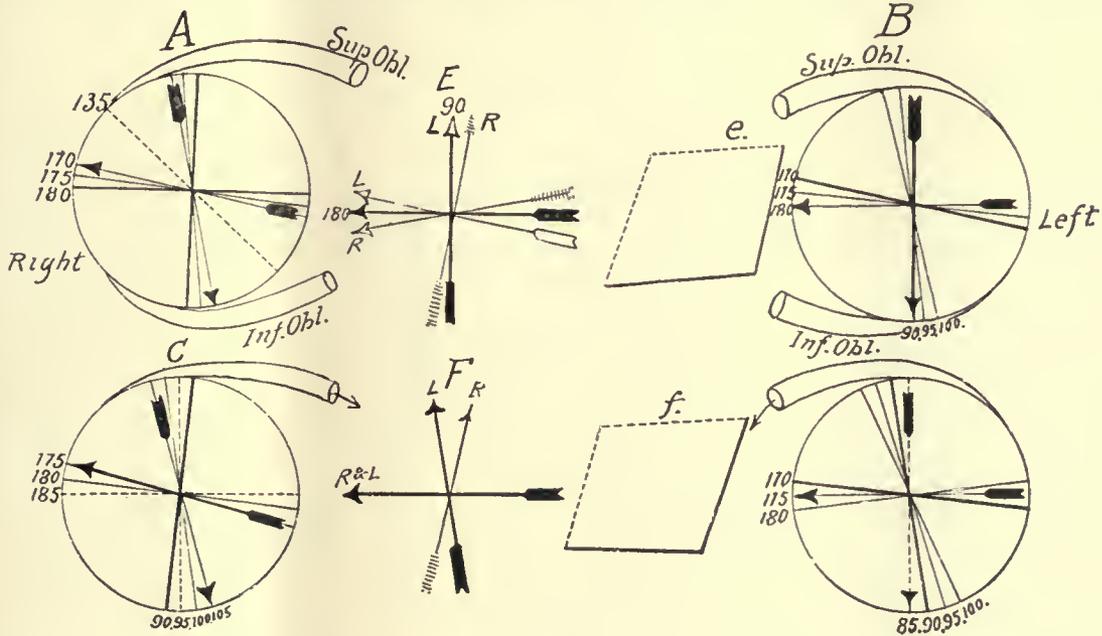

Fig. 4.

when the visual plane is elevated and converge less when it is lowered than is the case with parallel visual lines and similar positions of the visual plane."

Finally, Landois⁴ states under the head of "tertiary position," which he defines as "the position brought about by the movements of the eye, in which the lines of vision are convergent, and are at the same time inclined upwards or downwards; . . . the eye-ball is always rotated at the same time round to the line of vision and round its axis."

It will be noticed that Le Conte alone demonstrates a convergence rotation in the horizontal position of the primary visual plane.

Thus by the independent investigations of three careful and scientific observers, the outward rotation of the eyes in convergence has been for twenty years established as purely physiologic, yet as evoked by prisms it has not only been employed by Dr. Savage as the proof of a pathologic condition, but upon it he has actually based a therapeutic method, the value of which he has failed to substantiate by any adequate clinical evidence. I have satisfied myself by

in all cases of which the corneal surface is represented by a convex cylinder with its axis at the meridian of lowest refraction. Since each half of such a lens may be regarded as a prism with its base at the axis, the deflection of incident rays and the position of the resultant retinal image may be readily determined, as Dr. Lippincott has shown. Moreover the amount of deflection rapidly decreases in proportion as the lens is approached to the eye. Thus I have found that a -2.00 cylinder held before one eye at a distance of thirteen inches, deflects the horizontal line of an astigmatic test chart 6 degrees by measurement, while held close to the eye the deflection is but three-fourths of a degree. The deflection produced by the same amount of cylindrical effect at the corneal surface must be still less.

The drawings in Dr. Savage's article, (*Ophthalmic Record*, Vol. i, p. 1) illustrating the compensatory action of the oblique muscles, give with his description a plausible weight to his theory, but when closely analyzed it will be found that the supposed rotation, which would bring the retinal images of a

horizontal arrow upon corresponding portions of the retina, will at the same time not only fail to accomplish the same as regards a vertical arrow, but the images of the latter will be made to harmonize still less than before the rotation. In other words if a square card or astigmatic fan be viewed through a convex cylinder of 3 D. held about six inches from the right eye with its axis at 45 degrees, the other eye being closed, the right side or vertical line will be inclined 9 degrees to the right, and the lower side or horizontal line 9 degrees down to the left. (See Fig. 4, E and e). Now if the card or fan be rotated outward (which has the same effect as an inward rotation of the eye and lens) the horizontal line (side) will rotate to the right more rapidly than the vertical and will be horizontal; that is, its retinal image will be fused with the image of the same line as viewed by the left eye (Fig. 4, C and D). But the same rotation inclines the vertical line (side) still more from the true vertical, and its retinal image will be less parallel than before to that of the left eye. (Fig. 4, C and D). If each eye views a separate fan and each fan be rotated outward 5 degrees, the horizontal retinal images will coincide, while the vertical ones will be separated more at their tops by 10 degrees than before the rotation (see Fig. 4, F and f). Hence each rotation would defeat the very object for which it is invoked. But even if optical laws would permit of the correction claimed, it would not be necessary, for, as I have shown above, the maximum obliquity of the axis of the corneal cylindrical surface (45 degrees) produces a very slight deflection, and incoincident images lying outside the immediate area of fixation are habitually neglected. Indeed, upon the latter fact is dependent stereoscopic vision, since our conception of solidity results from the relief given to that portion of an object or scene binocularly fused in one plane, all other objects in front or behind that plane falling on non-corresponding points of the retina and producing double images which are neglected. This is very lucidly illustrated by Prof. Le Conte.⁵

As he states: "If we view in a stereoscope the fused image of the projection of a skeleton truncated cone as seen from two positions (Fig. 5, A and B) and are able to analyze our visual impressions, when the summit is fixed (Fig. 5, C) the base or larger circle is double, and *vice versa*, (Fig. 5, D) and still further that the lines a a' and b b' form a V or an inverted V or an X, according to the distance of the point of sight, which, by more or less convergence, is run back and forth, uniting different parts, and thus we acquire a distinct perception of depth of space."

In an article published two years ago by Dr. Harry Friedenwald on "Binocular Metamorphosis,"⁷ he demonstrated that if two parallelograms similar in shape to those seen by a pair of eyes with a +2D cylinder, axes symmetrically oblique (45 degrees temp.) when regarding a square card are placed in a stereoscope, "they are fused so as to give the impression of a trapezoid, narrow at the top, and which is apparently leaning forward so that the top seems to be much nearer than the base. . . . The appearance of depth points conclusively to the fusion of dissimilar images." That is, to such a fusion as illustrated by Prof. Le Conte's truncated skeleton cone. Dr. Friedenwald remarks that the above cited theories of Dr. Savage are "false in theory and dangerous in practice," and Dr. Lippincott states⁸ that for the production of binocular metamorphosis "the existence of

an astigmatic defect is not a *sine qua non*, although the phenomena are especially noticeable in cases of astigmatism of one or both eyes, in which the chief meridians are oblique." In such cases, he states further, "there ought to be an apparent inclination of one or both sides, as the case may be, of a square (so) that objects, therefore, and their retinal images do not correspond in form. Experience, however, derived especially through the sense of touch enables the mind to correct the erroneous information furnished by the sense of sight. *In other words, inaccurate retinal images are translated into more or less accurate mental impressions.*"—(Italics my own.)

As regards these theories then I conclude:

1. The phenomena included under the term, "cyclophoria," are physiological, being the result of the normal rotation of the eyes in convergence.
2. The phenomena in no way disturb binocular vision, owing to the habitual neglect or toleration of the incoincident positions of images outside the immediate area of fixation.

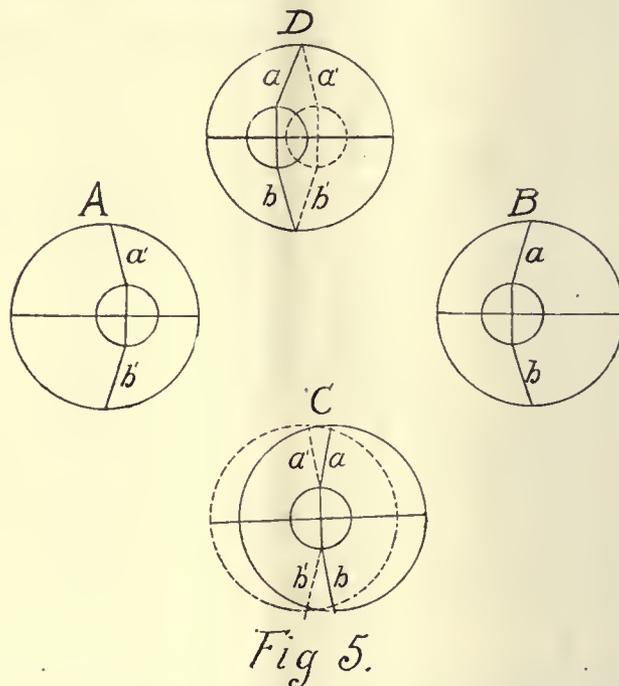

Fig 5.

3. A compensatory rotation of the eyes in cases of oblique astigmatism does not take place; if it did, it would defeat the very object for which it is invoked by the author of the theory.

4. If optical laws would permit of the alleged correction, it would not be necessary or expedient, since it would render stereoscopic vision impossible.

Another theory to which I desire to call attention, is that termed by its author, Dr. Geo. M. Gould, "Innervational Abnormalism the Cause of Heterophoria,"⁹ and which he has more particularly elaborated in regard to the etiology and treatment of exophoria, stating: "I now wish to go so far as to state that my experience shows that every case of exophoria (and possibly of divergent strabismus) is certainly and quickly curable by a rational and common method of ocular gymnastics—of a certain kind, however, mark well, and absolutely without operation." He states further:¹⁰ "It appears to me beyond question that in the vast majority of cases of exophoria, if not in all, the seat of the abnormality is purely, at

least primarily, and always principally, central and innervational. It is not at all a question of tendon insertions or of muscular strength." If therefore the seat of the difficulty lies in the innervational centers and coördinates, the treatment by tenotomy, or by gymnastic exercises (with weak prisms) seems to fall to the ground. We must instead seek to normalize innervation leaving the muscles and tendons entirely out of the count. In accordance with this, I have sought to break up the bad habit of exophoric innervation and reestablish normality in an erroneous nervous coördination, to heighten convergence stimulus, and to carry this increased stimulus, as well as the naturally heightened stimulus of convergence at near range, into distant and all-around seeing." The method he suggests is that of "weighting," or handicapping convergence by adducting prisms at the near point, "then slowly carrying the object gazed at fixedly and continuously from the near to the distant point. This is repeated until the eyes with 20 degree prisms (total) can hold objects all about the room easily. "This repetition is to continue several times daily until this adduction power is habitual, and until no diplopia is produced on first adjusting the prism fronts and looking at distant objects immediately. When this condition has been reached, the strength of the handicap prisms is to be increased say, to 25 or 30 degrees and the method resumed as before. Before an adduction of 30 degrees (total) has been reached, the symptoms of asthenopia will long have vanished, but the manifest or latent exophoria will still usually, and to some degree, be present. The treatment from 30 to 40 degree prisms should be continued until all manifest and latent exophoria has disappeared, and 2 degrees of esophoria has become manifest."

"Deficient adducting power," he emphasizes, "is the source of trouble and the thing to cure."¹¹

These views may be considered from two stand-points, viz :

1. In regard to the teachings of physiology.

2. In regard to the practical experiences of the ophthalmic surgeon.

1. The contention of Dr. Gould that the doubling or trebling by his method of the prism-adductive power at twenty feet, has nothing to do with "muscular strength or tendon insertions," is not in accordance with physiologic facts for :

a. The ocular muscles being striated muscular tissue are therefore subject to the laws of nutrition, metabolism, and the transformation of chemical into kinetic energy, in virtue of which, when made to vigorously contract, unlike other machines they are increased in strength and rendered capable of accomplishing more work.—(Du Bois-Reymond)

b. The mutual relations existing between the motor nerve-cells and the muscles, are not, however, inflexible. Physiologists tell us that "stimuli act as liberating or discharging forces."¹² "These discharging forces may themselves be very feeble, but they are capable of causing the transformation of a large amount of energy."¹³

Foster remarks that it "might be imagined that a muscle which, when loaded with a given weight and stimulated by a current of a given intensity, had contracted to a certain extent, would only contract to half that extent when loaded with twice the weight and stimulated with the same stimulus. Such, however, is not necessarily the case; the height to which

the weight is raised may be in the second instance as great or even greater than the first. That is to say, the resistance offered to the contraction actually augments the contraction; the tension of the muscular fiber increases the facility with which the explosive changes resulting in a contraction take place. And we have other evidence that anything which tends to stretch the muscular fibers; that any tension of the muscular fibers, whether during rest or during contraction, increase the metabolism of the muscle."¹⁴ That this property of healthy muscle tissue must modify the conditions and results of its innervation and coördinations, can not be doubted.

c. A strong muscle (well nourished and exercised) responds more powerfully to a given stimulus (*i. e.*, sets free more energy) than a fatigued or unexercised one, and it requires a relatively feebler stimulus to accomplish a given amount of work with the former than with the latter.

d. "Of two muscles having the same cross section, the larger can do more work; whereas if two muscles are of equal length, that which contains the greatest number of parallel fibers will do more work than the other."¹⁵

e. Congenital variations, such as assymetry of the cranium, orbit and face (Stevens, Landolt¹⁶); exaggerated distance between the centers of rotation of the eyes (Mannhardt, DeRosset¹⁶); exaggerated divergence of the orbits (Emmert,¹⁶ predispose the eyes to divergent strabismus, and much more to exophoria. "Abnormal conformation of the orbits," says Landolt, "giving rise to anomalies of origin or direction of the ocular muscles, may also cause a discordance in the direction of the eyes. Likewise defects of bulbar insertion and of the length and elasticity of these muscles upon which the most authoritative writers have strongly insisted. (Schweigger, von Hasner, Graefe and others.)"¹⁶

2. Let us now consider the innervational theory of the origin of heterophoria, and especially of simple exophoria in the light of practical clinical ophthalmology.

a. The author maintains that "deficient adducting power is the source of trouble and the thing to cure," in exophoria, and which he considers wholly central and innervational.

b. I note first that the author's device of carrying the "weighted-convergence-stimulus" from the near to the far point is of value in rapidly developing the positive portion of the patient's *relative* range of convergence for distance, and as such it is, up to a certain limit purely innervational, since with a very high maximum of convergence (power of adduction) many individuals can not, without practice, coördinate even a medium convergence while relaxing their accommodation for distance. When the distant object is brought near to a patient wearing adduction prisms beyond his immediate power of fusion at twenty feet, the displacement of the images rapidly decreases; they are seen to approach each other and are easily fused. As the object is withdrawn the prismatic effect increases in proportion. Precisely the same adduction can be accomplished at twenty feet by a revolving or variable rotary prism, but not as quickly.

c. When the patient has acquired a power of adduction at twenty feet of 20 degrees (total, = three meter-angles) which is the emmetrope's average maximum relative convergence for distance.¹⁷ the author's meth-

od becomes one of ordinary muscular gymnastics notwithstanding his emphatic contention that "with muscular gymnastics" as such, my plan has nothing in common except the mere use of the prism—very strong prisms, however, instead of weak ones." The writer has made use of prisms up to 50 degrees (total) for convergence insufficiency for the past five years. It is to be noted that the author has found that with an adductive power of 30 degrees (total) the manifest or latent exophoria is still present, but as the result of the gradual development of the interni by daily exercise with strong prisms, an adduction power of 30 to 40 degrees is attained "until all manifest and latent exophoria has disappeared and 2 degrees of esophoria becomes manifest." The pseudo-esophoria thus induced can fairly be attributed in young individuals to the habit formed of relative over-convergence and probably of over-accommodation, due to continued stimulation of both convergence and accommodation for distance.

d. The author argues that since "muscular tissue, as such, can not be made to double or treble its volume or its strength in a few hours or days, or even in a few weeks," while he can double the extreme adduction (twenty feet) of exophoric eyes in a minute or two by his device, that therefore such increase of adduction power is not muscular, but central and innervational. This is equivalent to stating that since a man who can lift 200 pounds and can not lift 400 or 600 pounds by main strength, but can balance a stick two yards long on his finger and in a minute or two can so balance one four yards or six yards long; that therefore the balancing is a matter of skill, that is, of innervational coördination, and not of muscular strength. For, a patient who at twenty feet has a maximum prism adduction of 10 degrees (5 degrees base on each eye) converges each visual line but 2.7 degrees which is the deviating angle of a prism of 5 degrees; the visual lines meeting at a distance of about twenty-six inches from the eyes. If by the author's device the adduction power for twenty feet is doubled so that 20 degrees (10 degrees prism on each eye) is overcome, the visual lines would intersect at the usual reading distance of thirteen inches or three meter-angles, representing still a very small quota of the average normal range of convergence, and requiring no unusual effort, nervous or muscular. The convergence is relatively great for distance, but small as measured by convergence after normal habit; in short, it is a feat of relative convergence. That such a degree of relative convergence may co-exist with deficient adductive power is often experienced. Thus, one of my patients who had abduction of 11 degrees and by rod orthophoria, but a maximum convergence of only seven meter-angles, obtained by Dr. Gould's method, esophoria 1 degree, abduction 7 degrees, but the maximum convergence remained at seven meter-angles. In this connection, the opinion of Schiötz is decidedly against the author's theory: "With insufficiency," he states, (*Arch. Ophth.* vol. xix, pp.178-179), "we find no limitation of the movements of the eyes in lateral rotation, while a considerable defect of convergence may exist. If the lateral movements of the eyes demanded as much muscular energy as is demanded in the movements of convergence, we should be obliged to conclude that the defective convergence could not depend upon a weakness of the muscles, which perform the whole work in the associated movements;

the insufficiency must, in this case, originate from anomalous innervation. Nevertheless, we are scarcely justified in identifying the muscular work produced by two different motions. We have found for normal eyes that the fusion near point lies about six centimeters from the rotation point of the eyes. The angle of convergence between the visual lines will then be about 60 degrees, therefore the rotation of each eye will amount to about 30 degrees. According to Alfred Graefe, the eyes in associated lateral motions can accomplish a version of from 42 to 45 degrees.

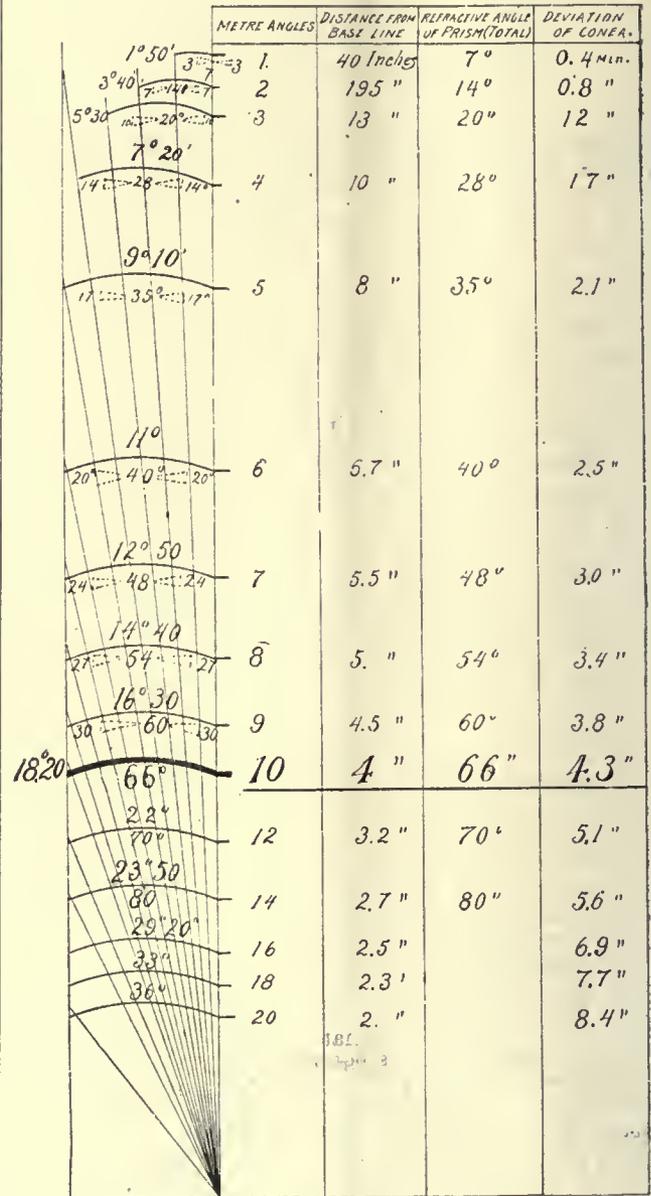

Fig. 6.

We find therefore, that the interni when normal and working in the service of convergence, accomplish only about two-thirds of the motion which they are able to give to the eyes when they act associatedly with the externi, and yet (if we grant to the sensations which we perceive in carrying out this experiment, any importance at all), we feel distinctly that the interni are stretched and exerted differently when we converge, than when we use them in associated lateral movements." I am sure that this greater

demand upon the interni in convergence is due to *contraction* of the externi, which are kept variably tense in convergence so that lateral movements may be made during convergence; indeed the eyes are rarely equally converged.

e. We may reasonably assume the average physiologic convergence (adduction) point should be as near as ten centimeters=(ten meter-angles = four inches) or a prism adduction power of 60 to 70 degrees (total) since Schiötz has found that what he terms the "fusion near point" should be no farther, this distance coinciding closely with what Landolt terms the average maximum of convergence; viz.:¹⁸ Nine and five-tenths meter-angles, and also with the point at which, according to Alfred Graefe, adduction and abduction are each 19 degrees 15 minutes and thus potentially equal.¹⁹ (See Fig. 6.) Now it is of practical importance to know whether a patient has or not this amount of positive convergence at his disposal for if he has not, at thirteen inches he will have no reserve convergence. It can not be determined, either conveniently or promptly by prisms, since as stated above, the habitual relations of convergence and accommodation are thereby disassociated, and even the author's device will not, I have found, enable it to be determined. Thus in testing a patient recently I found adduction at twenty feet was 16 degrees (total)=twenty-two meter-angles. By the author's device this was quickly increased to 26 degrees (total)=three and seven-tenths meter-angles. The direct maximum convergence upon a pin-hole in a card was ten meter-angles, nearly three times his prism convergence in meter-angles. My own prism adduction at twenty feet is 96 degrees (total)=thirteen and seven-tenths meter-angles; with concave lenses to correct the over-accommodation and properly centered (—thirteen D centers fifty millimeters,) it is 114 degrees (total)=sixteen and two-tenths meter-angles; while by direct convergence (pin-hole) it is twenty-two and two-tenths meter-angles, equal to a prism convergence of 155 degrees (total). In another experiment I fused images of a candle flame continuously with adduction prisms of 72 degrees (total) at twenty feet. At thirty inches I could hold the images momentarily with 84 degrees (total), nearer I could not fuse them. An assistant now slowly withdrew the candle and at fifteen feet fusion was easy, up to twenty feet. On approaching the candle it at first remained single, but between fifteen feet and thirty inches the effort increased until at the latter point diplopia again occurred and the images were infusible. Hence it is clear that the device is of no assistance when very strong prisms are used, since the fusion is accomplished mainly by voluntary muscular strength. Dr. Gould appears to underrate the responsive contractile power resident in the interni themselves, as well as the voluntary power of strongly contracting the interni possessed by persons whose general muscular system is vigorous. I can, for instance, strongly converge my eyes in total darkness, for when I make the effort and the room is quickly lighted, an observer finds them in that condition.

f. But Dr. Gould's reported cases²⁰ also show that while the innervational features of convergence (which he does not increase but only renders available) can be quickly brought into play, the muscular feature is more slowly developed, as he remarks: "Before an adduction power of 30 degrees has been reached the symptoms of asthenopia will long have

vanished, but the manifest or the latent exophoria will still usually, and to some degree be present." To me it seems that no decided muscular exercise begins until prisms 40 degrees (total) are used, necessitating a convergence of six meter-angles (= a point six inches distant) and 60 degrees or more may be necessary. In simple exophoria until such contraction of enfeebled interni is brought about, they are exercised little more than in reading, and until their static power reaches a certain limit through functional activity and consequent increased metabolism, any equilibrium test will show manifest or latent exophoria. The "rhythmic exercise" method of Dr. Savage appears to me the more physiologic treatment.

g. But while the development of the adductive power for distance has a certain value long ago conceded in the treatment of convergence insufficiency, that is of simple exophoria, a large percentage of cases showing a tendency to divergence are not exophorias in reality; says Dr. Stevens:²¹ "Indeed, if we select indiscriminately a considerable number of cases of even simple exophoria, and an equal number of cases of even moderate hyperphoria, we shall find that the average converging power in the cases of exophoria, is considerably greater than in the other. . . . The ability to converge is often much more considerable in cases where there is actual divergence of the optic axes than in some cases in which there is positive convergence." Dr. Hiram Woods in a late paper on heterophoria remarks:²² "I am skeptical about the adduction. In the first place, as has been pointed out by others, it is a *distance* test only so far as convergence can act independently of accommodation; *i.e.*, to the extent of the positive portion of the relative range of convergence for infinity. Dr. Randall says:²³ "Adduction can be made almost anything, if the patient and examiner have patience. It is striking how rapidly adduction increases as soon as the patient learns how to fuse images of unequal clearness. I have seen adduction of 48 degrees, while the balance test showed exophoria of 10 degrees." Practically, the experiences of the consulting room teach us that even after correction of all refraction errors, attention to the general health, to peripheral reflexes, etc., some anomalies, perhaps innervational, certainly at times abnormal tensions of the muscles of congenital origin, necessitate careful tenotomies or advancements, the results of which can only be successful when the operator's accuracy of diagnosis and technical surgical skill is approximately commensurate with the difficulties in the way of adjusting the mutual balances of twelve muscles. My own tenotomies and advancements have not disappointed me, and I have too often restored lateral equilibrium where actual exotropia existed, to doubt the efficacy of *complete* tenotomy of the superior or inferior rectus in suitable cases. Ocular gymnastics especially with the stereoscope will do much to readjust inharmonious coördinations, but the fact remains coming from no uncertain authority, that: "We may give the muscles the gymnastic exercise which may be accomplished by the overcoming of prisms. That good may be accomplished in this way I have long ago demonstrated. The fact remains that the method is but tentative. The anomalous conditions remain and the unpleasant symptoms will probably return. A vast experience with these methods enables me, I be-

lieve, to speak of them with some degree of authority, and I do not hesitate to say that while no one can afford to overlook them, they fall far short of the more rational measures of actual adjustments by means of equalizing the tensions in such a way as to establish practical orthophoria."²⁴

DISCUSSION.

DR. EDW. JACKSON of Philadelphia—The reader of the paper has perhaps made the best use of the time of the Section in calling attention to current errors, which are frequently very misleading to those who are not especially interested in the particular subject. I quite agree with him that the rotary displacement of the image caused by oblique astigmatism is entirely insignificant, but the cylindrical lenses placed before the eye to correct such astigmatism will cause such rotation of amount sufficient to be of very practical importance for the images of all lines not parallel or perpendicular to the direction of the cylinder axis. This rotation is the cause of very serious inconvenience in the first wearing of cylindrical lenses, and this inconvenience may prevent the wearing of correcting cylinders by persons whose astigmatism has remained uncorrected until after 50 years of age. While in all cases it is the cause of inconvenience, in young persons the inconvenience always passes away in the course of two or three months at furthest. And this ability to accept the suddenly developed and much greater rotation of the cylindrical lens, argues very strongly against any continuance of inconvenience from the extremely insignificant rotation produced by corneal astigmatism.

DR. GEO. H. PRICE, Nashville, Tenn.—The paper proposes to put in a state of doubt the question of insufficiency of the obliques, and I will use his diagrams. The claim that this condition is normal, as produced by Prof. Le Conte would be sufficient evidence if he were investigating this peculiar question, but as he is not, then I must differ from his conclusions. It is essential for binocular single vision that the image must fall on corresponding portions of the retina, hence in the cyclophoria induced by oblique astigmatism, or insufficiency of the oblique muscles, you have this disturbed, and this disturbance must be compensated for by a rotation of the eye on its antero-posterior diameter. These diagrams which I hand you will illustrate these points. No. 1 shows the result of observing with each eye where there is no astigmatism, and you will observe that the figure is a rectangle; Fig. 2 shows the same rectangle when seen by astigmatic eyes, while Fig. 3 shows the resultant figure. These points can be demonstrated by the use of cylinders of 3 D. Dr. Price then gave an explanation of the diagrams.

DR. H. V. WURDEMANN, Milwaukee, Wis.—Abnormality is but a relative term and should be used in a relative sense. For instance, astigmatism of 25 D. in one person may be considered abnormal, while 2.00 D. or more in another gives rise to no inconvenience and may be ignored. There are but few persons in whom it is *not* possible to demonstrate some form of heterophoria and this alleged cataphoria is probably a physiologic phenomena, despite the fact that theoretically, insufficiency of the oblique muscles is quite as probable as those of the recti. I will pass over this and turn to a subject of practical importance which was considered in the latter portion of Dr. Eaton's paper.

There is no doubt in my mind but that the method of treating exophoria proposed by Dr. Gould, is the best of our present known means for developing the strength of the internal recti. Unfortunately, Dr. Gould has referred the condition of exophoria to insufficient innervation. This is a factor, but those of improper insertion in the recti, increased pupillary distances, actual weakening of the muscular tissue can not be well ignored. In my hands, after a year's trial, I consider that this "gymnastic exercise" (for it is but that) not only increases the prism fusing power for distance, but in a less degree does so for near; it lessens or removes the exophoria for distance as well as the near, and actually increases the convergence for the near point, thus increasing the focal angle and all of this without establishing an over-action of the accommodation. For esophoria I have had less experience, but for the more common condition of exophoria I consider that the majority of cases may be cured by the Gould method, in connection with tonic treatment, more satisfactorily than by surgical or any other known means.

DR. SOUTHARD of San Francisco said, it is undisputed that it is indispensable for binocular image that there should be a clear and well defined image upon the fovea centralis, otherwise the result will be either diplopia or a diffused image. The passage of rays of light through an astigmatic cornea causes an irregular image upon the retina. If the astigmatism is oblique, the proof that rotation takes place in the endeavor to compensate this error lies in this, that between the far point and the near point the axis in astigmatism has been frequently known to change several degrees. A word as to Dr. Gould's treatment of heterophoria by prisms. He has to say that whether the theory be that of innervation or not, the practical results of such treatment have been found of inestimable value to the patient and physician. He is willing to grant that it may be only a gymnastic exercise of the occult muscles. It is claimed by some that its only good lies in the power to preserve binocular vision for distant objects. They claim that when we consider the dynamics of the eye, that it has not the same amount of effectiveness. On the contrary, many cases thus treated have given the best results for continuous work at the near point.

DR. KASPAR FISCHL, San Francisco—As it seems to me interesting to hear the experience of those who have tried Dr. Gould's method, I would like to state that I could relieve a number of patients from asthenopia caused by exophoria at the reading range by these gymnastic exercises. In most cases after a few minutes trial, with prisms, base out, I could find an increase in the adducting power of the recti interim. I hope that the members present will give us their experience on this point.

DR. H. BERT ELLIS, Los Angeles—Dr. Southard is no doubt right when he says that inequality of the recti muscles may be found in nearly every individual; but we may also say that with every individual the amount of inequality varies from time to time. And if we acknowledge inequality in the recti, it seems to me we should not deny the same con-

dition in the oblique. A year ago I corrected astigmatism in a girl, axis 60 degrees and 120 degrees—0.50 D. Two months ago, clear vision could only be produced with the cylinders at 90 degrees, and it does not seem unreasonable to consider this the result of changes in the oblique muscles.

DR. EATON, in closing the discussion, said—In attacking the theories of Dr. Savage, I have in view the objectionable influence upon the therapeutic practice of those who accept his theories. I can not see that the arguments of Dr. Price disprove the demonstrated facts I have submitted. The attempt to asperse the evidence of LeConte and Hering as being the result of strictly scientific experiment unrelated to pathologic conditions, is not justified, since no more patient and thorough investigations could be made. Hering has anticipated every phenomenon of oculo-muscular action that has been mentioned to-day, especially as regards the transition from one secondary position to another. I must again assert that it is impossible to find a human being who has not, according to the tests of Dr. Savage, insufficiency of the oblique muscles, provided the person examined can analyze his visual impressions, which patience will enable him to do. Dr. Price remarked that when a cylinder is held before the eye with its axis vertical, there is no muscular disturbance and no distortion of the object. Yet any one regarding a square card with a plus or minus cylinder held with axis vertical before one eye, will see that while the sides are parallel, the top and bottom appear inclined. Dr. Southard remarks that a clear image must be seen by each eye; that is, undistorted; yet Dr. Friedenwald has shown that if we place in a stereoscope a representation of the image of an object, as seen by each eye, with a cylinder axis oblique, they appear as if fused into an object having solidity; which proves that distorted images are tolerated, and produce no confusion.

Dr. Price gives no data by which we can distinguish the asthenopia produced by astigmatic refraction and the alleged asthenopia of insufficiency of the obliques; nor does he explain the existence of metamorphosis of individuals who are not astigmatic. No one, in discussing the question of compensatory rotation, in cases of oblique astigmatism, has harmonized the fusion of the horizontal lines with the exaggerated incoincidence of its perpendicular lines, produced by the supposed rotation. In regard to Dr. Würdemann's statements concerning Dr. Gould's method, I quite agree with him, but would again call attention to my experiences as regards the possibility of producing esophoria for distance, while the dynamic convergence power for the near point remains deficient.

REPORT ON THE VALUE OF OBJECTIVE TESTS FOR THE DETERMINATION OF AMETROPIA, OPHTHALMOSCOPY, OPHTHALMOMETRY, SKIASCOPY.

By the Special Committee of the Section on Ophthalmology of the American Medical Association.

EDWARD JACKSON, M.D., Chairman, Philadelphia; S. M. BURNETT, M.D., Washington; H. V. WÜRDEMAN, M.D., Milwaukee; and J. A. THOMSON, M.D., Kansas City.

The members of your committee are all in accord with the view held by most ophthalmologists that the objective methods of determining ametropia can not entirely replace the subjective method with test letters and trial glasses; and that, in so far as the subjective method is applicable, it may be regarded as

a court of last resort. Determinations of the refraction by the various objective methods, however, constitute an essential portion of the complete examination of any eye. They are essential parts of the whole, and no examination is complete without their use. The subjective method can no more fill the whole bill than can any one of the objective methods alone. All should be used in every case to avoid errors common to each. Although it is obvious that if the various measurements of a definite quantity are accurate, by whatever means they are made, they will agree.

The range of application of the subjective method is strictly limited to the determination of refraction at the fixation point, for patients of sufficient intelligence and honesty, with eyes possessing sufficiently good vision. It also requires a considerable amount of time for its application, varying with the form of ametropia present; and, where relied on alone, this consumption of time is, for the more difficult cases, an extremely serious drawback and (by exhausting the patience of the surgeon and the endurance of the patient), a source of possible inaccuracy.

The objective methods of measuring ametropia are of value:

1. By effecting a saving of time; and by this, and as confirmatory tests, securing accuracy.
2. They are applicable to cases and to uses for which the subjective method is entirely inapplicable and useless.

Thus the objective methods can be applied to determine refraction in the eyes of small children, in the mentally defective and in the lower animals. Also in the eyes of malingerers, conscripts, applicants for pensions, insurance, or society benefits, plaintiffs claiming damages for injury, or in general wherever the cooperation necessary for the subjective test is lacking, because of lack of intelligence, perversity or self-interest.

Ophthalmoscopy and skiascopy are also applicable to the determination of the refraction of points outside of the macula and outside of the retina, as the prominence of a swelling or the depression of the cup in the optic disc, or the position of opacities in the vitreous.

Again, keratometry (ophthalmometry) and skiascopy are of value in determining certain facts of scientific interest and importance, as the curvature of the cornea either in the visual zone or elsewhere with the ophthalmometer; and the position and limits of the visual zone, and the total refraction of the eye outside of it by skiascopy.

The objective methods are applicable in blindness and in amblyopia of all grades.

As specified in the resolution under which this committee was appointed, our report is concerned only with ophthalmoscopy, ophthalmometry and skiascopy, and in our opinion these are the objective tests of practical importance. It is concerned, too, only with the value of these tests, not with the methods of performing them. And although their value obviously depends on their form, and the skill with which they are applied, these will only be referred to in that our estimate of their value supposes them to be applied with the skill attainable by careful training and considerable experience, and in their best form. That is, for the ophthalmoscope, we suppose the use of an instrument with a continuous lens series in a thoroughly darkened room, where the pa-

tient will have a range of vision of four meters or over, conditions that it is perhaps the exception to find fully complied with in ordinary practice.

The ophthalmometer is to be used with the light from one-eighth of a hemisphere of clear sky, or the best artificial illumination; and so far as it is possible, the eye under examination is itself to be shielded from light. There must be steadiness of the instrument with the patient and surgeon in comfortable positions.

For skiascopy, is required the use of a sharply bounded, sufficiently small source of light, adjustable to the position of greatest accuracy; and a mirror with the sight-hole of not more than three millimeters, free from reflections.

As to the question of the use or non-use of mydriatics, there is no general difference between the subjective and objective tests. Either measures the refraction as it is found at the time of measurement, whether that be the true static refraction or something different. The objective tests are, however, to this extent slightly more favorable to the determination of the true static refraction. With the ophthalmoscope, strictly under the conditions mentioned, there is without a mydriatic, a slightly greater tendency to relaxation of the accommodation than with the test lenses and test letters.¹ With the ophthalmometer, the corneal astigmatism which may be the total astigmatism of the eye (but generally is not) is entirely independent of a mydriatic. And, with skiascopy, the total astigmatism present at the time of measurement can be ascertained with more certainty and accuracy than is usually possible with the test lenses in the presence of accommodation.

VALUE OF THE INDIVIDUAL TESTS.

Ophthalmoscopy.—The measurement of refraction with the ophthalmoscope enables us to immediately assign an approximately just share to the influence of ametropia in causing imperfect vision. The first ophthalmoscopic examination will in general give us the basis for a preliminary or approximate diagnosis of the refraction; the lens required to give the clear view of the fundus informing the observer of the hyperopia or the myopia present, and the distinctness of the view that it gives indicating the presence, degree and regularity of astigmatism. And all this is accomplished in perhaps a fraction of a minute.

The ability to measure by their refraction the relative position of different points seen by ophthalmoscopy, gives it an important value very imperfectly shared by skiascopy alone.

Of the ability of the ophthalmoscopic examination to reveal latent hyperopia, there must always be some doubt, for in a certain proportion of cases it fails to accomplish it. In this matter of rendering manifest the total hyperopia, it has not, in our own experience, shown any very pronounced superiority over the subjective method. Of the exactness of the determination made with it, we accept the statement of Loring that it will measure hyperopia or myopia to within 0.5 D. or recognize the presence of 0.75 D. of astigmatism and the direction of its principal meridians.

It must be clearly understood, however, that this accuracy can not be attained by all observers, or by any observer at all times and in all cases. There are some surgeons who fail to learn how at any time to completely control their accommodation, at least until an age is reached when the accommodation

normally ceases to be a factor to be dealt with. And, what is of more importance, all observers with considerable accommodative power are, after periods of prolonged or difficult eye work, likely to find their control of accommodation impaired, and their measurement of ametropia with the ophthalmoscope unreliable. Thus after a somewhat prolonged effort to obtain a clear ophthalmoscopic view of the fundus of an eye presenting astigmatism, the subsequent ophthalmoscopic determination may vary quite notably from accuracy.

The most serious hindrances, however, to constant accuracy of the ophthalmoscopic examination of ametropia are those dependent on the eye of the patient. If the patient's pupil be unduly small, the accuracy obtainable by this method is correspondingly diminished by the diminution of the circles of diffusion on the observer's retina. On the other hand, if the pupil dilate moderately, as it does in the majority of cases in a thoroughly darkened room, portions of the dioptric media will be exposed at the margin of the pupil that differ materially in their refractive power from the visual zone, and thus the refraction which may really be obtained by the refraction ophthalmoscope will differ essentially from the refraction of the visual zone which is sought,

On these accounts, the best observers we have known have been liable at times to inaccuracies of one or two dioptries in their ophthalmoscopic determinations of moderate ametropia, especially astigmatism, and in high myopia, more especially with astigmatism, the error is even greater, sometimes amounting to four or five dioptries.

Ophthalmometry.—Ophthalmometry would be more appropriately named *keratometry*. Had it been so designated from the start, some current errors with reference to its significance and value could scarcely have arisen. It measures the curvature of the cornea and this curvature alone. Its value as a test of ametropia, is entirely dependent on the relation of the corneal curvature to the total refraction of the eye.

What we have to say, refers to the instrument of Javal, the only one that has proven of importance in ordinary practice. As commonly used, it does not measure a continuous curve, but simply the angle between the two points of the cornea from which the margins of the mires (which constitute the extremities of the test object) are reflected. Between these two points or anywhere beyond them, the curvature of the cornea may essentially differ, though as a rule this curvature in the region measured is practically regular.

By measurement of the curvature in different meridians, the existence and amount of corneal astigmatism is determined to within 0.25 D., or less if the patient be steady, the other conditions favorable and the observer's vision not impaired by irradiation.²

The directions of the principal meridians of the corneal astigmatism are also determined with an accuracy dependent somewhat on the amount of astigmatism, but even for low degrees with practical exactness. Thus for astigmatism of 1 D., the principal meridians may be determined within 5 degrees. In a few cases, the meridians of greatest and least curvature vary noticeably from a right angle with each other. In such eyes, the direction of the meridians of the part of the astigmatism that is regular, (that is, the part which can be corrected by a cylin-

drical lens), must so far as ophthalmometry goes, remain in doubt.

We do not find marked variations in the curvature of the cornea at different observations, but believe that where such variations are noted, they are usually either due to unsteadiness of the patient's eye, causing a different part of the cornea to present, or where noted at different times, may be due to changes in the adjustment of the instrument.

What the ophthalmometer reveals is entirely independent of the influence of mydriatics; the curvature it measures, remaining precisely the same in all conditions of accommodation or when the accommodation is entirely paralyzed. But the ophthalmometer being simply a keratometer, gives no information as to the degree of hyperopia or myopia present; and only indicates what may be the total astigmatism if that conforms to the corneal astigmatism. Of the conformity of the corneal to the total astigmatism, statistics now before the profession enable us to judge. From them we draw only this conclusion, that the chances of conformity between the corneal and total astigmatism are not sufficient to justify reliance upon the ophthalmometer as a means of showing the cylindrical correction required in the individual case.

The practical value of ophthalmometry, therefore, is mainly that of a method of examination that will make an important suggestion as to the presence, degree, or direction of astigmatism, which when followed up by other methods of measurement, may effect a greater saving of time.

In addition to this, it is possible that when accurate ophthalmometric records have been made of the curvature of a cornea, subsequent changes in its curvature may indicate the occurrence and amount of change in the total astigmatism.

Aside from these practical applications of the instrument, it has a scientific value, and must be regarded as offering a necessary method for the elucidation of certain important scientific problems as to the existence and change of ametropia.

Skiascopy.—Skiascopy is on the whole the most accurate and reliable objective method of estimating ametropia. It measures the total refraction of the eye, whether this be the static refraction or the refraction modified by accommodation. Applied in the direction of the macula, it measures in the visual zone exactly the refraction that is measured by the subjective method; and at the same time, it measures refraction outside of the visual zone, as it is possible to measure it in no other way.

For eyes having a distinct and sufficiently extended visual zone, it is accurate to within one-eighth of 1 D.³ In its power of detecting latent hyperopia, that is, of allowing latent hyperopia to become manifest while the measurement is being made, it does not differ materially from ophthalmoscopy or from the subjective test. But, it is, if anything, slightly inferior to them.

The accuracy which is possible with skiascopy in the individual case is limited mainly by the definiteness or indefiniteness of the visual zone. When a certain portion of the dioptric media, large enough to be readily identified and studied, has the same refraction and is definitely bounded, the degree of ametropia of this portion, its hyperopia, myopia, or astigmatism, can be determined within the limits of accuracy named. When, however, this visual zone is

too small to study at a convenient distance or the refraction passes by imperceptible gradations into entirely different refractive conditions surrounding it, the difficulty of applying the test is greatly increased and the accuracy and certainty of its results diminished.

The eyes in which a definite visual zone can be isolated and studied are the rule; those in which this is not possible the rather rare exception. The degree of accuracy attainable in these latter cases will depend almost wholly on the minuteness of the study, a minute study being only possible at a comparatively short distance with especially arranged conditions of illumination. Such a study requires great care and patience, but with it even high grades of irregular astigmatism will often yield a distinct visual zone capable of comparatively accurate correction by lenses, which the test will indicate.

Skiascopy, therefore, offers for most eyes, a method for the easy and rapid measurement of ametropia, within the limits of practical accuracy for even the subjective method, except in eyes having more than the Snellen normal standard of visual acuteness. For the exceptional eyes, in which it is less accurate, it offers a means, which, carefully used, will give confirmation of subjective results, or a better correction than may be obtained by any other method. In nearly all eyes the result of a careful skiascopic correction will give the best or very nearly the best obtainable vision.

In addition, skiascopy informs the surgeon, as does no other method, in what portion of the dioptric surfaces the visual zone is situated, and gives him definite knowledge as to what changes in the optical requirements of the eye will be brought about by a change in the size of the pupil. It may, therefore, be relied on to indicate (while the pupil is dilated) whether in the individual case a repetition of the subjective test is especially required or advisable, after the recovery from the influence of a mydriatic.

In conclusion, your Committee would urge that the accurate determination of ametropia is best accomplished by the use of all of these objective methods in each case, and usually, in the following order:⁴ The ophthalmoscopic examination, measurement of the cornea with the ophthalmometer, skiascopy—these to be followed by the subjective determination, and, if this last does not agree with the previous measurements, its findings should be submitted to re-trial by skiascopy.

Even when this plan is followed, the accuracy of results obtained will depend on the experience, habitual accuracy of observation, physical health, mental alertness, and conscientious care of the observer. But without some such plan, the best observer will fail to do his best work; while with it, the poorest will be able to make the most of such skill as he has.

¹ Ophthalmoscopy without a mydriatic is relatively of greater value in revealing latent hyperopia than the subjective tests, but when the eye is under a mydriatic, the subjective method in intelligent patients is a superior test.—H. V. W.

² As the instrument is now made with a low degree of magnifying power and from the coarse adjustment of the lines thereupon ensuing, I do not consider it reliable for the corneal measurement under 0.25 D., but as this is the usual interval of the weaker lenses, this is sufficiently accurate for practical purposes.—H. V. W.

³ May be this accurate in some instances.—S. M. B.

⁴ I prefer to use the ophthalmometer before the other two forms of objective examination, since by it at a moment the amount of the corneal astigmatism is acquired and which may be taken as a guide in ophthalmoscopy and skiascopy in the search for the total astigmatism. Especially as the final measurements by the latter test are usually made under mydriatic, and keratometry may be done during the first few moments of a preliminary examination.—H. V. W.

RETINOSCOPY AS A CRUCIAL TEST IN MEASURING ERRORS OF REFRACTION.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY B. ALEX. RANDALL, M.A., M.D.

OPHTHALMIC AND AURAL SURGEON TO THE CHILDREN'S HOSPITAL, ETC., PHILADELPHIA, PA.

Except in the early-demonstrated value of retinoscopy in the recognition of conical cornea, as set forth by Bowman, the claims for the method seemed decidedly exaggerated by Cignet and other early advocates; and my study of it (as practiced with the concave mirror) affording no prospect of large usefulness, I dropped it almost entirely. In the spring of 1884, however, I began to employ the plane mirror in the test, and have ever since held it to be the most delicate objective test in measuring the refraction and its anomalies. Believing it to be unequalled in certain respects by any other procedure, I desire here to define the limits within which I particularly value it; and this the more, as I believe I differ from the general practice.

In my routine examination of a patient, retinoscopy follows the subjective tests for far and near of the vision and muscle balance. In the moderately darkened room, with an argand burner shaded by a metal chimney presenting an opening an inch and a half in diameter, the light is thrown by a plane mirror from a distance of three or more meters, while the patient gazes at a dark surface behind me. Under these circumstances a medium pupil (four to six millimeters, is almost invariably obtained, in which there is rarely any difficulty in seeing and determining the motions of the shadows. M. and H. are thus readily differentiated, with the presence and axis of any astigmatism, and a rough quantitative estimate can be made from the distinctness and rapidity of movement of the shadow. Mixed astigmatism, usually the most difficult error to uncover, is by this method the easiest and most unmistakable. With very narrow pupils, hazy media or unsteady patients, some little difficulty may compel a closer approach; but if the examiner's head be a little lower than the patient's, this can generally be avoided and the test satisfactorily made at even greater distances. As the pupil is not strongly illuminated, the mirror must have an ample sight-hole, free from annoying reflections.

Having thus qualitatively determined the refraction, I then pass to the ophthalmoscopic examination in the upright method, and while investigating the media and the tunics, measure the degree of any refraction error. The corresponding glass or combination is then placed in the trial-frame before the eyes and its accuracy tested—by the test letters, if desired—or where the subjective tests can not be trusted, I proceed at once to the crucial employment of retinoscopy.

For this, some painstaking in the illumination may be required in order to give readily the desired accuracy. Theoretically, we should obtain the emmetropic appearance at a distance of four meters only when $M=.25$ is present. Practically this rarely holds good, probably because the pupil is wide enough in most cases, even when no mydriatic has been employed, to give a peripheral refraction higher by thus much than that at the pupillary center, and also because we usually compare results with the subjective

correction for six millimeters, which is slightly over-correcting for distance. I look therefore, for a central, comma-like shadow, rotating or varying with the shifting light, yet moving neither against nor with the motion of the light upon the face. If this be obtained with $+ .75$, for instance, it will be found that $+ .90$, the old 42, gives a distinct myopic shadow moving in the pupil against the mirror, while $+ .65$ is as clearly an under-correction and gives a shadow moving with the mirror. So it is fair to claim that errors as small as 0.1 in any or all meridians can be recognized by this method under favorable conditions. Indeed, I have seen cases where 1 D. was as clearly too strong as .90 was too weak; and one could assert that there was not so much as .05 D. of astigmatism. For this minuteness of measurement is as true of one meridian as of all; and the axis of any uncorrected astigmatism can generally be determined within 5 degrees with the same ease and accuracy. It seems just to say, then, that this is the most minutely exact measure at our command.

It is a tedious business to do the coarse focusing of your microscope with the fine adjustment screw; and in like manner this method is not the readiest for the work intermediate between the rough qualitative and the minutest quantitative measurement. For this Dr. Jackson's method with the artificial far-point excels it. But within its proper field the plan deserves fuller recognition and employment; and only the "too old a dog to learn new tricks" is likely to fail of satisfaction with it.

I have sometimes met the claim that special skill or exceptional sharpness of sight are requisite to succeed with this method. My possession of $V=6/IV$. is doubtless no drawback in the use of it; and practice unquestionably facilitates control of the illumination, so as promptly to throw it into the pupil four meters away, and then precisely to make the small rotations of the mirror requisite to give the play of shadow in any desired direction. But I can not perceive that I have in ten years much improved beyond the skill gained in the first few months; and I have frequently brought a doubting tyro to unhesitating recognition of errors of 0.1 D. in a demonstration a few minutes in duration. The artificial eye, especially that of Frost of London, is an excellent aid to the beginner, although in some respects work with it is more difficult than with a tractable patient.

Finally, a word as to the utilization of this hair-splitting aid to accuracy. With intelligent, sharp-sighted patients the subjective tests are doubtless the most satisfactory for deciding minute differences; and the coöperation of the patient and his subsequent loyalty to your decision, can generally be thus best secured. Yet the objective tests often greatly aid us to help a doubtful patient to a decision, and the moral effect of independence of his answers is in every way good. With patients less well endowed, as so many are, retinoscopy rises rapidly in importance; and in intractable cases it can easily guide us when nothing else but the direct method can be used. The expert in this procedure may ask for nothing better, although it is a question if one can at all times control his accommodation and precisely allow for his own refraction; and where Loring was doubtful about accuracy to fractions of a dioptre, he who would be correct to one-tenth must be an ophthalmoscopist indeed. Even to such a one, it may at times be a great gain

to be so precise when fatigue or headache has set the ciliary muscle in a worry.

It is in the public clinic, where much of the detail work must be delegated by the chief, who must yet shoulder the responsibility of it all, that this method of retinoscopy has its most striking value. In one of my services, where a dozen or more refraction measurements had to be made each day, it was easy to give by the ophthalmoscope a rough estimate of the refraction to an assistant, who might be a mere beginner; and when he had finished his subjective tests and marshalled into the dark-room his patients wearing the correcting lenses in accord with his findings, it took a very few seconds to verify or revise his work in each case and to prescribe the glasses with full assurance of the precise error of refraction. Any error in the position of a cylinder or the strength of it or of a spherical could be at once detected, rectification made, and the result verified. Some men do not desire this accuracy in their hospital work; others will not take even this small trouble to obtain it; but to the conscientious ophthalmologist it is clearly needful, and it will be readily possible by this method of retinoscopy.

THE STATUS OF SKIASCOPY.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY H. V. WÜRDEMAN, M.D.
MILWAUKEE, WIS.

DIRECTOR WISCONSIN GENERAL HOSPITAL; OCUList AND AURIST TO THE CHILDREN'S HOSPITAL, AND TO THE MILWAUKEE HOSPITAL FOR CHRONIC INSANE; INSTRUCTOR IN EYE, EAR AND THROAT, ELMS HOSPITAL; AND TO THE MILWAUKEE COUNTY TRAINING SCHOOLS, ETC.

It is conceded beyond all doubt by those practiced in the objective methods for determining the ocular refraction, that skiascopy holds the first place as regards accuracy and minuteness of measurement. This you have learned from the special committee appointed last year and empowered to report at this meeting. The sum of our report may be put in one sentence: *The objective tests are essential to the proper examination of the ocular refraction and, although but preliminary to the subjective method, reduce the latter to simple proving of lenses found by the former, eliminating in a great measure dependence on the faltering judgment of the untrained patient, substituting therefor the skill of the expert who, reasoning from scientific data, is thus able to fit glasses in less time and more accurately with consequent satisfaction to himself and his patient.* Keratometry, ophthalmoscopy and skiascopy; "the greatest of these is" skiascopy. Thus in a few words you have the standing of the method designated by those familiar with the same.

This paper is not written for these, but for those on the outside who, either through ultra-conservatism, laziness or inability to master its minutiae, have not yet taken up the shadow test. It is a painful fact that there are men, in other respects good ophthalmologists, whose refraction work is but on a par with that of the glass-selling jeweler and the average optician. They pin their faith to the trial set and to the patient, whose hesitating replies are a constant source of error. As refraction examination forms fully one-half of the oculist's work, such must give way to those skilled in *measuring the eye*.

The estimation in which skiascopy is held by our eastern confrères is shown by the fact that a whole

week is given up to the teaching and application of *this method alone* at the Philadelphia Polyclinic, in a series of twenty-seven lectures and clinics by a large corps of professors, instructors and clinical assistants.¹

From the perusal of recent English and German literature, it would seem that even though the shadow test has been in common use in this country and France for a decade, the profession on the other side has not taken up the method to the extent that we have. In this country, I think that it may be said all of the progressive workers use it and do not consider the refracting of any case complete unless skiascopy has been called into service. Within a couple of years the acquisition of this method will be deemed as necessary by the foremost specialists of all the world as it is here. Six years ago I was astonished by the ignorance of the German oculists regarding skiascopy, as it was then, as now, foremost in my mind as being the principal objective method of measuring the eye. It is different now, and I understand that the shadow test is being generally taken up even in the clinics of Germany. Personally, I voice the opinion of its value given by your committee, and use it a number of times a day in my private practice.

In what cases should the shadow test be used? I should say in *all* patients for whom lenses are to be prescribed. I hold it to be an absolute necessity for the scientific refractionist to know in every instance the total refraction of the eye before putting on lenses. I would no more think of fitting spectacles to a presbyopic patient, by trying lenses at the near point alone without knowing his refraction, than I would of prescribing glasses in ametropia by one or more of the objective tests without recourse to the subjective method for confirmation.

The few instances in which skiascopy is unreliable or inapplicable are limited to those cases in which a definite visual zone can not be isolated. These eyes are the exception and yet where carefully used, in irregular corneal curvature, in conical cornea, in partial lenticular or corneal opacities and in very high grades of astigmatism, skiascopy is of value as a confirmatory test. "In nearly all eyes the result of careful skiascopic examination will give the best obtainable vision."²

For skiascopic results to agree with those elicited by prolonged subjective tests, the examination should be conducted in the visual line, the refraction of the macula only being measured. Skiascopy measures the static refraction of the eye when applied in the visual zone, exactly as it is at the time of the examination, whether modified by the accommodation or not. Thus, in young persons, as a rule, a mydriatic should be used. Skiascopy is of value in proving of measurements found by the other methods, just like the proving of an example in vulgar fractions: By again applying the shadow test with the combination of lenses decided upon from the trial case. It may thus be used as a check upon the other methods and upon itself.

Aside from the difficulty of acquiring the technique, (although not nearly so much time is taken by the tyro in learning it as is necessary for accurate ophthalmoscopic measurement), I would consider that the want of proper facilities for placing correcting lenses before the patient has been one of the greatest obstacles to the general adoption of the method. If

it be remembered that but one meridian can be considered at a time, and that the neutralization or reversal of the shadow movement by spherical lenses accomplishes the same purpose for the meridian under observation as cylindrical lenses, much of the difficulty is done away with. The placing and replacing of lenses in a trial frame is very consumptive of time, and the test case itself occupies too much space in the ophthalmoscopic dark room, which is usually but a closet.

To obviate these disadvantages, Doynne,³ of Oxford, Eng., in the Ophthalmic Section of the International Congress held in Washington in 1887, exhibited a large rotary disk containing many plus and minus lenses. Burnett's⁴ and my own⁵ rotary disks, modifications of this, were more simple, but mine at least has been laid on the shelf for several years, as being too cumbersome. The simple hand skiascope,⁶ here shown has all their advantages and the model I present has been used in my work several times a day for nearly four years, and I understand has been given a place by a number of our colleagues. This you see is a simple blade of hard rubber which contains twelve plus and twelve minus lenses. The patient raises and lowers the instrument at the word of the examiner until the neutralizing lens is found, the strength of which is always plus .75 D. greater than that of the actual ocular refraction in this meridian, and this over-correction should be allowed. The sphericals found by direct ophthalmoscopic examination are

usually worn by the patient in a separate frame behind the instrument. I find it convenient to have a couple of pairs of reversible spectacle frames in my dark room containing the one a + 1. D. and + 2. D. lens, and the other a + 3. D. and a + 4. D. lens; the strength of which when used for higher degrees of hyperopia is added to that of the instrument.

This simple instrument overcomes the principal difficulty in the use of the method. Thus skiascopic examination as practiced by myself and colleagues takes but a minute or two, the test itself giving mathematical data from which scientific conclusions are reached.

805 Grand Avenue.

Sewage Disposal by Crocodiles.—One of the representatives of Ceylon at the Columbian Exposition is said to have proposed a plan for the "destruction of the offensive matter now passing into and festering in the river and imperiling the health and lives of the citizens, without necessitating any alteration of the existing system of sewerage." The plan of the Ceylonese "sanitarian" is to construct at the sewer outfalls, suitable enclosures in which to rear and keep "crocodiles and alligators to serve as scavengers—a service which, from the fact of their being omnivorous, I am convinced they are eminently well qualified to render." The veracious chronicler in which this precious plan was published is said to have viewed the matter seriously.

THE VISUAL ZONE OF THE DIOPTRIC MEDIA AND ITS STUDY BY SKIASCOPY.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY EDWARD JACKSON, A.M., M.D.

PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC; SURGEON TO WILLS EYE HOSPITAL. PHILADELPHIA, PA.

One is liable to get the impression that, in eyes with perfect vision, only focused light reaches the retina, although the incorrectness of such an impression is readily demonstrated in various ways.

If we close the lids in any strong light, we can demonstrate that sufficient light reaches the retina through them to give quite accurate quantitative perception; and about the same amount of this light reaches the retina through the lids and the sclera when the eyes are open and in use for distinct vision. The ability to light up the interior of the eye by oblique illumination through the sclera or iris, we have all demonstrated. But skiascopy has shown that even through the pupil, always in the dilated pupil, often in the pupil as contracted by the ordinary daylight, a considerable part of the light entering, often the greater portion of it, reaches the retina unfocused.

While a flood of such unfocused light renders very accurate vision slightly more difficult and tiresome, it does not prevent it. The conditions may be likened to those that are obtained when a convex lens is held so as to form an image on a piece of paper in a well lighted room. A large part of the light reaching the paper is not focused light, and the image formed is on that account less vivid, yet more careful examination shows that it is comparatively distinct and quite complete. When the mixture of diffused and focused light falls on the retina, the former seems to interfere still less with the perception of the image formed by the latter, so that a comparatively small proportion of accurately focused light with a much larger amount of uniformly diffused light will still enable one to see distinctly.

The portions of the dioptric media through which the light is perfectly focused upon the retina I have termed the visual zone. Existence in the pupil of a visual and extra-visual zone, with some of the facts dependent thereon, have been impressed on me by prolonged use of the shadow-test, and I am conscious of having very slowly come to some realization of their full significance and importance. They have a most important influence upon the practical application of all methods for the measurement of ametropia, but the exact nature and significance of that influence is only revealed by skiascopy.

The fact that we are able to see by the focused light in the presence of much that is unfocused, enables us to use the subjective method; and the fact that only the focused light impresses consciousness by recognizable sensations has, in a large proportion of cases removed the subjective test from the inaccuracies and uncertainties that would otherwise be due to the admission of light through the extra-visual zone.

The existence of an extra-visual zone presenting refractive conditions entirely different from those of the visual zone, is a great obstacle to accuracy with the direct method of ophthalmoscopy. With skia-

scopy, however, the observer has spread before him, as it were in a complete map, the pupil in each portion of which the refractive conditions may be separately studied, and it is this opportunity offered for isolating and studying alone the different refractive conditions that occur in the same eye, that is the supreme advantage that skiascopy has given to the ophthalmologist. All else that it does can be done by other methods, and in other respects it is only the time-saver or confirmer of other methods. In this it stands entirely alone, and the information that it gives is just that which was needed to make practical physiologic optics an exact science.

The practical importance of the study of the visual zone, and the relation of its refraction to that of other parts of the dilated pupil is very great, and the facts revealed by such a study will powerfully influence the prescription of correcting lenses. How great this importance is and how much the practice of lens prescribing is likely to be influenced will only be appreciated by one has made at least a few careful studies of this kind. Leaving it aside for some future communication, I wish simply to speak now of essential methods for such study.

The area of the pupil that may be regarded as having the same refraction depends on the exactness or minuteness of discrimination that it is desired to make. If one says roughly a certain eye is hyperopic or a certain eye is highly myopic, this may apply to the whole dilated pupil. If he says the eye has so many dioptres of hyperopia or so many dioptres of myopia, and is willing to ignore variations of less than 1 D., what he says may apply to the whole of the pupillary area as it exists under conditions of ordinary illumination. But, if he desires to be more discriminating, to recognize the smallest differences of refraction that can be recognized by skiascopy, he will find in almost all cases that such a pupillary area presents marked variations. And, in a certain number of cases of eyes that would not ordinarily be regarded as exhibiting conical cornea, or marked irregular astigmatism, the area of the pupil even contracted by strong light and for near work will show variations in refraction of the greater part or a whole dioptre.

From these facts, it follows that the accurate application of skiascopy, the careful study of the visual zone and the relation of its refraction to that of the surrounding portions of the pupil is a study of the *movement of light and shadow in small areas* of the pupil, not across the pupil as a whole.

To study a small object one must bring it near the eyes; hence such studies of the pupil must be made within a comparatively short distance. Distinct movements in an area three millimeters in diameter can not be conveniently studied beyond the distance of a meter and can be most readily studied at a considerably shorter distance. There are not a few eyes capable of visual acuteness quite up to the normal standard, in which the light that goes to form definite images enters through a smaller area of the pupil than this, and the true refraction of the eye, therefore, can be studied only at a shorter distance; a distance of one-half or even one-third of a meter.

Again, to have a distinct area of light in such a limited space, it becomes highly important that the source of light be small. Such a study can not be made unless the ordinary lamp flame be covered with an opaque chimney with a small aperture. For my

own work, with the plane mirror, I have for the last year found an aperture giving a circle of light five millimeters in diameter most satisfactory. With such a source of light, properly placed close to the mirror, and the sight-hole of the mirror not more than two and a half or three millimeters in diameter, the study of the movement of light and shadow is as easily made at one-half meter, revealing the differences of refraction in different parts of the pupil, as is the rough study at one millimeter distance or more, by the methods ordinarily described which have so frequently misled the surgeon.

Recently, some of the best skiascopists have spoken of the test as being in some cases misleading. I am sure that it is misleading only when the movement of light and shadow is studied in the wrong part of the pupil. If one recognizes the true visual zone, and goes close enough to study the movement within it, the movement of light and shadow can no more mislead him as to the condition of refraction than a convex lens can have the effect of a concave.

We are dealing with simple physical facts. The misleading, I believe, invariably comes about by the surgeon's watching the movement of light and shadow in the extra-visual zone, and the chances of falling into the error are directly proportioned to the distance of the surgeon's eye from that of the patient and the consequent apparent smallness of the pupil.

With great variations in the state of refraction present in almost every eye, with the most of ophthalmic surgeons applying skiascopy in such a way that it was impossible to discriminate between the visual and the extra-visual portions of the pupil, it was no wonder that the test was regarded as one of uncertain value and not to be entirely relied upon. With the recognition of the real optical conditions to be dealt with, this uncertainty and distrust will disappear and the test will take its place for certainty and accuracy along side of the subjective test for intelligent, honest patients with perfect vision, and as distinctly superior to the subjective test in all other cases.

Such an application of the test is a very different matter from its use for a rough approximate determination of the refraction in which it has heretofore rendered most service. The phenomena to be dealt with opens an opportunity for the exercise of the highest skill in observation and the application of the most considerable experience. In my judgment, no other method of studying the refraction of the eye compares with the full application of the shadow test, either as to the possible value of the results to be attained or in the difficulty of the *complete* mastery of the method.

To demonstrate roughly the general refraction of of the eye, skiascopy is the easiest objective method. It may be grasped even by the tyro in a single lesson. But to reveal its full possibilities of delicacy and accuracy it will always require years of careful and intelligent application.

DISCUSSION.

DR. F. B. EATON—In the employment of the several objective tests under discussion without mydriatic, I prefer to begin with skiascopy, since a certain amount of accommodative adjustment is brought about by the subjective tests and by the fixation by the patient of the tube of the ophthalmometer.

I employ the ophthalmoscopic mirror with Dr. Würdemann's skiascope and without a mydriatic. If the pupil is

small, the patient must fix some object considerably to the right or left that a reflex may be secured; hence the importance of a very dark room and covered flame. I occupy a middle ground between the extreme views of those who eulogize and those who take as partial only the findings of Javal's ophthalmometer. I believe that many of the discrepancies between its findings and those under mydriasis result from imperfect illumination, and because the patient's head is not level. This latter defect can be remedied best by the American model, which provides a horizontal slit through which the observer can insure the levelness of the patient's brows with the top edge of the slit. Again, the patient must fix a point on the anterior lens of the instrument, which is in its axis, since then the observer measures the cornea at that portion cut by the visual line.

DR. S. B. DAVIS, Stockton, Cal.—In my use of the ophthalmometer, I have found that I had better results in most cases by placing the axis at 90 degrees, if the instrument showed it to be near 90.

DR. SIMONSON, San José—While the objective methods mentioned are theoretically within certain limits correct, yet it is a fact in practice that many mistakes are made by those relying almost wholly on these methods. Many of these cases require refitting, and ordinarily by use of the old trial case. Inasmuch as the various objective methods afford latitude for the exercise of much judgment, it is evident that all ophthalmologists are not equally endowed with skill and acuteness of judgment and this, accompanied by usual haste, results in many mistakes.

DR. R. D. GIBSON, Youngstown, Ohio—The results are not always the same in the same eye. A case showing plus .50 D. astigmatism may, after some months of over-taxation in school, return with conjunctivitis and an increase of the corneal astigmatism. This increase I have seen reach as high as 4. D. and after relieving the conjunctivitis and blepharospasm, the high degree of astigmatism vanishes and the results of the first examination found to be correct. Again, I have found astigmatism for which I have prescribed correcting lenses with great comfort and satisfaction, and after some months or a year, find no astigmatism, and only a spherical correction necessary.

DR. FRED BAKER, San Diego, Cal.—To repeat much that has been said, I wish to plead for greater charity in our treatment of our brother practitioners when we are called upon to overhaul their work. I have grown more charitable since finding that as large a share of my own cases show slight changes in a second test made after six months or a year, as of those which come to me from other practitioners, though I know that the first tests of my own patients were carefully made. Every one must find that certain patients show these changes after a time, which must be due to the relief of strain given to the ciliary muscles by the wearing of the first pair of glasses.

As to objective tests, while it must be true that all of us in the rush of business neglect to give sufficient time to all patients, still it must be admitted that the oculist who combines most methods of testing will do more accurate work than he who uses only one. I have yet to meet personally any ophthalmologist who has given any of the objective methods a full and careful trial, who has not admitted the practical value of the method.

DR. W. E. BRIGGS, Sacramento, Cal.—I agree with Dr. Riley in the statement that the trial test case will be our last and most important means of ordering glasses; but the more the profession uses the objective methods the more general they will become. I believe in time all ophthalmologists will use both skiascopy and Javal's ophthalmometer. These methods of testing are not always necessary, but cases are common in which we can not readily obtain a

result without some objective test. As for myself, I would feel quite at a loss to make my examinations without the ophthalmometer and skiascopy.

DR. ALBERT R. BAKER, Cleveland, Ohio—I am pleased with the report of the committee in that they have given great prominence to skiascopy as an objective test for the determination of ametropia. In 1891-'92 I spent considerable time in the Royal London Ophthalmic Hospital (Moorfields) about the time skiascopy was first introduced in that institution. Probably one-half of the patients applying for relief could not read and we found this objective test of great value in these cases. Upon returning to this country in 1883, I published several papers on this subject but as they received but little consideration I became somewhat discouraged in attempting to secure a hearing. I was greatly pleased when Dr. Jackson took up the subject and succeeded in placing this objective test where it belongs as one of the most valuable. No doubt the present excellent report will serve to make the use of skiascopy more general.

DR. J. R. RYAN, Galesburg, Ill.—The use of the old trial lens should not be discarded. The thoughtful physician and progressive man will use all the methods at his command. It is in the majority of cases a matter of personal preference. The man who studies skiascopy carefully and uses it extensively can do better work than one who devotes little time to it. The same might be said of the other methods of refraction. When we consider that the majority of cases of refraction are simple; that is, the axis of astigmatism are regular either 180 degrees or 90 degrees, and that the patients are people of average intelligence and perception, by the use of the trial case we can fit glasses more rapidly and accurately. We have all the benefit of the patient's intelligence as to clearness of outline and ease of glasses. By a careful study of subjective symptoms one can tell almost by intuition what the refractive error is, and in the vast majority of cases can make a rapid fit. In suitable cases, however, skiascopy and all the other methods are excellent, and should be used, but the old trial frame still has a place and an important one.

DR. H. V. WÜRDEMANN—Our branch of therapeutics is the most scientific of all the branches of medicine and this refractive work is or should be the most accurate, as it is based upon physical and mathematical data. The physician who bases his glass fitting upon such ground necessarily does better work than those who depend entirely upon unskilled testimony of the patient. In the opening sentence of the report of your Committee, the fact was stated that the objective tests were a necessary preliminary to the subjective method, and the latter is not to be done away with, but is the court of last resort. We may even go further with the subjective method, and say that the final judgment of the patient himself after he has had our prescription filled, is a highly important point. Thus we can not do without the trial case. The advantages of the objective method have been set forth in your committee's report and I need not repeat them here.

One of the most important offices of the objective method is the clearing up of doubtful points excited by the subjective examination. Thus at the trial case a patient may accept equally well one or any of the following combinations:

Plus .50 sph. \ominus plus 1.25 cyl.

Plus .75 sph. \ominus plus 1.00 cyl.

Plus 1.00 sph. \ominus .75 cyl.

Without repeated sittings, by the trial set alone it would be difficult for the operator to decide which would most nearly neutralize the patient's error of refraction. Skiascopy settles the question immediately to the skilled operator. There has been some question raised as to the fixation

of the patient's eyes. The examination should be conducted as nearly as possible in the visual line of the patient. Fixing the aperture of the mirror would do this, yet reflection of the same on the anterior surface of the cornea would confuse the operator, and when used without a mydriatic, the bright light falling most directly upon the fovea would tend to produce iritic and ciliary contraction. For general purposes it is better to have the patient look over the operator's shoulder at some distant object. I accomplish this purpose by having curtains at the door of my dark room, through which, when slightly opened the patient looks at a wall four meters distant. This method secures relaxation of the subject's accommodation.

In regard to the order in which the tests should be taken up, I consider it advisable to go from the coarser to the finer tests, as the former give valuable hints as to the finer measurements to be expected from the latter; taking up the examination in the following order:

Visual acuteness and astigmatic lines, keratometry, direct ophthalmoscopy, skiascopy, the subjective methods and then skiascopy again for corroboration of the whole test. Naturally, as in any other skilled work, much depends upon the observer, but even to those who either by reason of physical disability or mental hebetude have not been able to acquire sufficient skill for the finest work, these objective tests prove of material benefit.

DR. LEWIS H. TAYLOR, Wilkes-Barre, Pa.—In regard to the use of the ophthalmometer, I can say that I have recently come to regard it as a most useful aid to the rapid determination of astigmatism. A few years ago in a discussion of this subject we heard the ophthalmometer referred to as an instrument that might be regarded as an interesting toy, and which would soon be relegated to the lumber room as something too useless to occupy the busy oculist's valuable time. Now, Mr. Chairman, I do not so regard it, but I find it daily of more and more value. We mistake greatly if we regard it as an accurate determiner, if I may use the word, of the exact refraction; it is only an aid, but a most valuable aid. I formerly regarded the subjective test with atropia, as the only method worthy of serious consideration, but now I am free to say that I use atropia far less than formerly. Ophthalmometry will not entirely take the place of subjective tests, nor will any other method, but I have frequently had patients return who had been wearing glasses with reasonable comfort for whom I could get a much more satisfactory correction than by the old method. The difficulty too often lies in the fact that some one devotes exclusive attention to one method, and claims too much for it, another tries it superficially and does not get such good results; he denounces the method and discards it. Both are in error; the middle ground here as elsewhere is the safest.

DR. A. J. ERWIN, Mansfield, Ohio—I do not believe it important what instrument, or which of the methods in use be employed in working refraction, so that we are only expert in our method, and expertness is necessary in any method in order to have good work. In regard to the varying of the degree of astigmatism, in any case it is doubtless due to the power of the accommodation at the time of the examination.

DR. JACKSON, in closing the discussion, said:—Dr. Randall, in using skiascopy to obtain his extremely accurate results at greater distance than I have advised, worked with the undilated pupil, thus excluding the extra-visual zone. Yet even then he did not find it necessary to make the theoretical allowance for distance. Now it is a fact that in the majority of cases the refraction of the extra-visual zone shows higher hyperopia or lower myopia than the visual zone, so that for this extra-visual zone such an allowance is out of place. Evidently under these conditions, the results

have been appreciably affected by the refraction of this extra-visual zone.

In regard to the illumination of the ophthalmometer, it should be remembered that we are studying the reflection from a transparent membrane, and that its distinctness will depend both on the illumination of the reflected object and on the absence of light transmitted from behind the cornea, and for this reason it is almost as important to keep the eye shaded so as to illuminate the disc and mires.

In reply to the question as to the percentage of cases in which the ophthalmometer can be relied on for the prescription of lenses, I have recently, in 500 eyes, found that the corneal corresponded exactly with the total astigmatism in only 6 per cent. In about 20 per cent. the amount was almost exactly the same; in 60 per cent. the difference was not over 0.5 D.; in 52 per cent. the direction of the meridian corresponded exactly, and in 80 per cent. within fifteen degrees.

As to variations in astigmatism from time to time, it must be recognized that these do occur. They might be expected in progressive myopia, but they occur with hyperopic astigmatism as well. My attention was first called to this in my own case where the astigmatism has increased from 0.50 D. to 1.75 D., and some years ago I published seventeen cases that I had been able to follow from year to year, with determination under mydriatics.

THE MENOPAUSE.

BYRON ROBINSON.

CHICAGO.

Menstruation belongs distinctly to the tubes and uterus. It is a regular rhythmic action. It is controlled by the automatic menstrual ganglia situated in the walls of the tubes and uterus. These rhythmic little brains manifest themselves to the observer by circulatory change and increased motion. Menstruation might be named tubal motion. By direct observation in man and animals, I have noted the following midway between the monthly, or at times far remote from œstrus or rutting. The tubes and uterus are of quite a pale pink color. In short they are not congested, and still. But at the menstrual period or the season of œstrus the tubes and uterus are congested and in active peristaltic motion. The tubes are of a dark blue color from their dilated vessels being full of blood. The congestion of the uterus is intense but not so manifest as the tubes. The tubes are swollen, thickened and edematous. They are soft and pliable.

At this time a slight irritation while removing them soon excites them into active peristaltic motion. After removing such tubes and placing them in warm (salt) water they will keep up vermicular movements for half an hour by gently irritating them. I make these observations in women because I operate at any time in laparotomy, after careful preparation, whether it be in the midst of a menstrual period or remote from it. As regards animals I have examined several hundred genitals of recently butchered sows and the tubal congestion at the œstrus is more apparent in them than women. The sow's uterus is also probably more congested than woman's. Observation and experiments indicate that menstruation is a regular, periodical rhythm of a blood wave in the tubes and uterus induced by the automatic menstrual ganglia. The continually moving wave rises to a maximum and sinks to a minimum. The menstrual wave con-

tinues from puberty to menopause. It is a nervous phenomenon.

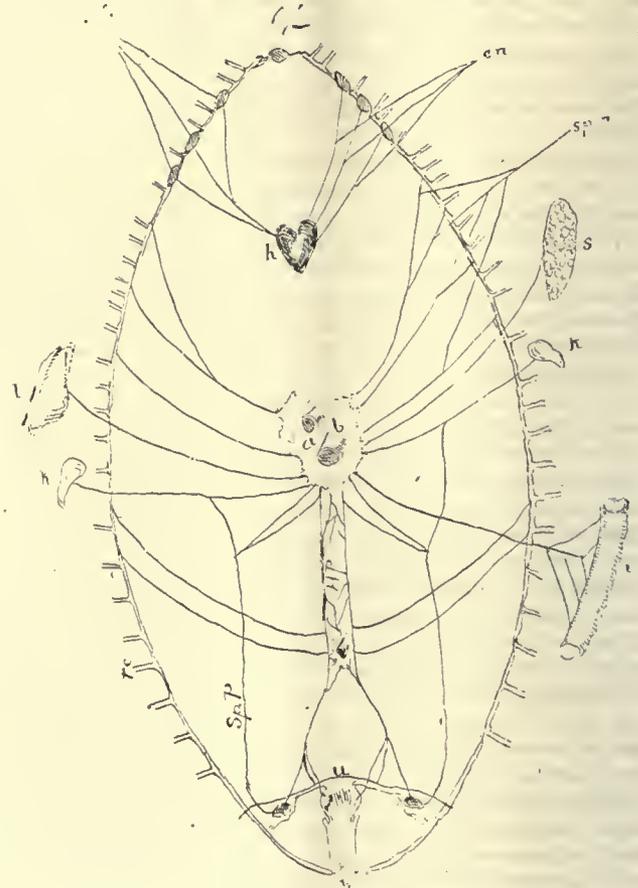

Ovulation is a progressive non-periodical process. It begins before birth and continues until the ovarian tissue is atrophied or worn out. It is liable to occur at menstruation or œstrus because of the vast blood supply at that time which hastens the follicle to ripen and burst. In the lower animals, so far as I can decide, menstruation and ovulation seem to be coincident, *i.e.*, they occur at the same time. I examined the cow, dog and sheep but my observation is especially based on the ovular and menstrual process as seen in the sow. By the examination of some two hundred and fifty specimens of sow's genitals in all conditions it seems to me that the œstrus of this animal embraced both menstruation and ovulation in one physiologic process at the same time. But as the scale of animal life ascends, the process of menstruation and ovulation seems to become more and more divorced. To my mind the best animal to begin with is the cow. In the cow one can see more and more distinct processes with the ovaries and tubes. Their separate workings become more apparent. In the calf, before and after birth, ovulation is very manifest. But the tubes and uterus before birth and for a considerable time after, are manifestly quiet and pale and rudimentary, non-functional. In woman it is my observation that menstruation and ovulation are found distinctly separate from each other. It is true that ovulation and menstruation may occur together, may be coincident but that is an accident. The processes are physiologically separate. In woman one can see ovulation before birth, and I have seen ovulation in a woman of 70, the specimens of which were presented to me by Dr. Burgess, of Milwaukee. Now, of these two great physiologic functions, ovulation is a life-long process. It begins before birth and ends with ovarian atrophy. But menstruation is a periodical process beginning with puberty and ending with menopause.

The menopause ends slowly, as puberty begins. It is frequently difficult to decide which produces the most profound impression on the general system. The popular belief is that the period of menopause is a time of danger to the woman. It is claimed that she is more liable to malignant growths of the genital organs or the breasts, and the average woman expects evils to arise in her, either bodily or mentally. Popular belief that woman is more liable to disease at the menopause is probably correct.

The symptoms of the menopause are: *a*, cessation of the monthly flow; *b*, flashes of heat; *c*, flushes of circulation; *d*, irregular perspiration. The cessation of the flow is a very irregular and indefinite matter, but generally occurs at about 45 years of age. It requires an average of eighteen months for a girl to become regular in menstruation; besides the genitals were being prepared for several years. It requires two and a half years for the monthly flow to cease, on an average. The flow ceases very irregularly even in normally physiologic cases. The flow may be scant one month, not appear at all the next and the third or fourth a flooding may occur. Should the flow cease without pathologic manifestations? I would answer, "No." Many no doubt will oppose this view and say that it is a purely physiologic process and if the woman is normally healthy she should have no manifest disturbance. So is labor a physio-

logic process, but it is frequently accompanied by pain and other disturbances. The cessation of menstruation means the death of a great function, the atrophy of a dominating organ which has the greatest nerve supply of all the viscera.

The nervous apparatus of the visceral organs may well be compared to the equalizers on the horse-power of a threshing machine. When the ten horses all pull evenly the gearing works uniformly, but the neglect of one team puts the gearing awry, and though the machine may run, its working is not of such fine

EXPLANATION OF FIGURE. A SCHEMATIC DRAWING OF THE SYMPATHETIC NERVE.

- X. Ganglion of Ribes.
 - Y. Coccygeal ganglion (Impar.)
 - L. Liver.
 - K. Kidney.
 - S. Spleen.
 - Sp.P. (Spermatic) ovarian plexus.
 - I. Intestine.
 - A.B. Abdominal brain (center of reorganizatiou).
 - Sp.N. Splanchnic nerves.
 - C.N. Cardiac nerves.
 - H.P. Hypogastric (aortic) plexus (coming from three sources).
 - U. Uterus, tubes and ovaries.
 - H. Heart.
 - C.G. The three cervical ganglia (secondary center of reorganization).
- The sides of the ellipse represent the lateral chain of the sympathetic. One nerve strand goes from the abdominal brain (a.b.) to each viscus to represent its plexus. Observe that the spermatic (sp.p.) arises from the abdominal brain, renal plexus and aortic plexus. Any irritation starting in any viscus will pass to the abdominal brain, where reorganization occurs, and the forces are redistributed over the plexuses to every viscus.

balance. The destruction of one function in a well balanced nervous system is sure to destroy the well established balance in the others. So that in my opinion pathologic disturbances may be looked for in the menopause. In order to make my views clear and reasonable, let us construct a diagram of the sympathetic system. Fig. 1, page 346, represents the sympathetic nerves. It is drawn in the form of an

elongated ellipse. At the upper end of the ellipse begins on the cerebral communicating artery at the so-called ganglion of Ribes. The lower end the ellipse ends at the coccyx or ganglion Impar. R. C. shows the connection of this ellipse to the cerebro-spinal axis. The interior of this ellipse is what gives us special interest, for here lies the vast and complicated network of this nervous ring. A. B. indicates the abdominal brain, solar plexus or semilunar ganglia—the center or reorganizing locality of the sympathetic system. From the abdominal brain, renal ganglia and the lateral sympathetic chain, passes off a large plexus of nerves, down to the aorta to the uterus, tubes and ovaries. This is known as the hypogastric plexus. (H. P.)

The observation which I note in the dissection of quite a number of old women, is that after the menopause the genitals not only atrophy, but the hypogastric plexus also shrinks away. It becomes smaller, finer, and no doubt some strands disappear on the entrance of the menopause. On this fact must be based the pathologic symptoms accompanying the cessation of the menstrual function. In dissecting infants which have lain in alcohol for some six weeks, the very opposite condition of the hypogastric plexus may be observed, for in the young child the hypogastric (sympathetic) plexus is disproportionately large and can be very plainly dissected out. The explanations of the disturbances of the menopause may be shown as follows: For thirty years, monthly rhythmic impulses have passed over the hypogastric plexus to the uterus and tube. A fixed habit has been established and the genital organs lie in the assimilating and motor grasp of the hypogastric plexus. The importance of the genital organs is shown by the vast nerve supply sent to them and also because the hypogastric originates in great central sources. It arises plainly out of the abdominal brain, the renal plexus and sympathetic lateral chain. It is intimately and closely associated with the whole sympathetic ellipse. Now, when this great nerve tract, known as the hypogastric plexus, will not transmit the higher physiologic orders it will unbalance all other parts of the ellipse. If the nervous forces can not go over an old established line they will go over the next lines of least resistance. The hypogastric plexus can not carry the orders as it is atrophied and destroyed for the old work. Thirty years of monthly rhythm established in the abdominal brain is not to die without a struggle. This explanation will enable us to understand the many pathologic manifestations of every viscus at the menopause. The irritation which arose by trying to pass more nervous impulses over plexuses than normal, gives origin to what is unfortunately known as "functional disease." It is just as organic as any disease, only we are not able to detect it. Acute atrophy is a pathologic condition and no doubt this is the condition of the hypogastric plexus at menopause.

After the cessation of the flow the most prominent symptom is what is called flushes. Over 80 per cent. of women will experience this peculiar phenomenon at the menopause. I shall include two distinct ideas in this subject. I shall define flushes as a disturbance of the vasomotor centers, and flashes as a disturbance of the heat center. Heat and circulative disturbances are so intimate and go together so frequently that I shall not attempt to separately describe them. Suffice it to say that the heart and vasomotor centers

are unbalanced by irritation at the menopause. They may come on rapidly and irregularly for a short period and then remain away for days. The patient would indicate that the disturbances were first manifest to them near the stomach and then rapidly spread over the head and chest. It would seem from carefully watching these women in menopause and listening to their description, that wave after wave succeeds each other. I have watched them under attacks and they seem to be under a desperate struggle to control themselves. The blood vessels of the head and neck seem to be the most affected, yet the skin of the whole body shares in the disturbance. The nerve impulse, *e.g.*, which should be emitted along the hypogastric plexus is abnormally forced over other plexuses and the vasomotor center becomes irritated, resulting in dilatation and contraction of the peripheral vessels. All molecular action generates heat, and it may be that much of the heat experienced is due to the rapid dilatation of the vast number of vessels and the rapid flow of fresh blood in them. As the cheeks glow the woman says she feels hot and the more the skin glows, red with flushing blood the more she claims she is hot. Besides the vasomotor and the heat center being disturbed the sweat center is irritated. The flushes and flashes are followed by various degrees of sweating. The sweating is just as irregular and uncertain. The quantities of sweat vary from a fine moisture to great drops.

The theory of disease at the menopause must rest on the unbalancing of the nervous system by changing the old established nerve channel through which they have carried impulses for a generation. It must rest on actually diseased genitals, or atrophy of the organs on the plexuses which transmit controlling forces to them. Disease at the menopause must rest on some irritating center which is chiefly the genitals and their nerves. Like many old gynecologists we need not look for the sole cause in the ovaries but her trouble is due to reflex irritation. Eighty per cent. of such women suffer in general from nervous irritability. Fifty per cent. suffer from flushes and flashes, which means simply disturbed heat and circulatory centers. Probably 50 per cent. suffer deranged sensations, hyperesthesia and anesthesia. Perhaps 40 per cent. suffer from headache, abdominal pain and perspiration. About 25 per cent. of women at the menopause suffer from leucorrhœa, sudden flooding and sweats. This means that all the secretory apparatuses of skin, mucous membrane and centers are deranged. The first thing I search for in such women is diseased genitals, *e.g.*, endometritis is an arch fiend.

Inflammation of some kind may be found in the uterus, tubes and ovaries. Acute atrophy—a form of malnutrition—must be recorded among diseases. If no pelvic trouble be found, examine the whole abdomen and chest for any disorder. I have found that the glycerin tampon twice weekly, and the hot douche gradually increased up to ten quarts twice daily, often cures such patients at least symptomatically. Curetting may be required. Radical disturbances in the menopause mean disease, and generally it is located in the pelvis. Women are expected to suffer from neuralgias at this time, nerve irritation, but their intellect is also often disturbed, especially in the will power. General treatment is right and reasonable. Baths, attention to food and evacuations. The

patients fret and worry and do not rest or sleep well. The bromids act well, especially given at night. I make over half the dose sodium bromid, as that does not irritate the stomach and skin so much as potassium bromid. The bowels are best regulated by having the patient drink a glass of water each night at bedtime in which there is from a half to a drachm of epsom salts with the additional advice to go to stool every morning immediately after breakfast, *i.e.*, after the hot coffee has stimulated peristalsis of the bowel.

Women take on fat at the menopause. This is a form of low grade nutrition. I have examined some half a dozen of this kind of patients who were considered subjects of tumors or pregnancy. But a little experience and patience will soon teach the physician that the tumor is simply abnormally thick, fat, belly walls.

Most of the pains arise around the stomach, *i.e.*, in the abdominal brain—the solar plexus. The pains that arise in the epigastric region are innumerable, indefinable, and baffle all systematic description. We must, however, have charity sufficient to allow the patient the doubt that such numberless disturbances are real. The “something moving in the stomach” may be abnormal peristalsis, induced by some diseased focus as in the globus hystericus. Whatever opinion is held by the physician a reasonable treatment should be introduced. Such patients have so much lack of confidence in themselves, their physician and their friends that they have not will power to keep up a systematic course of treatment. Hence they go around from one physician to another.

The duty of the physician is to locate the disease and remove it, or to attempt to restore order in a disordered nervous system which becomes unbalanced by reason of some irritation arising from atrophy, senility or inflammation. A thorough anatomic and physiologic knowledge of the sympathetic nervous system is required for intelligent practice in gynecology. The pathologic condition must be found in order to show skill in removing it. It must be remembered that a stormy puberty generally means a stormy menopause. The intimate and wide connection of the nervous system and genitals is phenomenal. The nervous connections of the genitals is profound and any genital trouble deeply impresses the whole being. It would not be strange, also, if one woman's uterus were found with vastly more nervous connections than another, or at least being much more sensitive than others. My experience in the dead-house and otherwise is that viscera vary much in size. In some a uterus is small, in others large without regard to the individual statural size.

Menstruation must be looked upon as arising and subsiding in the nervous system, especially in the sympathetic system. I would like to make a plea for more study of the nervous system, and particularly the visceral nervous system. From the lack of this knowledge physicians are mistaking nervous diseases for uterine diseases. A great evil is going on to-day in regard to misunderstanding, that a little nervousness does not always belong to the ovaries or uterus. The nervous system is a vast, finely ordered, nicely balanced machine which can be easily disordered without the least need of removing ovary, tube or uterus. Some general or local treatment may be amply sufficient. Too many laparotomies are being done to-day by unskilled men without proper facil-

ities. Sweeping removal of organs is a backward step in surgery, and the general disapprobation of the leading gynecologic surgeons must cry it down. It must be insisted on that he who would work on the peritoneal cavity must be trained. Training and skill, coupled with a decent sense of right, will alone stand the test of time in any branch of surgery. The colleges must begin with chairs of visceral anatomy and abdominal experiments for small classes.

A pathologic state is one manifesting abnormal conditions, whether it be recognizable changes in structure, or simple deranged functions without perceptible disordered structure. There are reflex neuroses, by which I mean disturbances in distant parts produced by irritation of some sensory or motor-peripheral area. It is easy to note that a woman is irritable and nervous, without in the least being able to locate the pathology from which the disturbance originated. One of the most marked features of a woman in the menopause is the kind of nervous irritability. It may be easily observed, if one will note quite a number of women in the menopause, that they do not suffer from tumors and malignant diseases so much as they do from disturbance in the sympathetic system and cerebral-spinal axis. Nervous irritability characterizes four women out of five during the menopause. How does this come about? Two ideas explain the complicated but slow course of the disease, *viz*: Reflex irritation and malnutrition. Any one can easily see that the nervous system is out of balance in the menopause. The beginning and end of menstruation is in the sympathetic nerves. Puberty is heralded by ganglionic rhythm, and the menopause comes in at the cessation of the rhythm. The entrance and disappearance of menstruation is a nervous phenomenon. The genitals then become a point of new irritation as puberty begins, and the genitals are again the focus of irritation as the rhythm departs forever. Menstrual starting chafes the system profoundly, but its cessation irritates the system notably with its dying struggles. By the figure it is plain that any genital irritation can be easily carried to the abdominal brain where re-organization occurs. This newly organized force will go to every viscus in the sympathetic ellipse and damage the rhythm. Now the visceral rhythm is for the purpose of nutrition, and pursues its even tenor in a kind of orderly manner. But irritation from a focus never comes or goes by rule. It goes at all times and any time, while the viscera are performing their nutritive rhythm. The irritation from the diseased focus forces itself up the hypogastric plexus to the organizing center and is emitted to all viscera, in addition to the normal nutrition and rhythm and disorders natural to visceral rhythm.

A few weeks or months of irritation gradually produces deranged visceral rhythm and consequent indigestion. The addition of indigestion to a diseased visceral focus makes a double burden on the whole system. The nerves become more irritable. The focus of irritation (the genitals) and indigestion persist and soon bring on distinct malnutrition—another burden to the ganglionic system of nerves. All this continues until anemia arises—waste-laden blood. Now it is apparent to all when waste-laden blood bathes all the thousands of ganglia and nerve strands in the body that the patient may be nervous or irritable. She is neurotic. The sympathetic

ellipse is unbalanced and its centers are disordered. It is a slow process for the woman to pass from a single focus of visceral disease to a neurotic condition. The whole disturbance become intelligent by comprehension of the nervous system and a knowledge of the condition of the diseased genitals. The intelligent practitioner always examines the genitals in a diseased menopause. A stormy menopause means diseased genitals. It means a focus of pathology which is nearly always situated in the pelvis. The effects on individual viscera may be described by noting how the irritation can pass up the hypogastric plexus to the abdominal brain and being reorganized be emitted to the digestive tract. The irritation goes on day and night; when it reaches the digestive canal by way of the gastric, superior and inferior mesenteric plexuses it first affects Auerbach's ganglionic plexus of nerves which lie between the muscular layers of the gut wall. This simply disturbs peristalsis and induces perhaps some colic. But as the irritation passes on to Meissner's plexus it disorders secretion. Meissner's ganglia control secretion, and irritation of this plexus may induce excessive secretion (diarrhea), deficient secretion (constipation), or disproportionate secretion (fermentation). Thus the great assimilating laboratory of life is deranged. Digestive disorders are common in the menopause. Liver disturbances are not uncommon. The irritation passes through the abdominal brain to the liver, inducing excessive, deficient or disproportionate bile, glycogen and urea. The rhythm of the liver is deranged. Its rhythmical activity and quiet repose is continually disturbed by reflex irritation. It is easy to observe disease of the liver from the condition of the patient in menopause,—skin and bowel abnormalities. The route from the genitals to the heart is plain from the diagram. The irritation from the diseased genitals passes to the abdominal brain, thence up the splanchnics to the three cervical ganglia, whence the re-organized irritation passes to the heart over the three cardiac nerves. The result is that the heart goes rapidly or irregularly—it palpitates.

After nervous irritability the woman in menopause probably suffers most frequently from flushes and flashes, *i. e.*, irritation of the vasomotor and heat centers. Her skin glows with fresh red blood or burns prickling heat. This seems to me to be merely an unbalanced condition of the nervous system due to a disordered focus. The transmission of nervous energy goes pellmell, or in a tumultuous manner, over roads which are not accustomed to so much commerce and the centers are not able to orderly reorganize it. The circulation floods or depletes the vasomotor centers.

One may observe that some women enter puberty with many indescribable pains, and they continue to complain of peculiar abdominal pains during the reproductive period, and at menopause they simply become chronic grumblers and complain more and more bitterly. What must be said of such women? We must not consider them as fabricating untruths for a whole generation; we must attempt to study the ganglionic system of the sympathetic in order to unravel all the trouble. We may say that women with these abdominal pains are in a poor state of nourishment. Debility characterizes the ganglionic disease, while irritability is the feature of cere-

bro-spinal axis troubles. Women with ganglionic disease are weak ill-nourished creatures, often unable to do a little housework. Can we not consider that such patients have hyperesthesia or anesthesia of the visceral ganglia? These ganglia are little brains, for they have all the elements of the cranial cerebrum,—nerve cells and process. In short every nerve cell is a unit in itself. It is an isolated anatomic unit, a neuron, a brain, a re-organizing center. The essential of the cell is the nucleus because it has the power of nutrition, hence reproduction. Hence each ganglia is a little brain, a re-organizing center. Now, a brain or ganglion cell receives sensation, sends out motion and controls nutrition. It reproduces itself, it controls secretion and lives in balanced relations with its environments. Can we not think that such patients have an over-sensitive or irritable abdominal brain? Their visceral nerve apparatus is abnormal, it is out of order. But this center holds in abeyance nerve energy and nerve force. It holds all the assimilating and circulatory laboratory in living tension. Such patients have not a perfect machine to work with. Such are generally congenital or made so by the acquisition of some profound function as menstruation. The female visceral nerves seem to be peculiarly liable to rapid derangement. Women faint frequently and slight occurrences disorder their viscera. The flying of a bird will make the heart palpitate. A sudden noise deranges respiration or circulation. A change of locality either puts in order or puts out of order the nervous system. The female nervous system is much more unstable than man's. And no doubt that this is the reason that so many physicians mistake nervous diseases for uterine diseases. Such physicians are either ignorant of the delicate nerve mechanism or are over-zealous operators.

The pathologic condition of the genital organs in the natural menopause is general atrophy. Absorption of fat and consequent shrinkage, lessened vascular supply and consequent smaller organs. It is a pure senile atrophy. The organs assumed action, served their purpose and subsided forever. Even in a natural menopause the distinct dying struggle may be expected in the hypogastric plexus. Puberty increases the volume of the organs while menopause lessens it. Puberty is the real birth while menopause is the real death, of the female genitals. The appearance of the individual organs at the menopause are peculiar. The vulva wrinkles and shrivels through the absorption of fat and other tissue. In dissecting senile genitals the pudendal sac of Bichat and Savage become more apparent than ever. One can push the index finger into it and the great labia will appear and feel very thin while the sac seems disproportionately large. The fat rounded form of youth obscures this peculiar pudendal sac even in dissecting. In old women the vulva flattens out and exposes the clitoris and small labia. The clitoris becomes smaller and blends with the surrounding parts so much that it is occasionally difficult to find its location. The vagina becomes smoother in its folds. It contracts in every direction and frequently it may seem to thicken but that is probably a delusion of blending with other tissue. The cervix gets smaller and may appear entirely absent, from the excessive shrinking and contracting of the vagina. The uterus becomes smaller and harder. It has a peculiar tough, elastic feeling from the atrophy of muscular

tissue. It assumes to some extent the form it had before puberty, except that the neck is more prominent before puberty. It straightens out. Its nerves and vessels shrink. The tubes are notably thinner and shorter. The circular muscular layers seem to suffer the most.

The ovaries shrink very much and resemble a peach-stone on the surface. In quite a number of old female cadavers I have found them the size of beans and in some it required considerable searching to find and recognize them. Then we found in the contracted and shrunken broad ligament the sheaths and nerves themselves atrophied.

In examining women with a stormy menopause it is not infrequent to observe subinvolution. While a pupil of Mr. Lawson Tait, several years ago, I gained some knowledge in regard to a disease of the vulva which may not infrequently be seen in women from 40 to 50, or about the menopause. It is a trouble that one would easily pronounce on a glance, eczema of the vulva. Mr. Tait remarked that it was due to a kind of climacteric diabetes; that it is a kind of eczema of the menopause. Dr. Martin, Mr. Tait's assistant, was very kind in displaying to me these unfortunate cases. The labia were swollen and edematous and the red flaming eczema extended far and wide beyond the vulva. The disease made the patient's life almost intolerable. Mr. Tait's treatment for such cases was a solution of hypophosphites of soda (an ounce to a pint of water). The solution should be applied every two to five hours as required, to destroy the germ which induced the itching. He then gave heavy doses of opium. Mr. Tait claims that there is a kind of diabetes mellitis during the menopause. Mr. Tait thinks it is a limited diabetes as they all finally recovered. The distress of the patient with this climacteric diabetes is due to the sugar urine on the vulva. Peculiar crusts form on the vulva, due to the multiplication of the vegetable germ known as *torula cerevisiæ*. The eczema due to this cause will spread over the buttocks, up over the abdomen and even down the thighs. In one case I saw the eczema extend so wide that the patient could walk only with difficulty. The hyposulphite of sodium arrests the formation of this germ. Mr. Tait would sometimes give as high as 1 grain of opium three times daily and then 2 grains at night. After a few months of such treatment the opium was lessened, and in from five to ten months such patients fairly recovered. They are liable to short relapses. Mr. Lecorche, of Paris, has also made researches independently of Mr. Tait and curiously enough they agree in many ways. Mr. Tait carried his views into more definite plans of treatment. This climacteric form of diabetes is then a disease which begins at the menstrual cessation and lasts a few years. Menstruation seems to give immunity to it. Nature appears to finally overcome it. If the hyposulphite of sodium is inefficient to arrest the trouble, on account of the fluid quickly running off the parts, an ointment of sulphur will remain on the vulva for hours. Any substance which will arrest the fermenting changes in sugar is an effective remedy. I have noted no special form of climacteric vaginitis, but one form is liable to arise which is due to laying bare of some peripheral nerves in the vaginal wall. The spots are red and most exquisitely tender; they occur mainly at the vulvar orifice and are very persistent. The treatment consists in applying cocain

and then sufficient caustic or Paquelin to entirely destroy the exposed nerves. These neuromatic patches are apt to arise in women at other times also. In severe cases it is best to anesthetize the patient and destroy the exposed nerves widely by the Paquelin.

The especial diseases of the uterus in menopause which I have observed are endometritis and subinvolution. Chronic endometritis with an excoriating discharge I have not infrequently noted. The uterus is generally slightly large. The mouth is red, bleeds easily and out of it runs muco-purulent substance of varied color. The hot douche (10 quarts) twice daily and the additional use of glycerin tampons cures most cases. Occasionally a curetting is required, followed by the thorough application of 95 per cent. of carbolic acid on gauze wound on a sound. I apply the 95 per cent. carbolic acid to the endometrium three times, so that it will destroy the old inflamed endometrium and drain with a little rubber tube or pack in gauze and remove it in twenty-four to thirty-six hours. Fortunately the senile endometritis is generally cured with one curetting unlike the stubborn endometritis of youth. Mild forms of endometritis in the menopause I have frequently noted. The subinvolution or suspended involution is a much graver matter to health. It has had a more evil and wide effect on health and especially the nervous system. It consists essentially of a metritis, and so far as I can observe rests on an old endometritis. Whether Klob or Rokitansky is correct, I will not at present attempt to decide. Whether the hypertrophic uterus is due to excess of connective tissue or muscle, or whether it is due to a natural proportionate increase of both is still undecided. It may be often observed that such women have a lax pelvic floor in addition. So far as my limited experience goes, the tampon and douche are insufficient or are too slow for satisfactory effects. Thorough curetting is the best means at command, with the application of 95 per cent. of carbolic acid to the whole endometrium. The cure is slow at best but finally quite satisfactory. The pathology of the climacteric or senile endometritis must not be lost sight of. At first the leucorrhœa is more abundant. It may be mucous, muco-purulent and finally pus. The explanation of the changes of the fluid secreted from the endometrium rests on the endometritic glands. At first the glands are able to be increased in their function; with time they atrophy, but the inflammation proceeds and finally only sero-purulent substance or chiefly pus from the glandular destruction and only now and then a glandular endometrium itself. The remnants only of the endometrium remain and these are involved in a state of low vitality. Low and wild forms of granulation are visible at the neck and can be scraped out of the uterus. Slow necrosis, local death, gradually proceeds until raw ulcerative surfaces are exposed and only pus will be secreted. The glands have disappeared. We must observe that cervical laceration frequently exists with this trouble. The reason such conditions do not heal well is because the blood supply and nerve supply to the uterus is now being cut off, curtailed, and it is imperfect so that nutrition is very deficient in the uterus. For thirty years the uterus has had high feeding from fresh blood and the fine control of a complicated nerve apparatus, but suddenly the high feeding is curtailed and the delicately balanced

nerve apparatus is impaired by the atrophy of the menopause. Hence low granulations, imperfect reproduction of cells, ulcerative surfaces may be expected. It must be remembered that there are other troubles than cancer in the uterus at the menopause. The essential feature of climacteric uterine trouble is imperfect nutrition. This will not astonish one so much after he has carefully examined and dissected or post-mortemed a dozen female cadavers above 50 years of age. In them he will note atrophy, shrinkage, contraction and pale white tissue.

The differential diagnosis between cancer and uterine trouble (endometritis) may be looked for in the case of cancer by infiltration, thickening and peculiar watery, sanaceous discharges. As regards ovarian tumors at the menopause they grow more rapidly. The vital power of the patient is at a lower ebb, and besides the nutrition of the ovary is degraded by curtailing its blood supply and atrophying its nerve supply.

It would appear that the branches of the hypogastric plexus which are sent to the bladder and rectum are not atrophied to the same degree as the branches sent to the genitals (uterus, tubes and ovaries). Yet in my post-mortems and dissections it appears to me that the vesical and rectal branches do atrophy sufficiently to be plain to the observer. The present idea of medicine is that there is an anatomic structure disordered somewhere to account for disease. A portion of a man only is diseased and pathologic anatomy could always indicate the origin had we sufficient acumen.

Now in the menopause the cerebro-spinal axis is disturbed through the means of the vasomotor nerves, and the circulation by some form of reflex neurosis. A woman's mind is often disturbed. She has lost her old will-power, her memory is impaired. She can not concentrate effort. She is liable to do damage from inability to control her own action. The law recognizes any deviation from rectitude during the menopause with leniency. The treatment of women during the menopause must be local, general and moral. The cog in the wheel which disturbs even physical existence must be remedied. General debility and irritability must be allayed by anodynes with both tonics and good nourishment. While the unhinged moral views must be removed by changing the life from the old ruts which caused it.

CONCLUSIONS.

1. The average menopause lasts two and one half years.
2. It comes on slowly as puberty does.
3. A stormy puberty means a stormy menopause generally.
4. The general rule is that an early puberty means a late menopause. In my opinion it simply means that early puberty and late menopause rest on a largely developed abdominal brain and hypogastric plexus. A vast nerve supply means also a large blood supply. Precocious puberty means well developed genitals and ganglionic nerves.
5. The disturbance at the beginning of puberty is profound, but since it is an active (depletive) physiologic process it quickly fits the growing and adaptive nervous system. But the menopause is a destructive process. It breaks up the harmony of the previous processes and unbalances the even distribution of nervous energy and circulation.

6. It is probable that every viscus receives an equal or greater shock at menopause than at puberty.

7. The changes at menopause consist in menstrual cessation, atrophy of the genitals and the hypogastric plexus.

8. Women do not suffer at the menopause so much from malignant diseases as they do from nervous troubles, neuralgias, mental deviations, disturbed visceral rhythm, disordered circulation, indigestion and above all neurosis.

9. The heat center (flashes), the vasomotor center (flushes) and the sweat center (perspiration) are the especial centers disturbed. Excessive, deficient or disproportionate blood supply characterizes the disturbed phenomena of these centers.

10. The etiology and pathology of the menopause lies in the sympathetic or ganglionic nervous system.

11. The systematic pathologic stages in menopause are: *a*, a focus of disease, or irritation (the genitals); *b*, indigestion; *c*, malnutrition; *d*, anemia; *e*, neurosis. It is a slow progressive process.

12. Atrophy is a disease just as much as hyper-trophy or inflammation.

13. Chief among the actual diseases in the menopause is endometritis. The peculiar floodings doubtless depend on this inflammation.

14. The menopause is characterized by various discharges (mucous membrane), leucorrhœa, bronchitis, hemorrhages from the bowels, epistaxis (skin) perspiration.

15. Circulatory, perspiratory and caloric changes are the common heritages of the menopause.

16. A characteristic phenomenon of the menopause is an unbalanced, unstable nervous system, cerebro-spinal (irritable); sympathetic (debility).

17. Debility characterizes the trouble in the ganglionic system, while irritability characterizes the cerebro-spinal axis.

18. The explanation of the various phenomena is only possible through the nervous and circulatory systems.

19. Excessive sexual desire at the menopause is indicative of disease.

20. In the menopause the nutrition is impaired as is shown by the occurrence of malignant disease in the sexual organs which are in a state of retrogression.

21. A chief feature characteristic of uterine disease is malnutrition from atrophy, curtailing blood supply suddenly, from the sudden degeneration of the genital nerve apparatus and consequent impaired control of tissue by a defective nourishment. Ulcerative surfaces, local death and purulent secretions arise from low granular cell formations.

22. In the menopause a disturbed point has arisen in the harmony of visceral rhythm. This pathologic focus must be looked on as the cause of the innumerable reflex neuroses at this time of life.

23. A reflex neurosis is a disturbance in distant organs caused by the irritation of a peripheral sensory or motor area.

Louisiana State Board of Medical Examiners.—Gov. Foster, of Louisiana, has announced the following appointments: Members of the Board of Medical Examiners on the part of the Louisiana State Medical Society: Drs. T. S. Kennedy, H. S. Cocram, T. Y. Aby, F. J. Kearney and A. F. Barrow; on the part of the Hahnemann State Medical Society: Drs. E. A. Murphy, O. J. Lopez, C. R. Mayer, Robert A. Bagley and J. W. Belden; Board of Control of Lepers Home: E. M. Hopper, Isidore Dyer, H. J. Schenck, Allen Jumel, A. A. Wood and C. J. Edwards.

BASSINI AND HALSTED OPERATIONS FOR INGUINAL HERNIA.

LIGATION OF FEMORAL FOR TRAUMATIC ANEURISM—
MASTOID DISEASE—PELVIC ABSCESS ESCAPING
THROUGH GREAT SACRO SCIATIC NOTCH
—HEMOPHILITIC KNEE JOINT.

(Surgical notes Presbyterian Hospital, June 10, 1894.)

BY ARTHUR DEAN BEVAN, M.D.

SURGEON PRESBYTERIAN HOSPITAL; PROFESSOR ANATOMY, RUSH COLLEGE.
CHICAGO, ILL.

Case 1.—The first case which I present to you is one of double inguinal hernia. This patient is 30 years of age, is a laborer; general health and history good. Has had this double rupture for twelve years. Examination demonstrates that they are oblique inguinal herniæ; from long existence the internal ring has been dragged down until it is opposite the external ring, thus simulating direct hernia. The term, straight hernia, is used to designate this condition. This man has continuously worn a truss, but even with the truss the condition has been a source of constant annoyance to him. My personal experience with the operation for radical cure of hernia, something more than thirty cases, has been so gratifying both with regard to permanence of cure and freedom from mortality that I feel warranted in advising this man to submit to operation.

On the right side I shall do a Bassini operation and on the left a Halsted, so that you may have an opportunity of comparing these two methods.

The Bassini.—I now make an incision through the integument and superficial fascia over the inguinal canal, about three inches in length, extending above the internal ring and down into the scrotum. This exposes the intercolumnar fascial covering of the hernia; this is the most superficial of the three coverings common to the cord and the hernial sac, the other two being the cremasteric fascia and the transversalis fascia. These three coverings must be divided before we can expose the peritoneal sac and separate it from the tissues of the cord. Many surgeons will tell you that it is difficult or impossible to distinguish these layers. I tell you that in almost all cases these coverings can be more readily demonstrated in an operation for radical cure of hernia than they can be on a cadaver in the dissecting room, and further that it is very desirable to be able to do this. It is only occasionally that we run across an old complicated hernia in which this is difficult or impossible. I shall give you a rule which will make it easy for you to identify these structures:

1. The intercolumnar fascia is exposed after the division of the skin and superficial fascia; it is the strongest, firmest, most fibrous covering of a hernia; this should be divided the entire length of the sac and as high up as the internal ring. The division of this layer exposes the second covering, the cremasteric fascia, which can be recognized from this fact and by the looped muscular fibers running through it. The division of this layer exposed the third, the transversalis fascia, which is recognized simply from its position. It has no distinguishing feature, beyond the fact that it is situated between the cremasteric fascia and the peritoneum.

It is at this point of the dissection that a layer of fascia sometimes presents itself which may confuse the inexperienced anatomist and operator, *i. e.*, the subperitoneal fatty layer which intervenes between the transversalis fascia and the peritoneum. This is often mistaken for the omentum. Its position, the ease with which it tears, its lack of large vessels and lack of peritoneal lustre enable the experienced operator to distinguish it from the omentum. I now expose the sac, separate it from the cord with fingers and forceps as high up as the internal ring. In this case the sac is very transparent. I can see that it contains neither omentum nor intestine and I shall not open it. I ligate the sac as high as possible and cut away the redundant portions. I now lift the spermatic cord out of its bed, separate the aponeurosis of the external oblique from the conjoined tendon with forceps and blunt dissector, free Poupart's ligament from the adjacent tissues, that is the superficial fascia and the cremasteric fascia. With silk sutures, seven in number, I close the entire inguinal canal by sewing together the transversalis fascia and conjoined tendon on the inner side to Poupart's ligament on the outer side. The spermatic cord is now laid over this closed canal and covered, by sewing over it the aponeurosis of the external oblique. The external incision is closed, without

drainage, by silkworm gut sutures placed an inch apart, acting as tension sutures, and a fine continuous catgut suture placed an eighth of an inch from the margin of the skin and one-fourth of an inch apart.

We shall now do a Halsted on the other side. The external incision is the same as before, except that it is carried nearer the anterior superior spine of the ilium. I separate the sac as before, but instead of ligating it I cut it open with scissors parallel to the external incision; this incision extends above the internal ring and divides the neck of the sac. This exposes the general peritoneal cavity. The opening in the peritoneum is closed with mattress sutures and the redundant portion of sac cut away. The next step in the operation is the ligation of the great mass of the spermatic veins as high up as possible and at a second point below the external ring. The portion between the ligatures is cut away leaving the vas deferens and a few vessels. The canal is now closed with sutures which pass through the conjoined tendon, transversalis fascia and external oblique internally, and Poupart's ligament externally. The cord is then laid over this closed canal and the external incision closed as before. An aseptic compress is applied and retained by means of a double spica. One little point in the dressing of these cases is to sling the scrotum up over the abdomen with a silk or gauze handkerchief to prevent the gravitating into the loose tissues of the scrotum, of the blood and wound secretions, an accident which I have had occur several times when this precaution has been omitted. Subsequent history: Case ran a normal aseptic course with perfect closure of canals.

The second case operated upon was shown later at a meeting of the Chicago Medical Society:

Case 2.—A young man of 20; four weeks ago cut himself with a bit of glass over the inner and upper aspect of the left thigh at a point near the apex of Scarpa's triangle and in a line with the femoral artery. Profuse hemorrhage occurred but was readily controlled by bandage. He was taken to Cook County Hospital; the case treated as an incised wound; discharged at the end of two weeks with small suppurating sinus. A few days ago noticed an enlargement at the seat of injury and was brought to the Presbyterian Hospital. The condition, that of traumatic aneurism of femoral is evident. The operation which I shall do is the old operation of Antyllus, *i. e.*, cutting into the aneurism, turning out contents of sac, ligating both proximal and distal ends of vessel.

Cutting directly into the aneurism I find the sac composed of the deep fascia, sheath of femoral vessels and intermuscular septa. Turning out the blood clot I find a wound three-fourths of an inch in length in the anterior wall of the femoral artery; the vein is to the outer side, the internal saphenous nerve between the two vessels. The artery is ligated above and below the wound in vessel and vessel divided between the ligatures. The sac is very thin and does not demand removal. Subsequent history: No interference with circulation of limb. Patient discharged at end of two weeks cured.

Case 3.—The third case which I now present is one of mastoid disease. History: Measles, inflammation of middle ear, later involvement of the mastoid. This last occurred about a year ago. He now has a sinus about two inches behind the external auditory meatus; this suppurates freely at times, at times closes and then the pus escapes from the ear. Opening up the sinus an opening into the cranial cavity is found which is in the line of suture between the mastoid portion of the temporal and the occipital bone. It is evident that in this case the pus has worked its way from the mastoid process or middle ear into the inferior fossa at base of skull between the bone and dura, or else that we have a case of suppuration of the lateral sinus to deal with, and fortunately for the patient the suppuration has found a means of exit through the temporo-occipital suture; following this sinus with a chisel it is found to lead into the mastoid antrum; this is carefully scraped out, great care being necessary because of the proximity of the lateral sinus, if indeed the suppurating tract is not the lateral sinus itself.

Subsequent history: No uncomfortable symptoms; patient about on second day; still under observation.

Case 4.—This woman was confined five weeks ago; had septic inflammation following confinement. She presents herself to us with this huge swelling over the buttock covered evidently by the gluteus maximus muscle; temperature 103.5; fluctuation is distinctly felt. Upon opening the abscess I find that I can insert my index finger easily into the great sacro-sciatic notch; this is evidently a case of pelvic suppuration escaping through the great sacro sciatic notch

It is the second case of the kind which has come under my observation. Subsequent history: Disappearance of symptoms; five weeks after operation there is still a small discharging sinus.

Case 5.—The last case which I present to you is one of great interest. This man 40 years of age has been complaining for some weeks of rheumatic pains. He comes to us with this great swelling in and around the left knee joint; this swelling extends half way up the thigh and half way down the leg; the surface is covered with patches of ecchymosis. Examining the man's body I find multiple patches of ecchymosis on his arms and other thigh. He tells me that these ecchymosed patches occur from the slightest injury; that whenever he cuts himself he bleeds very profusely; that once he had a tooth extracted with alarming hemorrhage following. He does not know that any member of his family is similarly affected. This is evidently a case of hemophilia. The joint is a hemophilic knee joint. The treatment we shall advise is rest, compression with a flannel bandage, careful avoidance in the future of injury. These cases sometimes after repeated attacks have ankylosis result. The subsequent history: Patient was seen at end of two weeks; had improved greatly. He then passed out of observation.

GRAFTING FOR THE CURE OF EPITHELIOMA.

BY P. D. KEYSER, M.D.

PHILADELPHIA.

The removal of epithelioma by the knife or caustic has so far, been seldom, if ever a permanent cure, and as this disease appears mostly on the face especially near the eyes or mouth and in persons advancing in years, it becomes a source of distress and pain as well as a blemish, and in the removal by knife or caustic often a very defective scar is left with contractions of the lids and mouth which interfere with the natural and proper use of those parts. Transplanting from neighboring parts creates a greater defect, really defacing two parts; that where the epithelioma was, and that from which the piece of skin transplanted was taken. The drawing of the edges of the wound together where the disease is cut out causes very much contraction, interfering with the opening of the eyes or mouth. Even after such an operation, return of the disease occurs in a very short time, no doubt caused in very many cases by the not complete and thorough removal of the growth in the first place.

Knowing now from the latest studies that epithelioma is entirely a local disease of bacteriologic origin its thorough removal is necessary to insure a cure; and in doing this the gap in the skin must be filled up in some way, and lately grafting has been suggested instead of transplanting, so as to leave as little defect as possible; it is also claimed that the placing of healthy integument in the wound creates a healthy condition of all the surrounding parts and removes the tendency to a return of the disease.

To test the efficacy of this procedure I have during the past winter operated upon a very interesting case which is presented in this paper.

Mr. M., age 54, of Virginia, has been suffering with a slow growing epithelioma in the inner canthus of the right eye for over twelve years. It commenced in a small spot on the lower lid just below the line of the canaliculus. It gradually grew up towards the canthus, when four years ago he underwent an operation for its removal by the electric cautery. It was reported that it had all been removed; the wound, however, never healed properly, but instead, it seemed as if the growth was increased in vitality and started to

grow rapidly, presenting the appearance of Fig. 1 as first seen by me.

Under an anesthetic I removed the disease completely with knife and scissors, and after stopping the hemorrhage, (which is always very free in such cases) by application of hot water sponges, I shaved a very thin graft from his upper arm, in size and shape so as to fit in freely and exactly the gap made by the removal of the diseased part.

Everything was done under thorough antiseptic preparation and influences. The solution of bichlorid of mercury being used 1 to 4000 on the eye and arm. The graft as soon as removed from the arm being

Fig. 1.

placed in a warm saturated solution of salt water, and then carefully transferred and fitted to the wound. The wound was covered with a piece of antiseptic oiled silk, over which were carefully laid and bound moist hot sublimate cloths and antiseptic cotton wool. As soon as the eye was bound up, applications of cloths steeped in hot water were constantly laid over the whole for an hour, and renewed after two hours. This being done to start up vitality in and around the graft. The latter applications I have always found a great adjuvant in the adherency and life of the graft in all such operations. After the

Fig. 2.

second day the oiled silk was removed and dry dressing applied for five days, after which the air was permitted to reach the graft through a thin dry gauze cloth laid over the part.

This operation has now been six months and the eye is as perfect as can be, there being no irritation or sign of the return of the growth.

Fig. 1. shows the case as first presented and Fig. 2 one month after the operation and as it is at present.

The success of this case recommends without doubt, this method of treatment of all cases of epithelioma on any part of the body if taken in time and before too large or deep and attacking vital parts.

A CASE OF ACUTE INFLAMMATION OF THE BRAIN IN A CHILD.

Read at a meeting of the Kalamazoo Academy of Medicine, May 15, 1894.

BY C. VAN ZWALUWENBURG, M.D.,

AND

I. H. NEFF, M.D.

In stating the following case, our attention is directed to the etiology and diagnosis of acute diseases of the brain; especially with reference to the effects of injuries; to the medico legal question involved; to the relation of infection to brain disease, and to the question of trephining after an injury.

The subject of the paper was a boy of Holland parentage, with an excellent family history, both as regards bodily and mental disease. He was a well developed child and the picture of health. No history of physical illness excepting a few attacks of gastro-intestinal trouble.

On March 20, 1894, he complained of headache and vomited considerably. The following day he fell, or rather slipped off the steps of a porch in a faint, as described by his parents. On this day or the day preceding, the exact date could not be determined, he was hit on the head by a stone thrown by a playmate. This produced a slight bruise on the right frontal prominence. He immediately complained of its causing him great pain. There was, however, but slight evidence of the injury and it was not thought to be serious. The headache persisted and increased in severity.

A week after the boy was injured I was called to see him. I found him sitting in a chair playing and talking with his playmates, but evidently suffering considerably; his head bent a little forward; his brows contracted; and his breathing irregular and shallow, each respiration being accompanied with a sigh. Every few minutes he would cry out, complaining of sharp pain in the head, indicating the position of the bruise as the seat of the pain. He maintained that any noise distressed him and apparently his pain was increased by this. At this time there were no symptoms of ocular trouble. After a few days he kept his eyes tightly closed, although not admitting that light caused any pain. However, when his eye-lids were forcibly opened, his actions indicated that light was distressing. Pulse 80, full and regular; temperature 99 F.; appetite capricious but no difficulty in swallowing; bowels obstinately constipated; vomiting had been repeated a few times but now, at the end of the first week, was absent. The left knee jerk could not be obtained and there was but little response on the right side; cutaneous reflexes normal. When asked to walk, he complied reluctantly. All his movements were slow, gait was very unsteady and he held out his hands as if afraid of falling. The walk was slightly ataxic, every step appeared to increase the pain in the head, his breathing was more "catchy," and all the symptoms were more exaggerated after any exertion. This was apparent when he was told to close his eyes when in an erect position. He then had extreme difficulty in maintaining his equilibrium and complained of acute pain. In the recumbent position there was marked abatement in the symptoms. The pupil of the right eye was at this time markedly dilated while the left was contracted. This peculiarity of the pupils was transient, and occurred when he was irritated or when there was any exaggeration in the symptoms. There was also slight ptosis of the right eye. Sensation was apparently perfect. The meningeal streak could easily be produced.

A diagnosis was made of meningitis and in consultation this was confirmed and was thought to be basal in situation.

The tongue now deviated distinctly to the left, there was lack of tonicity of the muscles of the left side, and movement was limited. During the next ten days, all these symptoms became increased and he continued to complain of intense pain in head, always indicating the frontal region as the seat of it. Delirium was present and became quite active. He talked incoherently on many subjects, was irritable and resistant. Ptosis of the right eye, dilatation of the right pupil, and the deviation of the tongue to the left side became very marked. The paralysis of the left side was now distinctly declared. Pulse varied but little, usually about 100, and was full, regular and about normal in character. He irritated the original bruise and there was now evidences of localized suppuration, although this was not connected in any way with the bone. Stupor was present

and he could only be aroused with difficulty. Ophthalmostic examination disclosed intense neuro-retinitis in both eyes.¹ Breathing was irregular and assumed the character of the Cheyne-Stokes respiration. There was considerable emaciation. Constipation continued but there was no vomiting. The stuporous condition rapidly deepened and coma was declared with the usual symptoms. It was now extremely difficult to get response to any external stimulation, the temperature continued about 99 and pulse was not much accelerated. Cheyne-Stokes respiration was now present in its characteristic form.

After remaining in this condition for two or three days, he began to rally and a remission developed, lasting for five days. All the serious symptoms disappeared and pulse and respiration assumed the normal character. For the next four days there was but little change in his condition. The temperature would occasionally rise to 101, but was extremely irregular. He continued to complain of intense pain in the original seat, varying in intensity, but there was noticed a gradual decline in his general condition; he became quite anemic and emaciation developed.

On the thirtieth day of his illness, he had a severe chill which was repeated on each of the four succeeding days. At this time he coughed a great deal but no disease of the lungs could be determined, although a hacking cough was present, unaccompanied with expectoration. There was now present a slight exophthalmos of the right eye—the day following the lids of both eyes were edematous and there was marked chemosis of both conjunctivæ. The protrusion of the eyeballs continued for about a week and then entirely disappeared. Although the paralysis of the left side was quite well declared, he would at times apparently recover power but never regained the normal motion either in the hand or foot.

In the fifth week of his illness, an exacerbation in the symptoms was pronounced but, owing to the comatose condition, they were not well declared. He rapidly lost strength, the original symptoms became prominent, and he died from cardiac asthenia.

Autopsy, twenty-six hours after death. Body emaciated; rigor mortis well developed; post-mortem lividity in usual situation; pupils dilated. Permission was only granted to examine the brain. Scalp thin and anemic; calvarium thin; no evidence of displacement, disease or fracture of bones of skull. Dura mater normal, except in region of right occipital convolutions, where there was adhesion of the membrane to the bone and marked bulging in this region—also pronounced asymmetry. Gentle traction was unavoidably made, a rupture occurred and there was a flow of fetid pus to the extent of three ounces, resulting from the solution of continuity of convolutions in this region. The brain was then lifted from its situation. Externally there was no abnormality except in region indicated above. No disease of the sinuses could be determined. The lesion on convexity occupied an area of two to three inches in circumference and was localized, namely: At the posterior part of the first temporal sphenoidal convolution. There was marked thinning and softening of gray matter in this region and an external communication, as above mentioned, produced by manipulation.

The brain was thoroughly hardened and transverse sections were made. Nothing unusual except indications of anemia was noticed anterior to the Rolandic convolutions. The right hemisphere, posterior to the Rolandic fissure, was extensively diseased and gave evidences of intense suppurative inflammation involving the entire white matter posterior to the fissure noted above. The lateral ventricle on same side was dilated and contained a small amount of pus extending to the opposite ventricle. The white matter of left hemisphere in corresponding region was considerably disintegrated and pus was irregularly distributed, but the inflammation was not so well declared. An examination of the base showed no abnormality. Pons, cerebellum, medulla and upper portion of the spinal cord appeared normal.

The difficulty of diagnosing acute brain disease in children is well illustrated in the description of the above case. The multiplicity of the symptoms, their transitory character, and the passive resistance offered by patients in this condition, often renders an accurate diagnosis impossible. In the case reported there was never any symptoms which would accurately localize the disease, and for this reason an operation was not deemed justifiable. The treatment was entirely palliative. The prognosis was thought to be grave during the entire course of the malady.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 84 AND 86 FIFTH AVE., CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

SATURDAY, SEPTEMBER 1, 1894.

THE HODGKINS FUND PRIZE.

In October, 1891, THOMAS GEORGE HODGKINS, of New York, made a donation of \$200,000 to the Smithsonian Institution, the income from a part of which was to be devoted to "the increase and diffusion of more exact knowledge in regard to the nature and properties of atmospheric air in connection with the welfare of man." The atmosphere in its hygienic relations, its influence upon the public health, and upon individual health, comfort and well being was MR. HODGKINS' hobby; he believed that good air was of prime importance to good health and thence to good morals. The study became his life work, and before he died last year he had the satisfaction of approving the initiatory steps taken in administering the Hodgkins Fund by the Smithsonian Institution. These steps consisted in establishing a number of prizes, the most important of which is one of \$10,000 for any new and important discovery in regard to the nature and properties of atmospheric air—these properties to be considered not alone in their bearing upon meteorology or other branch of physical knowledge, but also in relation to biology and especially to hygiene and public health.

At the recent meeting of the British Association for the Advancement of Science an announcement was made which is now construed as a claim for this prize. LORD RAYLEIGH, Secretary of the Royal Society, and PROFESSOR RAMSEY, F. R. S., claim to have separated a hitherto unidentified gas, probably elementary, from the nitrogen of the air. They obtained this gas by passing sparks from a Ruhmkorff coil through a vessel full of air; after the resulting oxides of nitrogen are absorbed in caustic potash, a residue is left which is neither oxygen or nitrogen. It is believed by the discoverers that this is the *tertium quid* needed to explain the discrepancy, long recognized in the atomic weight of nitrogen obtained

from the air and of that obtained from other sources—the density of the former being about one-half per cent. higher; no satisfactory explanation has ever been offered to account for this difference, but the discovery of another gas, previously unknown, may solve the mystery. This new gas answers to no chemical test yet applied, but possesses a very distinctive spectrum, consisting of a single blue line, much more intense than the line of the same wavelength in the nitrogen spectrum; it is present in the air to the extent of only 1 per cent., and up to the date of the announcement only a small quantity—about 100 cubic centimeters had been obtained.

Since the receipt of the information of the discovery in this country it has aroused considerable skepticism. The general ground for disbelief seeming to be that the many experiments in atmospheric research which have been made within the past few years would certainly have revealed, if not the new element itself, at least some trace by means of which its existence might have been previously discovered. Other critics point to the sensational conditions under which the discovery was exploited—*i. e.*, at a stated meeting of the foremost scientists of Great Britain, without previous intimation of an event of such interest to scientists; while the *farceurs* suggest that English chemists have the advantage of American in the possession of an atmosphere about London in which anything might be found.

So far as this skepticism is seriously and honestly entertained, it might be answered—as to the objection that the new element had hitherto eluded detection—by referring to the recent discoveries of gallium, germanium and scandium, elements whose existence PROFESSOR MANDELÉEFF had predicated upon his law of the grouping of the elements into families whose members resemble each other in weight, volume, heat and laws of combination, and in which plan of families there are blanks because all the elements thus defined have not yet been discovered; there are three such blanks between the atomic weights of 19 and 23, fluorine and sodium, and it is surmised that RAYLEIGH and RAMSEY'S new element may fill one of them.

If it be urged that the discovery of an element forming only 1 per cent. of the atmosphere is of little practical importance it may be well to recall FARADAY'S Yankee-like reply to the Gradgrind visitor to his laboratory, who queried as to the use of some of his experiments: "Of what use is a baby?"

MEDICAL TRAINING.

Questions of medical education that occupy so much attention in journals and medical meetings, are often treated from a very narrow and erroneous point of view. The school that teaches such a great variety of subjects, with enormous faculties,

and almost wonderful system of division of topics, may fail to graduate successful men. Its students may have what PROF. GROSS used to designate as "photographic memories, and microscopic brains," and be storehouses of medical matters, and yet pass through a long life without ever contributing a single fact to science. Many teachers and even writers use the term medical education, as if it was something complete and finished. Diplomas are considered as evidences of this, and are offered as guarantees of scientific skill.

These are sad delusions; a medical education is never finished and no one can be called educated in any true sense. The true aim of medical schools is to train men to observe and think for themselves, not to load them with facts and theories. The facts of anatomy, physiology and chemistry, are of no value except as they teach one to observe and accurately note the relations to other things. The use of the microscope requires a constant observation and comparison of things, to eliminate sources of error, and to arrive at conclusions which appear to be accurate. To-morrow observations may bring new facts and new differences that were not seen yesterday. To be proficient here requires long practical training of all our powers of observation and comparison. The memorizing of the facts which are seen by the microscope would never make a practical microscopist. The same with anatomy; the facts must be sought for, and examined, and compared. One of the obvious reasons for the failures of medical men is this want of practical training. The assumption of truths without personal examination, and the inability and want of training to examine independently the various questions which come up in every day life are apparent to all. Many medical men turn to text-books and journals for help, where the facts could be ascertained by accurate study and comparison.

The college that will train students to be explorers, and how to examine and accurately study the various phenomena of health and disease is the ideal one. The teacher who can inspire the student to be a discoverer, ever on the alert for new facts and new truths, and new conceptions of old truths, who is never learned, but always learning is the ideal scientist. The blunders, inaccuracies, the dogmatism and errors of statement seen in medical journalism alone, are a sad reflection on the failures of colleges to graduate trained men. Even text-books are examples of bad training, in the use of language and statistics that are open to a great variety of meanings and widely different conclusions. The details of treatment and operations often give evidence of this looseness of expression and failure of accuracy in both comparison and observation. On the other hand, the most minute differences of symptoms and

diseased states are often given, plainly indicating imagination more clearly than accurate observation. The explorer in the Arctic regions describes the appearance of the country as he sees it, never assuming that his view comprises the entire field, or that some other observer may not point out many new facts which have escaped his attention. In like manner the trained physician describes the facts as they appear to him, with the reasons, fully realizing that other observers may reach different and more accurate conclusions.

Now that medical teaching has been placed on a more uniform and broader scale, the profession should require something more than recitations and memorizing of facts. The student should train his senses to observe and his brain to constantly compare, and understand not only the fact, but its relations to other facts; and this training must continue through a long lifetime. No college can educate a man in the true sense; all they can do is to prepare him to use his powers of observation and reason, and to be accurate and true. When the student realizes his limitations of sense and reason, and the personal equation of error that is liable to complicate his observations, he becomes a scientist in the highest meaning of that word, and his life work is a search for truth, that is constantly being verified by other observers. The medical fads and theories that for a time attract attention, then die away, would not be possible if medical men were accurately trained observers. New operations, new drugs, new methods of treatment, that after a short period of popularity are forgotten are the result of inaccurate observations and faulty reasoning. If they had been truths of science they would have lived, and no opposition or neglect could have killed them.

An English college has recently adopted a plan requiring all senior students to spend the last year exclusively observing and writing up cases, the notes of which are corrected by the teachers. In this the senses and reason are trained to observe and compare the relation of facts. Often the difference between a successful quack and a physician, is that the former is a closer observer and reasoner. If the physician had the powers of observation of the quack, the latter would have no place in his neighborhood. There is clearly a very wide field here for change and improvement. Our excellent colleges have not covered the field in their elaborate curriculums; the subjects left out are still extensive and very important. The matter taught is open to change and wide variation, but the manner of teaching concerns the failure and success of every student. No gathering of medical knowledge can make a medical man; he must be a student, an explorer, who will observe and examine for himself continuously through all his life. Such men are with us, but we want more of them.

DISTRACTION IN THE TREATMENT OF HIP DISEASE.

The subject of traction in the treatment of hip disease has again been studied by BRADFORD and LOVETT (*New York Medical Journal*, Aug. 4, 1894). Seven healthy hip joints in children between the age of 6 and 16 years were tested with a traction force of ten and twenty pounds; eighteen experiments were made. In three instances these resulted in one-eighth inch shortening; in five there was no change; and in the remaining ten there was lengthening, from one-eighth to one-fourth inch. From this it would appear that in the majority of instances traction of ten to twenty pounds will distract the healthy hip joint in children from one-eighth to one-fourth inch; but that in a certain number of cases this traction force appears to have no influence, and in a few instances it stimulates muscular contraction to an extent sufficient to actually shorten the limb one-eighth inch.

Twenty-four experiments were made upon diseased hip joints in twelve children between the ages of 4½ and 16 years. A traction force of ten and twenty pounds was applied. In no instance was there shortening; in five there was no change; and in the remaining nineteen there was lengthening of one-eighth to three-eighths inch. In one patient the tests at ten and twenty pounds were not verified on account of the pain produced. The five instances where there was no change were to the ten-pound force in four cases, and the twenty-pound force in a boy 16 years old. From this it appears that in the vast majority of instances a traction force of ten to twenty pounds distracts a diseased hip joint from one-eighth to three-eighths inch.

In all these tests the patient was recumbent; no tests were made with the patient walking; no tests were made to show how long these patients would tolerate a traction force sufficient to distract; and none to show how long the adhesive plasters applied to the limb would remain in place, or how long the skin would remain sound under the adhesive plasters. Thirteen cases are reported in detail where good results were obtained by the use of traction in their treatment, but in none of these is there any evidence that the joints were distracted; nor is it shown how many pounds traction were employed, nor whether the traction was maintained without interruption; in a word, the thirteen cases reported have no connection whatever with the experiments in distraction, although they appear to have, being placed between the records of experiments with distraction and the conclusions drawn therefrom.

It appears that diseased acetabuli heal more quickly after excision of the head of the femur, and that those parts of the acetabulum upon which the femoral head does not impinge show less distraction than other parts; also that these cases treated by

traction have less displacement upward of the greater trochanter than those not treated at all. But these observations appear to us to have no bearing upon the question of distraction in the treatment of diseased joints. The curative effect of surgical procedures upon tubercular tissues, of rest in bed, and of immobilization of the diseased joint are not taken into account in considering the results in the cases treated.

There is no question that certain joints, the metacarpo-phalangeal for instance, can be distracted, but there is still some question in the minds of some orthopedic surgeons whether the elongation of the limb obtained in these experiments is due to the separation of one articular surface from the other or the sliding of one surface upon the other. It would therefore have rendered the argument more conclusive had the experiments been made upon a joint where there was no doubt about the possibility of actual distraction.

These experiments in distraction are interesting in so far as they have bearing upon the anatomic conditions, but they should not be confused with treatment by traction splint or any other form of traction, for no one has yet even claimed to maintain the hip joint in the condition of distraction during any considerable period of time.

MASSAGE IN SURGERY.

The value of massage in certain surgical cases seems but imperfectly understood, and yet there are few expedients in surgical therapeutics that have a better defined place. In sprains, contusions and tendon adhesions, massage is nearly always indicated. In sprains after the primary swelling has subsided, or even at its maximum, no special treatment seems to unload the vessels more promptly than gentle massage; under this practice the plastic obstruction of the lymphatics gives way, absorption of the exudate commences, and venous engorgement disappears.

In the after treatment of dislocations, whenever passive motion is indicated, we find massage of great utility, and it is absolutely indispensable in the treatment of fractures of the lower end of the radius and of the leg. When these fractures take place in aged persons, especially in old women who are thin, there is an uncomfortable tendency toward contraction of the flexor tendons and adhesion of flexor sheaths. The statement has been made by some surgeons who are not very careful of their expressions, that well adjusted fractures are not liable to contract adhesions. This is certainly an error, for there are many perfectly adjusted fractures where, owing to exuberant callus, or other mechanical irritation a copious exudate is thrown out from the tendon sheaths; this exudate left to itself causes per-

manent thickening by consolidation of the exudate. Proper massage may prevent this by favoring absorption.

Contraction of tendons, that *bête noir* of the aged, may follow a fracture without a great amount of exudate, and this too requires massage for its prevention.

We have mentioned massage in general terms; it should be applied in a proper way to be of the greatest service. Mere rubbing will not answer; the tendons separately must each be gently manipulated from its insertion to the belly of the muscle, by the thumb and finger of the masseur, and gentle friction applied to the whole limb. All joints in the vicinity must be alternately flexed and extended. Should much swelling follow these movements, the treatment should be suspended for a day or two; although usually in the hands of a careful masseur the daily application of massage is better than to perform it on alternate days, but there are cases that will not bear it more frequently.

It is in such cases that the trained masseur may show his skill and ability to the greatest advantage. The true masseur should combine great muscular power with extreme delicacy of touch, therefore every man can not become a good masseur; thus, while much may be learned by practice, yet the fact remains that the best manipulators have natural qualifications for the absence of which, no training can compensate.

"SMALLPOX STILL LINGERS."

If there were no higher motive, the *argumentum ad pecuniam* alone should impel every member of the profession to do all that in him lies to delete smallpox from the list of current diseases. There's "nothing in it," as a source of professional income; one variolous patient will ruin, for the time being, a good paying general practice. An epidemic of the disease seriously impairs the commercial prosperity of a community, and the reflex is seen in the returns of the bill collector. Aside from this, the disease is a loathsome one to treat, and even the best results of treatment are too often unsightly and unsatisfactory.

For these, among other reasons, it is cause for regret that "smallpox still lingers" in many parts of the country to such an extent as to excite serious forebodings for the approaching cold weather. Besides its existence at many smaller places, the situation is especially grave in Newark, N. J., in Detroit, Milwaukee and Chicago; in some the health departments are demoralized; in others efforts at prevention and suppression are met with opposition in which, by turns, appeals to the courts and to arms, to injunction and riots, are resorted to; in all there is a dangerous ignorance or suppression of facts, either by officers, on the one hand, who report that

"smallpox has practically disappeared," or that "the disease is well under control," or, on the other hand, by the "antis" who oppose vaccination, conceal cases, resist restrictive measures and in other ways assist in the spread of the disease.

Concerted action by the profession—as well by public expressions of its organized bodies as by individual effort with the families of each member's *clientèle*—would do much to remedy this threatening state of affairs. The community still needs to be educated in the protective virtue of vaccination, in the necessity for inspection and for the fullest publicity, not alone of the whereabouts of actual cases but of those who have been exposed and remain unprotected. Health officers need the moral support which only the profession can secure for them; and municipal authorities in too many instances require to be told their duties in the premises with all the force and impressiveness which the professional dictum may command.

Such concerted action taken now, while there is yet time to "stamp out" existing contagion and to perfect the work already done in the line of securing vaccinal protection, should abolish the stereotyped phrase—"smallpox still lingers"—and enable the country to face the coming winter without apprehension of another smallpox epidemic.

CORRESPONDENCE.

Cataract Extraction as an Office Operation.

CHARLESTON, S. C., August, 1894.

To the Editor:—I have read with surprise three communications on this subject in the August number of the *Ophthalmic Record*, by Drs. T.E. Murrell, W. Cheatam and Robert Fields LeMond. Dr. Murrell's advocacy of this proceeding has been well known for several years, and I did not for a moment think that any one else would try to usurp his position as prime mover or would even wish to share such an honor(?) with him. Dr. Murrell is a progressive and intelligent ophthalmologist and as every man is apt to have a hobby or to be peculiar in certain views, I think but little attention was paid to this vagary of advocating the removal of cataract in his office or at a dispensary, and sending a patient to his home immediately afterward; but all thought that sooner or later he would sober down and tread the well-beaten path that all conservative surgeons desire to follow and which leads to the best interests of the patient. But poisonous germs will increase when planted in fertile soil, and now we see two more advocates of the proceeding, and there is no telling how many may spring up and how many eyes may be lost before these gentlemen realize that the proceeding is not an advance in eye surgery, is not scientific treatment, is not difficult in technique, does not conserve the best interests of the patient, is not necessary, but is rash—and therefore shows poor judgment—may cause loss of vision, and therefore should receive from every conscientious ophthalmic surgeon unqualified condemnation.

I ask if any ophthalmic surgeon thinks that he has honestly done his best for his patient when he extracts cataract in his office or dispensary, and immediately afterward allows the patient to walk or ride several blocks to his

home? If not, there are but two reasons for the proceeding and they do not concern the patient. They are: 1, it is more convenient and time saving for the surgeon; and 2, it gives him the reputation of being a bold and skilful operator who scorns the conservatism of the old fogies. I was taught, and believe, that the chief object of the physician is to heal the sick by the safest, surest and most available means at his command, and that in accomplishing this he gains the respect and confidence of the world. Every one must admire the bold and skilful surgeon who in an emergency does not hesitate to make use of any means that may save his patient, but the extraction of cataract is not an emergency operation and delay does not cause loss of the eye. No one will contend that it is as safe for a patient after removal of cataract to walk, or ride to his home as it is to remain quietly in bed, or seated in a chair. Would any of the gentlemen named take this risk with a patient from whom they expected to receive a fee of \$500 or \$1,000? Would they permit the operation to be performed upon their own eyes as they advise for others? It may be said that a physician's time is too precious for him to waste it in running around after the poor—then he should give up such practice to those who will and can attend to it. I contend that if but *one* eye out of a thousand is lost by accident occurring on the way home after cataract operation performed in an office, or dispensary, it is sufficient to condemn the practice and to render the operator liable to suit for mal-practice. If it were *necessary* to remove cataract in our offices, or at a dispensary, I should offer no protest.

CHARLES W. KOLLOCK, M.D.

ASSOCIATION NEWS.

American Medical Association. Section on Ophthalmology.

*Forty-fifth Annual Meeting, held at San Francisco, Cal.,
June 5-8, 1894.*

FIRST REGULAR SESSION, TUESDAY AFTERNOON, JUNE 5.

The Section was called to order at 3 P.M.

Address by the Chairman, DR. ALBERT R. BAKER, of Cleveland, Ohio.

The first paper read was by DR. F. B. EATON, of Portland, Oregon, on "The Physiology of Certain Oculo-motor Phenomena, with respect to Some Recent Theories of Asthenopia."

Discussed by Drs. Edw. Jackson, Geo. H. Price, H. V. Würdemann, W. F. Southard, Kaspar Pischl, H. Bert Ellis and discussion closed by Dr. Eaton. Drs. Hobby and Lydston were absent and Dr. Voorhees unavoidably prevented from preparing his paper.

The general meeting of the ASSOCIATION having directed the Sections to appoint alternates in place of absent members of Executive Committees, the chair appointed Drs. Edw. Jackson, W. E. Briggs and H. V. Würdemann. The same committee to act as nominating committee for the Section. As Dr. Jackson could not serve owing to other duties, Dr. A. R. Baker was by vote appointed Chairman of the Committee. Adjourned.

MORNING SESSION.—JUNE 6.

Called to order at 9:30 A.M. Minutes of the previous meeting were read and approved.

The first order was the reading of the report of the committee appointed in 1893, to report upon "The Value of Objective Tests for the Determination of Ametropia—Ophthalmoscopy, Ophthalmometry and Skiascopy." Committee: Dr. Edw. Jackson, Chairman, Philadelphia, Pa.; S. M. Burnett, Washington, D. C.; H. V. Würdemann, Milwaukee, Wis.; J. L. Thompson, Indianapolis, Ind.

As other papers were to be read, bearing upon the same subject, discussion was deferred until the same were read.

DR. B. A. RANDALL being unavoidably absent and having sent his paper to the Secretary, the latter on vote of the Section was directed to read Dr. Randall's paper on "The Value of Retinoscopy as a Crucial Test in Measuring Errors of Refraction."

The next paper on "Status of Skiascopy" was read by DR. H. V. WÜRDEMANN, of Milwaukee, Wis.

DR. JACKSON, of Philadelphia, then read a paper on "The Visual Zone of the Dioptric Media and its Study by Skiascopy."

The report and papers read were then discussed by Drs. F. B. Eaton, of Portland, Oregon; S. B. Davis, Stockton, Cal.; A. C. Simonton, San José, Cal.; R. D. Gibson, Youngstown, Ohio; Fred Baker, San Diego, Cal.; W. E. Briggs, Sacramento, Cal.; A. R. Baker, Cleveland, Ohio; L. R. Ryan, Galesburg, Ill.; H. V. Würdemann, Milwaukee, Wis.; Lewis H. Taylor, Wilkesbarre, Pa.; A. J. Erwin, Mansfield, Ohio; and discussion closed by Dr. Jackson.

The Secretary read a communication from the Secretary of the ASSOCIATION, calling attention to the fact that all papers read before the Sections and to be referred for publication, with all plates, etc., are regarded as the exclusive property of the ASSOCIATION.

On motion the afternoon session was fixed at 3 P.M., instead of 2 P.M., in order to allow members to attend the general session of the ASSOCIATION.

WEDNESDAY, JUNE 6.—AFTERNOON SESSION.

The report of the Nominating Committee not being ready, Dr. A. H. Voorhees, San Francisco, presented a patient on whom he had performed double cataract simple extraction; also instruments, cataract knife with double cutting edge and bulb apparatus for irrigating the anterior chamber.

The Nominating Committee reported as follows: President, Dr. Edward Jackson, of Philadelphia, and for Secretary Dr. H. V. Würdemann, of Milwaukee.

The Secretary was directed to cast the ballot in favor of the above named and they were declared unanimously elected.

DR. S. D. RISLEY listed for the next paper being absent, DR. H. M. STARKEY, of Chicago, followed with a paper entitled, "Are Low Degree Lenses of Purely Mythical Value?"

DR. C. M. HOBBY's paper on "Asthenopia" was here presented and the Secretary by vote of the Section directed to read the same.

Discussion on the two papers followed, participated in by Drs. H. Isaac Jones, San Francisco; H. B. Ellis, Los Angeles; A. C. Simonton, San José; H. B. Young, Burlington, Iowa; Fred Baker, San Diego, Cal.; L. R. Ryan, Galesburg, Ill.; Geo. H. Price, Nashville; Tenn.; S. B. Davis, Stockton, Cal., and closed by Dr. Starkey.

The next paper, "Cyclophoria; Its Detection and Treatment," was read by DR. GEO. H. PRICE, Nashville, Tenn.

Discussion by Drs. F. B. Eaton, Portland, Oregon; A. J. Erwin, Mansfield, Ohio; A. C. Simonton, San Diego; and closed by Dr. Price. The time for adjournment having arrived, the chairman announced that the next paper, "School Children's Eyes," would be deferred until the first order of business on Thursday morning. Adjourned.

MORNING SESSION—JUNE 7.

Called to order at 9:30 A.M. Dr. Baker, Chairman, being detained by a meeting of the Medical College Association, Dr. Edward Jackson, of Philadelphia, was appointed chairman *pro tem*. Minutes of June 6 were read and approved.

DR. W. F. SOUTHARD, of San Francisco, then read a paper on "School Children's Eyes; A Plea for the Examination of Every Child's Eyes when Commencing to Attend School."

As DR. KASPAR PISCHL's paper was upon a similar subject, it was here called for, but as his charts had not arrived it was deferred.

Discussion upon Dr. Southard's paper followed, participated in by Drs. R. N. Miller, Los Angeles; L. R. Ryan, Galesburg, Ill.; F. B. Eaton, Portland, Oregon; H. M. Starkey, Chicago, Ill.; H. B. Young, Burlington, Iowa; Edward Jackson, Philadelphia, and closed by Dr. Southard.

DR. W. E. BRIGGS, of Sacramento, Cal., then read two papers: 1. "Sub-conjunctival Injections in the Treatment of Eye Diseases." 2. Optico-Ciliary Neurotomy, with Exhibition of Scissors."

Discussion by Drs. Edward Jackson and Kaspar Pischl, and closed by Dr. Briggs.

The hour fixed for special order of business in the general session of the ASSOCIATION having arrived, the remaining papers were deferred and the Section adjourned to meet at 2 P.M.

AFTERNOON SESSION—JUNE 7.

Section called to order at 2:40 P.M. Dr. Baker in the chair. The first paper was read by DR. X. C. SCOTT, of Cleveland, Ohio, on "Treatment of Purulent Ophthalmia."

Discussed by Drs. A. Barkan, San Francisco, Cal.; H. M. Starkey, Chicago, Ill.; Kaspar Pischl, San Francisco; H. V. Würdemann, Milwaukee, Wis.; J. Dennis Arnold, and discussion closed by Dr. Scott.

The next paper was read by DR. LEWIS H. TAYLOR, of Wilkes-Barre, Pa., on "Conservative Treatment of Wounds of the Eye-ball," and discussed by Drs. A. R. Baker, Cleveland, Ohio; W. E. Briggs, Sacramento, Cal.; X. C. Scott, Cleveland; H. H. Weer, Bluffton, Ind.; L. R. Ryan, Galesburg, Ill., and closed by Dr. Taylor.

DR. LE MOND being absent, the next paper, "Some Unusual Reflexes from Pathologic Conditions," by DR. GEO. H. POWERS, San Francisco, was read by title and referred to Committee on Publication.

The same with paper by DR. A. G. HOBBS, of Atlanta, Ga., on "The Treatment of Pterygia with the Galvano-Cautery," the paper having been sent to the Chairman, and Dr. Hobbs detained on account of illness in his family.

DR. KASPAR PISCHL read the next paper on "Report of the Examination of the Eyes of 1,900 Children of the Public Schools of San Francisco."

Discussed by Drs. S. B. Davis, H. H. Weer, H. B. Young, W. F. Southard, H. L. Burrell and closed by Dr. Pischl.

"Fractures of the Orbit," by DR. J. F. FULTON, of St. Paul, was read by title and referred for publication, as the writer was engaged as Secretary of the Otological Section.

DA. H. ISAAC JONES, of San Francisco, then read a paper entitled, "Eye Symptoms in Locomotor Ataxia—With Presentation of a Patient."

Discussion by Dr. H. B. Young and closed by Dr. Jones.

A paper by DR. EDWARD J. BROWN, of Minneapolis, on "A New and Convenient Arrangement of Rotary Prisms," was read by title, as was also one by DR. W. E. HOPKINS, of San Francisco, on "Deposit of Cholesterin Within the Anterior Chamber from Non-Traumatic Causes."

DR. W. T. MONTGOMERY'S paper on "Progressive Hypermetropic Astigmatism," was called for, but as the writer was not present this ended the reading of formal papers.

Miscellaneous business being in order, Dr. H. B. Young referred to legislation on prevention of blindness, and Dr. Southard asked the coöperation of all workers in ophthalmology in securing legislation in this direction.

DR. H. M. STARKEY presented the following, seconded by Dr. Southard, which was carried:

Resolved, "That it is the sense of the Section on Ophthalmology of the AMERICAN MEDICAL ASSOCIATION that the eyes of all children should be carefully tested by competent persons before entering upon school life."

Discussed by Dr. Ellis and Simonton.

The Executive Committee report as the topic for special discussion at next year's meeting, "The Examination and Care of the Eyes during School Life—Instruction of Teachers and School Authorities and Legal Provisions," and appointed the following Committee to prepare the report:

Drs. B. A. Randall, Philadelphia, Chairman; W. F. Southard, San Francisco, Cal.; H. B. Young, Burlington, Iowa; A. R. Baker, Cleveland, Ohio; George H. Price, Nashville, Tenn.

The Secretary read a communication from Dr. Savage, of Nashville, asking the Section to invite the International Ophthalmological Congress to hold its next session in this country, and suggested the appointment of a delegate or delegates to attend the meeting of the Congress to be held in Edinburgh in August next.

It was, however, the sense of the Section that as the Congress was not a representative body we could not properly send delegates to the same.

It was also deemed inadvisable for the Section to extend an invitation to the Congress to hold its next meeting in this country.

DR. R. D. GIBSON moved that the Section extend to its retiring officers a hearty vote of thanks for their labors in securing and carrying out the excellent program of the sessions. Carried by a rising vote.

The meeting for 1894 was then adjourned.

The Executive Committee of the Section on Ophthalmology for the ensuing year, according to the resolution adopted in 1891, will consist of Dr. J. L. Thompson, 20 West Ohio Street, Indianapolis, Ind.; Dr. S. D. Risley, 1722 Walnut Street, Philadelphia, Pa., and Dr. Albert R. Baker, 122 Euclid Avenue, Cleveland, Ohio.

A. R. BAKER, Chairman.

LEWIS H. TAYLOR, Secretary.

To Medical Societies:

OFFICE OF THE PERMANENT SECRETARY,
1400 PINE STREET, PHILADELPHIA, PA.

The Secretary of each Medical Society in the United States is earnestly requested to send to the undersigned the following information:

Name of Society——. Place and time of meeting——. Officers, with address of each——.

WM. B. ATKINSON, Permanent Secretary.

SOCIETY NEWS.

Mississippi Valley Medical Association.—The Secretary of the Mississippi Valley Medical Association has issued the following:

INDIANAPOLIS, IND., Aug. 25, 1894.

Dear Doctor:—The Twentieth Annual Meeting of the Mississippi Valley Medical Association will occur in Hot Springs, Ark., Nov. 20, 21, 22 and 23, 1894.

The Association is now in a more prosperous condition than ever before, and no efforts will be spared to make the meeting at Hot Springs not only the largest but the most interesting and profitable ever held. Indeed, its success is already assured, many valuable papers by most excellent authors having been promised.

Hot Springs is an ideal place of meeting, and November in that charming Southern health resort is the most delightful month of the year.

Socially, the visit will be enjoyable in the extreme, as the physicians and citizens with their characteristic hospitality are united and enthusiastic in their endeavors to make the sojourn of their guests pleasant.

The railroad rates will be very low and will be announced later.

You are cordially invited to be present at this meeting.

Respectfully,

FREDERICK C. WOODBURN, Sec'y.

SELECTIONS.

A New Method for the Treatment of Tuberculosis Pulmonalis.—Following a preliminary communication upon this subject (*Cent. f. Bakter. u. Parasitenk.*, Bd. XIV, p. 719) Carasso, of Genoa, now gives full particulars of his method of treating tuberculosis pulmonalis (*Cent. f. Bakter. u. Parasitenk.*, Bd. XV, No. 25, and Bd. XVI, No. 1, 1894).

He first reviews the work that has been done with tuberculin, and demonstrates its unsatisfactory therapeutic application. The clinical results of the creasote, guaiacol, and benzo-guaiacol treatments are reviewed, and while the author admits their successful application in cases of beginning consumption, he regards them as unreliable, and powerless in advanced cases of the disease. The experiments with the toxins, blood serum, and thyroid implantation are dismissed with a few words.

The author refers to the numerous unsuccessful attempts at inhalation treatment. Among the agents employed in inhalation therapeutics, Carasso discards carbolic acid, creasote, and the various gases, on account of their irritant and uncontrollable actions; and finally directs attention to the ethereal oils, as the most desirable drugs for this method of treatment. The investigations of Chamberland, Champonnière, and Koch have proven that many of the essential oils possess decided germicidal properties. Koch, for instance, has shown that the essence of peppermint (*menthæ piperita*) prevents the development of the anthrax bacillus in dilutions of 10 parts to 300; and that the vapor of the oil was fatal to the bacilli and spores of anthrax.

In 1888 Braddon reported the results of his clinical application of peppermint inhalations, and Kersch gave his experience with inhalations of various ethereal oils. These reports induced Carasso to begin his experiments with these remedies.

The author believes that *mentha* exerts a direct bactericidal action upon the bacilli in the respiratory tract, and that, by absorption into the circulation, it acts as a general disinfectant. Creasote acts beneficially in pulmonary tuberculosis by increasing the appetite and favoring nutrition. It also possesses some action on the secondary inflammatory exudates, favoring their absorption.

Carasso's method of treatment is, in detail, as follows: A piece of linen cloth, ten centimeters square, is folded to make a pad, five centimeters by two centimeters. By means of tapes this pad is secured in contact with nostrils. The tapes may be tied around the head, about the ears, or to the frames of a pair of spectacles. The pad is to be worn day and night, and only to be removed at meal times. In the case of patients with out-door occupations, who object to wearing this inhaler for cosmetic reasons, a quill toothpick, or a cigarette-holder may be stuffed with cotton and, after saturation with the mint essence may be used as mouth inhalers. The inhaling pad is to be moistened with five or six drops of peppermint essence, four or five times a day. The nostrils are to be greased with vaselin for the first few days to prevent irritation. The patient is instructed to take eight or ten deep inspirations with closed mouth; retaining the air as long as possible. After ten or fifteen minutes' rest, this procedure is repeated, and so on through the day. In case difficulty is experienced in keeping the pads in position at night, the bed pillow may be impregnated with ten or fifteen drops of the mint essence.

The following mixture is given internally:

| | |
|--------------------------------------|-------|
| Creasote, pure (beechwood) | 8.0 |
| Alcohol | 550.0 |
| Glycerin | 250.0 |
| Chloroform | 20.0 |
| Essentiæ menthæ | 8.0 |

A teaspoonful every three hours, in a half-glassful of water.

In certain cases the mixture may be further diluted with sweetened water, or the dose may be reduced. The nutrition is favored by the method of over-feeding. Two or three liters of sterilized or boiled milk are given daily; together with plenty of meat, cooked to taste; and with the addition of 400 or 500 grams of good wine.

All hygienic precautions are to be observed. The patients are instructed to carefully disinfect their expectoration, thus preventing reinfection.

The remarkable feature of Carasso's communication is the clinical report of the cases subjected to this treatment. In all cases the physical diagnosis was confirmed by finding the tubercle bacilli in the sputum. A careful weekly record was kept of each case, involving a complete physical examination. Many of the cases were well advanced in the disease, though no record is made of cases in which the lung destruction had advanced to the formation of cavities, recognizable by physical examination.

In all, forty-four cases are recorded. Of these there were six deaths, and thirty-eight recoveries. Of the fatal cases, five were subjected to autopsy, and four exhibited either general miliary tuberculosis, or intestinal and peritoneal tuberculosis, along with the lung disease. In one fatal case, the patient after once having the disease subdued, returned to her poor surroundings, and suffered a fatal relapse without again submitting to treatment. In another case of well advanced phthisis the patient died of capillary bronchitis soon after the beginning of the treatment.

From his record it appears that every case of primary pulmonary tuberculosis, treated by the inhalation method of Carasso's recovered; and that the fatal cases, with two exceptions, were ones in which secondary tubercular lesions produced death. The average duration of the treatment in these cases was *sixty days*.

The regularity of the improvement in these recorded cases is striking. The fever, cough and night-sweats rapidly diminished and ultimately disappeared. The bacilli in the sputum began to diminish in ten days, and all disappeared in sixty days; while the expectoration became first mucoid and finally ceased. The weakness, loss of appetite, and emaciation rapidly improved; the recovery in all the recorded cases seems to have been permanent.

The simplicity and harmlessness of this treatment of Carasso, together with the remarkably successful outcome of his cases, recommends the method for a thorough and systematic clinical test.—By A. P. OHLMACHER, 56 Fifth Avenue, Cleveland, Ohio.

The Glycero-Phosphates of Soda and Lime of Dr. Albert Robin; the so-called "Séquardine."—M. Robin has recently presented a paper before the *Académie de Médecine*, in which he makes claim to the discovery of the active principle of the noted Brown-Séquard liquids. This active principle is composed of phosphorus and glycerin, and is called the glycerophosphate, or the phosphoglycerate, of soda. It is also proposed to call the substance by a kind of memorial title, namely, "Séquardine," especially if there shall be a verification of the claims of M. Robin that he has made a veritable discovery. M. Robin has experimented with various combinations of the glycerophosphates of soda, lime and potash—now with one and now with the others—both by internal and by hypodermic dosage. He credits these medications with a powerful stimulative action over the nervous system, being in this respect the antipathic remedy to antipyrin. The latter stands as an agent against an excess of nervous excitation, whereas the glycerophosphates relieve nervous

depression. The following are some of the reported favorable results, and the supposed method of amending diseased nervous conditions:

"I inferred from my experiments that glycerophosphates could be advantageously used in cases where it is desired to restore nervous nutrition that is defective and to stimulate its activity.

"They have rendered good service during convalescence from gripe and other infectious complaints, in nervous asthenia of different origins, in a particular variety of neurasthenia, in some cases of torpid chlorosis in which nitrogenous oxidation was noticeably diminished, in phosphaturic albuminuria, and in one case of phosphaturia. They therefore seem to be indicated in all morbid conditions in which nervous reaction is unsatisfactory.

"I can mention, among others, the case of a man of 25 with Addison's disease. Thin, scarcely able to walk, cachectic, already weighing fifty-six kilograms, who from January 5 to 25 received a quarter of a gram per diem of glycerophosphate of lime in subcutaneous injections. On January 26 he weighed fifty-nine kilograms, and had recovered his strength.

"He left the hospital February 9 to resume work, but I saw him again April 5, as he came to let us know that the improvement in his case had persisted."

"M. Robin reports further that some of the ataxic patients increase in weight at the rate of fifty grams a day. The treatment produces in them a tendency to moist skin, a feeling of warmth in the extremities, less apprehension in walking, and especially a very noticeable decrease in the fulgurant pains. The incoördination in walking is not changed to any degree.

Success was not invariable in the ataxic. In two cases no improvement occurred, while in a third there were signs of cerebral excitation after the fourth dose, with insomnia and slight hallucinations.

M. Robin has offered this as a preliminary report, with the following approximate results:

"These injections do not give rise to any local symptoms when made with the usual antiseptic precautions; they cause a burning feeling that rarely amounts to pain, and a more or less lasting redness of the skin.

"To resume the question: The glycerophosphates are powerful therapeutic agents which stimulate the general nutrition by means of their action on the nervous system.

"Their leading indication is nervous depression.

"In hypodermic injections their action is at least as energetic as Brown-Séguard's liquid, which in all probability owes its effects to the organic phosphorus it contains; it can therefore only be advantageously to use them in place of this liquid, since in this way we substitute a well defined substance that can be given in accurate amounts in the place of an uncertain preparation, that varies constantly and can not be preserved.

"The cases mentioned above allow us to hope that these injections will be of service in the treatment of nervous asthenia of different origins, of phosphaturic albuminuria, of Addison's disease, of some forms of sciatica and of tic douloureux of the face. In locomotor ataxia the results are more uncertain, and there seems to be nothing beyond an alleviation in the fulgurant pains."

NECROLOGY.

MEDICAL DIRECTOR PHILIP LANSDALE, U. S. N., on the retired list, died August 21, while on a visit in Connecticut. He was born in Maryland, in 1817, and entered the Navy in 1846, as Acting Assistant Surgeon. He was promoted Surgeon January, 1861; Medical Inspector 1871, and Medical Director June, 1873; retired with rank of Captain, in 1879, and since then has made his home in Philadelphia.—W. C. DABNEY, M.D., of Charlottesville, Va., August 20, after an illness of three weeks. He was born in Albemarle County, Va., July 4, 1849, and was educated at the University of Virginia. He was made the first President of the State Board of Medical Examiners, and held that office until September, 1886, when he was elected Professor of Obstetrics and Medicine in the University of Virginia. Many of the former pupils of Prof Dabney are in practice and join in

sorrow at his death. He represented the Medical Society of Virginia in the National Medical Congress, held in Washington, D. C., in 1887; was a member of the AMERICAN MEDICAL ASSOCIATION, the Association of American Physicians, and honorary member of the West Virginia Medical Society. In 1873 Prof. Dabney was the prize essayist on medical chemistry of Harvard University.—J. W. CAMPBELL, M.D., of Ottumwa, Iowa, August 26.—M. O'Brien, M.D., at Topeka, Kan., August 28, aged 54. He was for a number of years a member of the State Board of Health, and four years its Secretary.

PUBLIC HEALTH.

Leprosy in Prussia.—A number of lepers have been discovered in several places in Eastern Prussia, especially at Königsburg and at Memel, about seventy miles from Königsburg. In this latter district alone ten genuine cases of leprosy have been found and the disease has been officially declared to exist in these districts.

A Medical Party in Politics.—The London *World* announces, with approval, the formation of a medical party in the English House of Commons, and says that it has been suggested that a Public Health Bills' Consolidation Act would be a good starting point for the efforts of such a party. The *Lancet* is not so sure about this proposal, but thinks that the influence of medical men will be greater in proportion as they avoid all appearance of party or partisan action; and adds: "Public health bills and bills restricting the sale of drugs are in the interest of the public, and the medical members should regard them as being outside all party questions. Otherwise we should be charged with interested views. We should be glad to see many more members of our profession in Parliament—but not to make a new party."

State Board of Health Bulletins.—The extreme to which "red tape" was carried in the office of the Third Assistant Postmaster-General, while dealing with the Tennessee State Board of Health in its efforts to have its Bulletin entered as second class matter is characterized by Dr. Lindsley, the Secretary, as falling "but little below the methods of a Persian satrap." The Secretary finally cut the tape by securing the following amendment to the Post Office appropriation bill:

"That from and after the passage of this Act, all periodical publications issued from known places of publication at stated intervals, . . . including the bulletins issued by State Boards of Health, shall be admitted to the mails as second class matter, and the postage thereon shall be the same as on other second class matter, and no more.

This means a reduction of some 95 per cent. in the postage accounts of the Board and should correspondingly increase the field of this useful class of publications.

Smallpox Prospects.—Dr. A. R. Reynolds, Health Commissioner of Chicago, has just completed an extended tour of inspection, covering the hospitals—especially those for contagious diseases—in the leading cities of the country, with a view to incorporating their best features in the new contagious-disease hospital for Chicago. As a result of his investigations the pavilion plan has been recommended, and it is announced that work will be begun at once upon its construction, for which the sum of \$300,000 will be required; it is expected to complete enough of the structure to meet the requirements of the coming winter. Dr. Reynolds reports that there is a great deal of smallpox in the country and that physicians and sanitarians generally anticipate that the disease will again assume epidemic proportions throughout the country next winter. He is cited as saying that he does not expect that Chicago will wholly escape, but believes

that "inasmuch as vaccination has been so general there is no occasion for alarm. It is the history of the disease that it is worse the second winter than the first. Already the pest has broken out in certain sections of the city to an extent that is alarming. During the first few days of this month over 100 cases were reported."

Vaccination Technique.—One prolific source of confusion in attempts at tabulating the results of vaccination is the wide variety in the technique of the operation. The size of the area of the absorbent surface exposed, the method of exposure, the number of areas and other details which affect the evidence of the resulting scars, as well as the amount of protection afforded, lack so much in uniformity as to seriously impair the value of vaccinal statistics. This consideration lends additional importance to the observations of Dr. Ortega, who has noted in the epidemic of smallpox which occurred in Mexico in 1890, that a large number of railway employes who contracted the disease presented the very large and unsightly cicatrices of vaccination by *grattage* (scraping). Among those vaccinated by *piqûre* (sticking) a very small number only contracted the disease, and in these it was mild, while in those vaccinated by *grattage* it was, in general, severe. The re-vaccination by *piqûre* in those previously vaccinated by *grattage* was almost always successful, while this was the exception in those vaccinated by *piqûre*. The patients vaccinated by *grattage* almost always suffer from inflammations in the vaccinated member of greater intensity and of longer duration than subjects vaccinated by *piqûre*. Finally, vaccination by the former method frequently produces cicatricial keloids. The pustules developed by *grattage* are probably septic, not vaccine pustules, because the larger surface allows the absorption of septic elements, while by the *piqûre*, although repeated several times, vaccine lymph only is introduced.

Diphtheria Diagnosis, Treatment and Prophylaxis.—The medical sensation of the day, at least in the daily press, is the antitoxin treatment and prophylaxis of diphtheria; columns are devoted to fairly accurate descriptions of antitoxin, its methods of preparation, and its modes of use in treatment and for immunizing purposes; and the reader is told that "not since Jenner's discovery of vaccination has there been a more important step in advance than the treatment for diphtheria put forth from Dr. Koch's famous laboratory in Berlin." All of which may or may not be so—time alone can tell; and all of which may or may not be profitable literature for the lay reader. Certain it is, however, that the reports, which we find in our foreign exchanges, of the results of the antitoxin treatment thus far fully warrant the claims made for it—*qua* treatment. Obviously, sufficient time has not yet elapsed to determine the extent and duration of the immunity conferred by this agent. But its use for the protection of inmates of infected dwellings and for the protection of the inhabitants of localities or districts in which diphtheria is prevalent, is confidently recommended by Dr. Aronson, who furnishes instructions for its use for such purposes with the supplies made under his supervision.

An appropriation of \$30,000 is asked for by the New York City Board of Health, with which to defray the expense of producing antitoxin—mainly for gratuitous use among the city poor, who furnish the largest number of victims of the disease. Our English cousins look with favor upon the New York method of diagnosing diphtheria by bacteriologic examination. (It seems proper to call this the "New York method," since it was the Health Department of that city which first made such examination feasible and practical; although its general adoption throughout the country might now entitle it to be called the American method.) In his

annual report for 1893, Dr. Francis Allen, Medical Officer of Health for the Strand district of London, advocates the adoption of this method of prompt diagnosis and appeals to the Metropolitan Asylum Board to make arrangements for the supply of culture tubes and the carrying out of the necessary cultivations, etc.

The Cholera.—The situation in Europe *re* Asiatic cholera, has not materially changed from that summarized in last week's issue of the JOURNAL. Up to the close of August the weather had been generally so cool on the continent as to retard any serious extension of the disease beyond the localities then reported infected. Our English exchanges confirm the gravity and extent of the outbreak in Galicia and Bukovina. The most prolific center of the pestilence is the town of Zaleszczyki, which has become a very hotbed of cholera. Nothing like it has, at all events, been known in Austria for the last two years. In the brief space of about two months no less than 5 per cent. of the entire population in the town have been attacked by the disease. Seventeen districts in Eastern Galicia are declared infected; they form one united area, subject to the same sanitary regulations. These districts lie in the basins of Dniester and Pruth. The same spot formed the cholera center of last year. This and similar recurrences have revived speculation as to the probability of the cholera germ having become domesticated in Europe. It is recalled that in 1892 the epidemic of Nanterre, a suburb of Paris, could not be traced to any outside infection, but in the asylum at that place there had been previously some cases of Asiatic cholera; from here the disease apparently spread to Havre, then to Hamburg, and then to this country. In 1884 all the drinking-water wells in Naples were closed because a company had laid water conduits; in 1893, in the lowest part of the city, some of these wells were re-opened without the consent of the municipality, and cholera appeared in just that portion of the city; Naples had very little if any commerce with India, and it is now thought highly improbable that these cases were due to outside infection.

The German authorities are displaying the greatest activity in efforts to prevent the disease obtaining a foothold, and since his return from England Emperor William has ordered that full reports be furnished him with reference to the measures taken to prevent the spread of cholera. Dr. Koch has had an audience of several hours with the Emperor, who entered into the details of the precautions necessary and displayed great concern at the possibility of a recurrence of the pest on any great scale in Germany. It was upon the report of Dr. von Gossler, President-in-Chief of the Province of West Prussia, as to the extent of the disease in and around that district, that the abandonment of the military maneuvers in Western Germany this year was decided, and it is said that hardly a day passes that the Emperor does not confer with some expert or administrative officer engaged in combating the disease.

There has been one more death among the cholera cases at Battersea, on the Surrey side of the Thames, but the other patients are convalescing and the alarm has subsided. Rigid precautionary measures are, nevertheless, enforced; masters and officers of vessels are required to report every case of diarrhea occurring on board while within the limits of the port of London, and physicians of Edinburgh and some other seaport towns are required for the next two months to report their cases of British cholera and choleraic diarrhea in addition to the diseases previously required to be notified.

Blank Applications for membership in the ASSOCIATION at the JOURNAL office.

MISCELLANY.

Monument to Claude Bernard.—A statue of Claude Bernard will be unveiled with appropriate ceremonies at Lyon, France, October 26, next. The French Congress of Internal Medicine will hold its annual session at Lyon on the same date.

Painful Accident.—We regret to learn that our colleague Dr. John V. Shoemaker, editor of the *Philadelphia Medical Bulletin*, sustained a painful injury in London, which incapacitated him from attendance on the annual session of the British Medical Association lately held in Bristol.

New Hospitals.—The Rockford, Ill., City Hospital was endowed August 28, by William A. Talcott, S. Barton Talcott, Fannie E. Prentice, and Mary C. Pettibone, of Chicago, for \$5,000, the gift being for two free beds, in memory of their parents, Mr. and Mrs. Wait Talcott.

The corner stone of the Julia F. Burnham Hospital was laid at Champaign, Ill., August 23, with Masonic ceremonies.

Catgut Drainage Tube.—M. Desguin, of Antwerp, presented at the last meeting of the Society of Surgery of Belgium, drainage tubes obtained by interlacing of long large threads of catgut, forming tubes of different dimensions. He was able to obtain sterilization by heat or chemicals without altering. They are less rigid than decalcified bone tubes; absorbable and porous, and constitute ideal drainage tubes.—*Gazette Medicale de Paris*, Aug. 18, 1894.

Survival of the Fittest.—Russian courts have reversed the assumption of American tribunals that when a husband and wife are drowned in the same disaster, the wife dies first. The Russian doctors have testified unanimously that the man would be the first to die, because the woman is more agile and keeps herself longer above water. Another fact to support the argument of the Darwinian doctrine!

Poison in the Chalice.—Controversy over the individual communion cup still rages. A correspondent of the *New York Sun* suggests that if religious sentiment or belief requires that, "in order to carry out our Lord's order, separate chalices should not be used, it seems to me that the scientific objection to the single chalice might be removed by providing each communicant with a glass tube through which to partake." And adds that "any one objecting to this method on the ground of worldly association could hardly possess a mind pure enough to entitle him to the privilege of the holy ceremony."

The Late Congress at Rome.—The *Lancet* for August 4 points out the fact that an unusually artistic set of photographs has been prepared by a Roman artist, Cardilli, not only of the nineteen Sections of the Congress, but of the principal speakers in the open conferences. The *Lancet* specifies the portraiture of Virchow, of Koch, of Pasteur, of Lombroso and of President Bacelli himself as being very successful in depicting the features and characteristic expression of those leaders of modern medicine. Dr. Bacelli has been presented with a "first copy" of the album, or collection of photographs, and has expressed his approbation thereof and his hope that the fine work shall have as wide a diffusion as possible. The name of the artist is Giovanni Cardilli. The cost of the album to intending purchasers is not mentioned in the *Lancet* article.

A Septuagenarian's Holiday.—The *Lancet* invites attention to what Prof. Virchow, Rector Magnificus of the University of Berlin, has pledged himself to perform during his summer holiday at the age of 73. First, he will repair to Stockholm to take part in the "Americanist-Congress;" next, he will

appear at Innsbrück as the most conspicuous figure at the Congress of Anthropologists; thirdly, he will assist, *primus inter pares*, at the "Naturforscher-Congress" in Vienna; fourthly, his presence will be one of the chief attractions at the Hygienic Congress to be held at Buda-Pesth; and finally he will close his scientific itinerary by entering an appearance at the Bosnian Archaeological Congress, which is to meet at Serajewo. And not only will he leave those assemblies the richer for his participation; but he himself will profit by the experience, ascribing as he does to such periodical encounters with younger minds the re-invigorating effects which explain his phenomenal vitality.

Correcting History.—Dr. Edward Worthington, a delightfully garrulous "old-timer," furnishes *The Medical Age* his "Reminiscences of Early Practice," full of sound sense, kindly humor and "paukie" Scotch wit. Telling of the days when "a medical man would as soon have dreamed of going to church without his prayer-book, or of going to bed without saying his prayers, as of going out on his daily round of duty without his lancet-case in pocket," he recalls the fact that the "fat friend" of Beau Brummel's sarcasm, the profligate and licentious George IV., lost first eighty ounces and, within twenty-four hours, another fifty ounces of blood on account of a cold. Dr. Worthington prefaces the account thus: "When George, the great Father of the American Republic, lay dying, at midnight, Jan. 29, 1820—I do not mean George Washington, but the other George, the Third George,—his most affectionate son the Prince Regent, 'the First Gentleman in Europe,' was unable to attend at his father's death-bed." Thus has it remained for a medical man, with his professional penetration in determining first causes, to vindicate the truth of history and ascribe the paternity of this Republic to its proper source.

In Borrowed Plumes.—Commenting editorially upon the scurrile jests upon doctors indulged in by *Life*—a comic weekly paper—the *New York Medical Record* takes occasion to show up the professional humorist as a very cheap sort of a plagiarist. *Life's* definition of a doctor—"a person who, when you are ill, comes and guesses what is the matter with you"—is shown to be an adaptation of, but not an improvement upon the original given by Voltaire in 1740, to-wit: "A doctor is a person who pours drugs, of which he knows little, into a body, of which he knows less." Our scholarly contemporary cites other illustrations to show that the material for similar definitions of doctors exists in literature from ancient to modern times; that the sum and substance of the medical jokes of the past two thousand years, or at least samples of them, are all in print and form a part of accessible literature. "We could refer the amiable malefactor who writes his weekly medical jokes in this New York paper to the volumes in which all the above facetiæ are compiled, but he shows that he possesses them." After which neat hit the *Record* asks *Life* why—if it can not give the world some new medical jest nor give proper credit for its borrowed ones—it can not sometimes be pleasant and show the other side. "Even Voltaire, who was a bigger man after all than the average New York jest-maker, said: 'Nothing is more estimable than a physician who, having studied nature from his youth, knows the properties of the human body, the diseases which assail it, the remedies which will benefit it, exercises his art with caution, and pays equal attention to the rich and the poor.'" It strikes the *JOURNAL* that, big as the philosopher of Ferney may have been, the comparison of the professional libellist and lampooner who made a scoff of religion—"Deo crevit Voltaire"—and prostituted his talents through sheer wantonness, with the "average New York jest-maker" who distorts the truth for the sake of a facile sneer at vivisection and "conveys" his slanders of the medical profession from the "Joe Millers" of the past, is particularly felicitous.

Epileptic Colony in Sweden.—More than twenty years ago a Swedish lady, Madame De Ramsay, began a small Home for Cripples and Epileptics, at Wilhelmsro. The support given by benevolent citizens has been sufficient to maintain the institution according to the plans of its founder, down to the present time, but advancing years and other causes have impelled the lady founder to look forward to soon laying aside this work, and she is anxious to secure an endowment for the colony before she passes the management over to other hands. In a recent report, she has sketched her relations to the cause of the epileptics and others. A portion of this report is given below:

"Several members of our royal family became interested in the progress of the work, and at length Parliament resolved to give grants for the keeping of epileptic children in suitable homes, and institutions sprang up as seedlings from the plantation at Wilhelmsro.

"This summer a greater joy has been afforded me. A committee has been formed in Gothenburg of friends who, recognizing the necessity of such homes, and appreciating the excellent arrangements and the self-sacrificing management of the Wilhelmsro homes, wished to show their respect in this matter by purchasing 'The Hope,' the largest of the homes, fitted up for thirty children. The committee, moreover, is henceforth answerable for the funds. During the past winter, when lying at the point of death, it was my constant cry, 'O Lord, let not these unhappy children be scattered in a world that does not care for them.' The prayer was heard, life was prolonged, and true friends came forward, which greatly hastened the recovery.

"But for that timely relief it would not have been possible to open a very much needed new home at Wilhelmsro, 'The Refuge,' for the worst cases among epileptic children, those who, in addition to their great affliction of epilepsy, are deaf, dumb, idiotic, paralytic, and sometimes blind! The sufferings of these unhappy beings are greater than can be described, and I have longed for years to provide for them a 'refuge.' It will be a great satisfaction to spend the last years of a long life in providing for these unfortunates, and I hope that in due course the same committee will also be responsible for 'The Refuge.' But the future is left to God; the present object is to work for the neglected beings, and, in the cases of cripples and epileptics, to press upon the public the duty of making humane provision for their needs."

Washington Notes.

GARBAGE REMOVAL.—During the stay of the Pythian Encampment, garbage will be removed daily in order to better protect the health of the city.

PHYSICIAN TO DISTRICT JAIL.—Dr. D. K. Shute, Professor of Anatomy in the Columbian Medical College, has been appointed Visiting Physician to the District jail.

HEALTH OFFICE APPOINTMENT.—Dr. Austin O'Malley has been appointed by the Commissioners, Chief Medical Sanitary Inspector in the Health Department *vice* Dr. Osman, deceased.

CONTAMINATED PUMP.—The Health Officer has forwarded to the Commissioners two reports of Dr. Walter Reed, of the Army Medical Museum, giving the results of bacteriologic examination of water from the well, corner of Sixth and O Streets northwest. Both reports show conclusively that the water is contaminated by fecal bacteria.

ANATOMICAL BILL.—Congress has not as yet agreed to the bill for the promotion of anatomical science and to prevent the desecration of graves, which provides that bodies of paupers may be given to medical colleges under certain stipulations. This is practically the same bill that was vetoed by President Cleveland during his first administration.

CONGRESSIONAL LIBRARY.—The annual report of Librarian Spofford, which has been presented to Congress, shows that the library contains 695,880 volumes and 223,000 pamphlets; 18,594 volumes were added during the present year, and 53,956 copyright entries were made. Of these 18,498 were books, 16,273 musical compositions, 11,094 periodicals, 4,920 photo-

graphs, 1,810 chromos, 1,814 maps, 918 lithographs, while the balance consisted of paintings, maps, chromos, etc.

PORTABLE DISINFECTING CHAMBERS.—The Marine-Hospital Service has completed two portable disinfecting chambers at Philadelphia, Pa., which are to be used when necessary for municipal disinfecting. The apparatus consists of one large chamber for steam and one for sulphur fumigation. They may be brought to Washington, for use in the Health Department if necessity require.

AN ABORTIONIST IN CLOSE QUARTERS.—Dr. Edward Leon, an "irrigator," who was last fall convicted of having produced an abortion which resulted in the death of the child, was first found guilty of murder in the first degree and allowed a new trial, resulting in a verdict of manslaughter, desires a stay of sentence and a third trial. He is innocent, so he says, and claims to be able to prove that the crime was committed by another doctor.

DEATH OF DR. OSMUN.—Dr. Charles J. Osmun who for several years was Chief Medical Sanitary Inspector in the District Health Office, for infectious diseases, died on the 14th instant after a three days illness with malignant diphtheria. This is a particularly sad death, the disease being contracted during the faithful discharge of duty. Dr. Osmun was unmarried. The Medical Society and Health Department held special meetings and adopted appropriate resolutions of respect.

ASSISTANT CORONER FOR THE DISTRICT.—The act creating the office of Assistant Coroner for the District has become a law. This will prevent, after he is appointed, a repetition of the embarrassment arising during the "Ford's Theater" inquest when it was announced that only the Coroner could conduct the investigation. The inquest was about completed by the Coroner's substitute when this fact was brought out by the attorneys, and the proceedings began anew by the late Coroner, Dr. De Witt C. Patterson then confined to bed by illness, but who notwithstanding, reported for duty and conducted the case, greatly to the detriment of his health.

THE PRESIDENT has signed the bills to prohibit the interment of bodies in Graceland Cemetery and to provide for the sale of the property of that cemetery and the removal of the bodies already interred there. This cemetery has been outgrown by the surrounding neighboring community and almost surrounded by dwellings. It has been deemed a matter of only common precaution to remove the possibility of infection from the presence of these bodies in the midst of a thickly populated community, and this enactment is in the line with all similar legislation in other cities to remove burial grounds beyond municipal limits, and provide for the sale of new tickets by the street railway and herdic companies of the District. The nuisance of old, tattered and germ-laden tickets has been borne more or less patiently by the patrons of the local companies for many years, and this bill granted great relief by compelling the companies to issue their tickets in sheets of six for 25 cents and to cancel each ticket presented for fare so that it could not be used again. An appropriate penalty was provided to punish proved violations of the law. Since the expiration of the thirty days' margin granted to the companies after the passage of the act there has been inaugurated an era of clean, crisp and wholesome trip slips such as has never before been seen in Washington.

Philadelphia Notes.

The health of the city during the heated term has been remarkably good. With the exception of a limited outbreak of diphtheria in one of the suburbs, there has been nothing that approached an epidemic, although some instances of the contagious zymotic diseases have occurred and a few cases have been received into the municipal hospital; ty-

phoid fever cases also are reported occasionally. It is evident that the efforts put forth by the Board of Health and private citizens, under the stimulus of the cholera scare for the last two years, have resulted in a greatly improved sanitary condition of the city. The back streets and alleys have been kept clean, public bath houses have been well patronized, the food-supply is watched and, in particular, dishonest dealers in milk have been frequently detected and punished, so that there is a distinct improvement in the quality of this staple food article. In this connection might be mentioned an agency that has not been without its favorable influence upon the lives of the children. A little more than two months ago Rabbi J. Leonard Levy, of this city, founded the Philadelphia Sterilized Milk and Ice Society for the purpose of supplying these necessities to the poor at cost, during the summer. Mayor Stuart consented to act as President, with Rabbi Levy as First Vice-President, and the City Treasurer, Mr. McCreary, as Second Vice-President. This charitable work appealed to the benevolent and like the similar organization in New York City, it was at once successful. Since it began operations, it has sold over 7,300 bottles of sterilized milk, several tons of ice, beside fresh milk and infants' food. Disinfectants have also been distributed with directions as to their use. In one week, 13,509 persons were helped by this organization. The receipts have averaged about 3 cents for each purchase. The Society has now five stores or depots in different parts of the city and employs about a score of persons. It is difficult to fully estimate the practical good which such a work may exert upon the health and mortality of the crowded portions of the city. It is strictly in line with the college settlements and guild houses, which have been doing a civilizing and humanizing work in the congested precincts for several years, and with encouraging results.

Another agency, which should not be overlooked, on account of its effects upon the children particularly, is the Sanitarium Association for Children, which has its plant situated on the New Jersey side of the Delaware River about twelve miles below Philadelphia. This noble charity keeps two large steamboats running between the city and the large grounds; where the children are brought by their care-takers to spend the day under the trees, where hammocks, swings, etc., are provided. There is also a small well appointed hospital for children, who require attention or are too ill to return to the city, and who can here receive proper medical care from the resident physicians and nurses. The entire service is free, including a luncheon both for children and care-takers. Up to the evening of August 16, 139,959 persons, (including adults with children) had been admitted in 69 days, an average of 2,332 per day. It is not unusual, on a hot day, to have more than double this number to enjoy the hospitality of the Association. A new bath house for infants and small children has just been put into use and is well patronized.

The Children's Country Week Association, which has sent several hundred children out of the city during the hot weather, has undoubtedly contributed to the improved health of the city. The city streets are now cleaner than ever before, owing to the fact that the railway companies have introduced the trolley system very generally; thus doing away with hundreds of horses, and also by city ordinance they were obliged to re-pave the streets with asphalt or some other improved pavement, so that the cobble-stone pavement has disappeared from all the principal streets.

The water supply of the city will soon be increased by the completion of the new Queen Lane reservoir, consisting of two basins, brick and concrete lined, with a storage capacity of 386,000,000 gallons of water. A system of sand filtration is under consideration and probably next year will be introduced, which it is hoped will have the same effect here as in the cities of Europe, and greatly reduce cases of typhoid fever and bowel disorder.

The diminished mortality from sunstroke of late years is attributable in part to the popular appreciation of the danger of alcoholic drinks and the greater care in their use

during hot weather, and in part to the fact that patients affected upon the street are rapidly taken in the city ambulances to the hospitals, in nearly all of which cases of insolation are treated in tents (or in the open air) and promptly cooled down with ice or cold bathing.

Among the numerous agencies tending to reduce the mortality of the city may also be mentioned the action of the City Board of Health in circulating leaflets on "The Care of Infants in Hot Weather," and "The Prevention of Tuberculosis." This has doubtless led to a reduction in the number of cases of summer complaint, and consumption.

Medical College Notes.

DR. GEO. M. PHILLIPS, of Maysville, Kentucky, has been called to fill the Chair of Genito-Urinary Surgery in Barnes Medical College, St. Louis. Dr. Phillips is a graduate of the College of Physicians and Surgeons, of Baltimore, and goes to his new field of labor after an abundant clinical experience and with the best of home and foreign recommendations.

New Orleans.

DR. J. D. BLOOM, formerly Assistant House Surgeon, upon the death of Dr. Albert B. Miles, was promoted to the House Surgeonship of Charity Hospital. Two Assistant House Surgeons were appointed on equal footing, Drs. W. E. Parker and H. Mark Fortier. All of these gentlemen are graduates of the Medical Department Tulane University of Louisiana, and reflect great credit on the younger members of the New Orleans profession.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from August 18, 1894, to August 24, 1894.

Capt. ALFRED E. BRADLEY, Asst. Surgeon U. S. A., is granted leave of absence for one month, with permission to apply for an extension of one month.

Capt. JOHN L. PHILLIPS, Asst. Surgeon, is granted leave of absence for two months, to take effect on or about Sept. 1, 1894.

First Lieut. MADISON M. Brewer, Asst. Surgeon, is granted leave of absence for three months, to take effect on or about Oct. 1, 1894.

Capt. WILLIAM H. CORBUSIER, Asst. Surgeon, is granted leave of absence for one month, to take effect on being relieved from duty at Ft. Supply, O. T.

First Lieut. WILLIAM H. WILSON, Asst. Surgeon, will be relieved from temporary duty in the Department of Dakota by the commanding General of that Department, when his services are no longer required with troops in the field, and will return to his proper station.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 25, 1894.

P. A. Surgeon I. W. KITE, ordered to hold himself in readiness for orders to the U. S. S. "Constellation."

P. A. Surgeon T. B. BAILEY, ordered to hold himself in readiness for orders to the U. S. S. "Machias."

The Journal of the American Medical Association

VOL. XXIII.

CHICAGO, SEPTEMBER 8, 1894.

No. 10.

ORIGINAL ARTICLES.

ARE LOW DEGREE LENSES "MERELY OF MYTHICAL VALUE?"

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY HORACE M. STARKEY, M.D.

CHICAGO.

The leading editorial of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, of Feb. 3, 1894, entitled, "Superfluous Spectacles" has attracted much attention and elicited considerable discussion and criticism. Most critics have, so far as observed by the writer, agreed that the editorial is, in the main, timely and excellent. The object of the editor was to enter a protest against what seems to him to be a growing tendency on the part of many ophthalmologists to find in the eyes a cause for all the ills to which flesh is heir, and also to fear that ills will come to the most vigorous if any error of refraction is allowed to go uncorrected. As a protest against the prescribing of spectacles without a clear indication for their use, and against considering the eye apart from the organism as a whole, we believe it is strong and timely.

The editor, however, not only protested against the prescription of lenses without clear indications for their use, but he also stated that certain lenses, namely spheres of less than 0.75 D. and cylinders of less than 0.50 D. were never indicated because they are valueless and so should never be prescribed. All of these low degree spheres and cylinders are to him "superfluous spectacles." In this your essayist believes he is mistaken, and to bring out the reasons for this belief as clearly and forcibly as possible is the object of this paper. As the editorial in question may not be familiar to all present, some quotations will be made from it, followed by extracts from a letter by the writer, commenting on this editorial, published in the same JOURNAL two weeks later:

QUOTATION FROM EDITORIAL.

"Of all facts in medicine, none are the better founded than the knowledge that even moderate degrees of far-sightedness or astigmatism lead in many persons to discomfort in the use of the eyes and often to headaches and other nervous disturbances. The basis for the rational prescription of convex glasses and cylinders is hence as positive as the results are gratifying.

"But does every optic defect need correction and is every case of painful vision curable by glasses?"

"No ophthalmologist can overlook the fact that many persons can tolerate moderate optic defects and some even high degrees of ametropia without ever suffering therefrom. . . .

"On inquiring into the general health of patients

complaining of eye-strain and its consequences, it becomes apparent that the amount of optic imperfection which can be tolerated without distressing sensations depends on the vigor of the system at large, and especially the condition of the nervous system. It is not rare that patients call for correction of moderate far-sightedness or astigmatism, accept the glasses with satisfaction for the time, but lay them aside as unnecessary after some improvement of their general condition.

"Since errors of refraction are stationary conditions, (except progressive myopia which is foreign to this topic) there is hence no object in correcting them, unless they cause some annoyance, be it by poor sight or in the form of discomfort or headache or distress of any kind. If, however, any discomfort referable to the eyes is present, what is the lowest amount of ametropia which can be considered as the cause of the eye-strain?"

"It is the general experience that a hypermetropia of 0.75 D., or any degree of hypermetropia uncorrected to the extent of 0.75 D. can cause distress in many persons. But that a hypermetropic eye can appreciate a correction of half a dioptre or less will not be admitted by most observers. There is more diversity of opinion as to the amount of astigmatism which may require correction. While again 0.75 D. represents the lowest cylindrical lens which is ordinarily of benefit, cases do occur beyond doubt in which half a dioptre of astigmatism leads to discomfort or headaches.

"Such cases, however, are exceptional and occur as a rule only when the general health is below par. It is true that a cylinder of 0.25 D. is not only employed but even highly recommended by a few prominent oculists, but they have as yet furnished no proof that such lenses benefit their patients. The majority of oculists have learned from their own experience, as well as from the failures of the champions of the 0.25 D. cylinder, that such weak glasses are merely of mythical value."

QUOTATION FROM LETTER.

"The editorial in the JOURNAL of February 3, under the above title, 'Superfluous Spectacles' is on the whole excellent. There are some points, however, which, it seems to me are open to criticism. You seem to argue, though that is not very clear, that if a patient when out of health has glasses prescribed which he wears with relief and comfort until the general health improves and then voluntarily relinquishes them, that the glasses were of no service. As well might you argue that the tonic of restorative medicine taken when out of health was of no benefit because not needed when the health is restored. I believe it is a very common practice with oculists (it certainly is with me) to prescribe lenses with the distinct expectation that they can be taken off when the general health and the eye health improves. The

rest given to the eyes by the glasses assists the eyes to so recuperate that they may be used comfortably without glasses; and the relief given thereby to the nervous and muscular systems, is, I am sure, a potent factor in the general restoration of health. It is not at all uncommon to find young persons suffering from almost constant headache from eye-strain, and in whom the headache is relieved at once and entirely by proper lenses, after a time gradually leaving off those lenses without a return of the headache. Does that prove that the glasses were of no use? Does it not rather prove that the eyes have been so strengthened and improved by the glasses that they are now able to do their proper work without the fatigue and pain formerly experienced? In such cases, where there is a moderate degree of ametropia only, I invariably instruct my patients that the glasses are a means, not an end, and that it is to be hoped that they may later be able to discard them wholly or in part.

You ask: "Does every optic defect need correction?" Certainly not, nor do I think that any prominent ophthalmologist so teaches. It seems to me that the indications for lenses are and should be very distinctly kept in view. They are but two; the relief of discomfort in the use of the eyes and the improvement of vision. If there is no discomfort from the use of the eyes but vision is improved by lenses the patient may, I think, elect whether he will wear glasses or not. If the bother of wearing glasses is greater than the pleasure of improved sight he may with propriety refuse them. (Except in progressive myopia which is foreign to this topic.) If, on the other hand, there is discomfort from the use of the eyes which can be relieved more easily by the use of the lenses than by any other means, whether the required lens be of high or low power, such lenses should be prescribed and worn so long as, and no longer than they are beneficial. And this leads to the consideration of what it seems to me is a most important misconception in your editorial, when you comment on the use of low degree spherical and cylindrical lenses. You argue that the eye can not appreciate a less degree than 0.75 D. sphere and a less degree than an 0.50 D. cylinder. If this were so it would very much simplify our trial cases of test lenses. It is illogical to say that the eye can not appreciate less than 0.75 D. S. below 0.75 D., and yet can appreciate a shorter interval above that; or that the eye can not appreciate less than 0.50 D. C. below 0.50 D., and can appreciate less than that above. So that if your statement is correct our trial cases instead of having, as usually now, twelve pairs each of spherical and cylindrical lenses up to 3.00 D. need have but four pairs of spheres, viz: 0.75 D., 1.50 D., 2.25 D., and 3.00 D., and six pairs of cylinders, viz: 0.50 D., 1.00 D., 1.50 D., 2.00 D., 2.50 D., and 3.00 D. The fact is, however, that many eyes can appreciate a difference of one-fourth of a dioptré and even one-eighth of a dioptré in weak spheres or cylinders. But the ability of the eye to appreciate such small differences is not proof that such differences are of practical importance; that must be determined by clinical experience. In regard to that you say: "The majority of oculists have learned from their own experience, as well as from the failures of the champions of the 0.50 D. cylinder, that such weak glasses are merely of mythical value." I think you are mistaken in that statement. So far as I have been able

to learn and observe, the oculists who believe that such weak glasses are of merely mythical value have not used them. They do not believe that such lenses can have any value, and so have never tried them.

Again you say: "It is true that a cylinder of 0.25 D. is not only employed but even highly recommended by a few prominent oculists, but they have as yet furnished no proof that such lenses benefit their patients." Now that statement surprises me very much, for I thought a great deal of proof of such benefit had been furnished. If it has not been presented it should, if available, be before the profession, and I will endeavor to furnish the proof to establish the fact, if it is a fact, that the 0.25 D. cylinder is a most valuable therapeutic agent."

"The majority of oculists have learned from their own experience, as well as from the failures of the champions of the 0.25 D. cylinders that such weak glasses are merely of mythical value."

In this one sentence of the editorial are three disputed points which we will now consider: 1, is the 0.25 D. cylinder of merely mythical value? 2, do the majority of oculists so regard it? 3, have a majority of oculists learned this from their own experience? In all of these points the writer believes the editor mistaken, but desires to view the subject from a calm scientific standpoint and if he himself is the one in error will still welcome the truth. The last two of these questions are comparatively easily determinable by simple inquiry; while the first may be investigated from three standpoints: 1, that of personal experience and observation; 2, the teachings of the textbooks; and 3, the personal experience and observation of other workers in this special field.

To assist in answering these questions the writer sent the following letter to one hundred ophthalmologists scattered throughout the land:

"Dear Doctor:—There appears to be much difference of opinion among ophthalmologists as to the value of low degree lenses. To assist in solving the problem will you kindly answer the following questions:

"1. Do you ever prescribe cylinders of less than 0.50 D.? or spheres of less than 0.75 D.?"

"2. If no. Have you ever prescribed such lenses and if so what are the reasons for discontinuing them?"

"3. If yes. In what cases do you prescribe them and what evidence have you of their value?"

Of the 100 so addressed, 75, located in 26 States replied. It would seem as if these replies must give some indication of the practice of ophthalmologists in general in this country. Most of those addressed were unknown to the writer except by reputation, and of very few of them was the practice in regard to low degree lenses known. Under these circumstances it is hardly to be supposed that a great majority of them should have been taken from a minority of oculists. The replies received are surprising, in that they indicate that a very large proportion of oculists employ both weak cylinders and weak spheres; a few only, prescribe one but not both, and yet fewer prescribe neither. Thus we find that of the seventy-five, sixty-six replied, Yes; they do use the 0.25 D. C. and the 0.50 D. S.; four reply, Yes, but seldom; three use the spheres but not the cylinders, and but two answer no, and one of those the writer of the editorial in question. Seventy do prescribe the 0.25 D. cylinders and five do not, and of the five, three prescribe the 0.50 D. spheres.

In answer to the second question there are replies from four; two who say that they do not now use

these weak cylinders because they have no evidence of their value, but do not state if they have ever used them; one who says he has quit because he is convinced that they are useless; and one who says he rarely uses them now, because he finds that atropia either shows at least 0.50 D. of astigmatism present or none at all.

The answers to the third question are fairly uniform, most of the answers being, in general terms, That the low degree lenses are prescribed in cases where persistent asthenopic or reflex symptoms are associated with slight errors of refraction, and the evidence of their value is the disappearance of these symptoms when the proper lenses are adjusted. A number of replies state that in many cases the symptoms remain absent so long as the lenses are worn and return at once when the lenses are omitted. I have tabulated these seventy-five replies, all that were received.

| OCULIST. | REPLIES TO QUESTION 1. | REPLIES TO QUESTIONS 2 AND 3. |
|--------------------|---|---|
| Allen, H.P. | Yes; 0.25 D. C. constantly; 0.50 D. S. also. | Relief of asthenopia and headaches. |
| Allport, Frank. | Yes; skeptical as to S. Positive of value of 0.25 D. C. | Relief of headaches, asthenopia, etc., in H. as obtain results difficult or impossible without their use. |
| Ayers, S.C. | Yes; 0.25 D. C. frequently; 0.25 or 0.50 D. S. often, especially in school children, frequently combined. | Improvement of vision and addition to comfort of patient. |
| Aschman, G. A. | Yes; but not till other means of relief have failed. | In cases of asthenopia after other means as rest, tonics, etc., have failed. Usually young teachers, students, etc., using eyes much. Evidence of value relief from asthenopia. |
| Baker, A.R. | Yes; very many such cases. | In all cases where there is headache or other evidence of asthenopia, particularly cylinders where axes are irregular. Most happy results in relief of symptoms. Low degree of ametropia cause more severe symptoms than high degree. |
| Blitz, Adolph | Yes; cylinders 0.25 D. and 0.37 D., sometimes 0.25 D. S. | Eye-strain with headaches, irritation of eyes, etc. Relief of these symptoms. |
| Bryant, D. C. | Yes. | Where there are symptoms of asthenopia, I correct errors of high or low degree. Complete relief of such symptoms. Asthenopia. Relief of symptoms. |
| Buckner, Jas. H. | Yes; rarely, 0.25 C. alone, frequently combined with 0.25 0.50 S. | Asthenopia. Relief of symptoms. |
| Carrow, F. | Yes; 0.25 C. and 0.50 S. and compounds of these. | Cases of asthenopia among the 4,000 students under my observation. Relief of asthenopia. Have exceptional opportunity to observe cases for long periods in Michigan University, State Normal School, etc. |
| Carvelle, H. D. W. | Yes; very often. | Cases of headache and inability to use eyes without discomfort or where sight is materially improved. Relief of asthenopia and improvement of vision. |
| Cheatham, Wm. | Frequently, especially the cylinders. | To improve vision and relieve pain, blurring, headache, etc. Relief of these symptoms. |
| Chisolm, J. J. | Very decidedly, yes. | 0.25 D. + — Most useful in list especially when astigmatism is oblique asthenopia. Change from inability to use eyes without headache to use all day without trouble and return of headache, etc., when lenses are left off. |
| Colburn, J. E. | Yes. | Asthenopia not otherwise relieved and reflex irritation not otherwise explained, in which low degrees of error exist. Cessation of symptoms so promptly follows that no other cause of relief can be assigned, other means having failed. |
| Cotter, Robt. O. | Yes; certainly and frequently. | Almost altogether in cases of H. and H. a. Comfort to patient arising from their use best evidence of value. |
| Coleman, W. F. | Cys. very constantly, 0.50 S. occasionally. | When they improve vision or relieve asthenopia. Simple 0.25 D. C.'s give remarkable relief in a few cases. |
| Connor, Leartus. | Yes; for more than twenty years. | Same class cases as require stronger lenses and relief of the same. Same relief from eyeache, headache, weariness, photophobia and other evidences of exhaustion as with stronger lenses when they are needed. Relief constant and permanent. |

| OCULIST. | REPLIES TO QUESTION 1. | REPLIES TO QUESTIONS 2 AND 3. |
|---------------------|--|--|
| Chase, John. | Yes; cys. frequently for ten years with satisfactory results. S. less often. | In cases of eye-strain where ametropia shows no higher degree of error. Relief of unpleasant symptoms. |
| Dickinson, Frances. | Yes; particularly cys. in oblique astigmatism. | In cases of asthenopia the weak lenses when they correct the error give the same relief that stronger lenses give in cases for which they are suitable. |
| Dunlavy, J. C. | Yes; often, because eyes demand them. | A large number of cases of asthenopia fully relieved by their use. |
| Fox, L. Webster. | Yes; both S. and C. daily. | Asthenopia and headaches. I consider these glasses most valuable. |
| Frothing-ham, G. E. | Yes. | In cases of asthenopia showing this amount of error under a mydriatic and am satisfied with the relief in a majority of cases. Formerly ignored these low degrees but soon became convinced this was an error. |
| Gardiner, E. J. | Yes; C. frequently; S. seldom. | It has been my experience that quite a number of asthenopic symptoms are caused by astigmatism of less than 0.50 D. and proper correction has relieved the difficulty, hence I prescribe them. |
| Gould, Geo. M. | Most certainly, yes. | Would not cure or keep my patients if I did not do so. Anisometropia, unsymmetric astigmatism and even in isometropia and symmetric astigmatism where relief of symptoms or occupation demands. Asthenopia and some reflex troubles that can not otherwise be explained. Relief of symptoms. |
| Hawley, Clark W. | Yes; more than of higher degrees. | Where vision is improved or asthenopia relieved. Asthenopia from ametropia is caused by the effort put forth to secure a sharp image, not upon amount of ametropia. I correct any amount of ametropia which diminishes visual acuteness or leads to fatigue. |
| Hobby, C. M. | Yes. | I prescribe them whenever on trial they render use of eyes at close work more comfortable. |
| Holmes, E. L. | Yes. | In the same cases and on the same principles where with higher degrees of error stronger lenses would be given and with the same results. |
| Hotz, F. C. | Yes. | Persistent asthenopia, aggravated by eye-work without other discoverable cause. Freedom from the previous pain, discomfort, congestion, irritation, etc., increased ability for eye-work and recurrence of symptoms on leaving off glasses. |
| Jackson, Edward. | Yes; but not often except in combination. | In all cases where necessary to relieve strain, I have for twenty-five years found them very serviceable and satisfactory. |
| Keyser, Peter D. | Yes; frequently. | Cylinders in one eye, if either has marked ametropia. Spheres not infrequently in young people of nervous temperament. |
| Knapp, Herman S. | Cys. exceptionally, Sph. frequently. | Not very frequently and only in cases where on trial decided relief to asthenopia or decided improvement in vision is obtained. |
| Kollock, Chas. W. | Yes. | Asthenopia due to slight errors. In a comparatively large proportion of cases, relief is obtained by their use. |
| Maire, L.E. | Yes. | Cases (mainly stenographers, book-keepers, teachers, sewing girls, etc.) with slight refraction errors with symptoms of eye-strain which are relieved by careful adjustment of lenses tried for several days. Relief of symptoms of eye strain. |
| Mann, Win. A. | Yes. | In cases of accommodative asthenopia, mostly in young people, marked relief is obtained by such lenses. |
| Miller, R. W. | Yes; cylinders often, S. occasionally. | Students and sewing girls. They give relief. |
| Minney, J. E. | Yes. | In all forms of asthenopia, especially ocular headaches which are, as a rule, relieved by these glasses. |
| Mittendorf, B. L. | Yes; frequently, especially cylinders. | Cases with frontal headaches and generally irritable condition of the eyes. Complete relief and ability to use the eyes comfortably. |
| Montgomery, W. T. | Yes; cylinders frequently, S. exceptionally. | The cylinders in cases of oblique astigmatism with asthenopia or headache in most cases give relief to the patient. |
| Moulton, H. | Yes; cylinders frequently, S. occasionally. | Correct all cases of astigmatism to 0.25 D. Give 0.50 D. or less S. as partial correction of higher degree of hyperopia. Relief from symptoms. |
| Murrell, Thos. E. | Yes; habitually and daily. | Asthenopia and other troublesome eye symptoms not relieved by other means. Relief of these symptoms. |
| Oliver, Chas. A. | Yes, for thirteen years. | Asthenopia. Relief of symptoms. |
| Pinkard, Chas. P. | Yes. | Asthenopia. Relief of symptoms. |

| OCULIST. | REPLIES TO QUESTION 1. | REPLIES TO QUESTIONS 2 AND 3. | OCULIST. | REPLIES TO QUESTION 1. | REPLIES TO QUESTIONS 2 AND 3. |
|----------------------|---|--|--------------------------|--|--|
| Price, G. H. | Yes; rather frequently. Nearly 50 per cent. of refraction cases receive one or other alone or in combination. | All cases of low degrees of astigmatism are corrected. Relief of distress in use of eyes. | Wood, Casey A. | Yes. | Most cases of astigmatism against the rule. Nervous symptoms, as asthenopia and weakness of accommodation, headache, blepharitis, general relief from symptoms. |
| Prince, A. F. | Yes; in 100 consecutive cases (200 eyes) 36 eyes received C. less than 0.50 D. and 50 received S. less than 0.75 D. | Cases with low refraction error with asthenopia, ocular headache or neurasthenia, not otherwise accounted for. Testimony of patient as to relief by use of glasses and the return of symptoms when glasses are discontinued. | Würdemann, H. V. | Yes; constantly as to Cys.; rarely as to S. except in combination. | Correct low degrees under same circumstances as I would correct higher degrees and with equally good results. Relief of asthenopia and occasionally of reflex disturbances as chorea. |
| Randolph, R. E. | Yes; 0.25, 0.50 D. cylinders more frequently than any others. S. less frequently. | In all cases where astigmatism of 0.50 or less is present. | Wilder, Wm. H. | Yes; both. | In persons with low degree of error who use their eyes much at close range presenting symptoms of asthenopia; as smarting pain in head and eye-balls, blepharitis, general debility, etc. Relief from symptoms. |
| Randall, B. A. | Yes; 0.37 or 0.25 Cys. not infrequently. Sphericals occasionally. | Patients having low errors with asthenopia not relieved by tonics, hygienic and other means; retinal and choroidal disturbance, etc., call for correction of those errors. Relief of distress, increased capacity for eye-work and disappearance of fundus symptoms. | Bettman, B. | Yes; but seldom C. and S. very seldom. | Relief of asthenopia when present. Never given simply because slight error is found. The prescribing of spectacles has been much overdone. |
| Richey, S. O. | Yes. | Always correct the static refraction fully, but do not often find these low degrees, not due to spasm. | Fiske, Geo. F. | Yes; very seldom. | In rare cases of anisometropia, often where from ill-health use of eyes is difficult except under most favorable conditions. Evidence of value cessation of headaches and ability to use eyes comfortably. |
| Risley, S. D. | Yes; frequently. | Anisometropia, antimetropia and asthenopia, especially in neurotic individuals. Much clinical evidence. | Ware, Lyman Young, H. B. | Yes, but very rarely. Seldom now. | Eye-strain, recovery or restoration of normal condition. Under atropia I usually find more error or none at all. In anisometropia of low degree I prescribe crossed cylinders. Occasionally in neurasthenics who have much eye-work to do I prescribe 0.50 S. I believe they usually have really no value, the burden of the glasses being greater than the burden of the error. |
| Ray, J. M. | Yes; where symptoms demand. Never simply because that amount of error exists. | Eye-pain, etc., give proper glasses whether of low or high degree. Relief of the trouble complained of. | Dowling, F. | Cys., no; S. rarely. | I do not think such a low degree of astigmatism needs correcting. |
| Savage, G. C. | Yes. | Correct all astigmatism from highest to lowest degree in all cases. | Erwin, A. J. | Cys., no; S. sometimes where accurate vision is required. | I have quit prescribing cylinders of less than 0.50 D., as I am convinced that as a rule a low degree astigmatism is less hurtful than the corresponding cylinders. |
| Schneider, Jos. | Yes; very often. | Cases with small error and large nervous manifestations. Relief of very distressing symptoms. | Sinclair, J. G. | Cys., no; spheres, yes. | In low degrees of H. and weakness of muscle of accommodation. |
| de Schweinitz, G. E. | Yes. | In all cases in which low degrees of astigmatism are the evident cause of asthenopia in the widest acceptation of the term; because an abundant experience demonstrates that relief follows such practice. | Gibson, Robt. D. | No. | With rare exceptions I obtain as good results with plano lenses as with these. (Try it). |
| Scott, X. C. | Cys. yes. Sph. except in combination, no. | Cases with asthenopic symptoms and conditions. Cases who could do no work with their eyes without headache which have been entirely relieved. | Gradle, Henry. | Very rarely, if ever, now. | No evidence that they are of any value. |
| Smith, F. T. | Yes. | Use them empirically where they seem to relieve asthenopia. In a few cases relief has been complete; in most the glasses were rejected after a few days. | | | |
| Standish, Myks. | Yes. | In all cases in which the asthenopia or nervous symptoms, headache, etc., are prominent. The evidence of my own eyes, in which 0.25 D. makes the difference between comfort and great discomfort. | | | |
| Stevens, Geo. T. | Yes; but Cys. rarely, now 0.50 D. S. frequently. | Rarely now prescribe 0.25 D. except combination with higher power. Usually 0.25 of astigmatism does not cause annoyance unless associated with muscular trouble and the correction of the latter is usually sufficient relief. | | | |
| Thompson, J. L. | Yes; most decidedly for past twenty-three years. | Evidence of value accumulates year by year. In hypermetropia, in simple astigmatism, and in compound hyperopic astigmatism. The evidence of patients is such in hundreds of cases that I am as fully convinced of the remedial power of these lenses as I am that the earth revolves upon its axis. | | | |
| Thompson, R. L. | Yes; 0.25 C. frequently. 0.50 S. occasionally. | Never simply to correct an error of refraction but to improve vision, to relieve eye-strain, blepharitis, marginalis, burning and blurring after use of eyes, headaches, pain in eyes, etc. Relief to patients from the symptoms mentioned. | | | |
| Tiffany, F. H. | Yes; both frequently. | In heterophoria I find them of value; they relieve asthenopia and assist in restoring balance and strength of the extrinsic ocular muscles. | | | |
| Turnbull, C. S. | Yes; with much pleasure and satisfaction. | Usually in cases of H., H., and a H., seldom in Ma and Ma M. | | | |
| Vermyne, J. J. | Yes; Cys. not very frequently. | Cases of constant headache and pain in eyes, etc., that have been treated by other means without relief, and other symptoms of irritation about eyes. As relief of these symptoms through rest of eyes and general treatment is always insisted upon, amount of benefit from lenses is difficult to determine. | | | |
| Wescott, Cassius. | Yes. | I correct all cases with measurable error if there are symptoms of eye-strain. Disappearance of headaches and other troubles under use of 0.25 to reappear when attempt is made to lay them aside. | | | |

So far as can be judged by these replies the editor is mistaken in questions two and three. We will now consider the first question. Is the 0.25 D. cylinder of merely mythical value, on the lines suggested? 1, personal experience; 2, the teachings of recent American text-books; and 3, the experience and observation of others.

1. Personal experience and observation. The writer has for many years prescribed the low degree cylinders rather frequently; the low degree spheres rather unfrequently. In the earlier years he believed, as he had been taught, that less than one dioptré of astigmatism was not worth considering. He, however, found cases requiring correction for less degrees, and gradually made more accurate correction until the 0.25 D. cylinder was reached. Then certain cases were found not entirely corrected by 0.25 D. C. and a little over corrected by 0.50 D. C. and so in 1890, 0.37 D. C. was added to the trial lenses and a little later in the same year 0.12 D. C., 0.62 D. C., and 0.88 D. C. An 0.12 D. lens has been prescribed a very few times, in cases requiring a higher correction for the other eye; 0.37 D. is used frequently; 0.62 not so frequently and 0.88 rarely. Cases are constantly seen where a difference of one-eighth dioptré in the strength of the correcting lens causes a decided difference both in the acuteness of vision and in the comfort of the wearer. This has been illustrated several times when a patient for whom 0.37 D. C. lenses has been prescribed returned with the statement that they did not seem right, and upon examination it was found that the optician had substituted

0.25 D. or 0.50 D. When the patient procured the proper glass the trouble disappeared. Those most frequently requiring these weak lenses are school-boys and girls about the age of puberty, medical and other students, stenographers, bookkeepers and typewriters, sewing girls and finally the neurasthenic and debilitated. Many of these require constitutional and other treatment, and most of them would recover completely with this and prolonged and complete rest for the eyes. But to many of them this rest is simply impossible, and anything which will assist them to bear their necessary load is eagerly accepted.

The lenses are fitted and prescribed with the utmost care. The general condition of the patient is noted, other sources of irritation are sought, and patients are encouraged to take rest, recreation and whatever general remedies may be indicated and to avoid the wearing of glasses unless really necessary. The refraction is carefully worked out and the lens theoretically required noted. But the crucial test is the actual wearing of the lenses. The patient is given lenses such as seem to be required, to wear about his regular work for one, two, three or more days, that he may determine with certainty the effect. This is easily done by having a number of pairs of frames with round cells and a number of cylinders of various numbers cut round so as to fit in these cells. The axis of the cylinder can thus be placed at any desired angle. Where doubt exists as to the value of the lens on trial, window glass so marked that the patient shall not know the difference is substituted and the patient tries that. Rarely one is found who accepts the latter as well as the lens, and he is advised to postpone wearing glasses and try other measures. A number of patients who have been wearing lenses a considerable time have, in the past few months, had their lenses replaced by window glass to see if they liked the one as well as the other. In none of these cases has the window glass given satisfaction.

A few illustrative cases will be given among those furnished by others. Very many equally striking could be added. Nearly all the patients whose cases are given, live in Chicago, have been frequently seen since the glasses were prescribed and have received the advice to try leaving them off but have been unable to do so.

2. The teachings of some of the more recent American and English text-books will be considered, the list not being complete as only the writer's library was consulted.

It is surprising to see how little is said upon this particular point in these text-books; even men who are well known, from papers read before this Section, to have very decided views on the subject, discussing it in a very indefinite and unsatisfactory manner.

Juler, "A Hand-book of Ophthalmic Science and Practice," 1893. Nothing about low degree lenses.

Roosa, "Schmidt-Rimple, 1889." Notes the necessity of correcting even low degree of astigmatism in presbyopia.

Nettleship, "Diseases of the Eye," 1890. Has only the most general statements concerning the relation of hypermetropia to asthenopia. Nothing as to the correction of low degrees of ametropia.

Tiffany, "Anomalies of Refraction and of the Muscles of the Eyes," 1894. Seems to advise the use of both weak spheres and cylinders in certain cases, but the teaching is not very clear or definite.

Fuchs, "Text-book of Ophthalmology, American

Translation," 1892. "The treatment of astigmatism consists in correcting it as precisely as possible by means of cylindrical glasses. In this way distinct vision can be secured and at the same time the asthenopia is relieved." This comprises all he has to say on the subject.

Berry, "Diseases of the Eye," 1893. Speaks of astigmatism of one-fifth or less as a cause of headache in certain cases, and of the necessity of correcting even low degrees of ametropia in such cases.

Noyes, "Diseases of the Eye," Second Edition, 1894, says: "The more pronounced are the asthenopic symptoms the more searching must be the search for astigmatism and the more accurate its correction. Then even slight degrees, 0.5 D. must not be neglected," p. 127. "But it must be emphasized that in susceptible persons small errors, especially hyperopic astigmatism calling for a cylinder with axis nearly vertical or even small degrees of hyperopia demand exact correction. As a fact, we have often to deal with a susceptible organism, and because it is easily set ajar we must remove even minute sources of disquietude." Pp. 197-198.

Norris and Oliver, "Text-book of Ophthalmology," 1893, are most decided and definite in their statements of the relation between slight ametropia and asthenopia and state that the correction of even 0.25 D. of astigmatism is often followed by marked relief of asthenopia and increase in visual power. Pp. 266 and 211.

De Schweinitz, "Diseases of the Eye," 1892. Advises in a general way the use of low degree S. and C. lenses but is not very definite.

The experience and observation of others. To obtain this the author wrote to fifty of those who had replied to the previous letter, asking that each one send notes of two cases for whom these low degree lenses had been prescribed, and that these be cases sufficiently long under observation to show results. Of these thirty-nine replied, most of them sending two or more suitable cases, some sending one and a very few sending cases that can not be used in this paper because not coming within the low degree lenses asked. To all of those, answering either of these letters, the writer wishes to extend most hearty thanks. Many have taken much time and trouble to look up cases and records. That work is appreciated and the author hopes the results will justify the labor. Fifty cases are given below, one only being taken from each contributor in most cases, and sufficient taken from the author's records to make the number an even fifty. While most of the cases are necessarily condensed to bring them in the limit of this paper, an effort has been made in each report to give the exact idea of the reporter and in as nearly his own language as possible. Many of those sending cases wrote that they could easily duplicate those cases by hundreds.

Case 1.—Reported by Dr. H. P. Allen. Miss P. R., age 19; student. General health good, November, 1888. Asthenopia; blurring after using eyes for an hour particularly at night; temporal headaches, not severe. Other members of family have similar eye troubles. V. 20-18 P. P. 3 inches. Correction R. 0.25 C. 30°. L. 0.25 C. 180°. Reported April, 1892, that she had entire relief. "Did not know that glasses could do so much for her."

Case 2.—Mrs. L. N., age 30. Perfectly healthy. September 1891. Reads several hours daily. Severe frontal pain sometimes with occipital pain and nausea after reading half an hour; has been using +0.50 S. without much relief. Orthophoria V. 20-18. Correction +0.25 C. 90° both. Relief almost immediate. Axes changed to 180° and without

patient's knowledge return of all trouble. Reported 1893: "I always use my glasses for near work. Never have any trouble now."

Case 3.—Reported by Dr. Frank Allport. Miss M. F., age 20. Healthy. Asthenopia, severe and protracted headaches. Competent oculists have fitted various convex spheres. No result. Tenotomy had been advised but declined. I find esophoria 4°. Homatropia correction +1.25 S. \odot +0.25 C. 90° each eye. Prescribed 0.25 C. 90° each eye for constant use. Patient perfectly well for one year and still wears glasses.

Case 4.—Dr. Frank Allport. G. G., boy. Age 14; good health. Headache in school, almost incessant winking and blinking, blepharitis. Homatropia correction. +1.50 S. \odot +0.50 C. 90° each eye. Lids treated and boy taken from school for a few weeks. Prescribed 0.25 C. 90° each eye for constant use. Has worn these for two years. Perfect result.

Case 5.—Reported by Dr. G. A. Aschman. N. P., 18. Seamstress. Eyes tire after sewing and smart and burn at night. Headache, twitching of lids, watering of eyes and blurring. Tonics and rest improve condition, but still considerable trouble. Correction +0.25 D. C. 135° and 45°. Relief immediate and one and one-half years later she still wears glasses constantly for work with complete relief. Broke one lens a few months ago and while having it repaired old symptoms returned, to disappear when lenses were resumed.

Case 6.—Reported by Dr. A. R. Baker. G. E. P., farmer's daughter, age 28. Comes to renew glasses broken for six months. Constant sufferer from headache from childhood till six years ago. She at that time received from me correction +0.25 D. C. 60° and 120° increasing V. from 20-30 to 20-20 and entirely relieving head. Since glasses were broken, headaches have returned; patient hoped to get along without glasses but could not. Renewal of lenses stopped the headaches.

Case 7.—Reported by Dr. B. Bettman. Dr. E., age 40; busy over-worked practitioner. Tired feeling and frontal headache increasing toward night. Refraction under cycloplegia 1. D.; after recovery accepts 0.50 D. S. These gave immediate and complete relief. Later after vacation and rest he finds them unnecessary and lays them aside.

Case 8.—Reported by Dr. J. H. Buckner. Miss M. H., seamstress. April, 1893. Much headache for two years. V. each eye 20-15. Correction under atropia. R. +0.25 S. \odot +0.25 C. 135°. L. +0.25 S. \odot +0.25 C. 45°. Ordered these. Entire relief from headache.

Case 9.—Reported by Dr. H. D. W. Carvelle. Fred N., age 21. Druggist clerk. July, 1888. Left eye enucleated in 1886; R. eye weak; can not read or write without headache and pain in eye so that he was obliged to give up his position. Correction with homatropia +0.25 S. \odot +0.25 C. 90° with which pain and headache disappeared and work was resumed.

Case 10.—Reported by Dr. Wm. Cheatham. Emma N., age 24. Health good. Nov. 12, 1892. Spots before eyes; discomfort in back of head when eyes are used. Mild conjunctivitis and blepharitis. Treatment for latter ineffectual. Atropia correction. R. +0.25 D. C. 90°. L. +0.25 D. C. 75°. Have worn these with perfect satisfaction since. Quickly recovered from the conjunctivitis and blepharitis. Reported a few days ago.

Case 11.—Reported by Dr. J. J. Chisolm. Mr. La C., age 30. May, 1891. Eye and head pains and photophobia. Can not use eyes without pain V. 20-20 and 1-1. Correction = 0.25 D. C. 180° each. These gave complete relief and have been worn since with comfort, but can not be left off for a single day without return of pain.

Case 12.—Reported by Dr. J. E. Colburn. Bertha W., 25. Health good. Frontal and occipital headaches. Blepharitis. Correction. R. +0.37. 90°. L. +0.25. 90°. These were prescribed but patient complained of pain in right eye; this lens was found to be 0.25 instead of 0.37. Pretended to change this but patient still complained. Changed to 0.37. These gave complete relief and she is still wearing them without headaches.

Case 13.—Dr. Coleman. Annie S., age 17. High school student. Any study in evening causes eyes to pain. Homatropia correction +0.25 D. C. 90° each. Seen several times since; says she has absolutely no trouble with eyes if glasses are worn but pains soon return if glasses are taken off.

Case 14.—Reported by Dr. Robt. O. Cotter. Mrs. C. V. W., age 53. Pain in eyes and head on any attempt to use eyes for distance, or for near points with presbyopic lenses. Correction +0.25 D. C. 90° each eye. These for distance with proper correction added for close work gave complete relief from the above symptoms and have been worn with comfort for four years.

Case 15.—Reported by Dr. J. C. Dunlavy. Miss G. Age 18. Teacher. August, 1891. Good health except almost constant headaches. Dizziness when headache is bad. Profound asthenopia. Correction +0.25 D. C. 180° both. Within four weeks all pain and asthenopia had disappeared and eyes were used without difficulty. Glasses now used for close work only.

Case 16.—Reported by Dr. J. C. Dunlavy. Miss P. Age 19. College student. August, 1891. So much eye ache and headache she had left school. Correction +0.25 D. C. 75° and 105°. In three weeks returned to school. Graduated last year and is now taking post graduate course. No trouble with eyes in all this work.

Case 17.—Reported by Dr. Geo. M. Gould. Mr. A. D. E. Age 25. Consulted many oculists in past six years for intense headaches in eyes and temples and occiput; reading ten minutes would bring on an attack which usually lasted a day. All had given—spheres or cylinders; wearing now -0.25 C. 90°. Mydriatic correction +0.62 S. \odot +0.37 C. 180° each eye. Use of these lenses gave at once complete relief with ability to read a normal time. This happy condition has continued for six months.

Case 18.—Dr. Geo. M. Gould. Mrs. A. M. W. Age 22. Trained nurse. Been wearing for eight years +0.62 D. S. Severe headaches, temporal and occipital, recurring of late years once or twice a week. The following correction has been worn over a year with relief of headaches. R. +0.25 S. \odot 0.25 C. 90°. L. +0.37 S. \odot +0.25 C. 90°. Headache at once returns if glasses are discarded for the shortest time.

Case 19.—Reported by Dr. E. J. Gardiner. Miss P., age 30. May, 1889. From early childhood has been a martyr to most severe headaches, coming on sometimes twice a week and prostrating her for two days at a time. With the lighter attacks she could go about the house, but the "regular attacks" sent her to bed in a dark room. Use of eyes for close work frequently brought on these attacks. All kinds of treatment had been found unavailing. The eyes had been examined and found normal; the headaches had been finally accepted as a necessary evil. Examination of eyes revealed nothing abnormal. R. E., V. 20-20 C. 25 S. a little better. L. E., V. 20-20, 0.25 C. 90° better. Most careful testing under atropia did not change this, so above were prescribed. Headaches began to diminish at once in frequency and intensity, and in these three months patient reported that she had "no more headaches." Six months later when on a long journey glasses were broken and headaches soon commenced again; by the time she got home she had one of her old attacks. New glasses again gave relief; she has continued to use her glasses until last year (1893) and lately has been going without them without any return of the headaches.

Case 20.—Reported by Clark W. Hawley. Miss K. F., 11, school girl. Good health. Occipital and frontal headache from study. Letters get mixed up when reading. Correction +0.25 D. C. 135° and 45° have given complete relief now one year. Glasses sometimes left off a few hours when old headaches return, at once relieved by resuming glasses.

Case 21.—Report by Dr. C. M. Hobby. Miss E. C., age 18. Asthenopia. V. 20-20 each eye. Under mydriatic R. +0.25 D. C. 60° 20 = 20 +. L. +0.25 D. C. 120° 20-20 +. With this correction vision remained comfortable permanently.

Case 22.—Reported by Dr. F. C. Hotz. Boy of 12. Constant frowning; eyes red and lids swelling after reading a short time. Ordered +0.25 C. 180° each eye. Was relieved. Eyes so well, glasses were left off after a time but in a few days he was compelled to wear them again because the old symptoms had returned.

Case 23.—Dr. F. C. Hotz. Bookkeeper, age 20. After few hours' work eyes burn and smart, and dull headache often compels cessation of work in afternoon. Very sensitive to light; can not read in evening. Conjunctivitis treated four months; improved but other symptoms remain. Ordered +0.25 D. C. 90° each eye and topical applications discontinued. Now after six months has been working over books every day without slightest discomfort.

Case 24.—Reported by Dr. Chas. W. Kollock. Female, age 29. V. normal. For two years use of eyes for close work causes blurring and lachrymation with pain. Atropia correction +0.25 D. C. 90° each eye. These have been worn now for six years with relief from symptoms complained of.

Case 25.—Reported by Dr. Peter D. Keyser. Mrs. C. E. D., age 27. Can not read five minutes without lids drooping and a sandy feeling in eyes. Persistence in work causes headache and nausea. Atropia correction +0.25 D. C. 60° and 90°. Has worn these glasses six weeks and is entirely relieved of her trouble.

Case 26.—Reported by Dr. L. E. Maire. Mrs. E. R., age 31. February, 1893. Nervous temperament. Periodical headaches not relieved by thorough constitutional treatment. Pain in head and eyes daily occurrence, interfering with her household duties. Fundus normal. Homatropia correction -0.25 D. S. each eye. These glasses give entire relief. Latter part of 1893, eyes were very comfortable. Glasses were omitted when headaches returned. Glasses resumed, relief again complete and has continued to this time.

Case 27.—Reported by Dr. Wm. A. Mann. Miss M. H., age 23. Stenographer. Had to quit work on account of "weak eyes." Head and eyes ache after using a short time; type blurs Homatropia correction. R. $+0.25$ C. 10° . L. $+0.25$ C. 180° . Complete relief from asthenopia symptoms, and says after three months she can't get along without them.

Case 28.—Reported by Dr. J. E. Minney. Dr. C. E. N., age 21. December, 1893. Constant headache, with temporary blindness when headaches are most severe. Correction. $+0.25$ D. C. 90° both eyes, gave relief which has continued now four months.

Case 29.—Reported by Dr. B. L. Mittendorf. Miss A. H., age 18. College student. January, 1894. Severe and almost constant headaches for years. Treated by family physician for a long time without relief. One year ago given $+1$ D. S.; worn since without relief. Headaches so severe she thinks she will have to give up study. Correction $+0.25$ D. C. 180° . January 27, headache very much better. April 20, has lost glasses. Study for one day without glasses has caused return of headaches with great violence. Similar correction again given. No headaches since.

Case 30.—Reported by Dr. W. T. Montgomery. M. De W., age 11. School girl. General health good. Jan. 1, 1891. Smarting and aching of eyes, frontal headaches for four years. Headaches now so severe, she had to give up school. Vision 20-20 either eye. $+0.25$ D. C. Axis 25° right eye, and 150° left eye. Vision 20-20. These glasses give complete relief so long as she wears them, with recurrence of headaches if she leaves them off.

Case 31.—Reported by Dr. H. Moulton. Miss S. E., age 24. Teacher. Fair health. Feb. 5, 1894. Eyes used with difficulty for three years. Blurring, pain in and behind eye-balls, constant frontal headache. Homatropia correction $+0.25$ D. S. $\odot +25$ D. C. 90° each eye. These gave immediate and complete relief. Head has not ached since, and patient can read as long as she desires without discomfort, but any attempt to lay aside glasses is followed by discomfort until they are resumed.

Case 32.—Reported by Dr. Thos. E. Murrell. Miss Adah H., age 17. Good health. Headaches and tiresome vision, relieved by $+0.25$ D. C. 90° both eyes. One year later wrote she had perfect comfort with the glasses, but leaving them off one day would bring on severe headache.

Case 33.—Reported by Dr. G. H. Price. Dr. G. H. P. (Myself); suffered with my eyes for about ten years, having been under treatment during each year more or less. Almost compelled to abandon college. Homatropia correction O. D. $+0.25$ C. ax. 60° . O. S. $+0.25$ C. ax. 90° . I have been able to read and study any time, and for hours without trouble, except now and then when I have a heterophoralgia due to muscular unbalance.

Case 34.—Dr. A. E. Prince. Frank K., age 32. Tailor. 1888 first seen. Conjunctivitis. Various astringents used for eyes. 1891. Gave him $+0.50$ D. S., each eye. These gave him some relief but trouble persisted and other symptoms arose. Correction after repeated and careful treating under atropia $+0.25$ D. C., axis 180° each. Gave entire relief. He is now able to do a large amount of work by artificial light as well as by daylight without discomfort.

Case 35.—Reported by Dr. Pinckard. Miss M. H., age 17. March 1, 1892. Had been under treatment for headaches over three years without relief. Insists that headaches have no connection with her eyes. Correction $+0.25$ D. S. $\odot +0.25$ D. C. Axis 90° and 80° . No relief for about ten days, after which headaches gradually disappeared. March 5, 1894. Has been able to work without discomfort.

Case 36.—Reported by Dr. Chas. A. Oliver. Dr. —, age 24. January, 1894. Severe asthenopia and lid irritation, unrelieved by local and general treatment for nearly ten years. Insufficiency of convergence so pronounced, that tenotomy had been advised. Fundi normal. Atropia correction $+0.25$ D. C. 25° and $+115^\circ$. This correction with 2° prisms, bases in, has been continually worn since, enables patient to perform an enormous amount of literary work without eye trouble. Twice through breakage lenses have been omitted for a few days with speedy return of old symptoms.

Case 37.—Reported by Dr. J. M. Ray. G. S., age 34. Druggist. Feb. 21 1894. Headache on use of eyes. Correction R. $+0.25$ D. C. 90° . L. $+0.50$ D. S. March 6, 1894. Been using glasses with complete relief from headaches, but if eyes are used without glasses, headaches return.

Case 38.—Reported by Dr. S. D. Risley. Miss C., age 26. Art student. March, 1894. Weak eyes, headaches, etc. Correction R. $+0.37$ C. 90° . L. $+0.25$ C. 90° . At the end of the month reports perfect comfort at her work but is compelled to use her glasses.

Case 39.—Reported by Dr. G. C. Savage. Mrs. M. B. D. Oct. 21, 1892. Ordinary symptoms of eye-strain. Under homatropin O. D. $+0.25$ C. ax. 105° . O. S. $+0.25$ C. ax. 65° . Reports relief from eye-strain.

Case 40.—Reported by Dr. J. L. Thompson. Physician of rare intelligence and very hard student. April, 1887. Intense sufferer for weeks with head and eyes. Vision 20-30 each eye. No muscular trouble. Atropia correction. Vision 20-20 each eye with $+0.50$ D. C. axis 65° . Right, 0.50 D. C. axis 130° , left. Prescribed $+0.25$ D. C., axes as above. Benefited in a few days. In six weeks could read all he pleased and has continued to do so until this day. Has several times tried to do without glasses but the old symptoms promptly return.

Case 41.—Reported by Dr. R. L. Thompson. Spokane, Wash. Miss T., school teacher. So much trouble with her eyes that she seriously thought of giving up her avocation. For this I gave her in May, 1893, a pair of $+0.25$ D. C. 90° . I saw her yesterday (April 25, 1894.) She is delighted with her glasses and says she has had no trouble with her eyes since she got them.

Case 42.—Reported by Dr. H. V. Würdemann. Mrs. B., age 43. Neurasthenic. Asthenopia and headache, marginal blepharitis and chronic conjunctivitis. Correction $+0.25$ D. C. $90^\circ \odot 0.75$ D. S. for reading. Lenses give satisfaction for reading, but headaches continue. Gave $+0.25$ D. C. 90° each eye for constant use which have given relief to this time from all symptoms.

Case 43.—Reported by Dr. H. M. Starkey. Frances G., age 13. School girl. April 7, 1893. Had cerebro-spinal meningitis three years ago. Much pain in eyes and in head particularly at base, when eyes are used since. Very severe paroxysms of headache occur about once a week. Sunlight and lamplight painful. Patient looks dull and forehead is contracted. Correction $+0.37$ C. 90° each eye. April 12, no headache with glasses. June 1, no headache. June 13, no headache and light hurts the eyes but little. October 10, has had practically no headache since getting glasses and school has been resumed. The change in facial expression when the glasses were put on was very pleasant to see and she always afterwards came to the office with a smile.

Case 44.—Reported by H. M. S. Miss E. A. P., age 28. Oct. 17, 1893. Severe and almost constant supraorbital headache. Had come to visit the World's Fair but pain is so severe when patient enters the grounds that she fears she must go back home without seeing the Fair. Esophoria 10° and 12° . Homatropia correction $+0.37$ C. 180° each eye. These glasses were prescribed and relieved head at once. Miss P. remained in city with but little eye trouble and attended the Fair until November 4, and had but one headache. Esophoria reduced to 6° and 4° by this time without other treatment. Have heard lately that Miss P. continues to wear the glasses with same comfort.

Case 45.—Reported by Dr. H. M. S. H. P. H., age 28. Book-keeper. Oct. 25, 1893. Eyes tire easily and give out entirely if used much. Feel full of sticks after use. Homatropia correction $+0.37$ C. 135° and 45° . These gave entire relief and have been worn constantly since though eyes are used constantly and closely. I see Mr. H. frequently and suggested a short time ago that he might perhaps get along without his glasses now, but he said he is so perfectly comfortable with them that he does not care to try any experiments.

Case 46.—Reported by Dr. H. M. S. Miss M. G. H., age 19. School girl and later teacher. Feb. 21, 1893. Always has had much headache in brow and temples particularly if tired. Dull headache most of the time; worse at evening. Correction: $+0.50$ S. $\odot +0.25$ C. 90° each eye. Likes the simple cylinders better and these are given and relieve the head. February 25. Headache relieved completely, but return if glasses are omitted and are again absent when glasses are resumed. May 20, 1894. Has much headache but not of the old character. Headache most intensified if glasses are omitted at all.

Case 47.—Reported by Dr. H. M. S. Miss J. H., age 25. Health much impaired from mitral heart disease. August 15, 1890. Eyes and head have been troublesome and painful

for a long time. Correction $+0.25$ C. 90° each eye. These glasses given and headache disappeared within a few days. Patient seen frequently since and says she can not get along without glasses. Seen May 20, 1894. Says leaving off glasses a short time causes headache and if they are not resumed nausea arises.

Case 48.—Reported by Dr. H. M. S. Miss C. M. S., age 25. Eyes have been troublesome for ten years. Severe headache and eyes smart after use. Homatropia correction. R. $+0.50$ S. $\odot +0.25$ C. 20° . L. $+0.25$ S. $\odot +0.25$ C. 160° . After recovery from cycloplegia gave $+0.25$ C. 20 and 160° . These relieved head and eyes. Saw patient a number of times in the following two years and she always expressed the greatest pleasure in the use of the glasses.

Case 49.—Reported by Dr. H. M. S. Miss J. W., age 18. Teacher. Health good except headache Dec. 15, 1890. Always had much headache. Worse past year and there has been pain and heaviness in eyes in bright light and after using them. Correction $+0.25$ C. 180° R. -0.25 C. 90° L. These relieved the headache and eye-strain. Have been worn ever since with relief from pain in head and eyes and increased ability to use eyes. Pain returns if glasses are left off.

Case 50.—Reported by Dr. H. M. S. Miss Dora W., age 18. School girl. One of a family of sisters all having slight degrees of astigmatism with much headache relieved by proper correction. Dec. 6, 1889. Always had more or less headache, very severe and almost constant past two years. Correction $+0.25$ C. 180° . Dec. 14, 1889. Has not had a headache when glasses are worn. May 15, 1890. Uses glasses almost constantly. Does not have headache when glasses are worn. May 8, 1893. Lost glasses some time ago and headaches have been increasing until they are now very bad again. After examination gave same lenses which again relieved from headache.

WEDNESDAY—JUNE 6.

Section was called to order at 3:10 P.M.

Before the reading of the papers a case was presented by Dr. A. H. Voorhies, of San Francisco.

DR. VOORHIES—Mr. Chairman: You have kindly given me an opportunity of presenting a case which came in this morning unexpectedly. It was an operation which was so applicable to this Section that I asked my friend to allow me to present it here. It is a case of double cataract. Some of the members asked me this morning a question or two in regard to certain methods. I am not going into a long discussion on extracting cataracts, but I will say it has been my habit for twenty-five years of making a simple extraction. Never in the course of my life have I made an iridectomy, without its being an enforced one.

Again, in regard to the point of section, as to whether it should be at the lower or the upper section. I say in the majority of cases that is immaterial—I would as soon operate in the lower section as in the upper. I thought it would be of interest to the Section to see this case and therefore have brought the patient. The case illustrates also the method used now by many, of irrigating freely the anterior chamber, which I do in all cases that require it. If the cataract is senile and the greater portion of it is dense, we have no occasion for irrigation, but in all cases of cataracts in which the upper portion is wholly soft, then we are called upon to irrigate.

In regard to the knife—I have possessed recently some modifications of the cutting knife, that is, of having a very narrow knife, twenty millimeters in length, with a cutting edge one-half of its length on one side and complete on the other. The narrow blade will accomplish all that is to be done in the way of cutting—it can make a wound small or large, according to the section. In case of accident the introduction of the knife the wrong way, without withdrawing the knife, it can simply be turned over and the section finished without bad results.

Again, as to the method of irrigating. I use a syringe which I improvise at the time (showing.) The tube being placed in a bottle and the fluid drawn up into this bulb. In regard to the solution, I used simply distilled water, boiled

immediately before the operation or at the time. I do not hesitate to irrigate the anterior chamber freely and have never had evil consequences from it, using distilled water. I have under certain circumstances used a solution of boracic acid, probably 1 per cent., and occasionally, a mere suspicion of common salt, using nothing in the way of bichlorid.

The report of the Nominating Committee was then read.

DISCUSSION ON DR. STARKEY'S PAPER.

DR. H. I. JONES, San Francisco—I agree with Dr. Starkey about his paper. I think a great many of these cases require weak spherical glasses. Most all of them suffer from some neurotic trouble, or some condition which can be cured by constitutional treatment. They are often bilious. Give them some blue mass or a good dose of salts and a little tonic afterwards and they will often get well without glasses, putting on colored glasses in the meantime.

DR. ELLIS—Mr. President: Somebody has remarked quite recently in our medical literature that oculists were getting to be simply expert opticians. I think, Mr. President, our oculists should be expert opticians, but to say they are only expert opticians is to say they are very wide of the mark. There can be no question in this day and generation, when the eyes are called upon for so much work and such continuous work, that they must be under greater strain than they were in times past, and than they are in other countries where individuals are less on the move and more on enjoying themselves. I do not believe that all errors of refraction should be corrected. Many individuals pass through life with errors of refraction amounting to 1 or 2 D., either with astigmatism, or ametropia, without any discomfort and use their eyes a great deal. In the majority of cases, these are individuals in a healthy condition. There are other individuals who have only one-fourth or one-half D. astigmatism, who upon every effort of use of the eyes for close work have a reflex manifestation; frontal, vertical or occipital. Where we have these conditions as the result of eye-work, I think there can be no doubt that the oculist is justified in correcting the trouble. In my own personal experience, I have had more good results from correction of astigmatism of from one-half to one-quarter D. than from greater degrees, simply from the fact that in a low degree we usually have excellent vision, and the eyes are used to the utmost capacity, whereas in greater degrees we have more or less impairment of the vision, and there is not that constant strain that there is in close work where the vision is good. I am heartily in accord with Dr. Starkey in his views.

DR. SIMONTON, San Jose—Mr. President, I have corrected a great many cases of optical error of one-quarter D., and as the gentleman has just said who preceded me, it seems to me that relief is sought in the low degrees than in the high degrees of astigmatism. In the high degrees the eye gives up endeavoring to obtain perfect vision, and hence there is less eye-strain, while in the low degrees the vision being almost perfect, the eye makes every effort possible to make it perfect; hence, the trouble. As to the necessity of wearing glasses—I have not heard it mentioned, but I suppose it is your universal experience that a much larger percentage of females call for the correction of optical errors than males. In my experience, I think it will amount to three-fourths females, if not more. For some reason, there are either not the optical errors existing in the male portion of the race that there are in the female, or else they do not call for correction. Is it because they are stronger or in better condition physically? It would seem that we would have the same amount of optical error in the male portion of our race as the female, but it is my observation that a much larger percentage of females require correction. There is a great difference in individuals.

A gentleman called at my office a few days ago, who was over 70 years of age. He had inflammation of the lids in mild degree and due to eye cyst in some shape. I found his glasses for short range work were two areas. I came to the conclusion that he was ametropic. Upon testing the individual with the letters at twenty feet, he was not ametropic. I suggested that he wear a stronger lens, as he was actually drawing on the axillary muscle, and he has done so since. I think it would be the unanimous expression of this Section if they would express themselves, that the low degrees of cylinder, especially quarterly are beneficial and their use is warranted in hundreds of thousands of cases. It has been mentioned here that persons may wear glasses for a long time and then cast them off and go without. My experience in that line does not indicate that many persons will do it. After the eye has been accustomed to the glass, and the optical error has been corrected, to take off the lens and put the eye under the old conditions brings on the trouble again, except in cases where the general condition has been so improved. Our experience leads us to conclude that very few persons of optical error can cast aside their glasses and not wear them.

DR. H. B. YOUNG, of Burlington, Iowa—My personal experience is that in a majority of cases, ametropia disappears, so far as the ordinary tests are concerned. I want to ask the advocates of the use of one-quarter D. cylinders to tell me how they determine when they have found a case of one-quarter D. astigmatism. You must oftentimes take simply the judgment of the patient, and we know how unreliable that is. I do not believe we can *measure* it reliably by the ophthalmoscope. In my judgment, those advocating the one-quarter D. cylinder, do so on the reply of the patient himself. I have found, however, that there is one way of getting a little more definite reply in regard to the one-quarter D. cylinder, but I think the cure is worse than the disease. At the meeting of the State Society in my State last year, I presented a paper on this topic, and then called attention to the fact that I doubted if any one person could take the one-quarter D. glass, and on the ordinary test card tell when a one-quarter D. had been removed. They must have a plain glass in front of them to give them the idea of looking through a glass in the first place.

I have found that in nearly every case where a one-quarter D. cylinder was accepted, astigmatism would develop in almost every case. As a result of that experience, I have nominally discontinued the use of one-quarter D. cylinders. This applies simply to those cases which have equal vision. I understand the discussion does not apply to those cases which have very marked ametropia.

DR. BAKER, San Diego—I do not want to offer myself in opposition to the last speaker, but I would like to give my experience in this test. In testing by the use of a wheel, the radiating spokes placed at angles of 10 degrees, the inequality of the wheel can be determined in a large per cent. of these cases, and the inequality corrected and the relief of strain is marked at the time. In my own case, I showed the one-quarter D. minus astigmatism, which without the use of the wheel resulted in a plus astigmatism, the use of the plus cylinder being necessary. For six or seven years of my life I have suffered from migraine of a severe type. For six or seven years previous to the wearing of the glasses, I found that by a strict diet, taking away all meats, I could be reasonably free from the attacks. I put on glasses and worked and in the intervening time I have had four attacks of migraine, as against an attack of once a week or once a month, and these four attacks have been all I had, notwithstanding the fact I have done as much work as I chose. The relief has been absolute, as I am thoroughly convinced. In reference to other cases, I have a number of them, and

two of them were absolutely removed by having a one-quarter D. glass. Another case which had been diagnosed tubercular trouble, where there was persistent loss of weight and apparent serious lung trouble, was absolutely cured by the having of a one-quarter D. glass. I used atropin five days. I could only get the test with the wheel; I could not make it by the test pad. After putting the glasses on I told the patient I was disappointed, inasmuch as there were errors which could not be corrected by glasses, and on taking the glasses off the patient immediately complained of nausea; on putting them back again the nausea disappeared. And after wearing the glasses the condition of nausea disappeared absolutely. Within a few days the case disappeared entirely and the patient gained fourteen pounds in weight, and has been absolutely well since. The eye trouble may not have been the original cause of the disturbance; this is evidenced from the fact that for the last year she has been in perfect health without her glasses. But there can be no question that the relief was immediate at the time, and that the cause was the fitting of these glasses I see no reason to doubt.

DR. RYAN, Galesburg, Ill.—The remarks made have called into question the possibility of getting a correction by plus 25 or cylindrical 25. I have had considerable experience in fitting glasses in the last few years, and find it a very easy matter to make complete correction by the use of cylindrical 25. The ordinary patient would not be able to detect any particular difference in the letters, but if you use the wheel, as has been said, you can nearly always make a complete correction. You can not do it if the letters of the wheel are very close together, but if the wheel is very distinct and the lines are four millimeters apart you can always do it. I have a record of cases in which I am positive that dozens of them have been fitted in that way, and the difference could be noted instantly if we changed from 25 to 50, or *vice versa*. I have seen it so often that I am positive that the ordinary individual can detect those differences where we use a wheel which is clear and distinct, and the lines far enough apart so that you can easily recognize the lines. Where the lines are close together, it is in my opinion impossible, because there is a slight blur.

DR. PRICE, Nashville—I rise to add my testimony to that which has been spoken on this subject. I received a communication from Dr. Starkey and one of the cases I noted in the reply was striking. That case required only the correction of twenty-five-hundredths of astigmatism, and as with the cases related by the doctors here, it seemed as if the case were too serious to be accounted for by so slight a deviation from the normal; nevertheless, the correction was given and the patient was entirely relieved.

Another case that is striking is my own. I had suffered for many years,—I was almost compelled to abandon study when quite young on account of eye trouble. I was treated at that time by various general practitioners, who treated me for all troubles and conditions from granulated lids, as they supposed I had, with a first-rate attack of conjunctivitis, and I received no relief. I went from bad to worse for about ten years, when I had my vision corrected. At that time it was an absolute impossibility for me to devote exceeding fifteen to thirty minutes to consecutive reading at night without suffering from eye-strain. After that time, and since that time, I have been able to read almost indefinitely and what work I feel disposed to do I can do. If I confine myself to work for several hours consecutively without my glasses I feel the effect of it, but as long as I use them in proper position so as to get the benefit of the cylinder correction I proceed with my work without serious interference.

So, I am of the opinion that very frequently the great

trouble lies in the fact that men presume that it is useless to make these corrections, and they do not give the patient the benefit of the correction. It is difficult to determine to the one-half D. whether they should be corrected or not, but I think by careful observation we may be able to determine it. As the gentlemen who have preceded me have said, it is almost impossible to do this by reference to the letters. We must resort to the radiating letters, and in this way we can arrive at the proper direction in nearly every case. I do not attempt to place the position of the axis by the cylinder, if that cylinder is less than 75, but get the axis with a stronger cylinder and then reduce the cylinder to the required strength. As to the value of those lenses, I have every reason to have faith in them on my own account.

DR. DAVIS, Stockton, Cal.—The last speaker suggested the idea of putting a stronger cylinder before the eye to locate the angle. I want to suggest that where I could not find any effect I have reversed the cylinder. Put the cylinder in at 90, turn it quickly and it very materially hurts the vision.

DR. McDERMITH, Colorado—Mr. Chairman, on account of the confusion that exists in the minds of the profession, growing out of the editorial alluded to in the paper, and also the replies that have been made, and inasmuch as there seems to be somewhat of a unanimity on this subject, my experience (while it is not very extensive) certainly accords with that of the gentleman who read the paper and the most of those who have taken part in the discussion. Inasmuch as confusion exists and probably will exist, it seems to me that it would probably not be out of order for this Section to place the stamp of its approval in some way so as to make it more emphatic on one side or the other, and I move you that it is the sense of this Section that it is in accord with the paper presented by Dr. Starkey, meaning that the criticism of the editorial is about the proper thing.

This motion was seconded and a rising vote called for.

DR. SIMONTON—Mr. President, just one word of confirmation. The gentleman at my right said that by using the 4 D. cylinder, it would not improve the vision. If we turn the 4 D. cylinder at right angles to the supposed proper margin, invariably it hampers the vision, if a person has astigmatism—turn it back and the vision is improved at once. If we have one-fourth D. astigmatism, and take a one-half lens, it will be more so and there will be no doubt about it, thus determining that there is astigmatism and the vision is greater when the cylinder stands in one position than when it stands in any other position.

DR. YOUNG—That is my point—if there is a 4 D. astigmatism and you turn a 4 D. lens to the opposite axis, it will give the effect of a one-half D. lens.

DR. SIMONTON—I have put the motion in the form of a resolution, which is as follows:

Resolved, That it is the sense of this Section, deduced from actual observation and experience that the one-fourth D. cylinders have a permanent and important value in correcting myopic errors."

I offer that as an amendment.

DR. McDERMITH—I offer the amendment, "may have," without committing ourselves to the assertion that we believe in every case.

THE CHAIRMAN—It is rather an important matter, if we are going to pass a resolution, that we do it in such a way that we will not be ashamed of it afterwards.

DR. JACKSON—Mr. President, with reference to this resolution, while I am thoroughly in accord with the views of the speakers, and the gentleman who offered the resolution, as to the value of the remedies, I think that a formal indorsement on any grounds of any measure in therapeutics would be entering upon dangerous ground, and establishing a

precedent that may trouble us in the future, and unless such an expression is clearly needed and meets some emergency, with which I am not acquainted, I think it would be better for the Section not to take such formal action.

DR. EATON, Oregon—Mr. Chairman, I wish to emphasize what Dr. Jackson has said. There are many other points in ophthalmology which may come up and might require some sort of resolution, and we would find ourselves making resolutions until we become the laughing stock of our brethren. I therefore enter my protest against this resolution.

DR. GIBSON—What would we say of the Section in *Materia Medica*, if they should adopt a resolution similar to this one, saying that calomel in one-twentieth grain doses has its merits.

DR. PAICE—I would suggest that this is a thing which can be demonstrated mathematically, and that can be demonstrated only by the individual case.

DR. McDERMITH—I do not think that question has been raised. And it is not likely to be—the question of one-twentieth of a grain dose of calomel.

DR. BRIGGS—Mr. President, I do not favor this resolution from the fact that it is a matter of opinion largely. In regard to this opinion, I do not think it has been demonstrated as a positive fact that the 4 D. lenses are of so much value or so essential that it is necessary for us as a Society to resolve that they are beneficial. We can use them and believe in them and find them good in a good many cases, but I think the resolution would be rather a backward step for this Section to adopt. It seems to me the almost universal indorsement of the paper itself is a sufficient indorsement of this Section, without the adoption of a resolution.

DR. STARKEY—I think the resolution is hardly necessary. I do not think it would make any difference with those who do not use them. I move that the resolution be laid on the table.

This motion was seconded.

THE CHAIRMAN—The motion has not been stated by the Chair, and I think there is no motion before the house.

DR. STARKEY—There have been several things brought out in the discussion, much more emphatically than I had gone over them. I should like to say, in the line of argument of the gentleman who spoke second, that more good results from low degrees of correction are found. That was expressed by the doctors in their replies—that they found in a given number of cases more cases of a low degree of error in which correction was made, than in the higher degrees. Dr. Simonton spoke of the constitutional test as being important, and I also dwelt somewhat upon the fact that I thought most of these cases, if they could only stop work would get well without glasses. His experience in regard to females being in larger proportion is somewhat different from mine, probably because I have a large number of medical students who raise the proportion, so that I should think I had fully as many young men as women on my records. The fourth speaker said he thought it would be the unanimous sentiment of this Section that the low degree lenses are of great importance—that lenses were seldom omitted after being worn. That is not according to my experience. It is to be hoped in the low degrees, that when the general health improves the ocular health will improve, and they will be able to leave them off, especially in the students and school children, and in book-keepers who get through with their work, so that the eyes are not used so much at the end of the day. I think the statement of Dr. Young that you can not tell within one-fourth D. was answered by others. One point you must have noticed, and it has not been alluded to, is the expression of the patient's face. How often you see the patient with that characteristic appearance of asthenopia, the corrugated brow, the

scowl—and when the 4 D. lenses are placed before the eye at the right angle, the face clears up and the physician can tell by the expression of the patient's face that you have something beneficial, and the patient returns to the other condition if the lens is reversed. In the test for astigmatism, the test by the radiating wheel, the reflex or shadow test was entered into quite fully. I know that persons become so expert that they can tell readily a one-fourth D. astigmatism.

ASTHENOPIA.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY C. M. HOBBY, M.D.
IOWA CITY, IOWA.

Asthenopia is to the visual function what dyspepsia is to the digestive, a congeries of symptoms differing somewhat according to the pathologic views of the physician in charge, and often like dyspepsia cured by the physician instead of by the prescription. As ordinarily employed, without reference to pathology, it comprises several groups of symptoms following the more or less prolonged use of vision at short range, but it is sometimes made to cover uncomfortable vision at all distances; the same symptoms occurring to a presbyopic patient are not usually considered asthenopic, although some logically include unrelieved presbyopia with asthenopia. Not infrequently reflex disturbances, unconnected with the visual organs, are considered as asthenopic phenomena; blepharitis marginalis, which is apparently frequently caused by refractive errors, and mild forms of conjunctivitis, are sometimes considered as symptoms of asthenopia rather than as causes for the ocular discomfort. Accepting hyperopia, especially when associated with astigmatism, as a cause for headaches, and even of the more violent migraines and hemicranias, and believing, as we may, that epileptic attacks have ceased after the correction of refractive error, do we not recognize under all these circumstances that the refractive error is only one factor in the cause, and that back of all there exists a predisposing systemic condition?

Without attempting to describe or define all the symptoms which are grouped around the term asthenopia, patients complain of "sandy feelings," "itching," "smarting," "sticks in the eyes," etc.; symptoms due to hyperemia of the conjunctiva, frequently accompanied by redness, lachrymation, and photophobia; again patients describe their difficulty as "pain in the eyes," "pain over the eyes," "drawing of the eyes," "brow ache," "headache," "shooting pains through the head," "hemicrania," "migraine," etc., some complaining that the pain comes on at once if they begin to read (or use the eyes at short range); others that they feel it if they use their eyes for half an hour; others who persist in reading or in work, especially sewing girls, that they have headache every afternoon except Sunday afternoon; these are the symptoms of overwork and occur normally when the individual uses the eyes too long, just as fatigue follows any excessively prolonged exercise; occurring after only a moderate amount of work, these symptoms are especially entitled to be called asthenopic. Another group of symptoms frequently referred to by patients concerns the visual act; "blurring after reading for a time," "have to change the position of the book," "see spots moving across the page," "some-

times see double," etc., and this group, like the last, may represent the effects of overwork, or when the symptoms occur after only moderate use of the eyes the symptoms may indicate disordered muscular coördination of either the intrinsic or the extrinsic muscles of the eye.

It would be of decided advantage if the term, asthenopia, could be restricted in its meaning to the effects produced by the use of one or both eyes burdened by some abnormal increase in the muscular labor of vision; that is, some burden upon the accommodative function, internal or external; but the symptoms called asthenopic occur in perfectly normal conditions, at least so far as the visual organs are concerned, and we are compelled to consider these cases with others.

No special form of refractive error appears to predominate in asthenopic cases; out of 1,205 cases of refractive error applying for relief from all causes, 58 per cent. complained of asthenopic symptoms; that is the continuous exercise of vision was accompanied with more or less discomfort. Of these cases, 77 per cent. could be considered hyperopic, and 23 per cent. myopic; 31 per cent. had hyperopic astigmatism and 14 per cent. myopic astigmatism; that is 45 per cent. of the asthenopic cases were astigmatic, against 40 per cent. of all cases, showing that asthenopic symptoms occurred in a little larger percentage relatively of astigmatic cases; but this is because the low grades of astigmatism, where there is little impairment of vision, only come under the observation of the ophthalmologist when the patient is suffering from some form of uncomfortable vision.

When we come to consider the great number of cases who have defective vision, from refractive and other causes, but who never complain of those symptoms called asthenopic we are forced, I think, to the conclusion that asthenopia indicates inadaptability to environment, and that it is the individual and not the eyes that are asthenopic. What is true in regard to errors of refraction is apparently true of the so-called muscular asthenopia; while records of heterophoria are not so extensive and the observations made lack the ripening effect of time, and while as in astigmatism of low grade the subject of heterophoria does not consult the physician unless there exists some form of uncomfortable vision, enough observations have been made to show that heterophoria without asthenopic symptoms is sufficiently common, and to lead to the belief that it is not to the muscular insufficiencies alone that the occurrence of asthenopia of the variety termed muscular is to be attributed.

When we observe the different expedients that at times afford relief to asthenopic symptoms, the same lack of coherence is to be found. Patients will often report that they have great relief from glasses that have increased instead of diminished refractive error; the spur of necessity often banishes difficulties of this kind; the uterine specialist, the rhinologist, and the electrician all number asthenopia among the ills relieved by their special methods; and tenotomies that have increased heterophoria have in some manner relieved discomfort.

As asthenopia is not a necessary result of any of the various conditions to which it has been attributed, and is yet often cured or materially improved by relief or attempts to relieve real or imaginary causes of increased effort, or by training the internal or exter-

nal muscles of the eye, as well as by systems of muscular exercise, we can not do too much towards establishing some basis for efforts at relief that shall be less empirical, without substituting a dogmatic physiology of the function of vision. And it is well at this time to protest against the tendency to consider everything connected with the visual organs, as governed by inflexible mathematical formulæ. The evidence is not in, which compels us to believe that the muscles of the eye are innately endowed with certain coördinative functions, or that they have a brain center which is prepared to correlate their movements without the necessity of the training that experience gives, or that their functional activity is exerted under different laws from those governing the rest of the muscular system. It may be believed that the coördinated movements of the muscles of the eyes to perform a given task is the result of the same kind of practice, the same kind of training that pursued through a long time gives to the fingers and hands of the typesetter or the musician their distinctive skill, the same kind of training and experience that the babe must go through with before standing on its feet and walking.

A man accustomed to the work may saw wood for ten hours, a woman may busy her fingers in knitting for the same length of time, but the man unaccustomed to the saw would soon find back and arms complaining of the unwonted labor, and the inexperienced knitter would soon feel fatigue in the fingers; the same is true with those who attempt to use the eyes at new and prolonged tasks; the adult whom will or circumstances kept from studious habits in early life, suddenly attempting to make up lost time; the woman who is suddenly deprived of her means of support and who attempts to gain her livelihood by sewing; the active man who attempts to confine himself to book-keeping; all of these are likely to exhibit asthenopic symptoms whether they have refractive error or not; correcting visual disorders is of undoubted service to them but complete relief awaits their adjustment to environment.

Another numerous class who continually excite our sympathies, and who are preyed upon by spectacle vendors are those who are attempting to work with their eyes for lengths of time out of all proportion to their physical strength; seamstresses who ply the needle from 7 in the morning until 6 at night, and desire glasses to enable them to put in extra hours by artificial light; such cases, like some opticians, look upon the eye purely as an optical apparatus that only requires a little mechanical adjustment to go on with its work.

Ill health is a fertile source of asthenopia, and with impairment of general health we find refractive errors assume a greater importance than would otherwise have been the case; here relief of the ocular strain often proves to be not only an assistance to the use of the eyes but also to the efforts to improve the general health.

Sometimes an individual is unable to concentrate his attention upon the work in hand and uses the eyes at irregularly varying distances, and in various positions as to light and direction of the object looked at, and thus multiplying work unnecessarily, suffers from fatigue where systematic work would have been borne with ease; the student who without interest pursues his task and constantly suffers may become interested in a novel and spend hours with

no symptom of "eye-strain;" there is less likelihood of fatigue when the mind is on the work, and there is much less irregularity of muscular work.

But in recognizing asthenopia as depending upon something more than disturbance of the purely mechanical part of vision, it is not necessary to reject the assistance afforded by mechanical measures in the treatment. We can believe that the most perfect possible adjustment of glasses will often fail to cure asthenopia, and that a large proportion of cases can be cured without glasses, without at all underrating the use of optical appliances. While fortunately, we are unable to trace very grave pathologic changes to misfits in spectacles, yet it seems as though it were time for the medical profession to call a halt upon the indiscriminate optical treatment of asthenopia by those who have no knowledge of general pathology, or even physiology, and who consequently see in "eye-strain" only disorder of the looking-machine. Where rest is needed, and where exercise and training are required, where asthenopia is a symptom of a general disorder, or where a patient numbers fatigue of vision as only part of general nerve disturbance, equally with the optical imperfections that take from the patient that soundness of body which with the sane mind is required for the perfect use of all the senses as well as all the muscles, all these conditions fall within the province of the physician and are entitled to his thorough scrutiny.

CYCLOPHORIA, ITS DETECTION AND TREATMENT.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY GEO. H. PRICE, M.D.
NASHVILLE, TENN.

Cyclophoria or the rotary tendency of the eye upon its antero-posterior diameter under certain conditions, known also as insufficiency of the oblique muscles, is now a matter of record upon the case-books of so many, as to no longer be a question of speculation. When the question of insufficiency of the obliques in certain cases of oblique astigmatism, was first presented and fully elucidated by Savage, of Nashville, Tenn., there was in the minds of some room for doubt as to the verity of the statement, but I am now ready to believe that this statement is received as a fact, by those who have given the question sufficient thought and have applied to it those tests which we now have at hand for demonstrating this condition.

For a long time only the grosser errors of balance of the obliques were considered of importance, and the methods of arriving at conclusive evidence were of such a character as to render it difficult, if not impossible, to bring out this defect unless well marked, or the patient was of that class of observers upon whose statements one can rely with certainty. These difficulties have been overcome, and the means of detecting the condition have been so much simplified that to-day we can not only detect but determine in degrees even small variations from the proper adjustment of these muscles.

Cyclophoria is not only found in oblique astigmatism, where we would naturally expect it, but is also present in many cases where there is no obliquity of the astigmatic condition and also in cases in which

there is no astigmatism at all; so we must conclude that it is not only a complication in some but in all forms of focal error, to such an extent as to cause it to be looked upon as an important factor, which requires us to exert ourselves in detecting and applying the necessary treatment. I have compiled a table of two hundred cases from our case books, showing the various forms of focal error and the muscle conditions complicating each, as well as the percentage in the whole, of each muscular variation. This condition as a causative factor in the symptoms of eye-strain is of prime importance, for if neglected, though all other conditions have received proper consideration and have been eliminated from the catalogue of complications, yet there will be complaint from your patient until you have met this feature and applied the proper treatment. Hence it becomes necessary to recognize the cyclophoria and be prepared to give your patient the benefit of treatment which can be successfully carried out.

It is now a well established fact that the tests for exophoria and esophoria must be determined before the use of a mydriatic, since the suspension of accommodation alters these muscular relations to such an extent as to mask the true condition, but in the case of cyclophoria the test can be made before and also after suspension of accommodation and the result relied upon as trustworthy; however, it is well to note it both before and after use of homatropin or atropia, to be satisfied upon this point.

The causes of cyclophoria, like those of other phorias, are dependent upon a variety of conditions, one or several of which may obtain in the same case.

I will call your attention first to that cause which gave the initial impetus to investigation in this line, viz., oblique astigmatism. In the first place, it is to be noted that if the astigmatism is of such a character that the meridians of greatest curvature diverge above, the superior obliques are kept constantly in a strain in an effort to converge the naturally vertical meridians so that corresponding portions of the retina shall receive the same impression. This constant effort induces fatigue or wears out the normal contracting power of the superior obliques and thus induces an insufficient action, relaxation or cyclophoria.

Again, as the inferior oblique acts in conjunction with the inferior rectus, and is augmented in its action by the action of the former, and as the inferior rectus is constantly in action during all efforts at near work, an extra amount of duty is hereby imposed upon the superior oblique, which extra work it frequently finds impossible to sustain, the failure manifesting itself in cyclophoria. This complementary action of the inferior rectus can be easily demonstrated, and has been noted heretofore, hence it is a factor in cyclophoria of that variety involving the superior oblique.

Again a faulty insertion of the external and internal recti will augment one or the other of the obliques in their action, thus becoming a factor in the production of this condition. This condition of variable or faulty attachment has been observed by all who have operated on the tendons of these muscles. If the tendons of these muscles are inserted more below than above the horizontal diameter of the eye, then we find that the internal rectus augments the action of the inferior oblique while the external rectus will assist the superior oblique, but as cyclo-

phoria manifests itself principally when the eyes are in a state of convergence, when the internal rectus is stimulated into action and the external is in a state of more or less relaxation, we can readily see that as a result the muscular equilibrium of the obliques is overcome and the superior muscle fails to accomplish the extra duty demanded of it.

If we should have these muscles placed correspondingly above the horizontal plane, then the reverse would obtain.

So also can we find that faulty attachments of the superior and inferior recti may complicate the action of the obliques.

Faulty attachments of the obliques themselves are to be considered as factors; especially is this probably the case with the superior, since there are two points at which faulty adjustment may creep in, viz., their insertion on the globe of the eye and their physiologic origin, the trochlea. The latter may become elongated from protracted tension, or it may be located too far posteriorly, either of which conditions would result in deficient action. Failure of development of the obliques, or lack of innervation may also be remembered as probable causes of insufficient action. It is, of course, a difficult question to decide as to the immediate complicating causes of each case, but then the probable factors may be held in mind.

A very noticeable fact, in the study of this condition, is the frequency of that form involving the superior oblique and the rarity of that in which the inferior oblique is involved.

From a table of two hundred consecutive cases, taken from our records, before alluded to, I find cyclophoria, insufficiency of superior obliques, in 25 per cent. of all cases (the same percentage has been noted by others) while there is but $\frac{1}{2}$ per cent. of cyclophoria in which the inferior oblique is at fault. There must be a reason for this and I think it can be accounted for in the following way:

The third nerve, known as the motor oculi, presides over the greater portion of the muscular machinery of the eye and is that nerve which is called upon most frequently. In convergence and accommodation there is direct stimulation of all of its fibers except those which supply the superior rectus, hence we see the inferior oblique augmenting the action of the other muscles while the superior rectus, a part of whose duty it is to antagonize the inferior oblique and inferior rectus, is in a state of relaxation, partial or complete.

Again the superior oblique by its action aids in depressing the cornea, by drawing up the posterior part of the globe, at the same time producing slight abduction, and in this very fact while aiding in a general way, also partially counteracts, its own special function. How is this accomplished? In producing abduction it tends to turn the entire anterior part of the globe outward, but in this it fails, for the lower half is prevented from making this outward excursion by the combined action of the inferior and internal recti and inferior oblique. In this I think we have a sufficient reason, and it seems to be borne out by the additional fact that those who make near use of their eyes are those who suffer most from cyclophoria of this type, though there are exceptions.

Let us now look into the question of detecting the presence of cyclophoria in any given case. After

having tested the lateral muscles, before homotropin or atropia has been instilled into the eyes, and these are noted for the near and distance, then with the same double prism in front of one eye, thus producing a double image in that eye, we hold a card (on which we have a well defined red or black line) in front of the patient. The eye in front of which is the double prism will see two lines upon the card while the uncovered eye sees only one line. The card must be held in a plane parallel to the plane passing through centers of rotation or tangent to the corneas of the eyes, otherwise the two lines seen by the eye, in front of which is the double prism, will not be parallel. Now if there is no defect in the balance of the obliques then the middle line is parallel to the other two lines, and is half way between them (provided there is no hyperphoria or cataphoria) but if there is insufficiency of either of the obliques then the middle line will dip at one end or the other, according to the condition present.

If the double prism is in front of the right eye, the two images being seen by this eye, and the middle line seen by the left eye, is inclined to dip at the right hand end, then we know at once that the superior oblique of this eye is failing to do its duty, thus allowing the perpendicular meridian to rotate outward or the horizontal upward at the inner extremity, where the line is seen to rotate or move in the opposite direction, that is downward at the right end. If this dip is but slight the eye will adjust itself so quickly to the faulty condition by a demand upon the superior oblique, that the patient may fail to discover the lack of parallelism with certainty. Instruct him to close both eyes gently for a few seconds, this rest causing the muscles to assume their ordinary relations, then when he opens them tell you if the lines are still parallel. This little procedure takes the eyes off their guard, consequently when he opens them if the cyclophoria is present the middle line will be seen slightly dipping, but soon the guiding sensation of the retina calls upon the oblique and after a few slight oscillations it may assume a parallel position, or so nearly so as to render it difficult for some to discover the lack. If there is reason to suspect the presence of cyclophoria, and your patient is not a careful observer, then we have a proof test which can be applied with much satisfaction. To apply this test the frames should be adjusted to the pupillary distance of the patient, then with a cylinder, say 2 D. in front of the eye being tested, (which is the left in this case) having the axis at 90° , which position does not affect the result, turn the cylinder to 100° , thus throwing additional strain upon the superior oblique, and almost immediately the patient will say the line is dipping to the right. If now the cylinder is brought back to 90° the lack of parallelism is still observed and it will have to be moved to, say 80° or 75° , before the middle line will come up to its proper position. In marked cases of this condition the 2 D. cylinder, and in some rare cases, even a 3 D. cylinder must be rotated to 45° before parallelism is established and maintained. In case the inferior oblique is deficient the dipping is reverse; that is, in the left eye the middle line dips to the left, therefore in case the proof test has to be applied we would have the reverse position of the cylinder in the foregoing. If the condition is suspected and the proof is applied, the cylinder being turned to the right or 100° and then to the left or 80°

and the same amount of dip, first to right and then to left is noted, we conclude that there is no cyclophoria.

There is another test for this condition which I have devised and used in a crude form in some cases, which may prove of service. The testing apparatus is a combination of the double prism and the Maddox rod in front of one eye and the rod in front of the other, and is used in conjunction with the candle or gas-jet at twenty feet. The double prism converts the single line of light made by the rod into two lines, which lines are parallel and about 18" apart, while the rod alone in front of the other eye produces a single line of light, which should be half way between the upper and lower lines (provided there is no hyperphoria or cataphoria) and parallel to them. If cyclophoria is present there is a deviation or dip which will be of the same character as that shown by card test at eighteen inches. This little device I present for your inspection. Though this condition at first was looked upon as one to which no treatment could be applied, yet I am glad to say that through the study and investigation of my friend Savage we are now in possession of a plan which in our hands has proven most satisfactory, and to this I will now direct your attention. It will be remembered that in making the test for detecting cyclophoria we made use of a cylinder, by means of which we can increase or lessen the strain upon the oblique muscles. This principle is made use of in the treatment of this condition.

It is a well established practice now to exercise the recti muscles, and this is done by gradually increasing the strain upon the individual muscle by the use of prisms so placed as to call the muscle into action, and the same plan is followed in the case of the obliques, but we use the cylinder instead of the prism.

If the patient under treatment is suffering with cyclophoria superior (insufficiency of superior obliques) we then with a cylinder of 1.50 D. in the frames, and the patient looking at a light fifteen or twenty feet distant, we begin by turning the cylinder in the right to 75° and that in the left to 105° (thus putting the superior obliques slightly upon the strain) and instruct the patient to raise and lower the frames every four or five seconds. Looking through the cylinders at the light induces slight action or contraction of the obliques and raising the cylinders allows them to relax. This is continued for say five minutes, after which the cylinders are again turned, in the right to 60° and the left to 120° and the patient put through the same exercise as above mentioned, continuing it for three minutes. This causes increased action by reason of the fact that the cylinder in this position causes greater strain upon the obliques in their effort to overcome the greater deviation from the normal condition. Finally the cylinder in the right is turned to 45° and in the left to 135° , and the exercise repeated for two minutes. This position of the cylinder causes the maximum strain upon the obliques. If the cyclophoria is inferior, or insufficiency of the inferior obliques, then we pursue the following method of exercise:

With frames on and cylinders in them, we place the cylinder in right at 105° and in the left at 75° and exercise as before directed by raising and lowering the cylinders in front of eyes while patient looks at the distant light. Then move cylinders to 120° in

right and to 60° in left, and finally to 135° in right and 45° in the left. This exercise should be taken twice daily for a time, though the amount of exercise may be varied according to the symptoms manifested by the patient; for instance, if the patient complains that the exercise causes pain, then instead of taking the full amount, this can be altered to suit the case; thus allowing him to exercise only one-half or even one-third of the time divided between the three steps, or even allow him to exercise for the full time with the cylinders in the first position, and gradually increasing as the patient will bear it.

It will be well to bear in mind the fact that the symptoms of which the patient has been complaining will in many cases disappear before his cyclophoria does, hence it is well to keep him under the influence of the exercise for some months, resorting to it daily or every other day, or even once a week. This treatment has proven of the greatest benefit to many patients upon whom it has been tried, and I have great confidence in it.

We must keep in mind the fact that cyclophoria is a condition which must influence us in the adjustment of lenses, and especially those in which we find a cylinder needed for the correction of astigmatism. While in cases where the axes of the cylinders are seemingly at 90° in each, when the eyes are tested separately, both with lenses and ophthalmometer, yet we may find that the cyclophoria, say of the superior obliques, may prevent the comfortable use of the glasses if the axes are allowed to remain at these points. More particularly is this the case if you have noted any disposition of the cylinder in the right to go toward 100°, and that of the left toward 80°, which positions would be favorable to the weak superior obliques.

Again, if your ophthalmometer shows in the right the position of the cylinder to be, say 100° with tendency to 105°, and in the left the axis is to be at 80° with tendency to 75°, and the test lenses showing the same tendency on the part of the cylinders, it will be advisable to place the cylinders at 105° in right and 75° in left, thus removing the strain from the obliques, and at the same time correcting the astigmatism. If the axes of the cylinders converge above, from the nature of the case this increases the strain upon the superior obliques, and consequently this must be remembered, and due allowance made for it. In such a case say the cylinder in right by the ophthalmometer should be at 60°, and in left at 120°, that is the axes converging above, and that test lenses confirm this, but that the cylinder in right tends to 65° or 70° and in the left to 115° or 110°, then it would be good practice to favor this by placing the cylinder at 65° in right and 115° in the left, thus decreasing the convergence, thereby removing a part of the strain from the superior obliques. Unless these points are watched discomfort follows, as I have learned by experience. A case or two bearing on these points may be of service:

V. S. P., real estate agent, came complaining of his eyes. He was using lenses which were unsatisfactory. Under homatropin his condition was as follows:

O. D. V. 20-xx w. +.25 C +.50 cyl. ax. 80°.

O. S. V. 20-xx w. +1.50 cyl. ax. 90°.

Each eye was tested while the other was covered by disc. These lenses were given him and he began to use them. In a short time he found the left eye so painful as to hinder him in his work. This lens was changed and had substituted therefor +.50 C + 1.00 cyl. ax. 85°; this position of axis seeming to be preferred at this time. This was much more com-

fortable though vision was not so good. After a time we put in the +1.50 cyl. ax. 85°; this gave him comfort and good vision at the same time. You see this allowed the axis to converge less above, thus reducing the strain on the superior oblique which brought the ease. We did not fully appreciate the significance of this at the time, but now since we know the part played by the superior obliques in such cases it is apparent. We noted later cyclophoria superior.

Another interesting case is that of Mrs. B. H. R., who consulted us about her eyes; this was about the same time as the above named patient. She was refracted and the following record made:

O. D. V. 20-xx w. + 1.00 cyl. ax. 70°.

O. S. V. 20-xx w. +.50 C +.50 cyl. ax. 110°.

This was given for distance and a 2.00 D. each for reading to be worn in front. This was in 1891 and the patient, who resided out of the city, was not seen again until a few weeks ago, when she stated substantially as follows: Can not use the distant glasses all the while as they cause pain in eyes, most marked in right (where she has the strong cylinder at 70°, increasing the strain upon superior oblique). Has been more comfortable with a simple + 2.25 used for near work. Cyclophoria superior being present, and detected at this time, she was put on exercise for same, and told to use her glasses for distance.

Two weeks later she reported again with some improvement but not comfort as yet. At this time the cylinders were revolved in the frames, the right to 80° and the left to 100°, exercise continued, and patient to report in two weeks. The two weeks having passed she reported, and her condition was flattering; the annoying symptoms having subsided and she was wearing her distant lenses all the time. The cyclophoria being also reduced by the exercise showing increase in strength of the superior obliques; the lenses were turned about 2° back toward their original position.

The last case to which I will call your attention is that of Mrs. T. M. O., who came complaining of the ordinary symptoms of eye-strain. Under homatropin we found the following condition:

O. D. V. 20-xx w. +.75 cyl. ax. 90°.

O. S. V. 20-xx w. +.50 +.75 cyl. ax. 90°.

Four degrees exophoria in near, before use of homatropin. Cyclophoria superior, slight. This correction was given her and she was put on exercise for the exophoria as this was looked upon as probably the most annoying factor in her case. When she received the lenses and began the use of them they gave her trouble. She applied to an optical company and their refractor gave her a cylinder for the left of +.75, the axis being at 75°. This gave her relief since the position of this cylinder took the strain off the weak superior oblique and put it on the inferior, which was more able to perform extra duty. In this case it would have been better to diverge the axes in both, placing the right at 95° and the left at 85°. It must be remembered that this change in the position of the axes of cylinders where cyclophoria is present should be used only as a temporary means of relieving the symptoms (for it does not remove the cause), until the insufficient obliques can be brought up to normal activity by the proper exercise. Hence the lenses may be turned in the frames to induce comfort, while the exercise of the obliques is resorted to, and as the obliques recover full power the lenses can be gradually revolved to their original and correct positions; then with exercise, as may be demanded by the case, we should expect to see the patient get complete comfort.

There are in these cases, as in all cases, factors of individuality which can only be known and watched by the physician in charge, and upon close attention to these will often depend our successes or failures.

DISCUSSION.

DR. EATON—In my paper yesterday I put myself plainly on record as opposed to this theory of cyclophoria. It is hardly worth while to go into detail. I wish, however, to present two arguments which I did not present in my paper. There are a very large number of men in the profession who do not believe in this theory, far more than I think the reader of the paper will admit. One of the greatest reasons I have brought against this theory is the inability of many persons to find one who has not the phenomena—in whom we can not bring out the phenomena by the very means he

has described, of insufficiency of the sphere of light. The greatest objection that has been made (not by me but by others) to this theory, is the interference with these cylinders, the ignoring of the ancillary muscles in the interests of the oblique muscles. I also refer to the paper to-day by Dr. Hobby, who says that in cases of asthenopia supposed to be caused by cyclophoria, the majority of the cases are caused by ametropia and not by hypermetropia. Referring to the fatigue which Dr. Savage attributes from his exercise with cylinders, to the exercise or strain put upon the oblique muscles—nobody, who has not had astigmatism corrected by cylinders put on—can look through cylinders at any time without suffering a certain amount of strain. He details the fact that when the cylinders are turned or worn for awhile, the strain is felt to be upon the obliques. This is pure assumption. I will draw attention to the fact stated, of the rarity of the insufficiency of the inferior oblique muscles. Now, it has been practiced as I said yesterday, known for twenty years that rotation of the eyes upon their posterior axis takes place in convergence, and I have satisfactorily proven that such rotation takes place in convergence at a distance of twenty to eighteen inches, and increases in proportion as the objects are brought nearer. According to the experiments made by Dr. Savage's test, or by the cylindrical prism, that all this immediately disappears as soon as the object is 45 degrees below the primary plane of vision. Meissner attributed this fact to the action of the inferior oblique muscle. Another thing that Dr. Savage nor Dr. Price ever has done—submit to the profession a series of cases followed out an adequately long time in which, after the exercise has been followed out, any relief which is claimed has been secured, whether the same careful testing obliquity of the line is present or not. I venture to say, no person can be found in whom any amount of exercise can overcome the inevitable rotation of the eyes and convergence. If any person will put the candle at twenty-five feet and put the cylinders before their eyes they will find that there is not the slightest incentive to any fusing of the light—supposing the cylinders are put on an oblique so as to cause the lines of the candle to be drawn out at an angle—place the cylinder with the axis nearly vertical, and you get the horizontal line. There is no such incentive as in a line drawn upon a piece of paper, but there is a decided strain upon the ancillary muscles, caused by the cylinder.

Another thing I draw attention to is the insistence on Dr. Savage's part that such weak cylinders as one-half or one-fourth D. or 110 degrees or 105 degrees—that such a slight change will bring a strain upon one or the other oblique muscle. As I understand, the change made in the cylinders by Dr. Savage favors one muscle or the other, in the case of very weak cylinders. Again, he attributes a very weak amount of astigmatism, such as one-half or one-fourth D. as causing a strain upon the oblique muscle. I said decidedly yesterday that the amount of disturbance of the retinal image caused by a strong cylinder of 2 D. is considerably less at a distance of thirteen inches. The 60 degrees of variation becomes 40 degrees, at 45 degrees, its greatest deflection. You can therefore imagine how much deflection on the cornea is caused by an astigmatism of one-half D.

I wish to say in making the opposition I have to this theory, I am actuated by a conscientious motive. I do not believe in the indifference shown to theories which have not been worked out with due deference and care when they are originally presented to the profession. I may say that this theory was sprung upon the profession without due regard to the writings of physiologists, nor with due consideration of the facts which I have given, and I believe it takes the attention of the future ophthalmologists from things which they should attend to, to things for which there is no foundation.

DR. ERWIN, Mansfield, Ohio—Mr. Chairman, unfortunately, I was not here early enough to hear Dr. Price's paper. And I have not studied Dr. Savage's doctrine enough to know all that there is in it, but there is one point I notice. It is that the oblique muscles are affected by the cylinder, especially if the cylinder is an oblique cylinder. The disbursement of the image on the retina by the oblique cylinder gets up a new kind of action on the part of the eye. The muscular action of the eye is so habituated that it becomes almost, if not altogether, involuntary. Now the least deviation from the habitual impression of the object upon the retina causes a complete change in the use of the oblique muscles of the eye, so as to require a voluntary action on the part of the oblique muscles. When you have upset the habitual action of these muscles, and you make it necessary for a voluntary act on the part of the muscles, you see how likely you are to get a disturbance of that muscle in a short time. It is my observation that oblique cylinders had better not be prescribed at all, if there is only a low degree of astigmatism, unless you have a patient that is willing to suffer a good while before the muscles acquire their new use, that they have to acquire before they can become comfortable.

DR. SIMONTON—Mr. Chairman, I do not wish to make any technical argument on this subject, for I do not know anything about it. I confess I have not given it sufficient consideration, but wish to say that when Dr. Stevens first brought out his ideas in regard to hypermetropia, the whole profession pooh-poohed it—it could not be so, it was impossible—the results which he claimed could not be true. It has been demonstrated that most of the positions which he took are true. Now, this theory of cyclophoria is new to us and it is yet under discussion. It is not a settled matter, and it is quite likely it will prove true to a greater or less extent. I am open to conviction.

DR. EATON—Mr. Chairman, I would say that there is a little difference here. I was one of the first to recognize Dr. Stevens' views. I was operated on myself by Dr. Stevens. The conditions are quite different.

DR. PRICE—(In support of the theory advanced in his paper on cyclophoria, the Doctor then referred to his own case as an illustration.)—Twenty-five per cent. of all the cases of whatever error that fall under our observation are from insufficiency of the superior oblique, and we test every case of insufficiency of the oblique muscles as we do insufficiency of the other eye muscles, and we invariably do that before we put anything in that eye. The Doctor has referred to my not presenting cases. Gentlemen, if there is any one thing in the world that a Society or Section or body of men does object to, it is a great array of cases. I can produce from our record books hundred of cases in which we have detected cyclophoria, and in many cases where the cyclophoria has been relieved, I could relate case after case. The second case upon which we successfully used the cylinders for the purpose of correcting this condition by exercise was a lady who told us that for twelve years, she had not been able to read, write or sew. She had been in a condition of absolute idleness on account of her eyes. We did not know anything about cyclophoria then and we tried everything in the world that we could think of. She tried constitutional treatment for two or three years by physicians here, there and everywhere. She had consulted men everywhere; oculists, ophthalmologists, opticians and everybody else. When we did find out about this thing and put her upon exercise, the patient began to improve and in a short time left Nashville and went to the City of Mexico, and she says now she reads, writes and sews.

QUESTION—Is there any direct relation between astigmatism and cyclophoria?

DR. PRICE—Yes sir; from the fact of the perpetual oppo-

sition to the horizontal, the muscles have to bear the strain. If you use an ordinary ophthalmoscope you will get your axis of 90 degrees. Your weak muscle is not put upon such a strain and your strong muscle is not put upon so much tension, and you do not get the pronounced effect until the patient recovers. I have made mention of but three cases for the simple reason that I knew it would be tiresome.

QUESTION—Why not use a prism instead of the cylinder after exercise, if there is no astigmatism in the case?

DR. PRICE.—One point about this detection of cyclophoria is—I have thought that probably I could take an ordinary prism—

DR. EATON—You don't think I question that the superior and inferior obliques rotate the eye?

DR. PRICE.—Not a bit—I am satisfied that they do. The Doctor said and said decidedly yesterday in his paper that a cylinder twenty-five or fifty hundredths would produce no effect.

DR. EATON—I did not say anything of the kind. I said that a cylinder of 2 D. will produce three-fourths of a degree at the approach to the eye, but I said that I can not make the movement with a one-half D. cylinder.

DR. PRICE.—My experience is this: I have cyclophoria; I have never subjected myself to systematic and constant exercise, but occasionally I take exercise for this reason, that after prolonged work I slip up with a case of neuralgia. If I exercise for five minutes with these cylinders, exercise my inferior obliques, the trouble begins to disappear and I begin to come out of the shadow of the vale and feel better. The oblique cylinder in this case is like the oblique cylinder in the case represented in his paper by the Doctor. It makes no difference whether it is one one-hundredth or 10 D. If that cylinder is incorrectly placed, it will give trouble. I have seen patients with the axis 140 in one eye and 135 in the other, and I have seen them with twenty-five one-hundredths place 15, 20, 30 or 10 degrees even from the line of horizontal, or proper correction, and that patient never gets any satisfaction until the cylinder is changed in position. Why is it that exophoria should be such an annoying factor? If one muscle is insufficient, why not another muscle insufficient? There is not a man in the room that can stand perfectly still for five minutes. Watch a body of men in a military company—every man is swaying, because there is always a slight adjustment. The same thing occurs with the eyes. The opposing muscles on some side are a little too strong. Show me a man with his head on one side and he has hypophoria. It is a strange thing to me that the Doctor seems to think that because certain investigators have discovered that in most cases there is this variation from the normal, in all eyes that they have examined, that consequently it is normal. That is a great mistake. Gentlemen, I could relate case after case, but cases are not the thing. If you can get it into your mind that these cases do occur and are there, it is all right and you can demonstrate it. A man can oppose anything in the world, because he believes he says what is right and his experience is along that line. I trust the Doctor will yet become converted.

THE CHAIRMAN—We have one very interesting subject to come up this evening, but it is getting so late and we all want to attend the dinner, so that the first order of business to-morrow morning will be Dr. Southard's paper.

The Sir Astley Cooper Triennial Prize.—The next triennial award of this prize takes place early in 1895. The value thereof is £300. All competing essays should be in the hands of the physicians and surgeons at Guy's Hospital before Jan. 1, 1895. The subject for the competition is "the anatomic distribution of the lymphatic vessels and the physical forces concerned in the movement of the lymph." This prize is open to the whole world, except certain of the attachés of the Guy's and St. Thomas' Hospitals, London.

SCHOOL CHILDREN'S EYES—A PLEA FOR THE EXAMINATION OF EVERY CHILD'S EYES, WHEN COMMENCING TO ATTEND SCHOOL.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY W. F. SOUTHARD, M.D.

SAN FRANCISCO, CAL.

Looking over the annual report of the public schools of the city of San Francisco for the year 1893, I find that there was an average daily attendance of 31,002 pupils between the ages of 5 and 17. Of this number 69 and sixty-three-hundredths per cent. were in the primary grades. This includes all children between 5 and 10 years of age. Twenty-six and six-hundredths per cent. were pupils in the grammar grades, while but 4 and thirty-one-hundredths per cent. were high school pupils. These pupils between say, the ages of 10 and 17 were divided between the grammar grade and the high school. I wish to emphasize the point that, though this does not state the total enrollment of pupils, it does very correctly give the daily attendance throughout the year. An analysis of these figures will give us some very important results. In the first place, you will observe that from the primary grades over one-half, or 50 and forty-three-hundredths per cent. fail to enter the grammar grades. These children at this time are about 10 years of age. At the close of the grammar grades, 71 and sixty-eight-hundredths per cent., or more than three-fourths, fail to enter the high school.

Finally, to show more vividly the enormous decrease of school attendance between the tenth and seventeenth years, we learn that there is a total loss of 96 per cent. as between the primary school attendance and the high school attendance. Let us see if we can discover the cause for such a tremendous variation in attendance between the three departments of our public schools. We shall find, I think, that not one only, but many circumstances, conspire to bring about these results. The average person will be very likely to say that removals, deaths, sickness and discouragement ought to be a sufficient explanation. I am sure that a more thoughtful examination into the causes will convince us, that not only the above mentioned, but other reasons exist for such a condition of affairs. To my mind this fact is a cause for greater surprise and alarm than that but 4 per cent. of our primary pupils reach the high school, insignificant as is that number. At the age when pupils enter high school a very large number are withdrawn to become wage earners; they must assist in providing for the family. A very large percentage of the parents of these pupils think that completion of the grammar grade is all that their children need to fit them for all ordinary vocations. But this can not be the case at 10 years of age, for the percentage of permanent bread winners of 10 or 12 years of age must be very small in this State.

We find on examination, that is, by questioning teachers, superintendents and those who are daily brought into contact with children, that the number dropping out because of their inability to keep up in their studies must be very large. It is possible that as we examine this particular cause for loss more carefully, we may discover the very material we are after by which our proposition may be maintained. I have held for some time in my arguments with edu-

cators, that if curves showing the mental capacity of a thousand children of the same age, could be drawn, they would show but a very slight variation one side or the other from a given mean. I believe that we shall find that the brain capacity of our children can be measured with as good results as we have obtained in other branches of anthropometry, a study which has been brought to a very high degree of accuracy. For example, Prof. Bowditch, of Harvard University, Prof. Gihon, of Annapolis, and Prof. Hitchcock, of Amherst, have together measured some 40,000 persons between the ages of 5 and 25; the design being to show the rate of growth of the body, for the different ages. From these measurements a certain mean standard of physical development, height, weight, chest measurement, length of body sitting and standing, etc., to which the great majority nearly attain has been found. The deviation above or below this mean is found to be about the same.

That there is a tacitly recognized uniformity in brain capacity, powers of comprehension and general intelligence among children of the same age is proved by the fact that school books have been prepared, hours of study, and the studies themselves arranged to meet this. We may question the wisdom of making text-books on such a rigid plan; we can not deny the facts. It follows therefore, very clearly, it seems to me, that very nearly equal results should be attained by the great majority of pupils. If this is not true then there can be no law governing our intellectual powers. If, then, we find in the same grades at school a very wide departure from the standard, we must conclude either that the general standard is too high or a very large percentage of our children have some disability. Why should so many children become discouraged? Their work is not particularly difficult, their hours are comparatively short, and in the primary grades they are not expected to study at home. Ill health is an important factor; thousands of children are already invalids before going to school; inherited weak constitutions; impoverishment of bodies from deficient or unwholesome food, bad hygienic surroundings at home, all unite to handicap such children in school work. The stooping forms, eyes bent close to the desk before them; the shuffling walk; the notched teeth; thin faces and other physical defects are to be seen every day and in every primary school. If we examine this class of children we find that they have in nearly every case marked deficiency in visual acuteness. We cease to wonder that such pupils can not compete in the struggle for an education.

There is again, a large percentage who fall out of the ranks from among the apparently healthiest and brightest children. For a term or two they may have no trouble, but later on they drop behind, when they in turn become discouraged. We are able to positively state that they have no impoverished bodies, that they have always been well and have never complained before going to school. As they fall behind their classmates they are called mischievous, stupid and other epithets of like character are bestowed upon them. Many of these children come home every afternoon complaining of headache, or if they have no headache they complain of feeling tired, they get listless and hang about the house. They are being constantly corrected for not paying attention. In fact one of the most frequent complaints from teachers is, that such children never look upon the

work before them more than a moment or two at a time. They are being constantly diverted to whatever is going on about them. It is needless to ask what is the outcome of this condition; the teachers get impatient and become constant fault finders, the child gets discouraged, and the parents in many cases become dissatisfied and remove their children from school. It is among just such material as this that we find the evidences which confirm us in our theory that there can be but one way to treat this whole subject. We find that the very largest proportion of these children have errors of refraction or some disturbance of the visual organ. We find also on looking into the matter more closely that the school environment is not of the best, school rooms are imperfectly lighted in most every case, the proportion between windows and floor space is less than the standard. Many rooms are so situated as regards light that they can not by any means get good direct light. But too often the best light in the school rooms is a reflected light from some adjoining high building. Such a light is most injurious to the eyes and to the nervous system. Then there is the question of heat and ventilation, serious questions too. The proper seating of the pupils at their desks, the character of the seats themselves are in too many cases the cause of permanent injury to the growing child. Poorly printed books, and poor paper have much to do with strain upon the eyes. Though much has been attempted to remedy some of the most evident of these defects, we can not but feel that the rights of the child have not been considered when we let contracts for building school houses. Politics govern our school system, in most places, to too great an extent. We spend money enough to get the very best results; it is, however, becoming evident that enormous sums are most unwisely spent. Each of these points just mentioned needs more discussion than can be given at this time. Given these imperfect surroundings together with some defect of vision, and we have a combination which must sooner or later be detrimental to the child, physically or mentally. Is it any wonder that he has no concentration?

In pursuing this subject of our public schools a little further, we have to note that in the primary grades there was enrolled at the commencement of the year a number equal to thirty-two and thirty-five hundredths in excess of the number in regular attendance. They mostly dropped out during the first two or three weeks of school. Such a number of units thrown upon the community unable to read or write must become in time a serious burden upon it. I am most firmly convinced from personal observation that poor eyes must be a leading factor in causing this great loss. A law compelling a rigid examination of the eyes of every child when he begins to go to school would seem to be demanded. Let every child come to school bearing a certificate stating the exact condition of its eyes. By such means the teacher will be put in possession of facts which will be of inestimable use to him and to his pupils. A plan so simple ought to commend itself to every physician, to every educator and to every parent.

Having shown the intimate relationship existing between imperfect eyes and lack of power to apprehend, a long step forward has been taken. Statistics have been made of many thousands of school children in Europe and America, by a large number

of competent observers during the past twenty years. An examination of these results most clearly shows that there is a most intimate connection between education and defective vision. It has been proved that myopia (that form of defect to which all eyes tend) exists in but 1 per cent. of the primary scholars in country districts. This is due to obvious causes; country children go to school a less number of hours daily, or if they attend, less is expected of them. They also attend a less number of weeks during the year and they read or study but little at home. An examination of the city schools shows at a glance a different condition of affairs. Myopia is found in these schools in far greater proportion. As we ascend from grade to grade, from primary school to grammar school, from grammar to high school, from high school to colleges and universities, up to the highest institutions of learning, myopia is found ever on the increase, until in the very highest schools in Germany over 90 per cent. have been found myopic. In other words it is now an accepted fact that myopia is a product of civilization, one of the results of our modern methods of education. It is not our purpose to discuss these methods on this paper, simply to draw your attention to a fact now generally accepted.

Having shown that there is this relationship between myopia and education it may be said, But this does not account for the first proposition, viz.: That such a vast percentage of pupils drop out of the ranks at the early age of 10 years. At 10 years of age myopia has been found even at its maximum to be only 10 per cent. Myopia, then, can not alone be a sufficient cause for so great a loss at so early an age. This is very true, but myopia is not the only error of refraction causing disturbances. It has been very satisfactorily shown that all infants are born hyperopic. We may also assume that a very large percentage are born astigmatic; of these probably 75 per cent. have hyperopic astigmatism. From 5 to 15 years the child's body is developing most rapidly. A greater amount of nutriment is now being taken in proportion to its weight than by adults. Tissue changes are taking place in a most rapid manner. Physiologists claim that during these years a large part of the twenty-four hours should be given to body building by means of sleep, food and exercise. The visceral organs, for example, may be altered by too great and too continuous compression. It needs no philosopher to tell us that we must expect more or less alteration in the shape of the eye-ball from too great and too continuous use of the eye at the near point. If we admit that this may take place in the so-called normal or emmetropic eye, how much the more likely are changes liable to follow over use when the eye is in its undeveloped stage? We know that the ciliary muscle of the hyperopic or undeveloped eye, from its very nature must be in a constant state of activity during all the waking hours. At the far point as well as the near point the effort is being constantly made to force the rays to a focus upon the retina. This effort means strain, and the strain means disturbance of the nervous system. The effort to maintain visual acuteness by the expenditure of force upon the ciliary muscle is not the whole story. According to the degree of hyperopia there is a change in the angle, "alpha," which means that the attempt to maintain binocular vision must be attended with expenditure of force, and this often

leads to strabismus. This proposition brings us to the point I am to make, viz.: That children's eyes are from their very construction just the sort of eyes which will cause the greatest discomfort from over exertion. The two factors, the attempt to produce visual acuteness by forcing the ciliary muscle to powerful contractions, and the effort to maintain binocular vision by forcing the extra ocular muscles, is liable to produce varied and peculiar symptoms upon the nervous system. I assert, then, that those children having hyperopia and hyperopic astigmatism are the real sufferers. Their constantly nagged nervous apparatus tends to become wearied to the extent that they can not give close attention to the work before them. They must look up often to rest their wearied muscles. Therefore, to expect continuous application and good attention is most unreasonable. That such children may lose interest in their school work on account of the difficulties surrounding them we can readily understand. We could, did space permit, show that these imperfections may have a very marked effect in the development of the child's character.

In my examination of the eyes of the students of the University of California, for the past five years, I found that the percentage of refractive errors was 68 per cent. Of this number only 6 per cent were myopic. In a detailed analysis of 1,300 errors of refraction I have shown that 75 per cent. were hyperopic in some degree. I found in looking over the list of symptoms attending these cases that pain of eyes, headache, muscular spasms and nervous symptoms generally were confined to this class of cases. The myope but rarely complains of anything more than inability to see at a distance.

It is not to be denied that myopia is greatly to be dreaded; since it can not be stayed in its progress in many cases, even though corrected with glasses. We are willing to believe that it is the end toward which a vast proportion of eyes tend when overworked. We claim, however, that our sympathies are rather to be directed to the youthful hyperope. Could we but examine every case during the first few years, we would not be sending to our universities young men and women with eyes just ready to break down. The remedy is examination and constant watchfulness. We must bear in mind that the tremendous waste unnecessarily taking place through the effort to work under the disadvantages of a refractive error is not easily measured. Individual suffering, and loss of power to work, may cause great material loss. From this cause the community has to be taxed to support asylums; from this cause many eyes tend toward disease and ultimate blindness. These are among the possible results of neglect on our part to do our whole duty. We may build asylums for the blind, we may do everything possible to remedy the defects already existing, yet unless we go down to the very foundation of the trouble and alter existing causes for disturbance we shall in time have as great a percentage of spectacled beings as is now seen in Germany. Remember that this is an age of conservation of energies, not waste.

DISCUSSION.

DR. MILLER, Los Angeles—This subject is of great importance. The too familiar statistics of Germany are highly instructive. While examination of the eyes of young school children is highly important we must inquire still farther

as to the causes of these troubles. I am not satisfied in my own mind just what those causes are. Our people seem to be becoming more and more neurotic. Children living in cities should have more outdoor exercise. The result of our higher state of civilization is to develop a decidedly neurotic state in our entire population. I think we must look well to this and develop a state of general health if possible—greater freedom and more outdoor exercises. I think also that particularly in this State the great variety of work ordinarily given to children at schools is prejudicial. It seems to me there are educators undertaking to cover too much ground, and there are too many studies in our schools requiring numerous and rapid transitions of the mind from one subject to another, and maintaining constantly a high degree of nerve tension. It takes some little time for the pupil to get his mind onto a given subject, and about the time he begins to get well under way he must suspend that and take up something else, and so on—we have a constant rapid change from one subject to another, which brings about the nervous tension. This I believe to be operative, as well as several other causes. Much more attention must be given to lighting, warming, and ventilating your school rooms. It might be well when the child enters school to have him present not only a certificate from his physician that he has no ocular impediment, but that he has no nervous or other impediment to his doing the work ordinarily done by children of a corresponding age.

DR. L. R. RYAN, Galesburg, Ill.—I think the question is not so much to get at the cause of myopia because that is well known among the fraternity. The main thing is to get the people to appreciate the disease and take the means to prevent it, and we have to get the people who have an influence with the children interested, especially the teachers. I can recall a great many cases where children had been forced out of school absolutely on account of defective vision; the teachers have classed them as dullards simply because they could not read or study. And it is only a few days ago that a little girl came to me almost crying because the teacher said she was lazy, and she had a very high degree of hypermetropic astigmatism. It was absolutely impossible for the little girl to study; her sister who was a twin was very bright indeed and the two were compared and she was almost driven out of school. I think we ought to enforce upon the teachers the idea of paying attention to hygienic conditions as far as the eye is concerned—to have the light properly arranged, to have the desks arranged so that the children can study in school without getting into a cramped position; to instruct them in hygienic means and to have the idea carried to the parents at home so that everything can be arranged and they can study properly. You will find in a great many cases, especially among children of the lower classes, that the children are packed off in a dark corner and compelled to study there, while the old people are given all the advantages as far as light is concerned. I think if you will visit the great majority of our public schools and examine the hygienic arrangement as to light and desk facility you will find that they are sadly at fault. I can recall cases where the primary children have been put away down in the basement where the light was very poor indeed and where it was absolutely impossible to see an ordinary pin. Then, too, I have studied the question of the arrangement of the desks. You take the little children in the primary department and you will find that they have their chins right on the edge of the desk and the book is set at such an angle that it is absolutely impossible for them to read without getting their noses onto the books, and in writing or getting their lessons their chins will be down at this angle. (Describing the angle). Now any one who knows the question at all knows

that the eyes are used under such circumstances at a very great strain, and the development of myopia is very easily produced, and I think as a Society we ought to try to get the people and especially the teachers to appreciate those hygienic conditions.

DR. F. P. EATON, Portland, Oregon—Mr. Chairman: What the doctor preceding me said in his closing remarks I think has hit the main point of this matter. We are quite well aware of the injury done to the school children, but the problem is how to work upon the public. Ordinarily the public understands that the myopic eye is the product of school work. It is not, however, clear at all to the public that the hypermetropic eye, and the astigmatic eye are both of them equally productive of misery and discomfort and injustice on the part of adults to children. I hesitate myself to make a motion as far as this Section is concerned in any way that would call attention of the educational portion of our communities to the importance of having the eyes of children examined. It has occurred to me and I suggested it to Dr. Southard that some such committee be appointed by this ASSOCIATION or by this Section to endeavor to have the various State Medical Societies formulate certain resolutions so that the various Legislatures, or at least the municipal authorities, might act upon the school teachers in such a way for the benefit of the children as we have heard this morning.

DR. H. M. STARKEY, of Chicago—Mr. Chairman: I am very glad indeed that I am one of the few here to hear this paper of Dr. Southard's. It is a very important subject. I don't know that I can add anything to it that hasn't been entered into in the question of the general examination of the eyes of school children. I think the point of the education of teachers is a very important one. We see a great difference in teachers, and their treatment of pupils; for instance I not infrequently have children sent to me and say the teacher told them they could not come to school again until they had their eyes examined. The teacher has seen that there is something wrong with their eyes, and having said two or three times that they should go and see a doctor and they not having done it, the teacher after a time has said: "You can not come back until you have your eyes examined and see what is the trouble." It certainly is a most important point as we all know from experience. We see the pupils ordinarily—that is if we see them at all—when they have been overtaxing the eyes which are hypermetropic or having hypermetropic astigmatism, go on for years perhaps until a permanent injury has occurred. And if by precept and example or even by legislation at a later time, when we have inculcated into the public mind the necessity for such legislation, if anything can be done so that every school child in his study whether in the public school or otherwise shall have the eyes thoroughly tested it will be a great advance.

DR. H. B. YOUNG, Burlington, Iowa—Mr. Chairman: Following the line of thought suggested by Dr. Eaton and the last speaker, I desire to call the attention of the Section to the fact that in many of the States the school teachers are very strongly organized; in fact it is a compulsory organization known as the State Normal, and by addressing our communications to the State Teachers' Association we perhaps could get an entering wedge which would be very valuable in this connection. As far as I individually am concerned, I have for some years past at the invitation of our local Normal Teachers' Association, had some talk on the subject; and I think every member of this Section would be very willing to volunteer such instructive talks to the Association in his own respective district. I know I have done so upon the express invitation of the Superintendent of the Normal department.

DR. SOUTHARD—I would like to hear from the President; I think he has had some experiences in that line.

THE CHAIRMAN—It only occurs to me to say that I have had some experience in the examination of school children's eyes and I think that this subject would perhaps be a very profitable one for a special discussion such as we had this year for the objective tests, and to make that suggestion to the Nominating Committee, which I think would be the proper one to bring forward the subject at the next annual meeting. It is certainly an extremely important subject, and one which can be elucidated by general discussion—at least by general discussion we can arrive, I think, at practical means of working out the result that we want to accomplish.

DR. SOUTHARD—I will not occupy much of the time of the Section. I am not egotistical enough to believe that I have written anything at all in this paper that is new to any of the gentlemen present. I did not expect to bring in any array of scientific data, but thought it would be well to have the subject started. There is no member of the Section, but who is fully aware and well posted on all statistics that have been made, and during the past twenty years the enormous amount of the statistical matter which has been made is sufficient in itself to prove the point that there is abundance of errors. I want to bring it in shape to get an expression of opinion as to some method of procedure. I myself believe that that idea of engaging the attention of the government of municipalities is a very good method; but my purpose has been to show that the great failure is in the schools in the early age, that is the primary schools. I do not expect that we can correct it after 20 years of age; we don't expect to make changes then. We then give them glasses and let them go on as best they can. It is at the primary schools that we must commence if we are to make the change. Now the fact is as I said, I do not present any array of statistics but I simply say this: As between the primary schools in this city which have an average attendance of 31,000, and the grammar grade which is the next grade above that, and begins at 10 years of age—I say that with an average of 31,000, say up to 10 years of age, that that attendance at the next grade above, within a comparatively few weeks drops over 50 per cent. That can not be all due to the causes which I have enumerated—a desire to work, and so forth—because we don't have much of that in this State with children at that age. I have had the privilege of speaking to the State Teachers Association in this State; and several times I have talked upon the subject with different County Teachers Associations; I have had the privilege of bringing this question in a little different but analogous form to the Stanford schools, and I have endeavored to show them that the immediate cause for a great deal of our disturbance, this inability to concentrate the mind, is that children get disturbed because they can not concentrate their minds where they ought to be able to use their eyes, for instance ten or fifteen minutes at a time, and they are the ones who deserve our sympathies whatever it may lead to. I speak of myopia in my paper, but as we know it does not exist in our country to a very large extent. A myopic child can see pretty well. It is hypermetropic and astigmatic cases and, as I have stated, the results that I have obtained are entirely under the average. When I say that hypermetropic and astigmatic cases are 75 per cent. of all, I am within the bounds of my own personal examination of those cases. And I believe this, that if we were to make a change by which we could analyze a larger percentage of the pupils through the schools up to the high school though not beyond, but to the high school point, where they are then fitted to go to work, that this is a very important point. Now I acknowledge that there are a great many other

causes as Dr. Miller says; for instance, the hereditary tendency to disease is very apparent, especially among certain classes. If our Section could give some inducement to this question of the necessity for a compulsory law, there is no doubt in my mind but what the law can easily be carried out. In this State we have a compulsory law for vaccination. It is a law that does not need the approval of every member of the community, but it meets the approval of such a large number that we carry it out very effectually, and it is a law which has been passed upon by the Supreme Court as a constitutional law. Therefore it is not a law that might be put under the head of class legislation. A law which would perhaps be of greater value than even that, if we can allow such a thing, would not only meet the support of physicians and teachers and educators, but of those who are interested and who have children themselves. The methods of getting at it are to be developed later on. I am sure that it could be done, but the teachers and educators and politicians and all this class of people must have this thing brought to them by inducement of those who have had experience, such as the men in this Section have had.

In answer to a question as to what kind of certificate would be required of children, the Doctor replied as follows:

The provision should be that every child when it first comes to the primary school shall bring a certificate to the teacher; that when that child enrolls its name it shall have a certificate saying that its eyes are in a condition which will permit it to take up the ordinary course of studies that children of the same age usually do. Now it does not mean that there are to be paid oculists for every school. But it means that their eyes are normally constituted to do that, and if they are not normally constituted that they are to have glasses fitted to them to pursue the studies which children of the same age take up. You see how it is. I have found in my experience among teachers in the schools here, those so ignorant on the subject, that they have pointed out to me in the schools that such and such children were probably deficient in mental power, and I have seen those children and can call to mind several of them in fact. But there is one case that came under my observation—a child who was sent to the Home for Feeble-Minded Children. That child is wearing glasses and is now one of the brightest pupils of his age. There was nothing at all the matter with the child but inability to concentrate himself upon his work; he could not see; his whole horizon was bounded by just the little about him and his contact with the world was such that he knew very little of it. He was sent to the Home for Feeble-minded Children and the intelligent man at the head of it saw at once there was eye trouble, and that was corrected at once.

(Question was asked as to re-examination.)

I have no doubt but that every five years they should be re-examined. That would be included in the law. It would be easy enough to have the thing worked up in time. The object is now to get at the point that there is a necessity and that we are in favor of this law.

SHOULD CASES OF TUBERCULAR CONSUMPTION BE REPORTED TO LOCAL BOARDS OF HEALTH?

Read at the Meeting of the Northern Tri-State Medical Association, held at Angola, Ind., July 17, 1894.

BY J. F. JENKINS, M.D.

MEMBER OF THE MICHIGAN STATE MEDICAL SOCIETY, NORTHERN TRI-STATE MEDICAL SOCIETY, AMERICAN MEDICAL ASSOCIATION, THE NINTH AND TENTH INTERNATIONAL CONGRESS, TUCUMSEH, MICH.

The question with the above heading should be stated somewhat after the following manner: Should a case of pulmonary tuberculosis be reported to the local board of health as a case of contagious disease?

It has been estimated by very competent men, that tubercular consumption carries off about one-seventh of the human race. When we take into con-

sideration the great number of diseases that "flesh is heir to," this must be considered a very high death rate from a single disease.

The efforts put forth by the various governments of the civilized world to prevent the spread of Asiatic cholera are very great indeed, yet the death rate from cholera with all its ravages is never equal to the death rate of "the great white plague," pulmonary tuberculosis. The disease has invaded almost every part of the habitable world; it enters the palace of the prince, as well as the hut of the peasant; it casts its blighting scourge over the fairest lands in both temperate and torrid zones: It is doubtless as fatal to-day as when Abraham fed his flocks on the plains in Judea. Notwithstanding these facts, the disease never creates public alarm nor has it at the present time attracted the attention of a single national government, either in Europe or America, so much so as to enact laws in order to control the disease, although something has been done notably by the governments of the United States and Germany, in order to prevent the spread of tuberculosis among the lower order of animals. In the past there has been only one locality, which I am able to cite to you, where any effort has been made to control the spread of tuberculosis, viz: the city of Naples. Long before bacteriologists had demonstrated that pulmonary tuberculosis is a contagious disease, the government of Naples had passed restrictive laws in order to control the spread of consumption among its inhabitants. "Smell Naples and die," is a proverbial remark long in use, uttered in every European tongue, in order to point out the unsanitary condition of that city, yet, restrictive laws relative to pulmonary tuberculosis reduced the death rate from this disease, which had heretofore been high, to a very low mortality.

Without doubt, heredity is an important factor in the production of tuberculosis, that it is only one, but not the least important factor in producing consumption is doubtless true. Since the discovery of the tubercular bacilli by Koch, it has become an established fact that pulmonary tuberculosis is a contagious disease; that the tubercular bacilli enter the lungs through the larynx, thence into the bronchii, where we frequently find tubercular deposits upon post-mortem examination.

Tubercular consumption is spread by means of the sputa that contain the bacilli. When dried the virus is carried in all directions by the atmosphere. Osler states that between three and four billions of tubercular bacilli have been thrown off by a single patient in twenty-four hours. A large proportion of patients disseminate the disease throughout the suppurative stage by means of the sputum, which is usually sown broadcast wherever the infected subject may choose to travel, either by sea or by land. Tubercular patients frequent churches, schools, opera houses, dance halls, and court rooms, wherever business or pleasure calls them, disseminating tubercular virus in all directions. These microorganisms are certain to find a proper soil where they take root and grow; but unlike the virus of scarlet fever, smallpox, cholera, and many other contagious diseases, the incubative stage lasts months, yes, and even years; hence it is that the public, and even the professional mind is seldom aroused by this fatal disease which has proved in the past, as well as in the present, the greatest enemy of the human race.

Probably the most instructive as well as the most

exhaustive experiments relative to the contagiousness of tuberculosis have been made by Cornet of the Berlin Hygienic Institute. His material was gathered from various sources; from three asylums, two prisons, and from twenty-one wards in seven hospitals, from the surroundings of sixty-two private patients suffering from tuberculosis and twenty-nine different localities which were the resort of transient patients. From Cornet's experiments, negative results were found in those places occupied by transient patients, while virulent tubercular bacilli were found in the dust from the walls of fifteen out of twenty-one wards occupied by tuberculous patients. Dr. Cornet cites the case of a tuberculous female patient. Six weeks after her death he examined the dust from the neighborhood of the bed and found it highly infective. While it has been proved beyond the possibility of a doubt that the dried sputum from tuberculous patients is highly infective, it has also been found that the expired air of these patients is not infective.

The death rate from pulmonary tuberculosis in prisons, almshouses, cloisters, and among nurses in tuberculous wards in hospitals is unusually large.

During the past twenty-five years Dr. Flick, of Philadelphia, has been studying the distribution of tuberculosis in a single ward in that city. He found nearly one-third of the houses infected with pulmonary tuberculosis, and that 33 per cent. had more than one case in it; he also found that more than one-half the deaths from consumption in the year 1888 occurred in these houses. Osler states that out of 427 cases of pulmonary consumption at the Johns Hopkins Hospital, in 25 either the husband or wife had been afflicted with it or had died from the disease. Cases are reported where the husband has lost four wives, others three and some two. I think there are very few physicians whose experience has run through a score of years, but what can relate cases where two or more in one family have died of pulmonary tuberculosis.

It is frequently mentioned by those opposed to the idea of tubercular infection, that monkeys in the African jungles frequently die of pulmonary tuberculosis. It is a singular fact that the venereal passion is strong among tuberculous patients; doubtless the same passion exists in the tuberculous monkeys inhabiting the jungles of Central Africa. If true, they would live in sufficiently close proximity to infect one another with tuberculosis.

The evidence is strong that tubercular infection is principally confined within the walls of buildings, and that outside of enclosures the chances of infection, if any are almost *nil*. Among bacteriologists at least, if not among medical men, there is a consensus of opinion that pulmonary tuberculosis is a contagious disease, and that patients and nurses should be instructed in every means necessary to prevent infection.

That pulmonary tuberculosis can and should be restricted is generally believed, and in order to accomplish this object it becomes necessary to report every case of pulmonary tuberculosis which may occur in a community, to the local board of health. It is not necessary to placard the houses of tuberculous patients, or to restrict individual liberty, and as long as the patient is able he should be permitted to follow his usual avocation, providing he implicitly follows out the instructions given him by the local health officer.

The State Board of Health of Michigan has made it obligatory on the part of physicians and householders to report to the local board of health all cases of pulmonary tuberculosis, so that the State Board may give information to patients and attendants through the local health officer relative to the prevention of the disease.

"FEMALE WEAKNESS."

BY C. E. RUTH, M.D.

PROFESSOR OF DESCRIPTIVE AND SURGICAL ANATOMY IN THE KEOKUK MEDICAL COLLEGE, AND CLINICAL SURGERY IN ST. JOSEPH'S HOSPITAL, KEOKUK, IOWA.

For relief from the above feminine terror we find three-fourths of the married and a large proportion of the single women consulting the family oracle. Frequently he looks at the tongue, feels the pulse and orders some internal medication with the promise of prompt relief. Not benefited she returns or seeks one who has the reputation of being a good woman doctor, and after the patient's diagnosis has been confirmed she is started at once on the road to certain cure (?) the means being, astringent injections, orange blossom, vaginal tablets, etc., which are sure to rid her of the unnatural whitish or yellowish discharge which she is told comes from the womb. Months and years go by, menstrual pain and leucorrhoea now better, then worse, till it is finally discovered that she has a fearful ulceration of the womb that is the cause of all her trouble. Then the robbing begins in earnest; the vaginal speculum is introduced at once, twice or three times per week and the iodine, hamamelis, glycerin, wool, and cotton series are fairly ushered in with their deception and allurements. Another decade has passed; she is physically no better, financially much worse, but the iodine wiper is tolerably well fixed. All that he has ever seen pathologically of that patient was the os uteri, and its pathologic condition was due to remote causes of which her attendant had never dreamed. But the symptoms were being faithfully treated. These patients are nearly always examined in the recumbent posture, which is the most comfortable to the patient usually but often gives the physician a very incorrect idea of the usual positions occupied by the woman's pelvic organs when about her work, or in the position in which she has the greatest suffering. The speculum is nearly always used which obscures the condition of the perineum, rectal and vaginal walls, with the tendencies of the latter to prolapsus, and frequently also hides the urethra, besides making the examination of the outlines of the fundus uteri, ovaries and tubes an impossibility.

If the iodine wiper is a fraud, obtaining money under false pretenses, what shall we say of the man who undertakes to cure all of the ills to which human female flesh is heir, by amputation of the cervix, or the fellow who pretends to do perineorrhaphy and after a little scratching makes a skin perineum which only puts the defects out of sight. They both go a step beyond the former villain and add mutilation and possibly murder to robbery. In these days of brilliant surgical triumphs the doctor is hard to find who has not had his head turned just a little, and is only waiting for a victim to enable him to step at once into the field of surgical glory, especially if he can record a successful laparotomy; rather, I should

say a case that did not die. The cases that are not buried in a short time after their abdominal contents are aired, can not all be said to be well. Often they are worse than before. We hear these men explaining all mystery in female genito-urinary pathology by their wonderful knowledge of the ovaries and Fallopian tubes. Most of these men who are so anxious to rip open some belly have never seen or by touch recognized an ovary or tube in the human subject, in either a normal or pathologic state. It is seldom that they can outline the subjects of their mental aberration by the most painstaking examination. They will go into the abdomen and remove appendages for pathologic conditions that exist only in the mind of the medical attendant. They jump at the conclusion that what their superficial examination and reasoning fails to reveal must be due to grave tubal and ovarian disease. The spectacle they present when lost in the abdomen and are stirring its contents for an idea is sickening, to say the least.

Is it any wonder that the laparotomy death rate is so high in some of our communities that it is almost impossible to have the most necessary operation done? It is interesting to examine the specimens in some of our laparotomists' office jars, and listen to the explanations of their pathology. Longitudinal bands of muscular fibers are mentioned as bands of dangerous adhesions that necessitated the operation. If the patient survives the criminal effort which unsexed her, the bands of adhesion will probably be ample for easy demonstration. How do some of these men become possessed of the knowledge and daring that makes them such dangerous elements in society? It seems to be born with a few, developed in some by remarkable reports of our shining lights, but usually they are hatched in a few days in Chicago, New York, or St. Louis, etc. They boast of their great opportunities, when in reality they have scarcely enough anatomic knowledge to make safe general practitioners. The masters at whose shrine they worshiped for a few short days, have toiled alone patiently for years to master the fundamental principles on which their success has been based, and those who would succeed in the same line and do not wish to be mere traffickers in human life and happiness must go and do likewise.

Much brilliant operative surgery in which is left out of sight the tiresome, difficult, and uncertain diagnostic hill which was climbed in each case, is in part to blame for the errors mentioned. These abuses and criminalities must continue till the mass of the profession are taught that ocular inspection and digital examination of the perineum, anterior and posterior vaginal walls, and urethra will enable them, without the vaginal speculum, to recognize the lesions which cause most of the trouble for which they now treat the os uteri and are anxious to remove the uterine appendages. We certainly have no use for the speculum to enable us to determine the condition of the tubes and ovaries. Bi-manual examination with one or two fingers in the vagina or rectum, if need be under anesthesia, will enable the educated touch and brain to recognize the nature of most female genital pathology that can be diagnosed without the use of the knife. It leaves very little from a diagnostic standpoint for the sound and speculum to do. It would be better if there was one vaginal speculum where there are now one hundred. With a vaginal

speculum introduced under cover, and the examination made complete with it in position, the best gynecologist will fail to correctly diagnose three-fourths of the abnormalities needing attention. The diagnosis first, and inspection of the os afterwards. It is to be hoped that the younger members of the profession will not become factors in engrafting on the profession such abominable terms as "female weakness," which had its origin in an attempt to cover up ignorance. The time for these things to be winked at has gone by, and the man with imperfect preparation for great responsibility in gynecologic practice should receive encouragement only in the line of preparation for good work, rather than professional sanction for mutilation and murder of human beings. The man who takes money for medical treatment that he knows will be useless is no less a confidence man than the one that the law of our land would seize.

I call to mind a goodly number of cases of irritable bladder, cystitis, or nephritis so-called, permanently relieved by removal of an urethral carbuncle, repair of lacerated perineum, removal of hemorrhoids, repair of lacerated cervix, or amputation of some one or all as the case seemed to require.

Formerly I did these operations singly, or but two at a time, but for past three or more years have been doing them all at one sitting, if need be, and the patient's condition justified it. The causative factors must all be removed in any case if we expect satisfactory results. Amputation of the cervix, curettement, etc., will not cure a case of subinvolution due to causes that still continue active. The most that it could be expected to do would be to bring temporary relief, and thus gynecologic surgery is brought into disrepute. If we carefully reach and eliminate all the causative factors in each case, whether it be by surgery or medicines, we will be successful. If not, our results will rate us in the community unpleasantly close in importance to the average charlatan. Flexions have caused me more trouble than all other cases. Gradual dilatation with the Tait dilator has given me more satisfaction and my patients more relief than all other plans that I have tried. Though my patients are satisfied with it, I am not. They must, like the male urethral stricture case, have another *séance* once in one, two or more months. I have not done the Alexander operation in retroflexed cases on account of theoretical objections, but am inclined to think more favorably of it than formerly. From the operations that I have seen done extraperitoneally on the round ligaments, I am sure that the man who undertakes this operation should have the most accurate anatomic knowledge possible. No one should do an ablation of the appendages who can not palpate the normal ovaries and detect marked enlargement of the tubes. Ventral fixation bids fair to become quite popular in the near future, as it can now be done without an incision into the abdominal cavity.

From experience and observation, I am satisfied that intelligent surgery will permanently relieve or cure three-fourths of our gynecologic cases. I believe that obstetricians, midwives and the general ignorance of the community are responsible for one-half of the misery and ill health of our women.

All women should be examined in two weeks after delivery, and all lacerations of the cervix should be repaired before the woman is allowed to be on her

feet, especially if the tears be laterally placed. All lacerations will be repaired by nature if located anteriorly or posteriorly, and I am satisfied that if the woman did not assume the erect posture for four weeks, those that are placed laterally would also unite. The difficulty is in the woman's assuming the erect posture, and as the utero-vesical and rectal ligaments, so-called, furnish the uterus with its principal support, as soon as the woman is on her feet the anterior and posterior lips are forcibly separated and union is prevented, and finally we see the condition remaining one of permanent eversion. With care in our obstetric and gynecologic practice the life-long invalidism and justly dreaded maternity may soon become things of the past. Then the term "female weakness," and the occupation of the iodine gynecologist will be gone forever.

SOME UNCOMMON OR SINGULAR CASES.

Read before the Pennsylvania State Medical Society, May, 1894.

BY JOHN M. BATTEN, M.D.

PITTSBURG, PA.

Dysmenorrhea, Catalepsy, Hysteria.—In 1867 a female, single, age 18 years, of nervous temperament, came under my observation and treatment for a period of three years. There were dysmenorrhea with scanty and irregular discharge, tenderness over spine, hyperesthesia over surface of body, and great tenderness over the region of her genital organs. There developed during the early part of this period, many strange and unusual symptoms and she exhibited many remarkable freaks. One day she would have a jumping toothache, the next day she would be hysterically insane, almost uncontrollable, the following day she would be in a profound catalepsy, the day after she would be a songster and the following day she might be rational. Another day she would suffer colicky pains in the abdomen, followed by all sorts of contortions of the body. These conditions would repeat themselves, period after period, in various forms. In the evening of her catalepsy day while lying in bed quietly, she would suddenly spring from the bed, surrounded by the bed-clothing, and alight head foremost on the floor. On another evening following her song day, she would stand before a looking glass in the dim light from a smoldering fire in a grate and arrange her toilet, sing a song, or read a chapter out of the Bible. At other times she would run around on the furniture of her room, or dance on the "piano." One evening she endeavored to drive me from the room with a poker. Sometimes, in the evening, when sitting in a chair after the well day she would become paralyzed and have to be carried to bed. These varied conditions continued without interruption for about two years, when she commenced to convalesce. The last symptom or condition which manifested itself was invariably lighted up when a young man visited her. On the occasion of his visit she would become paralyzed or powerless to remove herself from the chair on which she was sitting, and would so remain until after the young man had left, after which she would be carried to bed. During the night she would recover the use of her limbs. This female afterwards married the then young man and now is the mother of three intelligent, healthy children, and is enjoying reasonably good health herself. I have no doubt if a similar case now, should fall into the hands of a laparotomist there would be an operation performed.

Dysmenorrhea.—In 1888 Mrs. J., age 21, used ice cold water as an injection immediately after having had intercourse with her husband and a short time before her expected period. In a short time thereafter a group of very painful and distressing symptoms presented themselves which were difficult to control. Among these were dysmenorrhea, tenderness on pressure over the abdomen, colicky pains in abdomen, borborygmus, functional derangement of the heart, insomnia, irritable temper, and loss of appetite. After a time, under my observation and treatment, she became dissatisfied and wanted to be relieved quickly; she consulted a laparotomist who advised laparotomy with a view to removing the left ovary. After considering the matter for some time she returned to me for further treatment. She is now enjoying good health and has had one miscarriage.

Stenosis of Cervix, Supposed Phthisis.—In 1869 M. C., a female, single, age 21, had been treated by a celebrated physician for two years for what he diagnosed as phthisis pulmonalis, and had made a very unfavorable prognosis. At this time I was called in to treat her. She presented the following symptoms: Emaciation, cough, expectoration, amenorrhea, tenderness over abdomen and over spine, anorexia, constipation, periodically colicky pains in the abdomen and inability to walk. This condition had continued with varied symptoms for a period of two years. I made a thorough and careful examination and, after weighing and examining all the conditions presented, I considered that this group of symptoms might have been caused by a stenosed cervix. Upon this conclusion I acted; dilated the cervix completely with a sponge tent and thereafter my patient soon recovered; she is now the mother of two children and weighs 160 pounds.

Prolapse of Uterus in Parturition.—Early one morning in the fall of 1872, I was called to see a case, a German woman in labor with her fifth child; she was attended by a midwife who undoubtedly to hasten labor had been giving the woman ergot. I found the head of the child outside of the mother with a portion of the womb covering head of child. The os was only partially dilated, not enough to allow the head to pass through. The part of the womb covering head of child outside the mother was thin and dry. The mother was still having light parturition pains. I quieted the mother with sulphate of morphia and anointed the parts of the uterus outside of the mother with lard. In about an hour the child was born. The uterus assumed its normal position and the woman recovered.

Fracture of Olecranon.—In 1882 J. S., a boy aged 15 years came under my care at the Pittsburg Infirmary with ankylosed right elbow joint, from an injury received while working on a farm. The fore-arm was in a straight line with the arm. I put him under the influence of chloroform and in breaking up the adhesions of the ankylosed joint I fractured the olecranon. I put the arm in a rectangular splint and kept it there for three weeks. At the end of this period on becoming alarmed because some cases of smallpox had been received into the hospital, he surreptitiously made his escape. About three years ago I saw him for the first time since his escape from the hospital, and he told me he had quite a useful arm.

Retained Pessary.—Mrs. T. J. A., age 30, was confined with her third child, Feb. 16, 1885. The breech of the child presented, and after a tedious labor the child was born. One year afterward I was called to see patient with inflammation and great tenderness of the vagina. The hasty and imperfect per vaginam examination I was compelled to make led me to think that the hard ring-like condition at the upper part of the vagina which presented itself on this examination might have been produced by an inversion of uterus after the last labor, causing thereby the constricted parts of that organ to slough away. After having been annoyed with the case for a week and no improvement noted, I chloroformed my patient and extracted a hard, irregular round pessary. The pessary had been the cause of all the irritation and distress, and had been surreptitiously placed there by a midwife during a vaginal examination. The woman recovered soon afterward, but has since died of phthisis pulmonalis.

Obstruction of the Bowels, Intussusception.—W. K., age 32 years, a large fleshy man, a saloon keeper and beer drinker, was attacked June 6, 1890, with cramps and nausea at the stomach; did not know exactly when his bowels had been moved. On Sunday, June 8, 1890, was called and found him in the above condition though more intensified. I prescribed calomel and opium in 1 grain doses each, in powder every three hours, followed by warm water enema. I continued with this treatment till Monday when the pains had become very much more severe. He was in a kneeling posture with his belly resting on the side of the bed to gain relief. The hot water enema was continued. For the calomel and opium, I substituted a pill of a quarter of a grain each of extract of belladonna and sulphate of morphia to be given every hour. In the afternoon Dr. A. M. Pollock, of Pittsburg, was called in as counsel in the case. He suggested that the warm water injections and morphia and belladonna pills be continued as before, and in addition thereto he recommended one-half grain of sulphate of morphia hypodermatically, administered every six hours or until the pains might be controlled by the morphia and belladonna pills. This treatment was kept up uninterruptedly night and day till June 12, when there was some indication of fecal odor in the warm water enema passed from the bowels. The treatment

was continued. On June 13 there was a thin fecal passage from the bowels with the warm water enema, and the hard and inflated bowels had subsided. He was considerably narcotized. At this time the morphia and belladonna pills and the hypodermatic injections of morphia were withdrawn. Strong coffee and Rochelle salts with hot enema were ordered to be given every three hours. On the afternoon of June 13 the bowels were well evacuated, pains subsided and the patient is in a fair way to recover. On the evening of June 13 he was attacked with delirium tremens which continued during June 13, June 14 and June 15. On that afternoon he slept three hours and also all of Sunday night. June 16, he was about the house and was well.

Some points in this case should not pass unnoticed. The amount of morphia and belladonna taken into the system in the four days was thirty-two and twenty-four grains respectively. The fact of his having delirium tremens would have precluded laparotomy.

Here we have the history of a case of obstruction of the bowels for just one week at least, and at no time during this obstruction did there arise a condition in the case which demanded an operation. If there had been a time during this obstruction in which the operation might have been demanded, it would have been early in the disease about Monday June 9, and that demand would have been only arbitrary. The point I wish to make is that there is no period in a case of obstruction of the bowels where an operation is called for until inflammation has set in, that we can prognosticate certainly that a case may not recover without an operation. Suppose this case had been operated on Monday, the third day of the obstruction, what would have been the result? Why certainly death! For no case of a recently opened belly could have survived such a strain as the belly of this man was subjected to during the time of his wild unmanageable delirium Friday night, Saturday and Saturday night, and Sunday forenoon, June 13, 14 and 15, so that in this case, at least, it may be said conversely to what I have heard a member in this Society state, that the laparotomist arrived just twenty-four hours too late to save life. The laparotomist, if one had been employed in this case, would have arrived just four days too soon in order to save the patient's life.

Abscess of the Liver.—In May, 1877, J. S., a farmer age 30, was admitted into the Pittsburg Infirmary suffering with what had been diagnosed phthisis pulmonalis by his medical attendant. He was very much emaciated, had cough, fever, expectoration, night sweats and anorexia. After he had been in the hospital a short time there was an abscess in the liver discovered to be forming and finally its contents, three pints of pus, were evacuated and the patient afterward rapidly convalesced.

Laryngeal Diphtheria.—M. R., a male aged two years and eleven months, was taken with slight cold, as the parents thought, on Sept. 5, 1892. The slight cold or cough got worse and worse, when on September 18 a doctor was called in, who told the parents that an operation was the only thing that would be likely to save the patient. The parents therefore looked with anxiety on the case and expected every moment that death would relieve the suffering of their child.

On September 19, 11 A.M., I saw the child, who was very restless, with extreme dyspnea; abdominal breathing, aphonia, beads of sweat standing out on the face, anxious countenance, ringing hard cough, injected eyes, patient reaching out from mother's arms to go to father, and from father back to mother again. No diphtheritic deposit could be seen in pharynx. I ordered 3 grains of calomel to be given every hour and inhalations from slaking lime every three hours and whisky *ad libitum*.

September 21. Patient whispers; cough croupy, breathing abdominal, bowels moved about five times since last visit. Countenance anxious, eyes injected. Has coughed up some membrane, pulse irritable and quick. Calomel and whisky

continued, together with inhalations from slaking lime. Membrane extends from larynx along trachea and bronchii.

September 23, 10 A.M. Patient rested better previous night. Had five stools. Breathing still difficult; patient restless. Slaking lime inhalations, calomel and whisky continued, together with lime water spray to throat.

September 25, 10 A.M. Breathing more freely, not so restless. Voice at intervals natural. Had seven stools since last visit and has expectorated membrane about twenty times, each of which added to the relief of the patient. The patient has taken a pint of whisky since I first saw him. Treatment continued.

September 27, 10 A.M. Took three-quarters of a pint of whisky and has had seven stools since last visit. Patient slept all last night. Has no difficulty in breathing. Voice aphonic. Ate well this morning for the first time since illness. Bronchii, trachea and larynx clear. Treatment continued.

September 29, 10 A.M. Has been speaking in higher nearly natural tones since Tuesday afternoon, coughs some and expectorates a little mucus. Breathing freely and natural. Bronchii, trachea and larynx still clear, sleeps and eats well. Has had ten stools and has taken three-quarters of a pint of whisky since last visit. Treatment, calomel and whisky every three hours.

October 1, 10 A.M. Appetite good. Has had six stools since last visit and took a quarter of a pint of whisky; sleeps well; voice a little husky; whisky and calomel ordered to be given every four hours.

October 3. Patient has had five stools and took one quarter of a pint of whisky since last visit. Patient has about recovered, except there is still a huskiness in the voice due to a relaxed condition of the vocal chords. Dropped calomel and whisky and put patient on the following prescription:

R. Tinc. ferri chlor gtt xxx ij
Potassii chlorates gr. x ij—(12).
Syrupi toluanus.
Syrupi simplex āā ʒij.
Aquæ ʒiss.

M. Sig. A teaspoonful three times a day.

October 7. The patient has entirely recovered.

During this child's sickness he took 876 grains of calomel and about a quart of whisky. I assert that calomel, in large and frequent doses, given a child suffering with laryngeal diphtheria prevents further exudation of membrane which will finally become detached and expectorated, and hence in the majority of cases thus treated if seen in the early part of the disease there is no necessity for intubation or tracheotomy.

The above makes a record of three cases of laryngeal diphtheria that have recovered under my care with the calomel and whisky treatment.

Renal Colic, Morphia, Convulsion.—I. K., age 32, well built and weight 160 pounds; suffering with orchitis, was attacked with renal colic on the evening of Feb. 14, 1894. At 8 P.M. he took an ordinary dose of morphia to relieve pain which afterward became more intense so that at 9:40 P.M. I gave him a hypodermic injection of one-quarter of a grain of morphia with one one-hundred-and-fiftieth of a grain of sulphate of atropia. For two minutes after the injection he felt nausea at the stomach when he was seized with a convulsion and remained in this convulsion three minutes, after which he returned to consciousness and said he felt better.

DISLOCATION AND DOUBLE FRACTURE OF THE UPPER THIRD OF THE HUMERUS.

Read before the Cincinnati Academy of Medicine, June 4, 1894.

BY B. MERRILL RICKETTS, M.D.

CINCINNATI, OHIO.

For the surgical history of this unfortunate state of affairs I can not do better than to refer those who wish to inform themselves upon the subject, to Dr. McBurney's paper and report of a case of this kind published in the *Annals of Surgery*, April, 1894. This is the most complete and concise article that I have read. It is more especially interesting as he

offers the means of a plan of reducing the disarticulation which he himself was the first to devise and execute. This was done July 1, 1893, and has been the means of revolutionizing the treatment of this class of cases when the condition of the patient will permit. That no surgeon thus far reported has met with more than five cases shows that the accident is exceedingly rare. The cause is obscure, the statements of the injured being very unreliable.

It seems probable that in the larger number of instances the dislocation is produced by the usual mechanism—that is through violent sudden abduction of the arm; as in a fall upon the hand or elbow, and the head of the bone having become fixed in its new situation that fracture takes place through continued abduction, combined perhaps with force rotation, the edge of the glenoid cavity or of the acromion acting as a fulcrum.

The complication has also been produced a good many times by the surgeon in his efforts to reduce a simple dislocation. The dislocation has been usually subcoracoid, occasionally subglenoid and very rarely subspinous. Unless there is very much swelling there should not be much difficulty in making a diagnosis, as the head of the bone can be felt and crepitus defined.

The treatment formerly practiced was either immediate reduction or reduction by using the arm as a lever after the bones have become firmly united.

Thirty-six of the eighty cases reported were reduced, while forty-four were failures and as six of the eighty died as the result of traction, rotation, etc., it will be seen that any attempt at reduction by any means other than open arthrotomy is exceedingly dangerous.

The fracture in the 117 cases reported was in 69 at the surgical neck; in 27 at the anatomic neck; at the "neck" in 11; both anatomic and surgical neck were fractured in 6 cases; 1 case was comminuted, and the 'upper part' of the humerus was fractured in 3, "thus showing the line of fracture to be varied."

The very unsatisfactory results from former treatment, together with a mortality from manipulation alone being almost as high as that of hip joint, amputations should convince the surgeon and practitioner in general that other means should be adopted.

PLANS OF TREATMENT.

1. Immediate reduction by direct pressure upon the head.
2. Manipulation after union of fracture.
3. Arthrotomy and reduction of the head.
4. Resection of head of humerus.

Immediate reduction by direct pressure upon the head should be attempted but without extension upon the arm, even though it is known that the periosteum has not become detached. If the fragment is short, reduction may be accomplished but perseverance should not be indulged in.

2. Manipulation after union of fracture being so dangerous and unsatisfactory must, I believe, be relegated. Arteries, nerves and veins may be injured to an irreparable degree, beside the loss of a life may be the result. The present mortality being something like 15 per cent.

Resection of the head of the humerus should be made in old standing cases of dislocation causing pain and the loss of the use of the arm; in cases where reduction can not be accomplished by any

means at any time and especially in young subjects. As a rule the arm is more useful after the resection of the head in adult life than where the head is allowed to remain intact. It is invariably better after resection in young subjects.

Arthrotomy and reduction of the head is surely the most rational means of treating this complicated injury if age or the condition of the patient following the injury will permit. The sooner after the injury the operation can be made the greater are the chances for a reduction and a useful arm.

If the dislocation is reduced the fracture can be more satisfactorily treated, especially if the fracture does not pass directly through the head. If reduction can not be accomplished by means of an arthrotomy, resection of the head should be made, as reduction could not in all probability be made later or by any means, and as the head left in these dislocations is a source of great pain and annoyance it is all the more advisable that it should not be allowed to remain if reduction can not be accomplished:

Case 1.—Mr. D., age 49; white and slender; in a fair physical condition; fell from a trestle fourteen feet upon the hard ground, receiving the blow upon the left shoulder, at noon time on Feb. 21, 1894. I examined the patient at 5 p.m. on the same day, finding a subcoracoid dislocation together with what afterward proved to be a fracture of both the surgical and anatomic neck. Crepitus could be felt, thus satisfying me of at least one fracture. The head could be plainly felt beneath the much swollen tissue. I at once decided to take him to my private hospital; night overtaking me I gave the patient morphia to relieve the pain about the shoulder until the following day. On the morning of the following day the swelling was much more extensive and the temperature was $101\frac{1}{2}$ F. There was also great tenderness, pain and discoloration over the entire upper arm, shoulder and scapular region.

Chloroform was given and an attempt made at reduction, first by manipulation of the head without traction. Then with both manipulation and traction, the traction not having been made to any considerable degree. Two or three attempts proving fruitless I decided to discontinue all efforts and await developments.

I could not at this time satisfy myself that more than one fracture existed; in fact I did not suspect the second one being present; however, I believed that there was a fracture of acromion, which was afterward found not to exist. The upper arm was placed in metallic splints and abducted. His physical condition was at a low ebb, the shock having been severe. Indeed it was a question as to whether or not gangrene would not result. While I informed the family of the gravity of the case, I suggested that arthrotomy could be made at any time his condition would permit.

The pain continued to be severe, the temperature 102 and the injured parts cold, swollen and very much discolored. This state of affairs existed for two weeks in spite of the application of dry heat. Morphia was used freely for the relief of pain. At the end of the fifteenth day the depression was so great that the head could not be raised from the pillow. It was not until the end of the sixth week that the patient could sit up in bed.

It was at the end of this time Dr. McBurney's article appeared in the *Annals of Surgery*. I immediately proceeded to have a hook made and prepared to at least attempt an arthrotomy, believing that firm bony union had resulted, especially as I had kept the patient under the influence of mercury during the first three weeks, a rule I usually adopt in cases of fracture in long bones. Realizing that within this short time the glenoid cavity could be practically obliterated by newly organized tissue, I believed the end justified the means, so proceeded to make the arthrotomy under the influence of chloroform.

An incision three inches long, one and one-half inches below and parallel to the clavicle enabled me to reach the head of the humerus without difficulty. Both the anatomic and surgical necks were found to be fractured and ununited. The surface of the head had become adherent with the soft parts which were greatly infiltrated with a dark bloody serum.

Non-union of the fragments prevented further operative

procedure. The wound was closed with silkworm sutures, the arm brought to the chest and the lower placed at a right angle to the upper arm and firmly secured with adhesive strips. Much comfort was experienced in the change of position of the arm and the patient left for his home at the end of ten days, hoping that the country air would add to chances of complete union of the fragments. During his five weeks absence from the city he has gained in weight and general appearance, but has suffered a great deal except during the last week when he has been practically free from pain. The question now is, Should the head have been resected at the time of the attempted arthrotomy? As the indications for the resection of the head of the humerus in irreducible luxations forms the topic of another paper, which I will soon present, I do not care to further occupy your time.

BOOK NOTICES.

A Treatise on Appendicitis. By GEO. R. FOWLER, M.D., Examiner in Surgery, etc. Cl., pp. 190. Philadelphia: J. B. Lippincott Company. 1894. Chicago: A. C. McClurg & Co. Price, \$2.

The book consists of thirteen chapters which have been reprinted from the *Annals of Surgery* after correction and revision. Chapter I considers the Anatomy of the Parts Involved; II, The Inflammatory Lesions of the Appendix; III, Acute Appendicitis, Clinical History; IV, Special Types of Appendicitis; V, Complications and Sequestræ; VI, Etiology; VII, Bacteriologic Conditions; VIII, Pathologic Anatomy; IX, Diagnosis; X, Prognosis; XI, Treatment (General); XII, Operative Treatment; XIII, After Treatment.

In regard to the etiology of the affection, the author asserts the rarity with which foreign bodies, such as seeds, are found within the appendix, and he asserts that the disease is due to: 1, infection from intestinal microorganisms; 2, to circulatory disturbances, 3, accidentally imprisoned fecal matter. Notwithstanding the dictum of our author, the reviewer insists that he has many times observed seeds in the appendix, and indeed has seen them forming the center of an extremely hard ball of fecal matter.

In the matter of treatment the author states, that in the majority of cases operative treatment is required, and he properly insists on such patients being taken to a well equipped hospital rather than to attempt "makeshift" operations at the patient's house. He gives a couple of sketches showing McNaughton's invalid coach, with its pneumatic tires, whereby the patient may be taken to hospital without a jar.

The book is an excellent one as far as it goes, but it falls considerably short of being exhaustive.

Flint's Practice of Medicine. A Treatise on the Principles and Practice of Medicine. Designed for the use of students and practitioners of medicine. By AUSTIN FLINT, M.D., LL.D., Professor of the Principles and Practice of Medicine, and of Clinical Medicine in Bellevue Hospital Medical College. New (7th) edition, thoroughly revised by FREDERICK P. HENRY, M.D., Professor of the Principles and Practice of Medicine in the Woman's Medical College of Pennsylvania, Philadelphia. In one handsome octavo volume of 1,143 pages, with illustrations. Cloth, \$5; leather, \$6. Philadelphia: Lea Brothers & Co. 1894.

The only radical change made in this well-known textbook consists in the entire omission of the section on General Pathology and confining the work to Special Pathology. The editor has added articles on Pulsating Pleurisy, "Weil's Disease," Syringomyelia, Beri-Beri, Hereditary Chorea, Acromegaly, Raynaud's Disease, Leprosy, Influenza, Lithemia, Rickets, Actinomycosis, Anthrax and Glanders. Throughout the book the editor has not hesitated to make additions where it was necessary to bring the subject *en rapport* with the accepted pathology of the day. The great charm of the book has been retained, however, by handing down unimpaired the clinical description of diseases. In

this particular, none of his countrymen have surpassed Flint, and his careful, clear expression will remain as a model for many years to come. It is to be regretted that the editor has not made use of the metric system in the prescription writing, the old British weights and measures being invariably retained.

Text-book of Normal Histology including an Account of the Tissues and of the Organs. By GEORGE A. PIERSOL, M.D., Professor of Anatomy in the University of Pennsylvania. With four hundred and nine illustrations, of which three hundred and fifty-eight are from original drawings by the author. Second edition. Cl., pp. 439. Philadelphia: J. B. Lippincott Company. 1894.

The first edition of this book was issued in 1893, and so favorable has been its reception that a second edition was made necessary within a year: few changes therefore have been made.

The study of normal histology, the essence of anatomy, naturally precedes that of pathology, and no student can more thoroughly prepare himself for the study of morbid changes, than by making the intimate acquaintance of the natural structure. As a guide to this study, Piersol will be found a learned and trustworthy one. There are nineteen chapters on histology proper, and an appendix on methods which will be found most useful. The plan of the book is admirably adapted for students and in the practice of the plan adopted in most medical colleges of regular recitations, there is no work on histology known to us, that fills the purpose better.

Addresses, Papers and Discussions in the Section on Surgery and Anatomy, at the Forty-fifth Annual Meeting of the AMERICAN MEDICAL ASSOCIATION, held at San Francisco, Cal., June, 1894. Cl., pp. 414. Chicago. 1894.

It was a happy thought on the part of the Business Committee of the ASSOCIATION, to commend the re-printing of the Section books. This volume, containing as its title indicates, the work of the Section under the Presidency of John B. Roberts, of Philadelphia, is one of the best surgical year books issued. The papers have all been printed in this JOURNAL. A comprehensive index adds to the value of the book. Chairman Roberts is to be congratulated on the high scientific value of the work of this Section.

McDonald's Cook County Medical Directory. A list of physicians in the county arranged alphabetically by post-offices; Chicago Physicians and Druggists arranged alphabetically and by streets; Chicago Dentists arranged alphabetically. Also, Medical and Pharmaceutical Laws, Medical and Pharmaceutical Colleges (with Faculty of each), National, State and County Medical Societies, with officers, time and place of meeting, Hospitals (with attending Staff), Asylums, Dispensaries, Homes and other Charitable, Benevolent and Humane Organizations. August, 1894. Eighth Edition. For sale by E. H. Colegrove & Co. Price \$2.50.

The annual edition of this well known directory lies upon our table. The present volume follows the well known lines of its predecessor, and is indispensable to all consultants, and those who wish to keep posted in the whereabouts of the medical men of Cook County.

Transactions of the Medical Association of the State of Alabama (the State Board of Health), held at Birmingham, April 17-20, 1894. Cl., pp. 418. Montgomery: The Brown Printing Co. 1894.

The annual reports of this Society are unique, for this Society by law controls the State Board of Medical Examiners and the State Board of Health; the executive officer of the latter body is our well-known fellow member, Dr. Jerome Cochran. The "Message" of the President is a model which it would be well if other Presidents of societies could follow. The annual reports of the senior and junior Vice-Presidents contain much interesting matter; they mention the work of the County Examining Boards.

The reports include: The report of the Board of Censors; The report of the State Board of Medical Examiners; The report of the State Board of Health and supplementary papers. The oration by Dr. W. H. Blake is one worthy of the Society and of the occasion. The current volume of the Alabama Association may well head the list of State Society Transactions by virtue of general superiority of work no less than by virtue of the place of the State in our National Alphabet.

Transactions of the Medical Society of the State of California, Session of 1894. Cl., pp. 337.

This is a handsomely printed volume containing the proceedings, papers and addresses of the annual meeting held in San José, April 17, 1894. The papers are excellent and well edited. The address of the President, Dr. Kinyoun, eloquently points out the necessity for organization and shows that of about 2,700 regularly qualified practitioners in California only 360 belong to the State Medical Society. Medical union is the great need of the profession throughout the United States, not less than in California.

Transactions of the Forty-fourth Annual Meeting of the Illinois State Medical Society, held in Decatur, May 15-17, 1894. Cl., pp. 568. Chicago: P. F. Pettibone & Co. 1894.

The frontispiece to this volume is a steel engraving of the late Charles Warrington Earle, whose biography is well told by the committee on necrology. There is also an excellent half tone portrait of the late John H. Rauch. The general addresses in this volume, by Prof. Victor C. Vaughan, Prof. Edmund Andrews, and Prof. Wm. E. Quine are above the usual level of annual medical society orations. As they have already been published in full in the JOURNAL our readers are qualified to judge of their exceptional merit. The papers are unusually good and the discussions have been fairly reported. The list of names of gentlemen reading papers includes most of those best known in the State, and many of international reputation. The Society will next year meet at Springfield under the Presidency of Prof. Daniel R. Brower.

Transactions of the Michigan State Medical Society for the Year 1894. Vol. XVIII. Cl., pp. 589. Detroit. 1894.

This portly volume contains rather more than the usual number of papers, and constitutes one of the best hitherto issued.

The President, Dr. Boise, in his address recommended that every local society should be a part of the State Society, and that every member of the local and State Societies become a member of the AMERICAN MEDICAL ASSOCIATION, by the title of FELLOW OF THE AMERICAN MEDICAL ASSOCIATION.

The paper by Dr. Victor C. Vaughan on Nuclein and Nuclein Therapy, is the same as that read by him at the meeting of the Illinois State Medical Society and published in this JOURNAL, June 2, 1894.

The discussion on Tuberculosis by Drs. Shurly, Gibbs, Vaughan and Baker was an interesting one, and we might well say that the discussions on papers in the transactions of our various societies, are frequently of more practical value than the papers which call them forth. The Secretary, Dr. Hitchcock, should be complimented on the promptness with which the volume was issued and the careful manner in which it is edited.

Transactions of the Forty-ninth Annual Meeting of the Ohio State Medical Society, held at Zanesville, 1894. Cl., pp. 488. Toledo. 1894.

The volume has for its frontispiece a portrait of the President, Dr. N. P. Dandridge. The annual address of its President is mostly occupied with a discussion of the professional need for more perfect organization, the duty of support of the State Board of Health, and the necessity for preliminary training in biology, chemistry and physics. Prof. Kellicott, of the State University, has a paper on the method of study recommended in that institution, as a course preparatory to the study of medicine.

There are many interesting papers in the volume by well-known authors.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 96 FIFTH AVE., CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

SATURDAY, SEPTEMBER 8, 1894.

THE FOREST FIRES.

This week is one that will long be remembered in Northern Wisconsin, Northeastern Minnesota and Northwestern Michigan. This region, bordering upon Lake Superior, comprises about all there is left within the United States of the magnificent pine forests of the country of the great lakes. There had been a long drouth; the dead leaves, always thick in a pine forest, became thoroughly dry, the small pools had evaporated under a hot sun, and many of the marshes had become dry as dust. In such conditions, an accidental spark from a passing locomotive engine; ashes blowing from the camp fire of a hunter, or from the pipe of a careless woodsman, was all that was necessary to start the forest fire. A strong breeze fanned the flames into fury; houses, trees and bridges were wrapped in fire and smoke, and every living thing was in danger. More than six hundred square miles of pine land have been burned over, a dozen villages destroyed and many lives lost.

It is not probable that the mortality will ever be accurately stated, as the victims in many instances were living in the forest far removed from human assistance. The relief committee which has been formed at Pine City, Minn., has authorized the statement that at least four hundred and fifty persons have been burned to death, or died asphyxiated, and that twelve hundred persons have escaped only to be absolutely penniless and homeless. Many bodies have been recovered from wells and cisterns, where the unfortunate wretches had fled for safety when the flames rushed upon them. Fifteen dead bodies were found in a well, in the ruins of the village of Sandstone. Hundreds are suffering from severe burns.

So widespread and distressing a calamity could not fail to excite the utmost sympathy, and hospitals have been hastily organized and carloads of provisions are on the way. Our own profession, as usual, have been foremost in deeds of mercy, and Drs.

LEWIS, NORTON, PERKINS and ALLEN, who are in the midst of the scene of suffering, have done and are doing full credit to the noblest instincts of our profession, which in times of distress discusses nothing but the best and most speedy means of relief to suffering humanity.

AN HITHERTO UNDESCRIBED FAMILY FORM OF
MOTOR NERVE TROUBLE DUE TO COLD.

DR. EZRA CLARK RICH, of Ogden City, Utah, *Medical News*, August 25, describes a unique and hitherto unnoticed form of motor trouble that adds to the rapidly growing list of family forms of nervous trouble.

DR. RICH designates the condition as one of paralysis, and if we apply the criterion of loss of voluntary motion alone we must regard the term as correct; at least the limbs are immovable. Now this may arise from a condition of hyperkinesis; the movement of a limb depends quite as much upon the ability of the person to relax the opposing muscles as in contracting those necessary to effect the movement. In catalepsy, katatonia and allied conditions there is no paralysis in the strict sense of the term, yet the affected person is in whole or in part unable to make voluntary muscular movements. In the affection described by DR. RICH we may have an allied condition. It would have been exceedingly interesting if the writer could have given us a study of the electric nerve and muscle reactions while the patients were in this state.

The affected persons number twenty-two, all in one family, embracing five generations. The disease never skips one generation to appear in the next, but when a child does not inherit the affection it is ended so far as its offspring are concerned.

The affection is alike in all the affected members of the family. When brought in contact with a cold damp atmosphere the muscles most exposed soon become fixed and immovable. The muscles of the face are most frequently affected, and in that case the expression becomes fixed, one side of the face may be drawn up and the other straight, and the suddenness of the disorder is indicated by the fact that the features may be fixed in the act of crying, laughing or whistling. Next in frequency the arms are affected, the muscles of the hands and forearms, owing to their exposed position being first attacked. The muscles are always attacked in groups; thus one thigh may be affected and the legs escape, or this may be reversed. One finger, arm or hand may be affected and the remainder of the body be normal. The tongue is easily affected by taking snow or ice in the mouth; when any of it is swallowed the function of deglutition is abolished for a time.

A severe attack is related as having occurred in the person of a young woman, who after dancing

and becoming fatigued had gone to bed in a cold room without removing her under clothing. She was soon helpless and could not move any part of her body except her tongue. The intellect remained clear and conversation could be carried on as well as at other times excepting that the lips could not be moved.

The sensation in affected parts is not altered, though the patients complain of a "drawing feeling" in the limb. Recovery is always complete and there is no pain either during the period of fixation of the muscles or afterward.

It is not every exposure to cold that brings on an attack, but fatigue, cold and dampness combined. Therefore the affection frequently occurs during the summer months. Muscles that are comparatively at rest are affected more frequently than those which are actively exercised. Walking on a cold day and sitting down to rest would be certain to bring on an attack and would be almost suicidal in one of these patients if assistance were not at hand.

Regarding the pathology of the affection little is to be said. DR. RICH suggests that it may be an obscure vasomotor change in the muscles. The fact that it is a family disease stamps it as one of those rare and peculiar affections on which the present knowledge of the pathology and physiology of the nervous system throws no light.

THE NATURE OF INFECTION AND IMMUNITY IN CHOLERA.

The continued presence of cholera in Europe has been the occasion of many new researches on the biology of the cholera bacillus and its mode of action in the animal body. Foremost among these are several publications from KOCH's laboratory by R. PFEIFFER, in conjunction with WASSERMAN, ISSAEFF and KOLLE (in recent numbers of the *Zeitschrift f. Hygiene*). Their experiments were made mostly with injection of cholera bacilli into the peritoneal cavity of guinea-pigs. While the mode of infection, so different from the natural way of entrance of the germs in man, has no direct bearing upon the etiology of human cholera, it has led to important knowledge concerning the struggle between the bacilli and the animal system.

Older cultures long kept in the laboratory lose their virulence gradually. Recent (solid) cultures, however, made from the discharges in cholera were found fatal to small guinea-pigs if injected in the quantity of about one-sixth of a milligram. The measure used in the laboratory was the quantity adhering to a platinum wire loop—by weight two milligrams, which dose was suspended in broth and subdivided. The injection in fresh animals causes no visible symptoms for the first four hours, except slight rise of temperature. After this time the temperature sinks

many degrees and excessive prostration leads to death within twenty-four hours or less. The effects of the bacilli are produced by a poison contained within their bodies which is not soluble in the culture fluids. This toxin of cholera bacilli is very easily altered by almost any mode of killing the germs, except by means of chloroform vapor. If altered by any destructive influence a comparatively stable but less poisonous body is formed.

Of the toxin of bacilli killed by chloroform, about thirty to forty times as large a dose is requisite in order to kill the animal, than when the living bacilli are used. This is due to the fact that the living germs *multiply* in the peritoneal cavity for some four hours, after which time only the peritoneal fluid begins to destroy them. Accordingly there are scarcely any effects produced during the first hours after inoculation with live germs, while if the larger quantity of dead bacilli is injected the symptoms of poisoning begin at once. If the culture is injected into the blood vessels, instead of into the peritoneal cavity, the dissolution of the bacillary cells begins immediately, the germs can not multiply, but the poison is set free and hence in this case there is no period of incubation and the required dose is the same, whether the bacilli be injected alive or after they are killed by chloroform.

When an animal recovers from inoculation with an insufficient quantity of germs or from poisoning with a non-fatal dose of the cholera-toxin it is found less susceptible to subsequent inoculations. By repeating the infections with increasing doses of living germs every three to four days about six or seven times, a degree of immunity can be established which permits the animal to resist a quantity of live germs forty times larger than the minimal fatal dose. Beyond this limit, however, the immunity can not be increased.

Unlike the state of affairs as it exists in diphtheria and tetanus, the animal which has been made refractory against the live cholera bacilli is not proof against their toxin. The inoculated bacilli can not multiply in the immune body, but their toxin results in poisoning proportionate to the dose employed. Hence although the immune animal will not die from thirty or forty times the fatal dose, it is severely poisoned thereby.

It had been previously learned by other observers that within a few days after recovery from cholera infection the blood serum acquires protective powers. When it is mixed with a fatal dose of living bacilli and this mixture is injected into the peritoneal cavity of a fresh animal this animal will escape death, but like other immune animals it shows the symptoms of poisoning. The serum therefore while possessing protective properties is not *anti-toxic* in the proper sense of the word, and even in large quantity can not

protect against infection with more living bacilli than correspond to the fatal dose of toxin. On the other hand, PFEIFFER found that within the limits described, the serum of highly immune animals is really protective in remarkably small quantities—even three milligrams serum being sufficient to avert death.

It has been asserted by KLEIN and repeated by HUEPPE and SOBERNHEIM, that other bacteria injected into the peritoneal cavity produce the same symptoms and results as the cholera bacilli, and that if an animal recovers from such a (mild) infection it is now proof against cholera infection. They conclude, therefore, that there is nothing specific in either the intra-peritoneal cholera infection nor in the subsequent immunity.

While PFEIFFER confirms it as a fact that intraperitoneal injections of typhoid bacilli, colon bacteria and various vibrios resemble clinically and pathologically the infection by cholera bacilli, he still asserts that the latter is a specific process due to a poison, perhaps comparable, but not identical with the toxin of any other bacterial species. In making this plea he first contends that while it is true that recovery from intra-peritoneal inoculation with some other bacteria protects to some extent against cholera infection, there is still a radical difference between the transient protection and the real immunity against cholera. Intra-peritoneal inoculation with these different bacteria, as well as with cholera bacilli produces a suppurative peritonitis, or at least an intra-peritoneal exudate rich in leucocytes. PFEIFFER, however, shows that any disturbance which causes an exudation of leucocytes, such as the injection of urine, normal blood serum, nuclein solution or even large quantities of $\frac{2}{3}$ per cent. salt water gives a temporary increased resistance against subsequent cholera infection. But this condition lasts only up to ten or at the most fifteen days, while the immunity after recovery from the specific infection exists still after the lapse of three or four months.

Furthermore, the protection following any such non-specific peritonitis can not be carried to the same degree quantitatively as the immunity after specific infection.

In another even more conclusive manner, PFEIFFER showed that recovery from cholera poisoning is followed by a specific immunity not obtainable by intra-peritoneal infection with any other germs. If after complete recovery the serum of the now immune animal be tested as to its protective effects it will be found that the serum, when used in suitably small doses can protect other animals *only* against that variety of bacteria, with which the first animal had been inoculated. In other words, the protective effect of the serum is strictly specific. Indeed PFEIFFER claims that the specific protection afforded

by the injection of such serum against a simultaneous inoculation with living germs is a most delicate test as to whether these germs are identical with the variety used for inoculating the animal which furnished the serum. By this method he has been able to distinguish between true cholera bacilli and other vibrios which resembled them to a confusing extent, both in culture-appearances and in their action upon animals.

One of the most interesting points in PFEIFFER'S researches is the explanation of the recovery and immunity. Aspirations from the peritoneal cavity with a fine pipette showed that the cholera bacilli multiply apparently unhampered for some four hours in animals not previously infected. At the end of this time the bacilli begin to disintegrate, breaking up into small globules and ultimately disappearing. If the dose has not been too large the peritoneal cavity may become entirely sterile one or two hours later, even though the absorbed toxin finally kills the animal. In immune animals, however, the disintegration of the bacilli begins at once after the injection. Likewise whenever there is partial protection by reason of a suppurative peritonitis from other causes, or when protective serum is injected with the living bacilli they are seen to break up within a few minutes. All these instances are accompanied by intense emigration of leucocytes.

At first sight, these observations seem to be a strong support for METCHNIKOFF'S phagocyte theory, and indeed this observer has previously held up experimental cholera infection as a confirmation of the importance of phagocytes.

PFEIFFER, however, considers the rôle of the leucocytes as a secondary one, and bases his position on the important point that in the immune peritoneal cavity the disintegration of the bacilli begins and proceeds very far before the migration of wandering cells has fairly set in. Within the first ten minutes after the injection the peritoneal fluid contains scarcely any cells and still the majority of the introduced germs are broken up within this time in the immune animal. He hence reaches the apparently inevitable conclusion that in the immune animal the peritoneal tissue secretes a substance destructive to the bacilli. This substance is not a common bactericide body but exerts a specific effect on one variety of bacteria only and not on others. For when PFEIFFER injected into a guinea-pig immunized against cholera a mixture of cholera bacilla and other vibrio only the cholera bacilli were at once broken up, the other surviving, while conversely when an animal had been made refractory against another vibrio, it was only this variety which succumbed while the cholera bacilli continued to multiply. The specific bactericide is formed by the peritoneum itself, its secretion continuing for some 20 minutes after the circulation

has ceased. It does not exist in the body pre-formed, but is secreted only in the presence of the specific bacilli and is evidently used up as the bacilli are being destroyed. Still when the peritoneal fluid of an immune animal is aspirated just at the end of the time when the introduced bacilli have been disintegrated it can be seen under the microscope that this fluid will break up cholera bacilli, but is without influence on other bacteria.

PFEIFFER hence refers the recovery from cholera infection and the subsequent immunity to the property which the tissues acquire by virtue of their struggle with cholera bacilli, viz., of secreting a substance specifically destructive to these germs. The same property is given to the tissues temporarily by the injection of serum from another immune animal.

ARGUMENTUM AD HOMINEM.

Dear reader, have you done your whole duty by the JOURNAL and the ASSOCIATION? If each member will influence *one* physician to become a member or subscriber, the JOURNAL would go at once to the front. It is already great, if we refer to the achievements of the past year, but the whole profession would be prouder of it, if it so far led all the rest as to make rivalry out of the question. Let us all help.

AN OPPORTUNITY FOR MEDICAL STUDENTS.

Medical students can do nothing of more benefit to themselves and their chosen profession than by obtaining new subscribers for the JOURNAL. See advertising columns for the handsome premiums offered.

CORRESPONDENCE.

"Inebriety."

ORAN, SCOTT CO., Mo., September, 1894.

To the Editor:—Dr. Crothers' articles in the August 18 and 25 numbers of the JOURNAL suggest the following thoughts: *Old* theories (or facts) are not necessarily false. Because whisky drinking (to excess) has long been considered a vice, time alone would not make this idea false one. Truth does not lose value by age. If drunkenness was ever a vice it is evidently one to-day. The preponderance of evidence is still in favor of the *old idea*. A few leading physicians believe that drunkenness is a disease. The only cause of this error is the mistake often made of taking the *effect* for the *cause*. Excessive drinking is a *cause* of disease, not a *disease per se*. Let us theorize a little. I have a patient who is drunk for the first time. I am trying to make a diagnosis. The man is unconscious, limber and has all the symptoms of being drunk. I say he is drunk. What caused it? Too much liquor. Is he diseased? No. I have another patient who is under the influence of ether administered by me. He, too, is drunk. Is he diseased? No; merely under the influence of an anesthetic. Neither patient is harmed unless the dose is too large or kept up too long. No one would think of calling these cases diseased because there is no harm done either of them by this first dose of alcohol or ether. But suppose we keep up the dosing (the cause) of

trouble. Soon we have disease. The ether patient develops pneumonia or nephritis, the other patient any one of the many troubles caused by the excessive use of alcohol. Next we find a toper who has been drunk off and on for a number of years. Examining him closely we find a diseased liver or kidney or both, but he is sober now, his reasoning faculties are good. He has as perfect a horror of crime as any one. He has no use for a drunken man, will not associate with one. You inquire farther into his condition. Ask him if has any desire for drink. Oh, yes; his appetite is good for whisky, cider and watermelon. (I live in the melon country.) He takes the two last mentioned but no whisky. Why? Because he knows it will cause him trouble. Now the question arises: Is this man insane or not? He has drunk whisky until his liver and kidneys are diseased, but he is not insane any more than the man who has liver and kidney disease from other causes. His brain has undergone the influence of many doses of alcohol but yet has not lost its functions. Judging by his acts you can see no evidence of insanity. He behaves like a sane man and does business like a sane man. Everybody, *physicians* and all, say that he is a reliable, straightforward, upright, truthful gentleman. Then how can Dr. Crothers say this is a mistake; that this man is really crazy, and if he in anger commits crime he ought not to be punished for it the same as some other man who has never been drunk?

Now we will go a little farther. Suppose this man knows that whisky will make him drunk and crazy while under its influence, and then voluntarily gets drunk and commits crime, get sober again and being questioned replies, Yes, I knew that whisky would craze me but I did not care. I wanted to get on a drunk and have a big time, but while I was drunk I struck my neighbor who insulted me. I would not have done so if I had been sober, but when I am drunk I am quarrelsome. Is this man innocent or guilty? Is he not guilty of two crimes: One was getting drunk, the other fighting. The law, experience, common sense and reason say, Yes; but Dr. Crothers and a few others say, Oh no; this is not a bad man, he is insane; he ought to be sent to the hospital and cured instead of being punished. Give him *pure air*, good food, nice tonics and cheerful surroundings and after a while his mind will be restored and he will not commit crime. This last theory is founded upon a false premise and will never be adopted. The results of such a theory are too apparent for the law-makers ever to adopt it. The hospital is the place for sick people, but the criminal deserves punishment. If not, all theories of right government heretofore are false and there is no sense in any of it. Kindness is due to the innocent and ignorant, punishment is due the vicious and criminal. These facts are so old and so true that all former laws are based upon them. The new order will be: Hospitals for the vicious, pleasant things for the wife-beater, food for the street-loafer, a new constitution dictated by the modern physicians who have discovered that *vice* and *insanity* are one and the *same thing*.

Now a few words in regard to the "poisoned air" theory. This is "*airy*," sure enough. Did Dr. Crothers ever visit the blue grass region of Kentucky where the air is as pure as the whisky, and where the "Kentucky Colonel" shoots his opponent just to see him fall? *Pure air*. It will not keep a man from getting drunk, neither will poisoned air make him drink. The air has a good deal to do with health, but cuts a small figure in *habit*. Men get drunk in all kinds of air. The correct solution of men sobering up who leave town is in the fact that they leave the *whisky* and *evil associates* behind. Let a man take his *bottle* and his *chums* to the mountains with him, and they will drink as long as the whisky holds out. It is no trouble to explain something that is so, but when men undertake to explain something

that is not so, they deal in *big words* and befog themselves and some of their hearers. Better let the law alone, gentlemen, and attend to sick people. The drunkard is not being imposed upon but is an imposition himself. Let your sympathy run out after those who deserve it.

Very respectfully, W. P. HOWLE, M.D.

SOCIETY NEWS.

American Public Health Association.—RAILROAD RATES AND OTHER ITEMS OF INTEREST.—The twenty-second annual meeting of this Association will convene in Association Hall, Y. M. C. A. Building, Dominion Square, Montreal, Canada, Tuesday, September 25, at 9 A.M., and continue four days. The following topics have been selected for consideration:

1. The pollution of water supplies.
2. The disposal of garbage and refuse.
3. Animal diseases and animal food.
4. The nomenclature of diseases and forms of statistics.
5. Protective inoculations in infectious diseases.
6. National health legislation.
7. The cause and prevention of diphtheria.
8. Causes and prevention of infant mortality.
9. The restriction and prevention of tuberculosis.
10. Car sanitation.
11. The prevention of the spread of yellow fever.

Special committees have been appointed to discuss these subjects. The Executive Committee have announced the following additional subjects, upon which papers are invited:

12. On the education of the young in principles of hygiene.
13. Private destruction of household garbage and refuse.
14. Disinfection of dwellings after infectious diseases.
15. Inspection of school children with reference to the eyesight.

Papers will be received on miscellaneous, sanitary and hygienic subjects, but preference will be given to the topics announced above.

The headquarters of the Executive Committee will be at the Hotel Windsor, immediately opposite the place of meeting. Railroad rates will be a fare and one-third. Tickets issued on the certificate plan, and include practically all the railroads of the country east of a line running north and south through Chicago, Ill. Western visitors will please note that the Western Passenger Association up to present date has declined to grant reduced rates. Delegates and members and their families residing at points west, northwest and southwest of Chicago who contemplate attending the meeting should purchase tickets to Chicago (providing they go that way), then procure through tickets from that city to Montreal, taking a receipt from the ticket agent for the amount paid.

Dr. Liston H. Montgomery, of Chicago, has sent to the editor of the JOURNAL a complete description of a proposed attractive itinerary that has been tendered to himself and others. The route going from Chicago is the Wabash railroad to Detroit, thence via the Canadian Pacific line through to the city of Montreal without change of cars. Starting from Chicago on Sunday afternoon September 23, at 3 o'clock, in a vestibule train, consisting of Wagner sleeping and parlor cars, as well as those operated by the Canadian Pacific railway system, this train will arrive at Detroit at 11:20 o'clock Sunday evening; Toronto, Monday morning at 8 o'clock, and Montreal at 7:55 o'clock Monday evening the 24th inst., passing through a number of important cities and beautiful country that comprises the "Garden of Ontario."

Stopover privileges will be granted to those desiring it, to remain in Toronto one day either going to, or returning from the meeting. Several attractions will be afforded the visitors while at Montreal. Notably that provided by the local Committee of Arrangements for a grand excursion to Grosse Isle. This excursion alone embraces a tour upwards

of 400 miles that will be provided (gratis) to all members in attendance at the meetings and their ladies, down the St. Lawrence, and includes the privilege of a stopover at quaint old Quebec. Arrangements for other detour trips are in progress, notably to Ottawa, the capital city of the Dominion, about one hundred and fifty miles from Montreal.

Returning, members can avail themselves of the privilege of visiting the city of Detroit for a day.

The round trip railroad fare from Chicago to Montreal for this occasion is \$24. Tickets are good going as early as Friday, September 21, and valid, leaving Montreal not later than Friday evening, October 2.

The meetings of the Association are open to the public. All persons of whatever profession or occupation interested in hygienic and sanitary matters are cordially invited to be present. The Secretary of the Association, Dr. Irving A. Watson, has announced in his circular:

"The indications are that a large number of the membership and their friends from the United States and Canada will attend, including a number quite remote, from our sister republic of Mexico, as the proceedings and discussions will officially embrace the French and Spanish languages in addition to English. That ladies are especially invited to be present and participate at the evening meetings, and all persons of whatever profession interested in the work of the Association will be made welcome."

We trust that a representative number from the Western States will find it convenient to attend the forthcoming meeting of the American Public Health Association. The good people and profession of the Dominion are enthusiastic over the meeting and will be prepared to extend a hospitable welcome to all who favor them with their presence.

The Medical Society of the Missouri Valley will hold its seventh annual session at Council Bluffs, Iowa, Thursday, Sept. 20, 1894. The following papers are promised:

A Plea for Patience in Obstetric Practice. F. Damour M. D., Bolckow, Mo.

Early or Preventive Treatment of Diphtheria. J. H. Talbot, M. D., Castana, Iowa.

Chronic Articular Osteitis of Hip, Analysis of 208 cases. W. Ross Martin, M. D., Omaha, Neb.

Report of an Interesting Case. W. O. Henry, M.D., Omaha, Neb.

Erosions and Lacerations of Cervix Uteri. Geo. H. Simmons, M.D., Lincoln, Neb.

A Case of Spurious Pregnancy. Adda Bowman, M.D., Reynolds, Neb.

Amaurosis, from Abscess of Frontal Sinus. Flavel B. Tiffany, M.D., Kansas City, Mo.

Two Interesting Cases which underwent Celiotomy. Donald Macrae, M.D., Council Bluffs, Iowa.

Absorbable Sutures. J. P. Lord, M.D., Omaha, Neb.

Sarcoma of Eye—Traumatic Origin. D. C. Bryant, M. D., Omaha, Neb.

The Treatment of Typhoid Fever. W. F. Milroy, M.D., Omaha, Neb.

Mental Deficiency in Children. George Mogridge, M.D., Glenwood, Iowa.

The Proper Management of Cases of Miscarriage. Mary Strong, M.D., Omaha, Neb.

Anal Fistula. J. C. Robertson, M.D., Council Bluffs, Iowa.

Two Cases of Intestinal Surgery in which the "Murphy Button" was Used. J. E. Summers, Jr., M.D., Omaha, Neb.

The Medico-Legal Aspect of Paranoia. J. Puntun, M.D., Kansas City, Mo.

Ovariectomy, with Dermoid Cyst. W. S. Ross, M.D., Omaha, Neb.

The Morbid and Curative Influence of Mental and Moral Emotions. W. H. Kerr, M.D., Fall City, Neb.

Muscular Asthenopia. C. M. Hobby, M.D., Iowa City, Iowa.

"Anthrax" or Malignant Pustule. W. Jepson, M.D., Sioux City, Iowa.

The Beginnings of Disease. A. B. Somers, M. D., Omaha, Neb.

Hyperemesis Gravidarum. B. F. Crummer, M.D., Omaha, Neb.

Operative Treatment for Vascular Naevus. A. F. Jonas, M.D., Omaha, Neb.

A Case of Quadriseptorial Hemianopia. M. F. Weymann, M.D., St. Joseph, Mo.

Total Hysterectomy without Ligation of Uterine Arteries. J. E. Summers, Jr., M.D., Omaha, Neb.

National Association of Railway Surgeons.—The Executive Committee of the National Association of Railway Surgeons met September 4 to make arrangements for the 1895 annual meeting of the Association, which will be in Chicago. The members of the committee are:

Dr. J. M. Dinuen of Fort Wayne, Ind., Secretary of the Association; Drs. W. B. Outten, St. Louis; S. S. Thorn, Toledo; R. Harvey Reed, Toledo; J. H. Ford, Wabash, Ind.; J. B. Murphy, Chicago; Alex Mullen, Jr., Michigan City; H. N. Warehouse, Danville, Ind.; B. Emmett Welsh, Grand Rapids, Mich.; E. R. Lewis, Kansas City, and Dr. Bouffleur of Chicago.

The Tri-State Medical Society (Illinois, Iowa and Missouri) meets in Jacksonville, Ill., Oct. 2 and 3, 1894. A large and interesting meeting is promised. Leading members of the profession of Chicago, St. Louis, Indianapolis, Kansas City and elsewhere have signified their intention of being present.

PUBLIC HEALTH.

Typhoid Renewal of Vaccinal Susceptibility.—Dr. William Finder communicates to the *Medical Standard* the results of his observations on typhoid fever patients with reference to vaccination. He finds that after recovery the susceptibility to the vaccine is markedly renewed. He has verified his observations many times during a number of years and suggests that others should test his conclusions. So satisfied is he with the correctness of his observations that he always re-vaccinates his typhoid patients on recovery.

Typhoid Fever at Elizabeth, New Jersey.—During the past month, this city has suffered from a re-awakening of typhoid fever; there having been sixty-two cases with five deaths. There are several now under treatment in hospital. The disease is alleged to have taken its start in a row of houses, whose back yards run to the margin of the Elizabeth River. This is porous "made-ground," and is permeated by the filthy sewage of a large portion of the city, for when the tide ebbs some of the bed of the stream is exposed to view, with repulsive sediment and giving off foul odors. The wells in this vicinity are supposed to be contaminated by the imbibition through the loose soil of typhoid germs from the noisome river bed. The inspectors have reported in favor of cleansing the river bed, at an expense of \$7,000. The Board of Health has ordered the closure of some of the wells, until cold weather sets in.

School Children and Vaccination.—On the 28th ult., Judge Bartlett of the Brooklyn Supreme Court, handed down a decision regarding the application for mandamuses in two actions, brought through the Anti-Vaccination League to compel school principals to admit pupils who refuse to be vaccinated. In denying the application Judge Bartlett said:

"The avowed purpose of the application is to test the constitutionality of Section 200 of the Public Health law of this State, which provides that no child nor person not vaccinated shall be admitted or received into any of the public schools of the State, and commands the trustees or other officers having the charge, management or control of such schools to cause this prohibition to be enforced. Upon the oral argument I expressed the opinion that this enactment was a valid exercise of the police power of the Legislature, and that view has only been confirmed by an examination of the authorities cited in the briefs of counsel. A common school education, under the existing Constitution of the State of New York, is a privilege rather than a right. It is created by legislation, and subject to legislative regulation. . . . It follows that the State can certainly exercise this discretion by debarring from attendance at the public schools such persons as are unwilling to adopt a precaution which, in the judgment of the Legislature, is essential to the preservation of the health of the large body of scholars."

Milwaukee's Unfortunate Notoriety.—Under the heading 'Anarchists, Anti-Vaccinators and Anti-Pasteurists,' the *British Medical Journal* (August 25), editorially comments upon the foregathering of these three classes of obstructives, as exhibited in an assembly of anarchists at a "friendly evening" at the house of the President of the Anti-Vivisection League in Paris, and in an outdoor gathering including a quaint collection of "Anti's" generally, to protest against the British Institute of Preventive Medicine. At this latter function a letter was read from Mr. G. W. Russell, a member of the English Ministry and—we have the *Journal's* word for it—"a man of culture," in which he announced that he detested Pasteurism—and, of course, also Listerism. Whereupon the *Journal* asks: "Why not add that he has a contempt for the equator and grave doubts about gravitation? To be logical, Mr. Russell should add the inevitable converse of his proposition, and declare that he loves smallpox, is much attached to hydrophobia, and adores blood-poisoning and high hospital mortality."

The article is here referred to as a striking illustration of the natural affinity certain classes of mischief-makers and destructives have for each other—not at all as affording any consolation, on the *tu quoque* basis of retort, for the disgraceful condition of affairs in Milwaukee. There is a common bond between the "Anti's." Scratch an opponent of vivisection and you will find an anti-vaccinist; and under the anti-vaccinist's skin will frequently be found an anarchist. To pose as "against all science," and to be "agin the government," whatever it may be, are correlative attitudes and, in their essence, are anarchism, pure and simple.

So far as its public health interests are concerned the city of Milwaukee has, for some time, been in the hands of the anarchists. Law is defied, its officers have been assaulted, excited mobs have been harangued in the most incendiary language to "resist to the death" the enforcement of vaccination and the removal of smallpox patients to the isolation hospital; and bloody riots and scenes of the most disgraceful violence have been the result. The State Board of Health and the State Executive have been appealed to, to take charge of affairs, to restore order and to enforce the laws.

And all this in the closing days of the nineteenth century and in a city of magnitude in the United States of America!

In the end there will be a return of sanity in the conduct of affairs in Milwaukee; the Health Department will be sustained and the supremacy of the law vindicated. But, meanwhile, although the State Board of Health, after a patient and searching investigation, finds that the Health Commissioner, Dr. Kempster, "has been faithfully, honestly and ably endeavoring to use all necessary precautions and to enforce needed sanitary regulations;" that it completely exonerates him from the trumped-up charges of incompetency, and finds the cause of the troubles that have arisen in "a most unfortunate lack of harmony between the Health Department and certain officials and other citizens"—whom it refrains from specifying; that it declares that there has been "unreasonable opposition and hostility to the efforts of the Health Commissioner," and that it pronounces, after special investigation, the condition of the isolation hospital excellent and commends "the methods of treatment there used and the care given the patients"—notwithstanding all this the state of anarchy at this writing still continues.

Milwaukee has suffered from labor riots that required the most heroic treatment to suppress; from a series of destructive fires; from several more or less questionable bank failures; from the smallpox itself. But none of these, nor all combined, could give it its present unfortunate notoriety.

Cholera Prospects.—If "no news is good news" as regards cholera, then this country is to be congratulated on the dearth of intelligence during the past week concerning the progress of the present epidemic. Except for a short-lived sensation over the disposal of a scow-load of sand—part of the ballast of the ship *Allers*, which arrived recently in New York harbor from Antwerp, described in the newspapers as

"a cholera-infested European port"—there has been nothing to give the *quid nuncs* any occasion for gossip. The scow was towed out to sea, the sand dumped into the Atlantic, and there an end on't.

But while we may congratulate ourselves upon this uninterrupted progress toward the end of the period of watchfulness and anxiety, the situation in Europe is, unquestionably, serious. At the beginning of July Asiatic cholera had prevailed in epidemic form in twenty-five districts in Russia, five in Austria-Hungary and three in German Poland; it had appeared sporadically in the departments of Morbihan and Finisterre in France, in two provinces of Belgium, Liège and Limbourg, and in European Turkey. Up to the close of August fifteen more districts of Russia and all the western part of the Empire, including St. Petersburg and Cronstadt, had been invaded; the disease had ravaged the basins of the Zbrucz and the Vistula in Austria-Hungary and Germany—those rivers having evidently become polluted; in the Low Countries the Meuse and the Sambre had become highways of infection, the disease appearing at many places on their banks and at their estuaries; while numerous scattered cases had occurred in various parts of France, as at Marseilles, where true cholera undoubtedly exists, and exclusive of the so-called "cholérine" in Paris and in the departments of the Meuse, Muerthe-et-Moselle, Vaucluse and Seine-et-Oise; imported cases, mainly from Russia, had appeared in Berlin, Bremen, Fejan (Sweden) and in London.

Since the last of August there have been further developments of the disease in the Low Countries, one case reported on the 2d inst., at Nieuport in West Flanders, one case at Spykenisse and one death at Boksmeer. On the 1st inst., it was reported that "cholera of a virulent type" is raging in Russian Poland. The medical authorities are said to be unable to cope with the disease owing to the fact that the inhabitants conceal their sick and treat them in their own way. The chief centers of the disease are Pinczow, Michow, Stopnica and Dzialeszyce, where the inhabitants are camping in the woods. And there is no abatement of the epidemic in Galicia where, during the first three days of the month there were reported 623 new cases and 313 deaths; during the same period there were 46 new cases and 25 deaths in Bukowina.

The English authorities do not attempt to conceal the gravity of the situation, but regard with concern the next four weeks, knowing that the westward march of the disease, when it prevails to its present extent, has usually brought it to their shores toward the termination of the summer months, thus making its seasonal incidence in the period between the middle of August and the middle of September. For this reason, among others, the utmost vigilance is maintained; medical inspectors are ready at a moment's notice to investigate suspicious cases, and it is reported that cases not to be distinguished from true cholera have been thus discovered—some of them in London itself—within the past few weeks. It is added that "the most rigid sanitary measures have been adopted in each case, and as yet, happily, there has been no extension."

It is obvious that in these precautions lies a great measure of safety for this country, but not sufficient to justify any relaxation of vigilance upon the part of our maritime sanitary authorities. It is recalled that two years ago this month, cholera actually invaded New York from Hamburg, and that there was an outbreak of the disease with a number of deaths in the city itself. It is also recalled that it was in September one year ago that the disease "got a foothold in England and prevailed most widely and with deadliest effect throughout Europe." If it be true, as suggested in the *JOURNAL* last week, that the cholera germ has become domesticated in Europe, and thence that the danger of cholera importation to this country has become permanent and continuous, our precautions must be permanent and continuous, and more especially must they not be relaxed during this period of seasonal incidence.

MISCELLANY.

Dr. O. W. Holmes.—Dr. Oliver Wendell Holmes was 85 years old August 29, and celebrated that event in his summer home in Beverly Farms.

For Congressional Honors.—The following doctors have been nominated for Congress: Dr. L. F. Weaver, of Niles, Mich., Dr. Bernard Groeser, of Le Mars, Iowa, and Dr. J. A. Hatch of Kentland, Ind.

Immoral Massage.—Possibly moved thereto by the unwelcome notoriety given to its "massage parlors" the city of Chicago has begun what the newspapers call "a crusade" against these dens of vice. An investigation has been commenced by the police and the licenses of nine of the most notorious have already been recommended for revocation. They are characterized in the report of the investigation as "little if any better than the lowest 'dives' in the city." The term "massage" had come to be so closely identified with the practices of these "parlors" that physicians were growing shy of recommending the treatment.

Reproduction of the Bacteria.—In a rather ill-natured report of the proceedings of the recent meeting of the British Health Institute, published in the *Sanitary Record*, August 4, there occurs this passage:

"The close of the day was devoted by some to seeing what was to be seen at the Covent Garden Theater—not Drury Lane, as originally announced. But previously there was a lecture in the Great Hall of King's College, on "Microbes and the Spread of Disease," by Prof. E. M. Crookshank, who among other minute but too pregnant facts, informed his audience that a single bacterium stood in about the same relative proportion to a man as did a grain of sand to the highest mountain, a postage-stamp being large enough to hold, spread singly upon it, no less than four hundred thousand bacteria. Though often appearing in questionable form and often in dangerous development, their existence in some form was essential to both vegetable and animal life, though bacteria were extremely lively, too, one (or did the lecturer mean two?) being able to reproduce more than sixteen millions of the same lively kind in twenty-four hours!"

Judging by the query enclosed in parenthesis, this reporter's knowledge of the mode of reproduction of the bacteria is extremely hazy to say the least.

Bellevue Hospital Alumni.—The society of this Hospital has published a circular, dated Aug. 1, 1894, stating an active membership of 200 with other evidences of virile youth. The society has prospered, and an invitation has recently been tendered to all former internes of the institution, wherever they may be located for practice, to join the society, as a means of bringing up the numerical strength and of increasing the contributors to the scientific outgivings of the meetings, the proceedings of which will appear regularly in one of the New York medical weeklies. For the present, no fee for initiation is required; the annual due of resident members is \$10, that of non-resident members is \$3. A general re-union of all the alumni has been canvassed to be held in January or February next, with a subscription dinner. The alumni, widely scattered throughout the country, will be glad to receive timely notice of this rather novel Medical Congress of Internes.

A New Use for Ammonia; a Defense Against Burglary.—A Brooklyn druggist recently succeeded in putting to flight two ugly burglars who endeavored to loot his store, in the dead of the night, by means of copious external applications of aqua ammoniac. The druggist was awakened by a man who had made entrance into his store by forcing the fanlight of the front door. The second thief also came in by the same ingress, while the druggist was considering his best ways and means of defense. A large bottle of ammonia was on

an inside counter, the cork of which he quietly drew, and filling up a large beaker he waited for one of the thieves to approach the prescription department. One of the men sought to break open the money-drawer, but without success. Then the pair of them set to work to rifle the show-cases. They had piled up a lot of valuable goods, when one of the men came quite close to the corner where the druggist stood. The latter, without delay, deluged the head of the man with a beakerful of the ammonia, causing him to fall gasping and unconscious to the floor. The comrade rushed up to see what had happened, when the druggist also gave him a beakerful in the neck. He was staggered, but not so far overcome, but that he was able to rush out and make his escape. The man who received the first invoice of ammonia did not succeed in getting away, and was held for trial.

Not for Mesdames.—In confirmation of the fact, heretofore noted in the JOURNAL,¹ that "the more beautiful women of a most beautiful country do not take kindly to the practice of physic," it is noted that in the enrollment of women attending university lectures, just made in Paris, of 155 on the list of the medical faculty only 16 were of French birth, while of the 164 on the faculty of letters 141 were French; 7 studied under the faculty of science and 3 under that of law. On the other hand, Russia, in response to a growing demand and long-cherished desire, is opening the doors of her universities to women medical students. A medical faculty for women is about to be established in St. Petersburg, a departure which is regarded as a proof that the opposition against the higher education of women in Russia is about to be dropped. The change in policy is said to be due to the influence of Prince Wilkowsky, whose speech at the Chicago Exhibition on the importance of education for the welfare of the State attracted a good deal of attention at the time in America.

A Confusion of Identity.—In its editorial notice of the special report of the State Factory Inspectors on "Smallpox in the Tenement-House Sweat-Shops of Chicago," our usually accurate and well-informed contemporary, the *Boston Medical and Surgical Journal* (August 30) does a serious injustice to the Illinois State Board of Health. In the first paragraph of the editorial it is said that, "The State Board of Health testified that no contractor or housefinisher had ever voluntarily complied either with the State law or with the city ordinances," etc. This testimony was given by the statistician of the City Board of Health, and not by the State Board (see page 7 of Report.) In the next paragraph the State Board is again referred to as receiving the reports of cases of smallpox, which, as communicated to the Factory Inspectors, proved to be "so small a part of those which actually occurred that other sources of information had to be sought for;" and it is added that, "After the middle of June, the State Board of Health declined to give information and is generally censured by the report as inefficient and even culpable." Without entering upon the question of the merits of this report or upon the justice of its strictures, it is due the Illinois State Board of Health that the statement above quoted should be corrected. There is nothing in the report to warrant it; the only reference to the State Board is that upon page 9, where it is stated that its representatives met with the representatives of the State Boards of Michigan, Wisconsin, Ohio and Indiana and the garment manufacturers of Chicago on May 10, and agreed "to institute an efficient daily inspection of all shops and work-rooms." There is no other mention of, or reference to, the State Board, either in the way of censure or commendation, from beginning to end of the report.

The Modern Jenner will Subjugate Leprosy and Cancer.—Dr. Keeley has one friend left, the Rev. Dr. Talmage. The latter having gone on a money making tour to the Sandwich Islands and to the far East, has taken the trouble to write back to one of his weekly papers in fulsome laudation of Keeley. In order to leave no doubt in the minds of his readers that he, Dr. Talmage, is wholly unfit to express an opinion upon any medical subject, the venerable divine goes so far as to try and draw a parallel between the great Jenner and the modern pretender whom he has befriended, and who has perhaps financially befriended the divine. The opening paragraphs are taken up with the consideration of the Molokai Island retreat for Hawaiian lepers, and of the incurable malady affecting about one thousand residents on that island. His aim is to show that leprosy and cancer will meet their conquerors, just as surely as that smallpox was virtually overthrown by the great Jenner. He says:

"But do not let us give up discouraged. Leprosy as well as cancer and all the other unconquered ailments will yet be cured. I do not know where the cradle now holding the coming doctor is being rocked, whether at Molokai, or in Honolulu, or on the banks of the Thames, or the Rhine, or the Tiber, or the Ural, or the Hudson, or the Savannah. Nor do I know from what college he will unroll his diploma, nor in what laboratory he will make his experiments, nor in what decade he will give proclamation of the world's emancipation from diseases as yet incurable, but he will go through the same persecutions that Dr. Jenner did because of his discovery of a way to halt smallpox, and as Dr. Keeley has endured because of his almost supernatural cure of alcoholism, and the new discoverer will run the gauntlet of caricature, and expulsion from medical societies, and will, like the most illustrious Being of all ages, become the target for expectoration, but the discoverer will give leprosy the command, "Thus far shalt thou go, and no farther," and that disease will wriggle and crawl and shrink out of the world, and after the medical emancipator is dead, the nations will build a monument so high to his memory that the granite shaft will dispute with the skies the right of possession, and in the epitaph thereon the clicking chisel will try to atone for the slanderous tongue, and the world that held back from the discoverer the bread of honest praise, will give him a storm of post-mortem commemoration. Forward, the whole column of surgeons and physicians for the conquest of leprosy and cancer.

New Orleans Notes.

DR. R. W. WALMSLEY, of New Orleans, has recently been appointed a member of the Louisiana State Board of Health, succeeding Mr. King.

THE LATE DR. ALBERT B. MILES, House Surgeon of the Charity Hospital of New Orleans, left \$10,000 each to the following institutions: Medical Department Tulane University of Louisiana; Charity Hospital of New Orleans; and the Hotel Dieu, also of New Orleans.

St. Louis Notes.

THE BEAUMONT MEDICAL College has found it expedient to lower its fees.

THE MISSOURI MEDICAL COLLEGE is making good progress with its fine new college structure on Jefferson Avenue near Washington Avenue. The building is of sandstone and brick, and its front already presents an imposing and attractive appearance. It adjoins the Polyclinic, and hereafter the school will have the advantage of being practically under one roof. The new building will not be ready for use before the latter part of the coming college year.

APPOINTMENTS.—Dr. C. B. Burns has resigned as Medical Superintendent of the Eastern Michigan Asylum, at Pontiac, and is now in charge of the private hospital for the insane at Flint, Oak Grove, until now under the direction of Dr. George C. Palmer, formerly Medical Superintendent of the Michigan Asylum at Kalamazoo. Dr. E. A. Christian, formerly Assistant Superintendent, has been made Medical Superintendent of the Eastern Michigan Asylum. Dr. W.

No. 11.

ORIGINAL ARTICLES.

REPORT ON EXAMINATIONS OF THE 'EYES OF 1,900 SCHOOL CHILDREN OF THE PUBLIC SCHOOLS OF SAN FRANCISCO.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held in San Francisco, June 5-8, 1894.

BY KASPAR PISCHL, M.D.
SAN FRANCISCO.

Since Professor Jaeger, of Vienna, in 1861 had begun the first scientific examination of the eyes of school children, over 200,000 pupils in all parts of the civilized world have been examined. All those investigations have proven that myopia stands in direct proportion to the education of the people. If I venture to ask your attention for a few minutes only to hear the report of the examinations made in the schools of San Francisco I do not pretend to show you anything new, but I hope it will be interesting enough to compare the conditions of the eyes of the children in this new country with those of other countries.

To enable you to judge about the value of the data of my examination, I will explain in a few words the method I employed. I examined the sight of every child, each eye separately, with Snellen's letters. When I found normal sight not impaired by putting before the eyes + 1° I marked hypermetropia. If + 1° blurred the sight, emetropia. This last column is not reliable. I am sure that many hypermetropic and astigmatic eyes were classed among emetropia. Those who with one or both eyes did not show normal sight were examined with the ophthalmoscope. Every pupil was examined regarding the conjunctiva and lids. A glance at Table 1 shows us at once an increase of myopia with the grade of the class; from 3.98 per cent. in the grammar school to 11.59 per cent. in the normal school. At the same time, the number of pupils with normal sight decreases from 90.20 to 75.71 per cent. This deficiency of sight and increase of myopia is most prominent among the girls of the high and normal schools.

SAN FRANCISCO SCHOOLS, 1891-92. PERCENTAGE OF.
Table 1.

| Schools. | No. of Schol- ars. | E. | An. | H. | M. | Conj. | $\frac{6}{6}$ B.E. | $\frac{6}{6}$ One E. | $\frac{6}{6}$ Both E. |
|-----------------------|-----------------------|-------|-------|-------|-------|-------|-----------------------|----------------------------|-----------------------------|
| Grammar. | 1,280 | 68.60 | 6.32 | 20.9 | 3.98 | 26.25 | 90.20 | 7.03 | 2.77 |
| Boys' High. | 305 | 76.06 | 13.12 | 4.56 | 6.23 | 31.11 | 85.91 | 7.86 | 6.23 |
| Girls' High. | 290 | 69.68 | 9.28 | 14.02 | 7.02 | 41.00 | 80.66 | 5.00 | 14.34 |
| Normal Class. | 69 | 63.76 | 18.86 | 5.79 | 11.59 | 41.42 | 75.71 | 1.00 | 23.29 |
| Total. | 1,953 | 69.52 | 11.89 | 11.12 | 7.20 | 34.94 | 83.7 | 5.22 | 11.65 |

This fact is quite in accordance with the observations of Dr. Gould and Dr. Southard, our esteemed colleague present, who in his examinations of the eyes of the students of the University as well as his analysis of 1,300 cases of refraction found myopia or refraction

errors in general more frequent in the female sex than in the male. He gives a clear explanation for it: They use their eyes more. In Europe we find the contrary to be the case. There the boy gets a much better education, boys only are admitted to the gymnasium and then to the university, and among those students we find over 50 per cent. myopia.

Of all the myopic pupils, 25.25 per cent. are of American parentage, 25.25 per cent. of mixed American and European parentage, and 49.50 per cent. are of European parentage.

With conjunctivitis I marked irritation, simple and follicular conjunctivitis. This affection increases in number with the classes.

The fact that myopia is much less prevalent here among children than in Europe or even in the East, may be explained by their better physical development, caused by abundance of good food, due to our fertile soil, and the almost constant outdoor life permitted by our wonderful climate.

In conclusion, I have remarked that these school examinations do not pretend to be of the exactness of the office examinations, but I consider them exact enough for statistical purposes. The column for myopia I believe to be reliable, the column for hypermetropia probably shows too small a percentage as some hypermetropic and astigmatic eyes are classed among emetropia having normal sight. An exact examination of refraction with mydriatic was impossible, as it would not have been permitted by the school authorities.

The great increase of the conjunctival affection with the grade of the classes points to the existence of eye strain which in a great many cases may be caused by hypermetropic astigmatism, therefore an exact examination of every pupil would be desirable.

DISCUSSION.

DR. S. B. DAVIS—In the Young Ladies' High School, I found many cases where astigmatism was reducing the vision to twenty-two-hundredths. In some cases, their vision was practically good and a slight correction made wonderful results. The difficulty was chiefly with those whose studies were pressing them, and we came to the conclusion before we examined 500 students in that way that they were getting their education at the expense of their sight.

DR. H. H. WEER—It strikes me that physicians assume too much in regard to the eye. If there is anything that makes an eye man tired, it is to see some one attempt to do some-

thing according to some hypothetic theory and make a dismal failure of it. I can not understand how the use of test cards is any test for hypermetropia or myopia. It strikes me that a person having astigmatism of very low degree and in ill health, would have disturbance of vision. I have been acquainted with one of the assistants of the Manhattan Eye and Ear Hospital in New York City who had 12 D. astigmatism and never wore a glass.

I would like to ask how in determining the hypermetropia and myopia, do you dispose of the accommodation? If I remember correctly, there is a vasomotor nervous system, and I have had pupils stand up in front of me whose vasomotor and spinal nervous system were so thrilled that they had lost entire control over every sphincter muscle in the body.

Now, you will all agree that one of our great troubles is our accommodation. This seems to me to be a point that should be taken into consideration in determining the hypermetropia of school children. In the dark room of the Manhattan Eye and Ear Hospital, we were requested to examine a very marked case of myopia. I examined the case with my ophthalmoscope, and I pride myself on the use of it. If I see the blood vessels and the velvety appearance I turn the glass, and if the velvety appearance comes out stronger than the white lines, then I say I have not here a case of myopia. I ran up to 8 D. and got a clear perfect vision of the disc, and the velvety condition of the retina. I remarked that it was a case of high degree of hypermetropia, and it was decided by the great Dr. Morrison that it was hypermetropia. There we had a patient who had been diagnosed by several physicians as myopia. That is merely a mistake. It illustrates the fact that if you rely on the test card to decide what the error is, and pronounce that child myopic and attempt to give it correction with the minus glass it would be entirely an error. There is another interrogation I would like to make for my own information. I notice, according to the chart, that as the school life advances, the conjunctivitis advances. Might not that be from eye-strain? Another thing—I have been so unfortunate as to just conclude fitting patients, when they took a spell of sickness. Upon recovery I found that my glass was entirely useless. This brings up another matter I wish to advance: Is not the hypertropic eye the normal eye? Is not the metropic eye, the uncommon eye, called the normal eye?

DR. H. B. YOUNG—I look upon all these statistics with regard to school children with a little allowance. If we could be sure that those marked for myopia were myopia—but with the methods hitherto employed, I think there is room for doubt about it. There is but one way I can imagine, without an enormous amount of work that we can get at it with anything like accuracy, and that is that we must make ourselves expert skiascopists. I should not be in dependence myself upon the lenses for half the cases. I believe when we get statistics by this method of examination, we will get something very much more reliable.

DR. W. F. SOUTHARD—The fact about statistics is this, that we have had gathered up by a very large number of gentlemen in the last twenty years an enormous amount of statistical matter, which has proved that there is a vast percentage of errors from refraction existing among school children, covering the ages between 5 and 25, besides others that have been carried on in the higher schools to which I referred this morning. The point that has been established is that nearly every child of 5 years of age is hypertropic. The second point that has been established is that myopia is but rarely seen in childhood. It has also been very accurately determined that myopia is a condition which does advance step by step in school life, as we go from grade to grade.

Now, throwing aside all the statistics relating to hyper-

metropia and astigmatism, one phase of myopia is not so difficult to arrive at. Myopia is very much more easily determined. In fact, it is found that using the same methods which do not show myopia at 5 years of age, it does show a percentage of myopia increasing with each grade of school life as we ascend from the primary schools into the grammar schools. If we take the European statistics, especially on myopia, because in Europe this examination has been more especially applied to myopia than to anything else—the most exhaustive paper written in the past ten years has been written and re-published in this country, and it covers the error of myopia more especially. I wish to call attention to the test which shows that more myopia exists in the peasant schools, and shows it to increase from grade to grade in rapid ratio in Germany. That is an important factor, whatever the methods established may have been. If we analyze the greater portion of these statistics that have been made, it is very curious that they have not given their methods of procedure more accurately, so that we could know what their methods were. I should say the work had been by the use of a test card and probably glasses. We have found by a less number of examinations, covering over a considerable portion of our own country, that we do have in America a vastly less percentage of myopia for the same grades as they have abroad. Dr. Shrady, of New York, in reviewing some statistics I have made, said he believed that was the result of older civilizations—that there would be found in them a much greater percentage than in the newer countries. We have a much larger per cent. in New York and Boston than here on the Pacific coast.

Now, it being certain that myopia is the accompaniment of civilization, we as oculists should advocate laws compelling the examination of school children. I have not much faith in examinations that are not made by ophthalmoscopic examination in the dark room. I have not examined a single patient without the use of the ophthalmoscope. I do not rely upon a test card. I think that in the entire series of examinations the test has but one value, which was to determine the equivalents. That does not determine the ametropia at all. Out of a large number of students the equivalents run to 60 and 70 per cent. and 20-20. I agree with the writer who states that ametropia is simply a stage in the progress towards myopia. I want to say that I am not particular about the statistics. I think the statistical matter has been carried to the extent that we now know we have this enormous percentage of errors. The question is to know how to prevent it. I have about seven or eight hundred papers of figures in my desk that have not been tabulated, because I concluded that there is enough of that work done to show the facts, and I want to bring before the teachers and others, methods by which the troubles can be prevented in an expeditious manner. I do not think that there is any need of our having any more than a very small percentage of error, if we do examine under the proper tests. It is proven that we have an enormous percentage of children in the primary and grammar schools who are suffering from hypermetropia uncorrected. My position in regard to children's eyes is that if we are to bring about any change in those who are older, we must begin with the school children. If we can have an examination made of the eyes of the school children, it is of just as much value as is the physical examination made in larger schools for the determining of their body power to study, as far as the functions go. Upon that point I have dwelt for some years and feel it is important for us as oculists to attempt to sustain any effort to secure legislation that will obtain compulsory examination of children at school.

H. L. BURRELL—Mr. Chairman, I believe that statistics of

myopia in children are absolutely unreliable, unless a course of mydriatics is given.

A MEMBER—Mr. Chairman, we did not say in our reports myopia, hypermetropia, or astigmatism. Our reports simply say "errors of vision brought out by the tests." My reports read "such a per cent., as nine, seven, six, five or one-tenth" as the case might be.

DR. FISCHL—Mr. Chairman, I started the examination in order to compare especially the myopia which I might find here with the schools in Europe. I knew from the beginning, and I said this in my paper, that in the schools I could not possibly find out exactly the hypermetropia or the astigmatism. That can only be done in the office. It can not be done in the school room, and would not have been permitted. It would have kept the child away from the school rooms and would have been impossible. Many of my scholars were hypermetropic or astigmatic as I said in the paper. As to those which were not, that could not be decided. But I think that the numbers for myopia are reliable. I do not think it is necessary to apply the ophthalmoscope for the myopia. The trouble in the conjunctiva, or the irritation, increased with the glasses to 41 per cent., showing clearly or at least hinting that there is eye-strain in many cases, and giving us the hint that not such a great portion have normal sight. They have errors which could only be corrected in the office.

SUB-CONJUNCTIVAL INJECTIONS IN THE TREATMENT OF EYE DISEASES.

Read before the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY WM. ELLERY BRIGGS, M.D.

SACRAMENTO, CAL.

Subconjunctival Injections in Ocular Therapeutics.—During the past four years Drs. Darier and Abadie, two very progressive Paris oculists, have been extensively using subconjunctival injections of mercuric chlorid solution in the treatment of many eye diseases. As I watched their work in their large clinic, during the experimental stage of the method I saw it tried in many diseases in which there was obviously little or no hope of benefit to be derived from any treatment. But from my observations I became convinced that good results were obtained in a certain class of cases. Since that time I have treated quite a number of cases by the method and have been led to the conclusion that many of them had done better than they would under the other treatments alone.

Most of the cases under my care have been of septic or syphilitic origin, so other treatments had been used in conjunction with the subconjunctival injections.

I deem it an injustice to a private patient to neglect the use of a remedy which is known to be beneficial in order to try some uncertain treatment. It is the class of cases to which this treatment is applicable that require prompt and efficient care. It is impossible to determine with any degree of certainty the amount of influence the injections may exert on the course of a disease process. We can arrive at our conclusions only in a general way by comparing the progress of a number of cases treated by usual methods with others similarly treated with the injections added. My conclusions may not be shared by many, but I believe that this method of treatment is a real advance and will establish a permanent place in ocular therapeutics. In Germany as well as in France

a number of prominent oculists have reported very favorable results from the method, but I have been surprised that so little attention has been paid to it in this country.

Previous to the adoption of subconjunctival injections Drs. Abadie and Darier had injected sublimate solutions directly into the vitreous. They claimed that this rather bold procedure had yielded good results but it was abandoned for subconjunctival injections as being less dangerous.

Dr. Darier injects two to five drops of a 1 to 1000 sublimate solution beneath the conjunctiva and not nearer than seven millimeters to the corneal border. If the injection is made too near the cornea the pain is likely to be severe. Care should be taken not to puncture a conjunctival vessel or unpleasant ecchymosis will follow. In case this does unavoidably occur it will soon disappear under applications of hot water. The conjunctiva should be thoroughly anesthetized by cocain previous to treatment. It is hardly necessary to mention that the solutions and instruments used should be perfectly sterilized.

In my practice I have generally employed three to five drops of a 1 to 2000 bichlorid solution. The frequency of the injections should be regulated by the urgency of the case and the severity of the reaction. In a few cases they can be made daily for a few times but in most cases not oftener than two or three times a week. Immediately after the injection a little bleb appears at the point the fluid enters. Frequently sharp pains are experienced for a couple of hours after the injections. This can be mostly relieved by cocain drops and hot or cold water. The position of the injection should vary to prevent excessive irritation—a point covered by one of the lids is most favorable.

Local treatment has been made in different parts of the body by injections in the location of the disease process with more or less success for a long time. We owe our knowledge of the method of action of subconjunctival injections to the experiments of Phlüger and some others. These experiments have demonstrated that after subconjunctival injections of bichlorid solution the salt is found in the cornea, aqueous humor, suprachoroidal space, vitreous humor, and the superficial layers of the lens. The mercuric chlorid reaches the tissues of the eye before being taken up by the general circulation. We can thus readily understand how diseases of septic or syphilitic origin are promptly benefited. These are the cases which experience shows are most improved by this method of treatment.

In years past patients suffering from local inflammations of septic origin were given mercury internally to counteract the septic process. I have no doubt that by administering bichlorid solution subconjunctivally in septic ocular disease the same end can be attained with greater certainty and rapidity than by means of general medication. In nearly all cases the subconjunctival injections should be supplemented by other treatment appropriate to the case. The constitutional treatment is of the utmost importance in most affections of the uveal tract. The injections are frequently of the greatest benefit on account of the promptness by which the mercury can be made to reach the disease process. But the constitutional treatment is of quite as much importance in order to eradicate the constitutional disease upon which the local affection depends.

In treating septic conditions of the eye, either after operation or from injury, other treatment such as cauterization of an infected wound, paracentesis of the cornea and washing out the anterior chamber, antiseptic dressings, etc., should be combined with subconjunctival injections.

The cases in which I have found the method of treatment to do the most good are syphilitic diseases of the choroid and septic ulcers of the cornea. It seems usually to exert a salutary influence on most syphilitic processes of the uveal tract except in the acute stage of iritis. In some subacute and late stages of acute iritis I have had prompt improvement from the administration. It often seems to help in a marked manner cases of choroiditis of rheumatic origin, and in recent vitreous opacities from syphilitic retinitis good results may be expected.

When there is great danger of infection after operation Dr. Darier recommends injections previous to the operation as a prophylactic against sepsis. Such cases are those in which we are obliged to operate when disease of the lachrymal apparatus or conjunctiva exists. In septic infection after cataract extraction Dr. Darier has found the injections to act well.

Dr. Darier has laid down this rule, that in case improvement is not manifest by the tenth injection that we need not expect good from the method. This conforms to my experience as we generally get perceptible improvement in from four to ten injections.

Case 1.—R. H. S., age 28. He had suffered for three weeks from iritis of the left eye due to syphilis. Posterior synechia were so firm that a 2 per cent. solution of atropin had little effect on the pupil in twenty-four hours. The pain and inflammation being of a moderate degree subconjunctival sublimate injections of 1 to 2000 were made daily for three days when the adhesions were mostly broken up. The injections were kept up every other day for ten days longer. Mercurial inunctions were also administered. The iris was entirely freed from the lens and vision was nearly normal at the end of two weeks' treatment.

Case 2.—Mrs. L., age 48. Had been suffering with rhinitis and vitreous opacities for three weeks. Vision reduced to 1-8. Patient was placed on mercurial inunctions and subconjunctival injections were made every other day for five treatments, then twice a week for two weeks more. Vision was then two-thirds normal and retinal exudate had nearly disappeared.

Case 3.—E. N. W., age 32, single, contracted syphilis seven years previously. He had been treated constantly for two years and believed himself "cured." For ten days previous to consulting me he had noticed dimness of vision which increased rapidly. Extensive choroiditis disseminata was found. Vision in right eye 1-8, in left 1-6. Patient was given mercurial inunctions daily and subconjunctival injections every other day for two weeks; at that time vision was found to have improved in right eye to 1-2 and in left to 2-3. The choroidal inflammation had greatly improved.

Case 4.—D., age 42. Physician. Had never had syphilis. Patient had noticed his vision getting blurred for a couple of weeks. When examined inflamed patches of choroid were seen in both eyes. Patient was given pretty large doses of iodid of potash and subconjunctival injections. The injections were made twice a week for a few injections and every week or two weeks for six weeks from the beginning of treatment. The vision was then found to be perfect in both eyes. The choroidal patches of inflammation had almost entirely faded.

Case 5.—G. B., age 55. Patient denied ever having had syphilis. He had noticed increasing dimness of vision for past three weeks. Extensive disseminate choroiditis was found in both eyes. Vision was equal to counting fingers at fifteen feet. Patient had been treated with blisters to temples and some eye drops. He was put on mercury and iodid of potash and subconjunctival injections in each eye every other day for five injections when vision was found to be two-thirds normal.

Case 6.—M. C. R., age 35. Patient had the right eye injured by a piece of rock in a mine. A small wound was

made just below the center of the cornea but as little irritation or pain resulted from the wound the patient continued to work for two days when he consulted me. The conjunctiva was found quite swollen and red with a free muco-purulent secretion. The corneal wound was about three millimeters long and ulcerating. The anterior chamber was half full of pus. The eye was intensely painful. Cocain solution was applied and four drops of 1 to 2000 bichlorid solution was injected. Iodoform was dusted into eye and dressed with antiseptic dressing. The next morning the eye was markedly improved. The same treatment was continued for three days when the hypopion had entirely disappeared and the eye was nearly well.

DISCUSSION.

THE CHAIRMAN—The method has not commended itself very strongly to my judgment and I have been slow about adopting it, but have noted this one interesting fact that it seemed very promptly to relieve pain especially in cases of keratitis, where pain has been very severe. I think that has been noted by every observer. It is a striking fact and one that seems rather anomalous that such effect should be produced without any apparent effect on the course of the disease.

DR. PISCHL—I wish to say that I tried it only in one case but the patient was so frightened by the swelling that I did not venture to continue it, and I am afraid that many patients will revolt against the injection.

DR. BRIGGS—Mr. Chairman, I have nothing particular to add. I am sorry that there is no more discussion on the subject. I think if Dr. Pischl tried it in cases of keratitis or some such trouble, he will continue to use it. My experience has been in certain cases quite favorable, and I am thoroughly convinced in my own mind that it acted very beneficially in quite a number of cases. A number that I have tried it in found no benefit, but I have not found the severe reaction that Dr. Pischl mentioned, and I have no patients who revolted or objected seriously to the treatment.

OPTICO-CILIARY NEUROTOMY, WITH EXHIBITION OF SCISSORS.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association held at San Francisco, June 5-8, 1894.

BY WM. ELLERY BRIGGS, M.D.

SACRAMENTO, CAL.

I wish to present for the consideration of this Society a modification of my ablation scissors: Scissors for performing optico-ciliary neurotomy. The original instrument was described in the *Archives of Ophthalmology*, Vol. xvi, No. 1. It consisted of two curved scissors placed parallel so as to enable one to cut a section of the optic and ciliary nerves without cutting any of the ocular muscles. The modifications consist in the addition of a pair of claws between the two scissors to insure the removal of the cut section of the nerves.

Any one who has to perform the operation of removing a section of the nerves by first dividing the internal rectus and then uniting the muscle with sutures, as is done by some operators, has found it quite a formidable operation if it has to be done without the aid of trained assistants. These operators, I think, will find these scissors of great convenience. In a few cases where I have been able to trace the condition of the patient for a few years I have found no return of pain in the eye, and as far as I could tell, the result has been as permanent and satisfactory as it could have been had the much more formidable operation of cutting the internal rectus been performed.

I believe the operation of optico-ciliary neurotomy deserves more attention than it receives from the profession. It should be done in many poor people who are unable to purchase artificial eyes, in preference to enucleation. A deformed eye if free from pain and danger of producing sympathetic ophthalmia is greatly preferable to an empty socket. In very young children it should usually be selected in preference to enucleation. It should be performed also in a very large class of cases which would require enucleation on account of pain or danger of sympathetic ophthalmia and in which the diseased eye looks better than an artificial eye can, or when the patient will not submit to an enucleation. In case of ocular tumors, enucleation is the only operation to be considered.

PURULENT OPTHALMIA AND ITS TREATMENT.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY X. C. SCOTT, M.D.
CLEVELAND, OHIO.

In speaking of purulent ophthalmology I embrace under the one name all forms of this disease as described in most text-books, under the name of purulent ophthalmia, gonorrhoeal ophthalmia and ophthalmia neonatorum. It has always been a mystery to me why authors persist in making this unnecessary division, unless it is to mystify the general practitioner or increase the number of pages in their books. It seems much more simple to designate all three forms of this disease under simply purulent ophthalmia or conjunctivitis blennorrhoea, for the parts involved are the conjunctiva and subconjunctiva, with a serous effusion into their tissues and also into the stroma of the lids. The only difference that can be found is the presence of the gonococcus of Neisser in cases of gonorrhoea, but these gonococci are not always present, and even their presence I am unwilling to admit renders the disease more dangerous if properly treated. Every one agrees that purulent conjunctivitis in any form is one of the most serious and dangerous diseases of the eye. I shared this opinion in common with others until within a few years, when I adopted a plan of treatment which has robbed this disease of all its terrors, whether it occurs in infancy, childhood or adult life, provided the cornea has not become dangerously complicated.

These cases have been cured within a week or ten days in every instance, instead of running, as the books say, a course of four or five weeks in the most favorable cases. It is not necessary for me to describe the ordinary course of a case of purulent ophthalmia, as you are all conversant with it. You well know the great source of danger is the corneal complications which may arise from the swollen chemotic condition of the conjunctiva, cutting off the blood supply for its necessary nutrition; 2, the swollen hot lids and the cornea being continually bathed with pus causes a continual fomentation of the corneal tissue, and thus favors ulceration and destruction of this membrane; 3, the corrosive effects of the pus itself.

The great question that concerns us is how can we overcome or prevent these three important, dangerous and injurious factors which have caused such terrible havoc with so many eyes of mankind? By

what treatment, or what is the best treatment, to cause these cases to run a short course and with a favorable ending without injury to the cornea?

You can not open any text-book but that you will find advocated, that in the formative stage of this disease, the conjunctival sac should be frequently cleansed of pus, at the same time using some imaginary antiseptic, but that it is extremely dangerous to apply any astringent remedies; that cold applications should be made continually to the lids until the conjunctival membrane becomes soft and succulent. This cleanliness and these cold applications are proper and certainly indicated, but in many cases if you wait until the conjunctiva becomes soft and succulent before making any applications to the surface of this membrane, changes will have taken place in the corneal tissue which can not be controlled and may finally end in the destruction of the eye affected.

Instead of a do-nothing and an expectant plan, in addition to trying to have perfect cleanliness and cold applications made continuously, I commence the use of the following prescription from the very beginning:

| | | |
|----------------------------------|----------|----|
| R Hydrastia sulphatis | grains 5 | 30 |
| Acidi boraci | grains 5 | 30 |
| Sodae biboratis | grains 5 | 30 |
| Tinct. opii. deodorate | drachm ½ | 2 |
| Aquae distillata | ounce 1 | 32 |

Mix and filter.

The attendant or nurse is instructed to cleanse the eyes every fifteen or twenty minutes day and night, by opening the lids and wiping away all the secretions possible; to make cold applications to lids by means of compresses which have laid on ice, and from four to six times a day with a long nozzled dropper and hot water to wash out all the pus held in the conjunctival sac under the lids, and afterwards to inject up and into the conjunctival sac of both the upper and lower lids an ordinary medicine dropper full of the above prescription. The nozzle of the dropper should be long and smooth and of sufficient length that it may be easily introduced without breaking under the upper lid.

The above mentioned solution seems to have a most beneficial influence on all acutely inflamed mucous membranes where there is a secretion of pus. I have used it in cases of other acutely inflamed mucous membranes with the same benign results and effects that have been experienced in the mucous membrane of the eye. When this solution is properly used in cases of purulent ophthalmia, there will be a marked improvement in the case within twenty-four hours, and within forty-eight hours there will be a remarkable diminution of the secretion of the pus, chemosis of the conjunctiva and swelling of the lids.

Once a day I turn the lids, and having cleansed away the pus apply a 1 per cent. solution of nitrate of silver to the palpebral conjunctiva by means of a large camel's-hair brush. Now you may say that this is falling back on the old treatment and that all the good comes from the employment of the silver salt. If this is true why did or do we not have the same benign results in the treatment of this disease from nitrate of silver, as it is the treatment recommended by all authorities as soon as the conjunctiva becomes succulent? I do not believe that the nitrate of silver has anything, to any great extent, to do with the aborting of the disease and the rapid

diminution of the secretion of pus, but I use it for two reasons: 1, it is recommended by every author writing on this subject as the sovereign remedy to be relied on in the treatment of this disease and if perchance, by any mishap, an eye should be lost and a case of malpractice should result the first question to be asked would be: "How did you treat this eye?" and when it was discovered that no nitrate of silver had been used as recommended by all authorities, the hue and cry would be raised that gross malpractice had been done, and that the eye had been treated in a way not recommended by any authority, consequently there would be a possibility of being mulcted for damages by an intelligent American jury; 2, I want to see my patient every day, and if something different is not done at each visit from that which the nurse did, many families not understanding the importance and danger threatened would think that there was no necessity for the physician visiting the patient so frequently, if the nurse could make all the necessary applications of medicine. In this connection allow me to enter my most earnest protest against either strong solutions or the mitigated stick of nitrate of silver ever being used in any disease of the conjunctiva. It always does more harm than good, and in cases of purulent ophthalmia may be the cause of starting corneal complications, which it is our great object to avoid. In cases where you are not called until the disease is well formed and the conjunctiva and lids are so swollen and edematous that they can not be opened, it is imperative that the outer canthus should be divided, and I would recommend that you go even a step farther than simple division and divide the ligament (if I may call it such) which holds or binds the upper lid to the outer margin of the orbit, so that all constriction is removed and thus free the cornea from this danger. The bulbar conjunctivæ should also be incised to favor the flow of their serum and thus lessen the chemotic condition. When the case is seen at the very start and before the lids and conjunctiva have become greatly chemosed and swollen, the above mentioned local medical treatment will cause the disease to abort in from three to five days, often within two or three days. In cases where the disease is in full blast with the conjunctiva and lids swollen, with a large secretion of pus, unless the corneal membrane has become affected all purulent discharge and swelling will disappear within a week. With this mode of treatment, as the disease abates, the conjunctiva presents an entirely different appearance from that which it presents under the ordinary manner of treatment, recommended in all our text-books. It becomes smooth and presents a normal appearance, like to what it was before the attack. Its mucous surface presents no velvety or villous appearance with deep sulci between the swollen papilla and folds of the membrane.

My experience and results with the treatment proposed have been so satisfactory that for several years past, when I have had a patient with one eye affected with purulent ophthalmia I have not in any case taken the precaution to hermetically seal the well eye, nor have I in any case applied leeches, nor has the well eye become affected. The integument of the lids of the affected eye should be frequently dried and anointed with lanolin or something similar in order to prevent excoriations and irritation of their dermal surface.

By employing the treatment recommended in this paper you will find that, if sufficiently early employed, it will prevent chemosis of the conjunctiva and swelling of the lids if they have not already taken place. It will prevent the formation and secretion of pus, and dividing the outer commissure of the lids or incising the chemotic conjunctiva or applying leeches. In cases where the disease has reached the acme, with greatly chemosed conjunctiva, large quantities of pus secreted and swollen lids, if the cornea is still intact, I have never seen it become affected when this treatment has been followed; but on the other hand the chemosis of the conjunctiva, swelling of the lids and secretion of the pus have rapidly disappeared, leaving no impairment of the eye. In regard to the complications that may arise from the cornea becoming affected it is only necessary to say that when this membrane does become affected the manner of management and treatment is sufficiently described in all ophthalmia text-books and it would be a waste of time to repeat them.

Since Von Graefe's time and because he recommended it, every writer writing a text-book has extolled the virtues of chlorinated water in the various forms and stages of this disease. After a faithful trial of it, in many cases, it has proved extremely unsatisfactory in my hands.

There is no doubt that many cases of purulent ophthalmia in the new-born child, can be prevented by proper washing and cleanliness of the parturient tract before birth, and proper washing of the infant's eye, before washing any other part of the body. I am prepared to go farther than this and say that with the care above mentioned of the mother and child, and a drop of this yellow solution instilled into the infant's eye three or four times daily for the first three or four days of its life, that there would be no more cases of purulent ophthalmia in new-born children, and our blind asylums would be deprived of 25 per cent. of their inmates, thus bringing untold blessings and happiness to these poor unfortunate ones who pass their lives in darkness, a burden to themselves and their friends. You may think that I am too much of an enthusiast for this treatment, and that it is impossible to obtain such wonderful results. To those who doubt and question that such an effect and results can be obtained, I can only say try it on your cases of purulent ophthalmia, and you will become as strong a believer and enthusiastic as I am. You will feel like publishing it from the housetops as a blessing, and a prevention of misery to our fellow-men.

DISCUSSION.

DR. H. V. WURDEMANN, Milwaukee—The result of any method of treatment depends upon the stage of the disease in which the same is used and the condition of the tissues. I consider the cleansing method of treatment with very weak solutions of corrosive sublimate or nitrate of silver the most important. I can not conceive that in all cases it would be possible to obtain such flattering results as reported by Dr. Scott by any method of treatment. All cases may not be aborted as is evinced by the occurrence of ophthalmia in the hands of our most antiseptic accoucheurs. I call to mind several cases. I am inclined to take the middle ground, and while always endeavoring to protect myself in the family by explaining the fearful nature of the disease, I have never yet, in a comparatively large experience with this disease during the last few years, had a case

go on to destruction or injury of the cornea where it has come into my hands at a sufficiently early date, before ulceration of the cornea had ensued. Despite this, I do not forget the fact that cases have occurred and have been reported by some of our foremost men in which the child has been properly attended from the inception of the malady and yet which have gone on to destruction. As has been noted, some of these patients are subjects of general cachexia and such, as I have had reason to note, are apt to prove intractable to any form of treatment. We should be a little careful in setting forth such rose-colored views of the question as have been advocated by the author of the paper lest material injury be afforded some of us by the occurrence of one of these unfortunate cases. I, for one, can not say that I have ever seen a case "aborted" where the disease had so far advanced as to be recognized by the family or attending physician and consultation called. Those of you having had experience in urethral therapeutics will agree with me when I say that after the first manifestations of gonorrhoea have appeared, the disease is seldom or never aborted, although testimony to the contrary has been brought forward. Such is, however, not the general experience. The disease may be mitigated and its course shortened by treatment. I am pleased to see Dr. Scott makes no distinctions in purulent conjunctivitis of infancy; these are almost invariably gonorrhoeal in origin and are to be treated upon the lines laid down for that disease. We can not do away with nitrate of silver, which used after suppuration has been well established is of marked benefit. This may only be applied by the physician or a trained nurse. I am particular about instructions to the attendant as regards thorough cleansing away of the pus. I consider that no hard instruments, such as droppers or brushes should be given into unskilled hands during the course of this disease, for the slightest abrasion of the cornea means infection of that structure and probably irreparable damage. Soft pads of absorbent cotton soaked in the solutions and the latter dropped into the eye for cleansing, and atropin when necessary in the form of an ointment are the least dangerous ways of applying the necessary medicaments. All manipulations by the attendant should be done with the utmost gentleness and thoroughness.

DR. A. BARKAN, San Francisco—I regret that Dr. Scott does not substantiate his statements with proper statistics. As he still continues the application of nitrate of silver many of us will go on and think that that remedy is the mainly curative one. We all know the excellent effects of nitrate of silver in blennorrhoea neonatorum. Why should not the same remedy act beneficially in purulent ophthalmia in the adult?

DR. STARKEY—I fear that I must come under the number spoken of by Dr. Scott, just at the close of his paper, who are skeptical as to the uniformly good results obtainable by any means, but shall gladly follow his injunction and try his method and hope to be convinced. My experience has been such in these cases, both in the new-born and in adults, that I can not take a very rosy view of the prospects of recovery in any case of purulent ophthalmia that comes under my care. It seems to me that, as was said in this Section last year, the only time in which purulent ophthalmia can be treated with universal success is before the disease occurs; when infection has actually occurred, it seems to me that a certain proportion of eyes will be lost by any treatment yet devised. Take a poorly nourished and perhaps premature infant with this disease—an infant that under any circumstances has all that he can possibly do to live, and the prognosis is exceedingly grave. We must all of us have seen such patients, with little discharge, easily controlled, also little swelling of the lids and little chemosis in which the

cornea seemed to melt away from lack of nutrition. No pressure, no maceration with pus and yet no nutrition. Now it seems to me that we should be very careful about asserting that all eyes with purulent ophthalmia can be preserved by this or that treatment. Such statements reach the public and may come up to confound us after we have had one of these unfortunate results.

DR. KASPAR FISCHL—May I call your attention to the publication of Prof. Burkhardt, of Berlin, who has a very extensive experience in purulent ophthalmia of young persons? He has discarded the application of ice and the use of strong solutions of nitrate of silver. He lays particular stress upon the removal of the gonococci from the conjunctival sac. For that purpose he instills into the inner corner of the eye, nitrate of silver 1 per cent. solution, and moves the lower lid rapidly up and down so that the fluid is thrown under the upper lid, and the cul-de-sac is thus thoroughly cleansed. This is repeated several times a day.

DR. J. D. ENNIS ARNOLD—The method of treating purulent ophthalmia, advanced by Dr. Scott, appears rather a step backward than a step in the advance; and yet I fancy we all feel inclined to make a trial of these medicaments, though the disease under consideration is one in which time lost in going after strange gods is likely to be fraught with dreadful consequence. The trend of modern treatment in all local disease is not the blind adoption of a fixed method with increasing faith in the power of a medicament to correct or cure the disease, but rather the rational adoption of procedures that have for their object the removal of material which we believe to be causative factors in producing the disease. In purulent ophthalmia we dare not destroy the living bacteria present, nor dare we even use substances able to prevent their multiplication, *in situ*.

By frequent cleansing all *materies morbi* must be removed from the conjunctival sac, and by punctilious vigilance we must stand always ready to prevent impairment of function by forestallment of tissue destruction. To-day there would be little excuse for him who would allow a corneal ulcer to penetrate spontaneously the anterior chamber, or for him who failed to relieve by section the pressure that threatened to produce tissue necrosis. The Credé method with the eyes of new-born children, is not a treatment of purulent ophthalmia, but an attempt, and nearly always a successful attempt, to prevent purulent ophthalmia.

DR. SCOTT, in closing—Gentlemen, I am not surprised at the remarks made about this treatment. It is simply because you have not had any experience with it. The books say it is generally four or five weeks in the most typical cases. I have not lost a single case with it, if I got the case sufficiently early. It is miraculous how quickly the discharge disappears. I do not get any of the indications of the ordinary treatment. The conjunctiva is comparatively smooth. If you will try it, every one of you, you will be just as much an advocate of it as I am. I have taken ordinary cases of pure ophthalmia in the new-born child, and in four days had them perfectly well. I do not believe the nitrate of silver has anything to do with it. I know this has been used in gonorrhoea where in three or four days it stopped entirely. There is not a particle of pain in its application. In my own individual case I have used it. I had a very severe attack in my head, an immense secretion of matter from the head and nose. I tried everything to control it until I used this solution and in two doses it disappeared. It seems to be antiseptic, to destroy the formation of pus, and to act beneficially upon the mucous membrane and secretion of pus. Try it thoroughly and you will be just as much an advocate of it as I am.

CONSERVATIVE TREATMENT OF WOUNDS OF THE EYE-BALL.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY LEWIS H. TAYLOR, M.D.

WILKES-BARRE, PA.

I do not propose to weary the members of the Section by attempting to discuss the subject of wounds of the eye-ball in all of the phases which that subject might present, nor will I even enumerate

the varieties and grades of these injuries, but will confine my remarks briefly to a consideration of some of the more serious forms, such as penetrating and lacerated wounds involving the iris and lens.

Living as some of us do, either in mining or manufacturing districts, we are frequently confronted with eye injuries of all grades, from the small cinder lodged upon the cornea, which in its effects is oftentimes by no means small, to the severe laceration of cornea, lens, iris and sclera.

The important question that at once arises is, to what extent shall I interfere with this eye? and how far dare I trust to the recuperative powers of nature to bring about a good result? We are taught in some text-books that if the iris is prolapsed, at once excise it. If the wound is a penetrating one and into or near the ciliary body, enucleate the ball in order to save the other. I can not in all cases agree with these teachings. I have had a number of serious injuries to deal with, in which the iris was involved in the wound and let alone with as good results, or better, than in similar cases where an effort was made to remove the adherent portion. It is difficult to remove the portion of the iris entangled in a bruised or lacerated wound, by iridectomy, and unless seen very early after the accident our patients will probably fare as well if the iris be left alone and allowed to heal over, fastened in the wound, as if we attempt its removal. I say, unless seen very early after the accident; I might say, if seen very early, the removal is not usually necessary, for it may oftentimes be replaced and freed from its entanglement in the wound. One of my earliest cases of this sort illustrates the latter statement:

Case 1.—Mr. H. came to my office within a few hours after receiving a severe blow upon the eye from a chip of a steel hammer. This had penetrated the cornea, wounded the iris and apparently the lens, the iris being fastened in the wound and protruding from the eye. After cleansing the eye I used a small spatula and gently replaced the iris, the pupil contracted and under a light compress bandage the eye made a most excellent recovery with normal vision.

I spoke of the lens being apparently injured, and yet there was no resulting opacity. I have repeatedly seen the same in injuries in which the capsule was undoubtedly penetrated and yet the wound healed without leaving any lens opacity. This point was ably brought out in a paper read before this Section by Dr. Milliken at the Detroit meeting in 1892, on "Injury to the Lens."

Case 2.—Martin S., age 33, came May 24, 1892, directly from the mines where he had been injured an hour or two previously. Examination of the eye showed a wound in O. S. through the sclera near the sclero-corneal junction, the iris being fastened in the wound and pupil irregularly ovoid. V. reduced to merely counting fingers. I had him go into my lavatory and thoroughly wash face and head, then after using cocain, I replaced the iris with a small spatula but it would not fully return. I dropped in eserin freely, put on a compress bandage and gave bromid and morphia to be used if necessary. On the following day he returned with pupil contracted but irregular. Iris not fully replaced but as the wound had closed I made no attempt at further replacement but used atropia instead of eserin. On May 27 he was doing very well, pupil well dilated and iris drawn away from the wound so that the pupil was slightly dilated and was irregular. V. had now risen to 20-C. From this time on the eye rapidly healed and the patient recovered useful vision with a natural pupil.

This would have been an excellent case in which to follow the teachings of the books and excise the protruding iris, and yet if it had been done, nothing would have been gained and much lost. Indeed it is

a serious question whether we do not do more harm in such cases by an iridectomy than we do good. If the cause of the injury remains in the eye it must be removed, unless it has penetrated so far that its removal is impossible, in which case enucleation will sooner or later become necessary.

Dr. H. Knapp, of New York, at a meeting of the American Ophthalmological Society in 1893, in discussing his paper on "Traumatic Dislocation of the Iris," says: "Now something about prolapse of the iris in eyes that have been injured. This is an exceedingly important matter, and I have made it a rule not to touch a prolapsed iris unless I could get it entirely fresh. I have never seen sympathetic ophthalmia where there was prolapsed iris which had not been wounded by the injury or by the surgeon's knife. If cases come in the first four or five hours, where a clean iridectomy could be made and I am sure that the foreign body was not an infecting one, then I make an iridectomy. If they come some time afterward, I leave the prolapse alone for it is very difficult to get at the lateral portions which will be incarcerated in the corners of the wound, and if operated on they are more apt to be followed by sympathetic ophthalmia or purulent infiltration than if left alone."

Case 3.—This is an exceedingly interesting one, on account of the severity of the injury and the high grade of astigmatism developed by it. It will not be necessary to relate all the details of the case. James McC., age 31, was a blacksmith, and on May 18, 1893, went into the mines to shoe mules. He had finished his work, and was standing in the center of the hoisting carriage at the foot of the shaft ready to start up, when a piece of coal fell down the shaft from above, struck a slanting board, and glanced off and directly into his eyes causing the wound. He came to my office about three and a half hours after the injury with V. in right eye reduced to mere perception of light. The wound was a formidable one, being through the cornea about one-eighth of an inch from its outer border, extending entirely across this portion of the cornea and into the sclera above and below, also involving iris and lens. I used cocain thoroughly, cleansed the eye with Panas solution, replaced the iris with spatula, used eserin and bandage. On the following day, the iris was again found caught in the cut and pupil ovoid, and again replaced. Same on third day when I again replaced it and began using atropia. From this time on the healing though slow was steadily progressive and he made an excellent recovery but with a slightly ovoid pupil. On July 14 the right eye showed, with the ophthalmometer, 12 D. of astigmatism, ax. 120, and the left eye none. With a correcting glass -7 cy. ax. 30 \ominus +5 cy. ax. 135 (not right angles). Vision was nearly 20-40. The patient now considered himself well and I have not seen him since.

Case 4.—Nicholas K., age 20, came Aug. 27, 1890, stating that O. D. had been cut about quarter of an hour before, by a piece of steel which had been driven forcibly against it. V. in O. D. nil; in O. S. 20-70. Inspection at this time showed the right eye already congested and somewhat painful. A cut in the horizontal meridian of the eye, starting about one-eighth of an inch from the corneal margin extended backwards three-quarters of an inch and penetrated through all of the tunics of the eye into the vitreous which was exuding from the cut. There was some hemorrhage into the eye, and it was impossible to tell whether the foreign body which caused the mischief was still in the eye or not, but from the patient's description of the accident, I concluded that it had fallen out at the time. The eye was very carefully washed out with Panas solution, the protruding vitreous snipped off, atropia instilled and a compress bandage applied. Morphia was prescribed to be used if needed for pain, and a very guarded prognosis given. August 28 reports that he slept well without morphia and had but little pain. The pupil is about half dilated and chemosis is already considerable. On the third day he reported that he had slept well each night and had not found it necessary to use the anodyne at all. The chemosis is now considerably less and the eye is doing well. In addition to the atropia, which

was used every three hours, I cleansed the eye each day with Panas solution and he used cold applications at home.

September 2. Is improving nicely; swelling is nearly all gone and he begins to see dimly; counts fingers. September 9. The eye is doing very well; the cut through the sclera has closed entirely; the blood has largely absorbed, but nerve and vessels can not be distinctly seen with the ophthalmoscope. The anterior chamber has been clear all the time. The pupil is dilated and he counts fingers at one foot. Discontinue atropia and use Panas alone. I last saw the patient on September 27, at which time the eye was looking well but from the excessive wound the scar contracting seemed to lessen the size of the eye in comparison with its fellow. He could now count fingers readily, the eye looked well and he had returned to work. I presume vision still further improved. I recently heard through another patient whom Mr. K. had sent to me, that he was doing well and his eye was all right.

Case 5.—Wound through sclera into vitreous. This illustrates one of the most serious types of injury and the preservation of useful vision was very gratifying to both patient and physician. Harry E., age 20. I was called to see the patient in consultation at the request of his attending physician, Dr. G. W. Guthrie, Oct. 6, 1890, about 9 o'clock in the evening. The history obtained at that time was, that he had been unpacking a barrel of bottled ale in the grocery store where he worked. The barrel was turned over on its side and the patient was leaning over it; while in this position, one of the bottles rolled out and against another causing an explosion and a shattering of the bottle struck. A piece of glass flew up and struck him above the eye, but he could not tell whether it had fallen out or not. (The piece was subsequently found stained with blood.) Inspection showed a ragged wound in the right upper eyelid about three-quarters of an inch from its margin and in a line midway of the two canthi. This cut extended through the lid, through conjunctiva and sclera, into the vitreous. The wound in the globe was about one-quarter of an inch from the bulbar-tarsal fold and extended downward nearly one-half inch and to right and left the same distance, forming a rough jagged opening exposing the vitreous beneath. Not knowing whether the glass had fallen out, and not being able to decide as to its presence with the ophthalmoscope on account of hemorrhage, I gently explored the vitreous with a sterilized strabismus hook, but could detect nothing. It now seemed advisable to close the wound, and not having at hand any very fine catgut, we used silk. A suture through the sclera tore out immediately, so two sutures taking a sufficient amount of tissue were inserted into the conjunctiva, drawing it firmly together over the exposed vitreous. Vision in O. D. nil. O.S. not taken. The eye was thoroughly irrigated with Panas solution, the external wound in the lid closed with catgut, dressed antiseptically, and both eyes bandaged. A very guarded prognosis was given. The patient was left in charge of Dr. Guthrie, his family physician, who removed the bandages and carefully dressed the wound daily. October 9. I saw patient to-day in Dr. Guthrie's absence. Doing well, free from pain, very little swelling, but conjunctiva intensely red, evidently subconjunctival hemorrhage. October 11. One stitch removed from the conjunctiva, the other could not be found, having probably dropped out at one of the dressings. He can now count fingers dimly, eye is free from pain and is not so much injected. October 16. Ophthalmoscope shows large floating shreds; details of fundus can not be made out. Conjunctival wound has healed kindly and congestion is passing away. He has been remarkably free from pain throughout, considering the serious nature of the wound. Atropia has been instilled once daily; now discontinued. October 25. Now comes to my office; pupil is well dilated. The eye is looking very well. Nearly all of the redness is gone, some congestion remaining over the wound. He counts fingers dimly at one foot. Sees large objects dimly. Ophthalmoscope now shows the red reflex but no details of fundus. Still keeps it bandaged. V. in O. S. 20-xxx. November 17. Now goes without the bandage and is doing very well. Counts fingers directly in front of him. V. 2-C. Sclera wound entirely well. December 11. O. D. 20-C., O. S. 20-xxx. Selects O. D. + 1.75 cy, ax. 75. 20-40 and on December 18, with +.25 = + 2.25 cy. ax. 75; V. = 20-xxx; some in xx. O. S. Selected + 37 cy. ax. 90; V. = 20-xx. The eye was now thoroughly well and to all appearances the same as the left. He had excellent vision with the correcting glass, and an eye saved that according to many, ought to have been enucleated at the start.

This last case illustrates the wonderful recupera-

tive power of the eye if it can be kept clean. This eye at first sight seemed to be in a hopeless condition and yet ended with most excellent vision.

Case 6.—Emil B., came Nov. 20, 1891. O. S. was cut in the morning about 8:30, with a piece of steel from a wedge which he had struck with a sledge-hammer. The wound extended through the cornea, iris, and edge of the lens and the iris was fastened in the corneal wound. Under cocain with a spatula, I partly replaced the iris, but as the wound had commenced healing this was somewhat difficult. I instilled a few drops of a 2 grain solution of eserin and had the patient wait an hour, at which time the iris was partly drawn away from the wound. I then instilled more eserin and gave him atropia to use at home. On the following day the pupil was three-fourths dilated but not round, rather ovoid, and I feared traumatic cataract from the wound of the lens. Continued atropia and in six days the eye was entirely clear. Another illustration of the fact that lens wounds sometimes heal without forming cataract. I saw the patient three months later when he called with a foreign body in the other eye. The left eye was entirely well. V. 20-xxx and only a slight scar remaining to mark the original injury.

I have a number of other cases, Mr. Chairman, but it is useless to occupy the time of the Section in a rehearsal of them. I have selected a few illustrative ones. I have also many others in which the prolapsed iris has been cut away, and in some of them with excellent results but in some, I am sorry to say, with such results as to leave me in doubt as to whether I had done just the right thing in attempting to remove the prolapsed portion.

Dr. Noyes says: "The danger consequent upon prolapsus iridis increases with its extent and its nearness to the ciliary body. Traumatic prolapse is more dangerous than anterior synechiæ resulting from inflammation and perforation. A wound through the limbus and extending into the ciliary region demands abscission of all tissues which present." My own experience, however, inclines me to conservatism, and I strongly believe that a large number of these cases will do as well or better if the iris be replaced so far as it can be and let alone, as if we attempt to remove it.

DISCUSSION.

DR. BAKER—Mr. Chairman, I am firmly of the opinion that many of us have removed eyes that might have been preserved. While the dangers of losing both eyes from sympathetic inflammation are very serious, I do not think that we should upon first seeing an eye and recognizing that there is a very serious injury decide on enucleation. During the past two years I have had two cases which illustrated this matter very forcibly. First, a boy about 12 years of age who had gone to one of the rod mills in the city. The iron rods as thick as your finger come out of these mills and shoot very rapidly forty or fifty feet across the room. One of these rods struck this boy in the eye, making a large opening in the lower part of the cornea through the sclerotic, so large that your finger could be very easily passed through this opening. Almost one-half of the circumference of the blow seemed to be torn open; the vitreous was protruding. I immediately proposed enucleation of the eye. The parents refused. I then put in a few stitches and brought the wound back as well as possible. To my surprise it healed and there is not a particle of reaction from it. I used eserin instead of atropia. The case went on to uninterrupted recovery and though the field was contracted the vision was almost perfect, that is he could read something like twenty or thirty feet, but the field of vision was contracted. I have watched this case since and have seen no bad results following.

A few months since a patient came to me for enucleation of the eye; he was engaged in ship building. A bolt had been knocked off and struck the lower lid, puncturing it and

making a very large opening in the sclerotic, almost as large as in the boy's eye. It was one of those injuries in which it seemed as if the whole eye had escaped. The iris seemed almost collapsed. The patient was very anxious to save the eye, if possible, and following the experience I had with this boy, I adopted the same line of treatment and used the eserine. This case ran along to almost uninterrupted recovery. I am certain that two or three times in my life I have removed eyes with similar injuries while in these cases I have, so far, had no bad results. The same thing is true with regard to injuries of the cornea. If it does involve the ciliary regions to any great extent, we can often save the eye where we are confident there is no foreign body and with the means we now have. In most of these penetrating wounds, in these large manufacturing centers, the foreign body is a piece of steel or iron and by the use of the magnet we can often exclude the foreign body in the eye. I think we should make an effort to preserve some of these eyes that formerly we should have removed.

DR. BRIGGS—In my earlier experience I have neglected eyes that I at present would treat, conservatively however. In case of prolapse of the iris, if I saw it when the iris could be returned I would certainly return it. I believe the danger in those cases is from infection, and the danger of infection is greater if the iris remains prolapsed than if returned. If I could not return it without too much violence to the iris, if it were not prolapsed to a considerable extent, I should use the galvano-cautery. In that way, I believe the danger of infection is lessened. In regard to the treatment of penetrating wounds, I think we are all becoming more conservative. Often we can preserve eyes from which we can extract foreign bodies, especially a piece of steel, with perfect vision. I have several such cases with almost perfect vision from which I have extracted pieces of steel, and in some of those cases, I have either excised pieces of iris or returned the prolapsed iris.

DR. SCOTT—Mr. President, the trouble I have had with prolapsed eyes has not been so much sympathetic ophthalmia, as I have had four cases of severe ophthalmia. One a case which had prolapsed eyes. I desired to remove the collapsed piece and they would not consent to it. All these cases of injury about the ciliary regions have been a source of great anxiety to me, and especially when the wound has healed and there is a contraction of a scar. I have seen few of these cases that have not been followed sooner or later by sympathetic trouble, and ultimately require enucleation.

Lately I had a very interesting case of injury; a man found a railroad torpedo and burst it open. It exploded and a piece of it went into his eye. I removed the prolapsed iris, and the lens seemed to be transparent. There was considerable hemorrhage and I questioned whether the piece had gone into the eye. I kept him under observation two or three weeks, and finally the eye-ball commenced to shrink. I advised him to have enucleation, and removed his eye a few days before I came away, and found that a foreign body had passed completely through the eye and lodged opposite the optic nerve, passing through the posterior part of the eye in contact with the optic nerve, so that when I came to cut through the optic nerve I found there was a foreign body to cut through. This piece was twice as large as a grain of wheat. I do not understand how that could pass through the lens and the ciliary region and the lens remain perfectly transparent, three weeks after the accident.

My experience in all injuries with the eyes is that injuries in the ciliary regions are much more serious than in any other. Also, I believe it is better where we have prolapsed eyes, unless we can easily reduce it, to remove them.

DR. H. H. WEER—Mr. Chairman: I recently had a case of a man attempting to drive a nail. The nail flew up and

struck him across the ciliary region, curving through the corner downward and outward. The aqueous humor at once discharged. He had to take hold of the nail with his fingers and pull it out of his eye. He then hunted for the nail in the dark, found it, drove it into the board, went into the house and retired. He suffered no inconvenience. Next morning he went to the nearest physician, who put him in his carriage and brought him to me. I saw that there had been a complete opening into the anterior chamber. There was hemorrhage in the anterior chamber. Fortunately the wound closed and the aqueous humor reformed. Having been taught by Dr. Rosie, in injury across the ciliary region, denominated by him "the danger line," to call for immediate enucleation, I used 4 per cent. solution of atropia in order to save my iris. When I next saw the patient I noticed that there was discoloration of the lens. The lens was in the anterior chamber. I made preparation for enucleation, when they came again. I found that the crystalline lens had retired from the aqueous chamber and out of sight. I was also met with a flat refusal to enucleate the eye. The case in my estimation was one of ocular anesthesia. That man never had a particle of pain. There was a greenish tinge to the iris. I repeatedly asked him if he had pain, any neuralgia of the forehead, nasal, temporal or molar, and I failed to get any indication of pain. I had the patient still under observation and the question in my mind was, the crystalline lens having retired within the vitreous chamber, whether or not it would be safe for me to attempt to take out that crystalline lens, running the risk of losing the vitreous, or whether I had better enucleate or await developments. I am still awaiting some symptom of danger. I still have the chance to take the alarm at the earliest moment. If the alarming symptom comes I can then enucleate at once. I merely wish to put myself on record as being one in favor of conservative surgery in injuries to the eye-ball.

DR. L. R. RYAN—I can recall a case that occurred a few months ago. A man was chopping a piece of wood and a splinter produced an injury to the cornea that prolapsed the iris. The prolapse was returned and by the use of eserin for several weeks the wound healed kindly and there were no symptoms of inflammation. I had two or three other cases treated in the same way, and it seems to me that eserin has a more important place in the treatment of the eyes than we attribute to it. It prevents the tendency to glaucoma, which is apt to follow any inflammation of the iris where we use atropin alone. If we would confine ourselves to eserin in connection with atropin in iritis, or inflammation of the iris from disease, our results would be far better than they are at present. That has been my experience in the last two years.

DR. TAYLOR—Mr. Chairman, I read by paper most hurriedly from the fact that there are several papers to read yet. It will not take a long time to discuss it. I do not wish to make light of the danger which every injured eye has; the danger from sympathetic ophthalmia. That is the danger, and yet if we keep that eye under observation we are ready at any time it becomes necessary to treat it. Oftentimes, our patients leave us and we fail to see them in time and it becomes too late. I recall to my mind one case of injury to the cornea, not apparently a very serious injury. The patient was doing, as I thought, well. It was a case in which there was no pain, and so the patient who thought she was doing well enough staid away. She came back in two or three weeks, and I found sympathetic ophthalmia had developed in the other eye and advised enucleation. The patient said: "No, I would rather be blind than have my eye taken out." She would not have it taken out and she is totally blind to-day in both eyes. And yet, the case

was not one in the first place that any one would have thought of enucleating. It was a case of neglect, not neglect on the part of the doctor, because he had no chance to see the case, as the patient did not come back.

I merely wanted to call attention in the paper to the fact that' as it was said by our chairman, I believe many eyes are enucleated which might be saved, keeping in mind the serious dangers in cases like those Dr. Scott has mentioned. If a foreign body remains in the eye, the eye must come out sooner or later, but if we are sure the foreign body is out, then I believe we should wait a reasonable time unless the eye is injured to such an extent that it is hopeless. A paper by Dr. Geo. H. Powers, of San Francisco, entitled "Some Cases of Unusual Reflexes from Pathological Ocular Conditions," was then read by title and referred to the Publication Committee.

A paper by Dr. A. G. Hobbs, of Atlanta, Ga., entitled "The Use of Galvano-Cautery Knife in Pterygium Operations," was also read by title and referred to the Publication Committee.

THE TREATMENT OF PTERYGIA WITH THE GALVANO-CAUTERY.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY ARTHUR G. HOBBS, M.D.

ATLANTA, GA.

I shall not presume that it is necessary in describing this method of operating on pterygia to even enumerate the many already in vogue. I should rather ask your forbearance for merely suggesting to you that yet another method is to be added to the list already, perhaps, too long; still it may be true that each of these operations has served its purpose in turn in the process of evolution. Since it is the cardinal point in making a pterygium operation to prevent two raw surfaces from remaining in apposition after the operation, which necessarily results in the relapses which we too frequently see, why not then convert each of the raw surfaces into an eschar at once to avoid such failures, provided we are able to demonstrate practically that this means will bring about that desired result?

For some years the galvano-cautery point has been resorted to in corneal ulcers, particularly in those indolent and intractable ulcers which have refused to yield to other methods of treatment. It was suggested to me a few years ago, after seeing some of the beautiful results of the cautery when applied to ulcers of the cornea that it could, at least, produce no bad results if properly applied to the neck of a pterygium for the purpose of cutting off the nutrition of its corneal apex. I hoped that it would prove a better means of severing the arterial supply to the apex as it crossed the sclero-corneal junction. This object is generally attained by the use of the knife and various methods have been resorted to, to accomplish the purpose. The failures in pterygium operations are usually due to the resulting reestablishment of the arterial circulation, and when this occurs the desired end of the operation fails in proportion to the number of the reestablished vessels. The great vascularity of a pterygium, with its vessels crossing over the sclero-corneal line to supply its apex on the cornea, renders it difficult to permanently sever all the arteries by a clean cut with the knife, hence perhaps a score of different methods of knife and scis-

sors operations have been resorted to by different operators to accomplish this end.

Each operator aims at one end primarily, and that is to completely cut off all the blood supply from the corneal apex. Secondarily, his desire is to destroy as little conjunctiva as possible. When the first end is attained, the corneal part of the pterygium has lost its direct nutrition and can then only share with the cornea proper for its sustenance which is indirect, or by imbibition. As this meager supply proves insufficient atrophy results and the partial, or almost complete, obliteration after a time will depend upon the activity of the absorbents. For this reason the best results are obtained in younger subjects in which as a rule, the lymphatics are more active, as is also the contractibility of the arterial coats.

In many cases when the knife is resorted to a secondary pterygium results in which sufficient nutrition is reestablished to the apex to perpetuate the corneal haziness even beyond its apparent margin to greatly interfere with vision. When the cautery section is well made I have not seen these secondary results that are often so difficult to prevent by a clean cut with the knife or scissors. In some cases, however, it may be best to combine the methods of operating as I have done in two cases not included in this report. These two pterygia were extremely vascular and muscular, hence I first used the knife in the usual way and then seared the divided edges with the cautery blade to prevent the secondary results.

The fine-pointed cautery blade, heated with a battery that can be perfectly gauged and always relied on, is applied horizontally to the narrowest portion of the growth which is near the sclero-corneal line; the touch is made at the moment white heat is reached and should be almost instantaneous and re-applied as quickly, if the tissues are not at first completely severed. If the growth is not adherent to the sclera and corneal margin it is best to grasp it with small forceps and slightly raise it from the sclera. When the forceps are used it is easier to be certain that the cautery has made a complete section of all the hypertrophied and over vascular conjunctival tissue.

When the corneal head is large and protruding it is advisable to make a cautery application in the same manner as in applying it to a corneal ulcer. In both cases the resulting cicatrix is less—it is more transparent. This is not altogether an unknown fact but one that has seemed never to have been brought out as prominently as its importance would suggest. For this reason one may be tempted often to resort to the cautery to reduce a large pterygium apex or a corneal ulcer, for the purpose alone of attaining this corneal transparency. The resulting eschar so completely severs the vascular connection, leaving no raw surfaces in apposition that a reestablished circulation is practically impossible; this can not be said when the knife or scissors have been used. In case the redundancy of tissue at the point of section should seem to require reduction, the scleral end of the section may be turned under and a transverse suture introduced.

I have made this operation fourteen times, and would have made it half as many more times during the last two years but for that decided objection to the cautery which we so often meet with and are bound to respect. This operation is more quickly

performed; it is followed by no bleeding; it leaves no ecchymosis; the wound heals more rapidly; there is less pain during and after its performance; it requires no bandages and the corneal haziness around the apex is less.

A weak solution of cocain, about a 2 per cent. is first dropped into the conjunctival sac, then after about five minutes a stronger solution, about 10 per cent. is applied at intervals, locally, by means of a small cotton probe for five minutes more; in the meantime the lids are held open. By this means the toxic effects are avoided except in those subjects that are unusually susceptible to cocain. In using cocain in this latter strength I try to avoid as much as possible, by the position of the patient, its contact with the cornea. It is now a well-known fact that when used in this strength, or even when much weaker, that this drug is disastrous to an abraded cornea if long continued.

The kind of galvano-cautery apparatus, the ease of its manipulation, the size of the blade, the confidence of the hand that presses the button, the requisite degree of heat which should be gauged by the turn of the screw are some of the necessary factors in this seemingly simple, yet delicate little operation, whether it be made to a corneal ulcer or to the neck of a pterygium. The only galvano-cautery apparatus in my knowledge that I would now be willing to trust for this purpose is a little transformer of an alternating current of fifty-two volts.

I am now using, in my consultation rooms the first two little instruments ever made for this purpose. I described the varied uses and advantages in a paper read before the Pan-American Congress last fall. So far as I know, the galvano-cautery has not hitherto, been used as a means of cutting off the nutrition of the corneal apex of a pterygium.

RELATIONSHIP OF OPTIC ATROPHY TO LOCOMOTOR ATAXY.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY H. I. JONES, M.D., L.R.C.P.E.

MEMBER AMERICAN MEDICAL ASSOCIATION, CALIFORNIA STATE MEDICAL SOCIETY AND SAN FRANCISCO COUNTY MEDICAL SOCIETY.

I desire to point out the special features of the relationship of the optic atrophy to ataxy, and have a case to demonstrate my topic:

J. W. H., aged 37, native of the United States. Past history: He has suffered for the last five years from rheumatic pains in various parts of his body, and from nervous twitching, lightning pain in leg, trunk and arms. No history of syphilis. He has used tobacco and stimulants freely. About a year ago he was advised to go to Paso Robles Springs and use the mud baths for his rheumatic pains; no relief was obtained; a few weeks after his return he complained of defective vision, first of the left eye, then the right. Jan. 31, 1894, when he first came under my care, I found that he was totally blind and suffering from a rapid nystagmus, and lightning pain in both legs. Ophthalmic examination showed atrophy of both optic discs; owing to the rapid movement of the nystagmus it was very difficult to make a thorough examination of the fundus. Physically he is in perfect health. He has Westphal's symptom, absence of the knee reflex, but lacks the tabes gait; he tells me that his gait has always been normal. Many patients see no relation between their pains and their amaurosis or ataxy, especially if these pains come on, as in this case, years before. He has Argyle Robertsons symptoms. Under treatment he has made slight improvement. Nystagmus is less, he can see shadows in my office; for instance he pointed out a picture frame in my consulting room. To test him and to show that it was not visionary, I requested him to walk up to the picture and

place his hand on the left hand side of the picture, which he did. Treatment has been both local and constitutional. Locally, blisters to the cervico-dorsal region, leeches to the temple, cautery of the spine, galvanic and faradic currents. Internally, strychnia sulph. hypodermically, and by the stomach arsenite of strychnia, pilocarpin, iodid of potassium and proto-iodid of mercury.

There are few diseases which present such a multiplicity of symptoms as are found in locomotor ataxy. This patient was totally blind when he came to consult me, so I could not test his field of vision, which is a very significant symptom in cases of atrophy in tabes. There is an intimate correspondence between the development and functions of the brain and those of the optic nerve and retina; the connection is still increased by the communication which exists between the lymph spaces of the eye and those of the brain and spinal cord. These anatomic conditions not only account for the occurrence of neuro-retinitis and other ocular changes in disease and injury of the spinal cord, but a Polish physician has traced a connection between errors of refraction and curvature of the spine. The eye is not a separate autonomous organ, living as it were a life apart, nor is it a mere appendage or accessory, convenient and advantageous to the rest of the organism; on the contrary it is in closest relationship with the rest of the body, and participates in its moods. Erb tells us that a brisk cutaneous irritation causes the pupil to enlarge; pinching a comatose man will often enlarge the pupil, but the pupil in tabes is not affected by such procedure.

In all cases of atrophy of the optic nerve we should inquire for lightning pains, test the knee reflex, whether gait is normal or not. The pains are often the bridging symptoms betwixt so-called uncomplicated amaurosis and tabes. Charcot and others attribute the cause of optic atrophy to gray degeneration and to be parenchymatous. The eye-ball and its appendages draw their blood supply from two main sources, the internal and external carotid arteries. By means of the blood vessels and the fluid which circulates within them, foreign or other morbid material may be carried along the blood current into the eye.

The eye and its appendages receive the whole or part of six of the cranial nerves, as well as many fibers of the sympathetic nerves which influences the nutrition of the eye, controlling the size of the blood vessels, and regulating the size, equality and mobility of the pupil. That a certain portion of the spinal cord exercises a direct influence on the eyes has been incontestably established by experiments of modern physiologists. Brown-Séguard demonstrated that the filaments of the sympathetic that supply the eye take their origin from that part of the spinal cord which is contiguous to the origin of the first pair of dorsal nerves, and that portion of the spinal axis which extends from the fifth cervical to the tenth dorsal vertebra possesses a distinct influence on the organs of vision, and has been termed by physiologists, "cilio-spinal" and sometimes "oculo-spinal." The conclusion that must necessarily be deduced from these observations is that the portion of the spinal cord, "oculo-spinal axis," includes within itself both vasomotor and oculo papillary filaments; which are connected with the cervical portion of the sympathetic. It is not surprising, therefore, that the eye is very susceptible to all those influences, healthy and morbid, which affect the nervous system generally, or the special innervating apparatus of the eye,

either at the center, the periphery or in any part of its course. The special feature in this case is the absence of the gait.

DISCUSSION.

DR. YOUNG, Burlington, Iowa—Some years ago, we had an interesting paper on myopia. At that time I had an illustrative case, and can now recall five cases which might be considered under this head. I want to give the Section, briefly, some peculiarities observed in the five cases. Two were cases in which rapid optic nerve atropia came on, and they went blind in a very short time. In those cases there was absence of the reflex and some of the other symptoms of dorsalis, but we could never make out a plain case. A few other cases of unmistakable dorsalis have come under my care and observation. Typical cases have had no eye symptoms whatever. The fifth case had typical dorsalis as the result of an injury, and he had rapid, progressive optic atrophy and became entirely blind. The question arises, Should we not make a better classification of dorsalis in connection with eye symptoms than we have at present? Are we to expect in all cases our visionary image of cases? I think not. My observation would be like this: Where we get typical dorsalis as the result of direct injury, traumatism, I should look for it. In pure asthenopic dorsalis where the symptoms come on with staggering gait, pains, etc., I have come to the conclusion that we can correct it very often.

A NEW AND CONVENIENT ARRANGEMENT OF ROTARY PRISMS.

Read in the Section on Ophthalmology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY EDWARD J. BROWN, A.M., M.D.
MINNEAPOLIS, MINN.

After much suffering from heterophoria and more or less satisfactory effort to relieve such trouble in myself and others, I hailed the paper of Dr. Geo. M. Gould as a ray of genuine daylight, and at once put his theories to the test. The results in my own and a good number of other cases have been highly satisfactory.

As a means of carrying out the Gould exercises, I found the prismatic arrangements at my command very cumbersome and unsatisfactory. Dr. Gould's double battery of forty prisms seemed altogether too unwieldy for convenient use. It at once occurred to me that an arrangement of rotary prisms, like Stevens phorometer, except that they should revolve in opposite directions, would answer the indications perfectly. With the assistance of Mr. Carl Thayer, a local jeweler, I have constructed an instrument which I find very useful. It consists of two 30 degree prisms mounted on two clock wheels, geared together so as to rotate in opposite directions, on a brass plate. The prisms are rotated by a handle firmly attached to one wheel, and a pointer and scale indicate at a glance the power of abduction and adduction in a given case, with a range from 0 to 60 degrees.

By a simple arrangement one prism may be disconnected from the other, and revolved alone for the purpose of measuring the strength of, or exercising the vertical muscles. A clip might be easily added to hold a third prism base up or down, but I find it better in practice to use neither device, but to exercise the vertical muscles by slightly revolving the instrument in abduction or adduction in the hori-

zontal plane, by means of a narrow vertical cross-bar which serves as a means of suspension above and a firm handle below. The whole is suspended from a swinging arm, and by means of a simple automatic clamp easily placed at the height of the patient's eyes. It might equally well be swung from the ceiling with a weight and pulley. The instrument serves perfectly its purpose whether we choose Gould's system of over-weighting the muscles, or Savage's rhythmical exercise.

I find in practice the best plan to be a modification combining the advantages of each, *i.e.*, rotating the prisms slowly up to and beyond the patient's power to fuse, when he closes his eyes for a few seconds and the prisms are again placed at zero.

In some cases this over-weighting, even for once or twice will cause a severe headache, and there is consequently need of a wise discretion in its use. This is especially true of forced adduction, or sursumduction with the rotary prisms, since the unbroken and gradual increase of prismatic strength adds decidedly to the ability to overcome the prisms.

Gould advises the use of his method in accommodation. A decided advantage of the rotary prisms is that in most cases sufficient strain can be put upon the muscles at twenty feet. A further advantage is the low cost of the instrument, which ought not to exceed \$10.

As regards results I will only mention two out of many cases. In one, after several months ineffectual use of rhythmical exercise, adduction was brought by Gould's method and rotary prisms from 6 degrees to 80 degrees in four weeks; and in a second, adduction of 10 degrees was brought to 70 degrees in two weeks, the patient having no other than a few moments' exercise daily at my office.

DISCUSSION.

THE CHAIRMAN—There is a matter which I think the Executive Committee have to bring before the Association. The Secretary has just gone out to call them in to report.

DR. STARKEY—Mr. Chairman, while waiting, I would like to suggest that we should have a time set and an invitation extended to members who have any little device that they are using that others may not have, that they should bring it here and show it to the other members. I find as I go about that I frequently run across something that I wonder I had not thought of, which some one is using constantly and supposing every one else is using the same. I think we should assist each other in every way as much as possible.

A MEMBER—Was there any report from the committee on the subject of blindness? There was a committee appointed last year. Dr. Howe, of New York, was chairman.

THE CHAIRMAN—I might say that a great deal of work has been done by this committee; I was chairman of the committee that was appointed in Ohio to secure the passage of a law similar to that in New York City and we went to Columbus and secured such a law in Ohio. A similar law has been passed in four or five other States and an effort will be made to secure the passage of some such law in all the States.

A MEMBER from Iowa—Mr. Chairman, I went to Des Moines and labored very hard with our Legislature, and got the Committee of the Senate to decide favorably upon a law. That is all that ever came of it. We kept it grinding as long as we could, and finally the thing fell through, and I do not look upon it as very favorable toward getting any legislation in Iowa.

DR. SOUTHWARD, San Francisco—That matter was brought

up here. I had considerable correspondence with Dr. Howe, as did other members in California, and formulated a law based upon a law passed in Maine. Maine has the best law of all. The New York men voted for it and in New York within the last month or two there has been a conviction under that statute. Here in this State it was brought before the State Medical Society. I spoke upon it before the Society, and we hope it will receive a favorable hearing in our Legislature next session. I think that California will come into the line as a State that is willing to pass laws in the interests of humanity as soon as any other State in the Union. I assert that in this matter of legislation we are working for the cause of humanity, and that we can not do anything detrimental in asking the assistance of those who are willing to give their time and energies to obtaining laws that will be for the benefit of the rising generation. And I hope that this Section will indorse any movement or law compelling every child when it comes to school to bring a certificate stating that its eyes are in proper condition for carrying on its work. Whatever may be our theories in regard to statistics, we know what takes place among children on account of their bad eyes, and we know that the attempt to do this work can not be injurious, no matter what our personal ideas as to statistics are, wherein those errors exist and are detrimental. We know that many a bright child has been thrown out of school, and many a bright young man has had to leave his career, and as old Dr. McKenzie used to say: "All such are advised to go to Australia by the cheap route." I do not believe any one can object to voting for resolutions that will permit us to ask for such legislation. Some of us are anxious to see what we can do in California, and would like to go to our friends in the State and say that we have the indorsement of such a learned body as this. We expect to learn and have learned a great deal from the visiting members, and we want their assistance in doing these things for the best in the future. I would like to have the sense of meeting as to the indorsement of the course that we are trying to take.

A MEMBER, Southern California—Next month the Southern California Medical Society meets in my town. They have a larger membership than any society in California. We have a membership of nearly one-fourth of the regular physicians in our District, comprising seven counties of the southern portion of the State, and each one of those counties representing more territory than most of the Eastern States. We have an enthusiastic Society there and one which could be interested in this movement. I do not want to crowd anything on the Section without proper deliberation, but if this Section were willing to pass my resolution of indorsement, which we would prefer should come from some other State than California, I could take that resolution into the Southern California Society and get their coöperation in that work. It would be a long step in the direction of educating the people along an important line. Our Legislature in this State meets only once in two years. If nothing is done now, we can secure no action before two years this coming winter. If we can organize now, it is probable we can move upon a line that will commend itself to every member here, of securing something which will educate the people up to the wrong they are doing to all the children when they let them do work they are not able to do without severe suffering.

DR. STARKEY—Mr. Chairman, to bring that before the Section I move the following resolution:

Resolved, That it is the sense of the Section on Ophthalmology of the AMERICAN MEDICAL ASSOCIATION, that for the good of children, the eyes of all children should be examined before beginning their school life."

DR. ELLIS—Mr. Chairman, while I am heartily in sympathy

in this matter I do not think it would be policy for us to adopt such a resolution. While it undoubtedly would be for the good of the children, I think if such a thing were done it would have the appearance at least before the California Legislature, with whom I have had some experience, of simply drumming up business for the oculists. Now there would be just as much sense in the Section on Orthopedics or General Surgery to ask that a law be passed that the backs of all the children be examined to see that there is no spinal trouble, or that the hip joints be examined to see that there is no trouble there, and so on. While I do acknowledge that it would be to the advantage of the children, I do not think it would be to the advantage of the Section to take any action.

DR. SIMONTON—It seems to me that the gentleman who has had the floor has not got the gist of the motion; the motion is not that a law be passed. It is that it is the opinion of this Section that it would be well that the children be examined. As the motion now stands, I can heartily vote for it—that we think it would be well for the children. If there was a resolution urging the Legislature to make such a law, making it compulsory, then I should oppose it. I think whenever we undertake such things as that we get ourselves into deep water. The public objects even to vaccination. When we talk about compulsory vaccination that seems to be un-American to a great many people. They think their liberties are being abridged in some way or another. I vote for the motion that it is the sense of the Section that it would be well for the children if their eyes were examined before entering the schools, but not to suggest legislation on the subject.

THE CHAIRMAN—I think before this question is voted upon, we should have the report of the Executive Committee bearing upon this subject. It would be to our interest.

A MEMBER—Mr. Chairman, the report of your Committee appointed to select the subjects for consideration for next year is as follows:

Examination and Care of the Eyes During School Life.

Methods of Examination.

Instruction of Teachers and School Authorities and Local Provisions.

Suggestions as to the Members of the Committee—Dr. W. F. Southard, Dr. Young, Burlington, Iowa; Dr. A. R. Baker, of California; Dr. Geo. H. Price, Nashville, Tenn.

A MEMBER, Southern California—Mr. Chairman, I wish to take issuance with Dr. Ellis, of Los Angeles, with reference to the question, and urge the Section to adopt the resolution. I believe thoroughly as Dr. Simonton has said, that it commits the Section to no action and no indorsement of any action towards the securing of legislation. That falls to the share of the individual workers in the State. I believe a great deal can be done in the way of educating the people up to an understanding of the conditions by a fight, even if it is an unsuccessful fight before the Legislature. Attention will be called to the fact that legislation is believed to be necessary by a considerable body of the people, and more attention will be paid to the question. I have taken no part in the discussion of the paper delivered to-day. I have taken great interest in the work and have done work in my own country. I have been urged into it by regular practitioners, by superintendents of schools and county superintendents, and I have recognized the fact that the appearance was as if I was drumming up business, and yet I have scarcely met with any opposition on that ground, either among practitioners or educators, and have met so warm a feeling in favor of doing something, and so much interest among educators in the county that I am convinced much good can be accomplished, even by a losing fight.

DR. TAYLOR—Inasmuch as this Committee has suggested

this very topic for next year's discussion, and suggested a competent committee to prepare this subject, would this not come with greater force from this ASSOCIATION next year than at the present time, if it should come after a full preparation of the topic, and a full discussion in the report of this Committee? I suggest that it be deferred for the present, inasmuch as this is a special topic for next year.

DR. ELLIS—The Secretary might be instructed to refer it to that committee.

DR. SOUTHARD—You do not assert that it means that this body of men here is not competent to claim that they believe it is well to examine children's eyes? President Jordan said to me within a few weeks that he never realized in his life the importance of this until recently, and he was very earnest in the hope that something would be done, and that I would continue to work in this line until something was accomplished. I would like to be able to go to teachers and others and say that our Ophthalmology Section does agree with me and others in the fact that it is well to have children's eyes examined. I should think we might have indorsements in that way, to assist us to carry out what we have already started upon. I believe that now is the time for commencing the work. It is simply a little indorsement I want from you in my lectures throughout the State.

DR. COE, of Seattle—We have our teachers' associations throughout the State, and local meetings of teachers, and if this matter can be brought before the State Societies, we can get the general practitioners interested in that matter. As has been stated, Dr. Jordan even was ignorant of the dangers to be incurred through these troubles. So you find it everywhere. I have no hesitation in trying to educate the public to this view of the matter and I think if we can only adopt this resolution it will come with added force when we take it into our State Society.

The question was then put on the amendment to postpone until next year and the motion was lost.

DR. STARKEY—I have no desire to push this matter but I thought, simply as an educational measure, it might be well to have it for use during the year without postponing.

The question was then put on the original motion and carried.

The Secretary then read a letter from Dr. Savage of Nashville, suggesting that the Section extend an invitation to the International Congress of Ophthalmology to hold its next session in this country and requesting to be appointed a delegate.

DR. TAYLOR—I do not know whether this is a matter to come before the Society or not, but I suggested the reading of this letter so that it may be brought up. Probably Dr. Jackson can tell us something about this Society, so that we will know whether it would be proper for us to take action.

DR. JACKSON—I think this Congress met in New York in 1874. A Congress met there which was practically one of this series of international congresses. So far as I know, the place of meeting of the Congress has not been determined by any invitation of the Society, but by the invitation or upon the solicitation of members from a certain place, who were present at the meeting. The Congress is not a representative body at all. It does not invite delegates from other associations. It has a different basis of membership. There would be a good many members of the AMERICAN MEDICAL ASSOCIATION who intend to be present, many of the most prominent members of the ASSOCIATION, but they have none of them asked to be appointed delegates to this meeting. While Dr. Savage may be as good a man for a delegate as anybody else, I do not see that we can appoint him simply because he suggests it. To appoint delegates where dele-

gates are not invited, would be rather undignified on the part of the Section. The question of the invitation is a different question, I am sure, if it is the feeling of the Section that it would be well to have the Congress meet here the next time it meets. But I think we would not improve the chances of our getting the Congress by extending a formal invitation. If the members who attend will extend the invitation as members of the Congress, they will be more likely to get it than if a formal invitation were extended by this body.

THE CHAIRMAN—American delegates, as a rule, are received over there very coldly. It has been the custom for so many years for men of ordinary talents to secure appointment that they have grown to look upon them in rather an unfavorable light.

On motion duly seconded and carried, the following resolution was adopted and the Secretary was instructed to forward the same to Dr. Savage:

"Resolved, That inasmuch as this Section has no representative in the International Congress of Ophthalmology, it is not deemed advisable that we appoint a representative."

The Secretary then read the minutes of this and the previous meeting.

A vote of thanks to the retiring officers was then carried and the Section adjourned.

THE SWEAT-SHOPS AND SMALLPOX IN CHICAGO.

BY BAYARD HOLMES, M.D.

PROFESSOR OF SURGICAL PATHOLOGY AND BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.

There is before me a document very significant to medical men. It is the first special report of the Factory Inspector of Illinois. This fifty-seven page pamphlet is a fair exposition of the condition of our western metropolis during the smallpox epidemic of the past winter and spring.

All of our readers may not know that a law was passed by the last Illinois Legislature defining the sweat-shops and denying the manufacture of clothing except by the residents in any room used for domestic purposes. This law also provides that all workshops and factories shall be open to inspection, and when articles manufactured in them have been found infected with vermin or with infectious or contagious matter, they shall be reported to the local health officer to be destroyed by him. Now it appears from this report that there are about 950 licensed shops in Chicago and 25,000 other rooms in which garments are made. The principal Factory Inspector, Florence Kelley, and her ten assistants, have had enough to do to enforce the other provisions of the law, especially in preventing the employment of children under 14 years of age in the factories; nevertheless in the fall of 1893 a few cases of smallpox appeared in Chicago. A Sister visiting the smallpox hospital on Twenty-sixth Street and Sacramento Avenue, had smallpox in Rock Island after her return, and a number of cases appeared in various parts of the State, but through the efficient efforts of the State Board of Health none of them became epidemic.

In January there was a real epidemic in the region of the Chicago smallpox hospital, and the local health officers began to show some activity. The smallpox hospital, which only needs to be mentioned to be condemned, soon became full to overflowing, and the death rate was enormous. The people began to refuse to be removed from their homes and cases

were concealed from the authorities. At last the place became so overcrowded that no more cases could be taken at the hospital and yellow cards were tacked, usually on the back doors or hidden sides of houses, in which smallpox was found.

The duty of the Factory Inspector evidently called upon her to protect the consumers of ready-made and custom-made clothing from the danger of smallpox contagion carried by the clothing they purchased from sweat-shops in which contagion existed; therefore she informed the 176 wholesalers and merchant tailors who have their work done by sweaters, that smallpox was epidemic and that there was danger of infection, and called attention to the provision of the law for the destruction of infected goods. Only a few of the manufacturers paid any attention to the suggestions of the Inspector and various other means were taken to secure compliance with the spirit of the law.

The first goods were actually destroyed by Health Commissioner Reynolds at 699 Allport Street, on May 12. In the meantime sporadic cases of smallpox appeared almost everywhere in the Western United States. The activity of the State Boards of Health was aroused in adjoining States, and a conference was held in Chicago May 10. The result of this conference was a contribution by the manufacturers of clothing, who employed Chicago sweaters, of several thousand dollars to be expended in the inspection of sweat-shops and in the vaccination of their workers, all to be done under the direction of the Illinois State Board of Health. In other words, the State of Illinois undertook to guarantee the non-infectious condition of the clothing manufactured in the sweat shops of Chicago for a gross contribution of \$5,000. How unsuccessfully this was done, indeed, how absurd the proposition was, and how much the country has been exposed to smallpox thereby, is shown by this report as well as by the spread of smallpox over the territory in which Chicago clothing is sold. As concrete instances are much more suggestive than any abstract dissertations I could prepare, let me copy the following cases from the Inspector's report:

May 13, 1894. John Cerenak, 645 Throop Street, coat-maker for A. A. Devore & Sons, Michigan Avenue, corner Adams Street; Inspector Bisno.

The Inspector found in Cerenak's shop, which is one of his living rooms in this tenement house, a coat for the Devore firm in process of manufacture on Sunday, May 13. A boy lay dead of smallpox on the same premises after several days' illness. The man declined to name any other owner for the coat than himself, and was notified by the Inspector not to remove it until it had been fumigated.

May 14. The firm of A. A. Devore & Co., were notified from this office of the facts in Cerenak case and replied by letter that the coat belonged to them and that they would rather it should be destroyed than returned to them.

May 15. An order was served on Commissioner Arthur Reynolds, to condemn and destroy this coat in accordance with Section 2 of the Workshop law. Dr. Henry Reynolds accompanied Inspector Bisno to the premises and demanded the coat from Cerenak, showing him the letter from Cerenak's employers, A. A. Devore & Co., asking for its destruction. Cerenak refused to give up the coat unless paid \$16 for it and for making another one which had been returned to the firm previously. Dr. Henry Reynolds then went away, saying to Inspector Bisno that he would return for

the coat the next day, bringing police to take it if necessary. Some days later he informed Inspector Bisno that he did not go back for this coat and did not know what, if anything, had been done with it. It was then too late for inspectors from this office to trace the coat, which had disappeared.

This shows where one of the most aristocratic tailors of the city has his coats made and it also shows the inefficiency of the Department of Health.

May 22, 1894. Anton Randa, 1636 West Twenty-second Street, custom tailor, for Kelley Bros., merchant tailors, 268 South State Street; Inspector Bisno.

The Inspector found Randa's shop in his living rooms in a cottage basement. There were nine people in the family, five of whom, Randa's wife and four of his children, were sick with the smallpox. The four small rooms are used for eating, sleeping, living and manufacturing, and in the room used for a shop are two machines, three chairs, two tables and one bed. No goods were found in the shop, nor was Randa there, but as the Inspector was informed by Randa's child, he had gone after more work. The five smallpox patients were at this time in the house.

At 8 P.M. the Inspector returned to Randa's house, found him and learned that the patients had been removed to the pest house. Randa at first insisted that he had not had any work for six months, but finally admitted that he had worked for Kelley Bros., 268 South State Street; that he had delivered to them a coat very recently and that he had also taken from them one coat to make on this day, May 22. Where this coat was he absolutely refused to tell, nor could Inspector Bisno find it on the premises.

May 23. Inspector Stevens went to the store of Kelley Bros.; neither of the partners were there; this case was reported, as above, to their cutter, and an order on Randa for the coat in his possession was obtained. This cutter also told Inspector Stevens that the other coat had been returned by Randa on Thursday, May 17, and had been delivered to a customer. The Inspector asked for the name and address of this customer, which the cutter claimed not to know.

An order was issued for Commissioner Reynolds to destroy, in accordance with Section 2 of the Work-shop law, any goods in process of manufacture found in Anton Randa's possession. Inspector Bisno, accompanied by two agents of the Board of Health, returned to 1636 West Twenty-second Street and gave Randa the order from Kelley Bros. for the coat. Randa then took them to 1616 West Twenty-second Street, on which premises he had concealed the work, and produced it. They found a boy in the family where this coat was concealed who appeared to have smallpox, and the Inspector remained there until a district physician was obtained, who diagnosed the case as smallpox.

The infected coat was then taken to an adjacent vacant lot and burned by the agents of the Board of Health in the presence of Inspector Bisno.

The district physician having given his opinion that the coat returned by Randa to Kelley Bros. on Thursday, May 17, was undoubtedly in an infected condition, Inspectors Stevens and Bisno went to the store of Kelley Bros. to make another attempt to trace the coat. This time one of the partners was in the store; he was told of the destruction of the coat found hidden at 1616 West Twenty-second Street and of the circumstances under which the coat, returned to him on May 17, was made. Inspector Stevens then told Mr. Kelley that the district physician had decided that this coat was also infected and again asked for the name and address of the customer who had received it. Mr. Kelley replied that the coat was still in the store and that he was willing that it should be destroyed. When told that his cutter had that morning reported the coat was delivered to a customer, Mr. Kelley replied that this was not so; that the coat was still in the store.

May 24. An order was issued for Commissioner Reynolds to destroy this coat in accordance with Section 2 of the Workshop law. Inspector Bisno went with the two agents of the Board of Health to Kelley Bros.' store, where they were given a coat which the city agents burned in the presence of Inspector Bisno.

Can the dangers of tenement house manufacture be more drastically manifested? Randa concealed from the merchant tailors who gave him the coats, the fact that smallpox was in his family, although even while he returned work to them and received

more from them, five victims of the disease lay in the tenement rooms where the work was done. Again he concealed the work from the State Inspectors, and in so doing exposed it still further by hiding it in another house where also there was smallpox.

April 30, 1894. J. Kolka, 625 W. Twenty-first Street a coat-maker for Pfaelzer, Sutton & Co., Franklin and Van Buren Streets; Inspectors Stevens and Bisno.

This shop is in the rear of Kolka's living rooms on the first floor; the entrance is by a side door used also in going to the living rooms. The Inspectors found Kolka and his wife, with two men visitors in the shop, and sixteen coats for Pfaelzer, Sutton & Co., in process of manufacture. The living rooms of the Kolka family were closed and in process of fumigation. A 10 year old son of Kolka died of smallpox on Saturday, April 29. The fumigator from the Board of Health had left the premises before the State Inspectors reached it, but he had not fumigated the shop nor disinfected the coats, telling the Kolkas that it was not necessary, although the parents of the child had attended their patient and worked on the coats at the same time. The Inspectors asked Kolka when he returned the last work to the firm employing him. Kolka does not talk English easily and Mrs. Kolka, who attends to that part of the business, positively asserted that it was several weeks since they had any work except the sixteen coats then on the premises and that none had been returned since the boy was taken sick.

Inspector Stevens reported to Pfaelzer, Sutton & Co., the infectious condition of the sixteen coats on Kolka's premises, and received their promises not to accept the goods until said goods had been properly disinfected. The Inspector repeated to them Mrs. Kolka's assurance that no goods had been returned to them since April 13 and requested them to ascertain from their books if this was correct. The books showed that Mrs. Kolka had returned to them sixty-one coats on April 23, while smallpox was in the house. They were enabled to identify the coats by their ticket system, and as these coats were in a separate lot they requested that these also might be disinfected and agreed to keep them boxed away from other goods until this was done.

Inspector Stevens went from Pfaelzer, Sutton & Co.'s store to the Board of Health and finding Commissioner Reynolds absent, reported this case in detail to Secretary McCarthy of the Board, receiving his assurance that both lots of goods should be disinfected the next morning.

May 5, Mr. Meyer, from Pfaelzer, Sutton & Co., after waiting five days for the City Board, reported to this office that no one from the Board of Health had yet visited their place; that the sixty-one coats were not yet disinfected; that the sixteen coats had been returned from Kolka without the knowledge of the firm, and that they feared these also were not disinfected. At his request, Mr. Meyer accompanied Inspector Stevens to Commissioner Reynolds office to inquire why the disinfection had not been done as promised by Secretary McCarthy. Neither Commissioner Reynolds nor his Secretary had any excuse to offer. They did not know why no fumigator had been to the business place of Pfaelzer, Sutton & Co., and had no records to consult to show whether the shop and coats at 625 West Twenty-first Street had been fumigated. The Inspector finally succeeded in getting a reluctant promise from Secretary McCarthy that the two lots of coats at Pfaelzer, Sutton & Co.'s should be fumigated that (Saturday) afternoon or Monday morning. In the presence of the Inspector, Secretary McCarthy tried to dissuade Mr. Meyer from having this done, because of the trouble involved.

May 7. Inspector Stevens visited Pfaelzer, Sutton & Co. in the afternoon and found that the city fumigator had not yet been there; then visited Secretary McCarthy and gave him until 9 o'clock the next morning to fulfill his promise.

May 8. At 10 o'clock a message was received at this office from Pfaelzer, Sutton & Co. that the fumigator was there.

The utter inadequacy of the measures taken to prevent the spread of infection by these seventy-seven coats is apparent. The Kolka boy was sick a week before a doctor was called, when the child was dying. Before the report of the diagnosis reached the City Board of Health, or this office, the child was dead and buried. It was nine days after this before the City Board of Health fumigated the coats and fumigation, under these circumstances, can by no means

be considered a guarantee of disinfection. These goods should have been burned, but the Commissioner of Health refused to comply with the Section of the Work-shop act, which enjoins the Board of Health to condemn and destroy goods under such circumstances.

May 14, 1894. John Smethoma, 1189 Albany Avenue, contractor for A. L. Singer & Co., 168-170 Market Street; Inspector Kelley.

Dr. Brand telephoned that he had found bundles of goods for manufacture on the premises of John Smethoma which he believed to be infectious for the following reasons: An undertaker, now living at 1117 Albany Avenue, had occupied the premises at 1189 Albany Avenue. One of his children had the smallpox there and recovered without the fact becoming known to the Board of Health; then another son was taken ill and the family was removed to 1117 Albany Avenue, where the second child died of smallpox. After the undertaker moved out of 1189, John Smethoma moved in, occupying the same flat which had not been fumigated and using for a shop a room to which the undertaker's family had free access throughout their illness. Dr. Brand had notified Smethoma to hold the goods until further notice.

May 15. Inspectors Kelley and Bisno, went to 1189 Albany Avenue and found the shop empty and Smethoma sitting in the street in front; he denied that he had had any work within four months and said that before Christmas he worked for A. L. Singer & Co. At this office his name was found upon the list of Singer's employes. The firm was then notified as follows:

Messrs. A. L. Singer & Co., 168-170 Market Street, Chicago.

Gentlemen:—There is smallpox at 1189 Albany Avenue where one, Smethoma, is working for your house. There has been infection on these premises since April 1, at least; one death and a series of smallpox cases. Day before yesterday, goods in process of manufacture were found in the shop and the man was ordered not to remove them until they had been disinfected; this morning we find that the goods are gone; they must have been returned to you or left in some other place, perhaps secreted in another equally infected place. Kindly let us know by bearer if these goods have been returned to you and if you have any other goods made up by this man in your stock. To prevent the spread of infection the goods the man has disposed of, must be found and taken care of in the proper manner.

Yours very truly,

FLORENCE KELLEY.

The following reply to this letter was brought back by Inspector Hickey:

A. P. Stevens, Assistant Factory Inspector:—We have not received any work from Smethoma, 1189 Albany Avenue, since April 26. We will find out if expressman delivered any work this week.

Respectfully yours,

A. L. SINGER & Co.

Later the following was received from this firm on the same date, May 15:

A. P. Stevens, Assistant Factory Inspector:—Since your man called here this afternoon, we have found that the expressman delivered to Smethoma, 1189 Albany Avenue, twenty-three men's coats and twenty-seven children's coats on the 11th inst.

Respectfully yours,

A. L. SINGER & Co.

May 16. Mr. A. L. Singer brought Smethoma to this office to state where the Singer goods were secreted; at this time Smethoma's own child lay dead of smallpox at 1189 Albany Avenue the death occurring this morning. Inspector Hickey went with Smethoma to see where the goods were hidden and reported that they were in barrels packed in a loft of a barn or shed on premises at 1189 Albany Avenue, with empty barrels piled on top of those in which the goods were hidden. Inspector Hickey reported also that on the way to locate the goods the man Smethoma entered two drug stores looking for a doctor to make arrangements for the burial of his child although, as he informed Inspector Hickey, he had not had his clothes off nor had he washed for three days during which he had attended the child now dead.

At 3 o'clock on this day (May 16) the Singer goods in Smethoma's possession were burned by an Agent of the Board of Health, in Inspector Hickey's presence, and with a mob of Smethoma's neighbors surging about the place

On this day the records of the Board of Health show that there were three new cases of smallpox at 1189 Albany Avenue. To this date there had been at no time any effort to quarantine the place.

May 29. Smethoma came to this office to get permission to resume work and produced the following certificate:

May 28, 1894.

To whom it may concern:—This is to certify that the store 1189 Albany Avenue has been fumigated on May 17, and no more smallpox exists about the place. He can be allowed to resume business.

W. E. MILLER, M.D.,

Medical Inspector Health Department.

The Health Department records show three cases of smallpox at this number May 17, and one new case on May 22, again in the family of Smethoma the tailor. Including the two cases in the undertaker's family, which were not made a part of the Health Department's records, there were seven cases of smallpox, at least two fatal, on these premises in May, yet this shop certificate was issued by a city district physician, that work could be resumed there during that month. It can hardly be needful to state that this permission to resume work was not indorsed by this office.

The history of this shop is the history of the fatal concealments incident to tenement house manufacture. The undertaker concealed from the Board of Health the fact that smallpox was in his family. The incoming tenant, Smethoma, was therefore not warned that there had been smallpox there in the family of the out-going tenant, the undertaker. Smethoma in turn concealed from A. L. Singer & Co., for whom he worked, the fact that there was smallpox in his family on May 16, and concealed their work on his premises from the State Factory Inspectors.

When it is considered that there has been throughout the epidemic in the Bohemian sweat-shop district, concealed cases of smallpox, so many that the district physician in charge once stated to an inspector, his belief that there were at that moment not less than five hundred cases within a radius of six blocks, the painful conviction forces itself upon us that the Smethoma case is typical of many which, with all our efforts, we failed to reach.

The inspection of the sweat-shops has been entirely ineffectual so far as concerns securing safety to the consumers of Chicago made goods. The appearance of smallpox in the better part of the city has not, so far as the writer knows, been traced to coats or other clothes made to order, but it seems incredible that such a source could not have been traced from some of the very many, otherwise unaccountable, cases which occurred last winter in respectable families.

There are many reasons why the public was not informed on this subject at the time; the principal one lies in the utter servility of the press to trade. There was at all times, during the epidemic, the greatest difficulty in getting the columns of the daily papers open to smallpox news. The conspiracy of silence was almost impregnable. In this conspiracy it seems very strange that the Commissioners of Health should have been involved but Inspector Kelley says, Section 41:

After June 10, the Board of Health adopted an avowed policy of concealment. From this time the lists of new cases, which had before been imperfect from a lack of system and of responsible book-keeping, were rendered absolutely worthless by order of the Commissioner of Health. District physicians were notified to give out no more information and the city hall lists were reduced to two cases per day. One example of suppression of cases may serve to show how far this policy has been carried. Since it was inaugurated three children of the McLaughlin family, living in a tenement house at 82 Brown Street, were removed to the pest-house on three different days. None of the three cases appear on any list. One omission may be explained away as accidental, but not three in the same family, the same house, the same month.

Throughout the epidemic there has been no mortality record by days or weeks from which we might have formed at least an estimate of the varying degree of danger. Admissions and discharges at the pest-house are known only to the Sister in charge of them, and the daily number has at no time been obtainable from the Health Department.

The yellow card which would be of inestimable use to us if posted, and kept in place upon infectious premises, as prescribed by the city ordinance, has been tacked upon rear sheds and in hall-ways, upon inside doors, up three flights of stairs and in many cases has never been posted at all. Cards have been torn down in scores of cases but not one prosecution has been instituted by the Board of Health for this serious offence against the public safety. Trade has been carried on in groceries, milk depots, cigar shops and drug stores, while the warning card was either gone altogether or carefully concealed in an upper story or a rear yard and customers, ignorant of their danger, visited the infected premises as usual. From this connivance of the local officials at the infamy of landlords and shop-keepers, the State inspectors have suffered with the rest of the community, finding cases too late to take any effective measures for the enforcement of the law, and often failing altogether to learn of the presence of smallpox until weeks after the burial of the patient. And this in spite of faithful daily searching in the infectious district.

The guarding against recurrence of the disease on the same premises with garment making, has been further hindered by the removal of the yellow card immediately after fumigation. Where a patient was removed in the morning and the premises were fumigated and the card removed in the afternoon, an Inspector calling an hour later would find no hint of danger and a sweater might go on with his work the next day undisturbed!

Throughout this whole epidemic the value of trade and the worthlessness of human life and health, in the estimation of those in authority, has been abundantly manifested. The pest-house would disgrace Siberia by its management; it was over-crowded beyond a military prison in war time; it received no proper medical supervision and aroused no effort to improve its condition.

In the State of Illinois, one hundred of the wealthy manufacturers have clubbed together to fight the constitutionality of this factory law. The brief which their well paid attorneys prepared for the Superior Court is before me. In it, property right and personal right over property, is the principal theme.

This review is written to arouse in medical men an interest in the protection of the consumers of sweat-shop made goods of all kinds; to show the utter wickedness and folly of allowing such manufacture at all; to stimulate an interest in factory legislation and to draw attention to the need of actual coördination of the various functions of the State for the protection of our coming generation and our own peace of mind. Unless we, the most altruistic of all the educated classes, the most in touch with the people, the best prepared to judge, interest ourselves in these maladies of the State, how can we expect any attention to them from the courts, the legislature or the clergy?

CAUTERIZATION OF THE NARES, AND ACCIDENTS THAT MAY FOLLOW.

Read before the Annual Meeting of the Illinois State Medical Society, Decatur, May 15-17, 1894.

BY E. FLETCHER INGALS, A.M., M.D.

CHICAGO.

Although from time to time articles have been written to show that serious accidents, often follow cauterization of the nares, I think that, when properly done, this operation is quite as free from discomfort or danger as any other minor surgical procedure.

I have occasionally heard of serious results following these operations, but have never had one in my own practice, and I believe that as a rule they are due to carelessness or inexperience upon the

operator's part which induces him to make extensive wounds or to repeat the burnings too frequently. By this I do not mean that all accidents after cauterization have resulted from carelessness or inexperience, for I well know that bad results after any operation, from various causes, may possibly happen to any one, even though the utmost caution is observed.

Looking over the records of my private patients, I find that in hypertrophic rhinitis, intumescent rhinitis, and simple chronic rhinitis, cauterizations have been done about one and one-fifth times on the average in each patient. I find 1,450 patients with hypertrophic rhinitis who have been cauterized 1,950 times; 450 patients with rhinitis intumescens, cauterized 150 times; and 700 patients with simple chronic rhinitis, cauterized 150 times; making 2,600 patients cauterized 3,000 times. These figures are not strictly accurate, but are as near as can be computed without actually counting the cauterizations done in each and every case.

Excluding the cases of simple chronic rhinitis (which have not been frequently cauterized). I find 1,900 cases suffering from hypertrophic or intumescent rhinitis, that have been cauterized 2,850 times, making an average of about one and one-third for each patient. An examination of these records, which have been carefully kept, reveals no serious accident in any case. With comparative frequency, probably in about 20 per cent. of the cases, especially when the cauterization is done in cold weather, patients suffer considerable inconvenience for four or five days afterward from the reaction, and in a limited number of cases, perhaps 5 per cent. they feel for ten or twelve days afterward as though they had taken an intense cold in the head. In warm weather these very uncomfortable symptoms are not often experienced.

Frequently I have observed patients in whom a linear cauterization across the whole length of the inferior turbinated body would cause excessive swelling, obstruction of the naris, headache, and considerable fever which might last four or five days. In most, if not all of these cases, if cauterization of half this extent were made, the uncomfortable symptoms would not follow.

The inconvenience which patients suffer after cauterization, as a rule, depends largely upon the extent of the burn, the frequency of its repetition, and the care exercised to avoid taking cold.

I have frequently observed slight adhesions following cauterization, especially where it has been done opposite a large spur from the septum, and where the patient has not been able to call upon me within the next four or five days after operation. In none of these, however, has there been any difficulty in cutting the adhesion, or very great trouble in restoring the patulence of the naris.

In one case only do I find serious hemorrhage to have followed cauterization, and when the patient returned to my office this was checked without great difficulty. In a case of superficial cauterization for hyperesthetic rhinitis, not included in this series of cases, serious hemorrhage followed; but I did not see the patient for several weeks after the operation, and think it could have been easily checked if he had been under my care. In no other cases do I find that excessive bleeding occurred.

It is not improbable that in this number of cases

there are those who have had slight inflammation of the Eustachian tube extending toward the middle ear, but I am sure that in none of them has there occurred inflammation of any importance, and I am unable at present to find records even of slight inflammation of these parts after cauterization.

The cases of inflammation of the Eustachian tube or middle ear that have been reported as having followed cauterization of the nares, I believe have in most instances resulted either from carrying the electrode so far back that the Eustachian orifice has been burned, from making an extensive wound and thus causing undue inflammatory reaction, or from neglecting antiseptic precautions, though such a result might follow from exposure or from peculiar predisposition of the mucous membrane to take on inflammatory action.

Inflammation of the tonsils is said sometimes to follow within a few days after cauterization of the nares, possibly having some connection with the operation, but I have seen no cases of the kind in which any evidence of cause and effect could be obtained.

Erysipelatous inflammation has been the worst sequel of this treatment that I have ever observed among my own patients, but it has occurred in only four persons out of 2,600. In two of these it seemed to have been the direct result of the cauterization, and in both of them it followed cauterization in the naris whenever it was done. In the other two the dermatitis came on at irregular intervals after the cauterization, and seemed to have been the result either of cold, or excessive inflammation resulting from some peculiar idiosyncrasy of the patient, either to the burn or to the remedies which were used subsequently.

In two of the four erysipelatous cases that I have seen, inflammation did not come on until from eight to ten days after the operation, and in one of these it recurred about a month after the cauterization, apparently in consequence of an oily spray which had been used in the nares. This appeared to me to be a case in which there was an idiosyncrasy either against the oil (liquid albolene), or the thymol or oleum carophylli which it contained in solution. In the other of these two cases, two cauterizations were done, one of which was followed by erysipelatous inflammation in about ten days, which appeared to me to be the result of an oily spray, similar to that used in the previous case. In this patient, redness of the upper lip and cheek continued for a number of days, and was found to increase when the oily spray was used, and to diminish when the cleansing of the nares was accomplished by a spray of saturated solution of boric acid. I have seen several persons in whom the use of a spray containing only two or three grains of menthol to the ounce would cause inflammation of the nostril and upper lip within three or four days. Dr. A. H. Gilmore reports to me a case in which acute dermatitis always followed the use of a one-grain solution of menthol and carbolic acid, each in an ounce of liquid albolene, within twenty-four hours.

In the two remaining cases the trouble followed closely upon cauterization, the patient seeming to suffer from a peculiar idiosyncrasy in which inflammation of the skin covering the upper lip, the side of the nose, and the cheek would follow speedily after any cauterization within the nasal cavity. In one of these, a healthy young man, 31 years of age,

suffering from rhinitis intumescens, who was cauterized four times, the erysipelatous inflammation succeeded the cauterization promptly within from twelve to forty-eight hours in every instance, but it was not very severe and only lasted from three to six days.

In the other of these cases cauterization was performed three times, and each time was speedily succeeded by erysipelatous inflammation. Once this came on the same night, the other times within a few days. These attacks gave the patient considerable inconvenience, but caused no danger.

In two instances I succeeded in reducing the inflammation speedily by the local application to the skin of pure guaiacol, recently recommended by L. Bard (*Lyons Medical*, lxxiv., 1893,) in facial erysipelas.

I have heard of so many cases in which serious, or at least very disagreeable symptoms have followed cauterization of the nasal cavities, that I am led to believe that the comparative infrequency with which such accidents have happened in my practice is largely due to the care exercised at the time of cauterization, to the antiseptic precautions by which it is followed, and to the rule (from which I seldom vary) that a second cauterization should not be made within from ten to fourteen days after the first. This allows time for the healing process to become well advanced and for all inflammatory action to subside before a new inflammation is set up. In a few cases, where for special reasons I have allowed myself to be over-persuaded by the patient, and have made the succeeding operation in the opposite nostril within from five to eight days, I have nearly always found that the patient afterward suffered great inconvenience from the obstruction, headache and fever. In such cases both sides are likely to become occluded as in severe colds in the head.

My usual course in the treatment of hypertrophic and intumescent rhinitis is as follows:

Having determined that the patient is frequently annoyed, especially at night, by stopping up of one or both nasal cavities, which interferes with nasal respiration and causes a collection of more or less mucus in the naso-pharynx, I recommend cauterization upon one side. Whatever subsequent cauterizations are needed should be made at intervals of not less than two weeks if upon the opposite side, or at longer intervals if upon the same side. Immediately after cauterization, the nasal cavity is sprayed with a solution of 5 minims of the oil of cloves to the ounce of liquid albolene, and this is followed by the insufflation of 2 or 3 grains of iodol. The nostril is then packed lightly with cotton, which the patient is directed to wear whenever he is out of doors for the succeeding four or five days in winter, and for two or three days in summer, changing as he may desire. The patient in most cases is also given a powder, one or two grains of which he is directed to use in the naris three or four times in twenty-four hours, providing the passage closes up by swelling—or not at all if this does not occur. This powder contains bicarbonate and biborate of soda, each $1\frac{1}{2}$ per cent., light carbonate of magnesia 3 per cent., and cocain hydrochlorate 4 per cent., in sugar of milk sufficient to make 3i; this gives in all not more than from one-twentieth to one-twelfth of a grain of cocain daily.

This is applied by means of a glass tube about four

inches in length, with a caliber of about one-eighth of an inch, to which is attached a rubber tube, through which the patient blows the powder into his nose. The glass tube is disconnected from the rubber, its round end moved about in the powder until it is filled up about one-fourth of an inch; the same end is then re-introduced into the rubber tube, and the flattened end of the glass tube introduced into the nostril. The patient then places the other end of the rubber tube between his lips and gives a quick strong puff; which forces the powder into the naris, some of it usually going through to the naso-pharynx. The patient is also given a solution of one-third of a grain of thymol with three or four minims of the oil of cloves to the ounce of liquid albolene, which he is to use in the nose thoroughly as a spray three times daily.

In many cases the cauterization is followed by immediate relief of the obstructed feeling in the nose, but in the majority the cavity is nearly closed much of the time for three or four days subsequently. The patient is directed when practicable to return to me in four or five days, in order that I may be sure no adhesions are taking place. At this time the powder just mentioned is reduced by the addition of 25 per cent. of iodol, and the patient is directed to use it for the next ten days, once a day only, if the naris does not stop up, or twice if it does. The spray is continued. Patients are never allowed to use any powder containing cocain for more than three or four weeks continuously, and then only in small quantity, and they are not given prescriptions for it, which might be refilled and thus engender the cocain habit.

I believe that the best results are obtained by making a linear cauterization the whole length of the inferior turbinated body, usually at the juncture of its middle with its upper or lower third. Commonly two cauterizations, occasionally three, and rarely more, are needed upon each side. In persons in whom the inflammatory reaction is severe after cauterization, a linear cauterization of only half this length should be recommended. Those who can not tolerate the full cauterization constitute about 5 per cent. of all those needing the operation.

Before cauterizing, the parts are thoroughly anesthetized with a 4 per cent. solution of cocain, applied by means of a small pledget of cotton wrapped upon a flat applicator; this pledget is moistened in the solution and carried quickly to the back of the nasal cavity. In bringing it forward it is rubbed over all the surface to be anesthetized, the application requiring about thirty seconds. At intervals of about a minute these applications are repeated, and usually two or three are sufficient to produce complete anesthesia. A knife-like electrode, having at its end a No. 21 platinum-wire blade about three-fourths of an inch in length, is then introduced to the back part of the nasal cavity and turned against the tissue to be cauterized. The current is then turned on and the electrode is drawn slowly forward to the anterior end of the turbinated body, burning through the soft tissues so as to just graze the bone in two or three places. Sometimes when the tissues are thick, the electrode has to be moved slightly back and forth two or three times before the bone is felt. It is my desire in all these cases to touch the bone lightly in the posterior, middle and anterior parts, in order that the soft tissues may be firmly bound down when cicatrization

takes place. More extensive cauterization than this at one time is seldom justifiable, because it causes such intense inflammation. I am not at all in favor of the frequent cauterizations, daily or every three or four days, which some physicians practice in treating hypertrophic rhinitis; neither can I see any necessity for causing the patient to return to the office every day or two during the treatment. When patients come to see me from a distance of two to four hours' ride, I usually make one cauterization and then direct them to follow out the after treatment carefully at home, and return for cauterization upon the other side, any time that suits their convenience after three weeks; but I prefer, when it is practicable, to see the patient once at the end of four or five days after the cauterization, in order that I may be sure that all is going well. In a very few cases, either because of unusual pain or excessive inflammation and swelling, I find it desirable to see the patient within two or three days after the operation.

From a study of these private cases I conclude:

1. It is important that antiseptic applications be regularly employed after cauterization of the nasal mucous membrane; and that the nostril be closed by cotton for several days whenever the patient is out of doors, to prevent taking cold.

2. As a rule, at least two weeks should intervene between operations upon opposite sides, and three or four weeks between those on the same side.

3. No serious results are at all likely to follow cauterizations made in this way.

4. Practically all cases of hypertrophic or intumescent rhinitis may be cured by this treatment, though occasionally portions of the turbinated bones must be removed.

SHOULD ERGOT BE USED DURING PARTURITION AND THE SUBSEQUENT INVOLUTION PERIOD?

Read before the Twenty-fourth Annual Convention of the Colorado State Medical Society, Denver, June 19, 1894.

BY E. STUVER, M.Sc., M.D.

RAWLINS, WYOMING.

MEMBER COLORADO STATE MEDICAL SOCIETY; MEMBER AMERICAN MEDICAL ASSOCIATION AND MEMBER INTERNATIONAL MEDICAL CONGRESS, BERLIN.

Fifteen or twenty years ago, it would have been regarded as almost sacrilegious to doubt the propriety of using ergot during parturition.

So much had it come to be relied upon to stimulate deficient uterine action during labor, and to prevent post-partum hemorrhage, and so extensively was it used by the medical profession, that any one having the temerity to doubt its utility in such cases would have been summarily suppressed or accorded that pitying toleration that so often falls to the lot of the innovator. Such a state of mind as this could have but one result, viz., the blind, routine and indiscriminating use of the drug by many physicians.

This practice was followed by so many accidents and unheralded tragedies, however, that it finally began to dawn on the minds of at least a portion of the profession that everything was not just as it should be. This led to a more careful investigation of the action of the drug and the dangers attending its use and pointed out some of the restrictions which should be placed upon it.

This question is now being actively discussed and

great names with all their prestige and authority can be found arrayed on both sides. Time will not permit us, however, to go into details or to make extensive quotations on this occasion.

In arriving at a conclusion concerning such a question as this we should be guided by certain well defined principles. In the first place, instead of entering the investigation with a cherished theory to uphold or confirm and making the facts conform to this theory, we should earnestly strive to arrive at the truth, regardless of the effect it may have.

The advantages and disadvantages arising from the use of a particular medicine should be carefully weighed, and if it be found that the latter overbalance the former its use should be strictly limited and the practitioner should earnestly strive to find some other means to accomplish the desired results without the attendant dangers. Approaching the investigation of the utility of ergot during parturition in this spirit, let us first briefly note its physiologic action, then consider its dangers and lastly ask ourselves whether any other agent or agents can take its place. In considering its physiologic action we shall not refer to the acute poisoning caused by toxic doses, but merely indicate the effect of small and moderate or full doses. According to Wood and other standard authorities ergot acts as a stimulant to the peripheral cardiac nerves; the frequency of the pulse is diminished, the arterial tension raised and the caliber of the terminal arteries and capillaries greatly reduced. While this constricting effect upon the blood vessels has a far reaching influence, still the most decided and important effect of ergot is its action upon the muscular tissues of the uterus. All the phenomena of nature manifest themselves in rhythmic or undulatory movements.

Given in very small doses the natural rhythmic uterine contractions are merely intensified, but if the dose be large enough to have a decided effect the character of the pains is entirely changed; they become much more severe and prolonged than normal and the natural period of relaxation may be completely abolished. The uterus is held in the relentless grasp of a tetanic contraction and the intermittent expulsive efforts are changed into one continuous strain. Here, as everywhere else in nature, great power if not carefully directed and controlled is attended by great danger. Could we but lift the veil that conceals the many young graves, shattered invalid lives and the mistakes of judgment that so thickly strew the victorious pathway of this potent agent, we would hesitate before conjuring up a power we may not be able to control.

The dangers of ergot are of a two-fold nature; that is, they affect the safety of both the mother and the child. The long continued and uninterrupted tetanic contractions may produce rupture of the uterus and speedy death of the patient. This result while of comparatively infrequent occurrence is so calamitous to all parties concerned when it does occur that it ever hangs like the sword of Damocles over the head of the physician who uses ergot freely. The danger of laceration of the cervix, perineum and other portions of the parturient tract is greatly increased by the use of ergot. I am firmly convinced that to its free, I might say reckless use, are we indebted for much of that wealth of material that crowds the gynecologic clinics and private hospitals of our large cities and is such a veritable bonanza to

specialists in that particular line of work. Hour-glass contraction of the uterus may be produced by this agent. In the early years of my practice I saw three cases of this complication, and am firmly convinced that at least two of them were due to the use of ergot.

One of the chief arguments advanced in favor of ergot is its power to produce strong contractions and thereby prevent post-partum hemorrhage. No one will dispute the fact that ergot produces energetic contractions, but that it is the only or even the best means to employ for that purpose is a very different question. Administered per os it requires from fifteen to twenty minutes to secure the desired effect, hence to obtain results it must be given, as was taught fifteen years ago, just before the head is born. This method has the disadvantage of interfering with the proper management of the third stage and may cause hour-glass contraction. If the administration is delayed until after the delivery of the placenta, dangerous or fatal hemorrhage may supervene before the medicine has time to act, even when given hypodermatically. The *habit* of placing such great reliance on ergot has, I believe, been responsible for the loss of many lives, simply because it has so engrossed the attention of physicians that they have failed to give that time and thought to the investigation of other means of relief that the importance of the subject demands.

I believe that all will bear me out in the statement that there is no emergency in the whole range of medical practice which more imperatively demands clearly defined methods of treatment and prompt action on the part of the physician than post-partum hemorrhage. Also that such an organization of the knowledge pertaining to the subject as will enable him to apply it in the most effective manner can only be obtained by a thoughtful, painstaking investigation of all the available means by which the difficulty can be overcome. Right here is where ergot has done a great deal of harm to the physician. Educated to regard it as a sheet anchor, many neglect to prepare themselves for those emergencies in which it fails, and are compelled to stand helplessly by or rush aimlessly about while the life blood flows rapidly away before their eyes; to see the dark clouds of sorrow settle over a happy home and feel that intense humiliation that must attend such a failure. Nor is it clear to my mind that an agent capable of producing the peculiar effects that ergot does, can have a permanently beneficial effect in promoting uterine action. As you all very well know, action and reaction are equal but opposite in direction and this applies to physiologic as well as to physical activities. Following out this line of reasoning one would naturally expect the intense uterine muscular activity induced by the action of ergot to be followed by a corresponding period of fatigue and relaxation. There is one possible deleterious effect that I have thought might follow the use of ergot. I have never seen an allusion to it in any work or journal and present it for your consideration and criticism.

It is a clearly demonstrated fact that intense muscular activity or effort is followed by the formation of organic poisons, ptomaines or whatever they may be called. This poisoning is, other things being equal, proportional to the intensity of the effort and the amount of muscular tissue involved. In con-

firmation of this opinion I desire to call your attention to the following authorities: Fernand Lagrange, M.D., in his work, "Physiology of Bodily Exercise," page 348, says: "In the opinion of all physicians in these days the fevers of overwork which are observed alike in animals and in men are due to a kind of poisoning of the body by its own elements, to an auto-intoxication of the system by the products of dissimilation which have accumulated in too great abundance in consequence of excessive work."

Prof. I. N. Love, in a paper read before the St. Louis Medical Society, Jan. 20, 1894, quotes from an address of Michael Foster, the great physiologist, delivered before the University of Cambridge, in which he says: "When we have excessive muscular exertion, the weariness may take a form of distress, and if the effort be continued the distress may become so great as to occasion such complete exhaustion that even death may result." "In excessive work of whatever kind it may be, in order for the work to be accomplished there is a greater demand upon the blood for oxygen." "There are many things besides carbonic acid which are swept into the blood as the result of the activities of the body; in other words the product of work in the human body is a poison which must needs be eliminated through the medium of the lungs and the other excretory organs." "As physical and mental efforts are continued the eliminating capacity unless carefully guarded is marred, the resulting poisons are more and more heaped up in the system, poison the muscles, poison the brain, poison the heart, poison at last the blood itself, starting in the intricate machinery of the body new poisons in addition to themselves." "The hunted hare run to earth dies not because he is choked for want of breath, not because his heart stands still, its store of energy having given out, but because the poisoned blood poisons his brain, poisons his whole body."

These quotations very conclusively show that for its healthy activity the human organism must have an abundant supply of pure air to oxidize the products of retrograde metamorphosis; that the eliminative organs must be in an active state and the various functions of the body be performed in a normal manner. I can conceive of no condition more favorable for the rapid formation of retrograde products than that presented by the uterus at the end of parturition. Here we have an organ enormously enlarged, all the functions of which are in a state of great activity and which under proper conditions should reach its normal size in two or three months. This involution according to recent authority (see JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, April 14, 1894, page 552) is caused by the conversion of the albuminoid elements of the muscular tissue into soluble peptones which are eliminated through the kidneys and other excretory organs.

In order that this process of retrograde metamorphosis may be carried on most effectively it looks reasonable to my mind at least that the natural rhythmic uterine functions should be maintained as nearly in a normal condition as possible; that the circulation of the blood with an abundance of oxygen to reduce the waste materials be free and unimpeded and that the excretory channels be in the best possible condition to dispose of the waste products. Right here is, I believe, a serious objection to the use of ergot, as there is no doubt but that it contracts the arteries and interferes with the circulation, and

it would appear to follow as a corollary of this proposition that it locks up the accumulating waste materials in the uterus and when relaxation occurs, allows them to be carried into the system in large quantities. It also seems reasonable to infer that such an action as this is capable of producing a change in the character of the products of muscular decomposition and from lack of oxygen permitting the formation of more virulent materials (ptomaines or whatever they may be) and thus producing acute attacks of fever and systemic disturbances for which we have hitherto not been able to assign a cause. Every obstetrician has doubtless seen cases in which, after the most painstaking care and scrupulous cleanliness attacks of fever have developed for which no reason could be assigned.

Is it not possible that these are cases of true auto-infection produced by organic poisons formed in the rapidly involuting uterus? Is it not also probable that the so-called *milk fever* is largely due to a similar cause?

While the use of ergot has many dangers for the mothers it is doubly fatal to the child. As you all very well know, during a violent contraction the passage of the blood from the placenta to the child is interfered with, or in other words its respiration for the time being is stopped. If this state of affairs lasts for any length of time the child is profoundly asphyxiated and in many cases passes beyond the range of the most consummate skill, and we have another added to the long list of cases of misdirected force and an existence cut short.

But it may be asked, when if at all, should ergot be used or what agents can take its place? Before the birth of the child I do not believe it should be used at all. Uterine inertia should be overcome by quinin, viburnum prunifolium, small doses of hydrastis, gentle kneading and friction over the uterus, with the correction of faulty positions, and the support of lax abdominal walls by means of a tight binder over the uterus and finally resort to the forceps when other means have failed. If the third stage of labor be properly managed, the physician giving careful personal attention to the mother from the time the child is born until the complete expulsion of the placenta which should be removed by the Credé or some modification of the Credé method, I have reason to believe that very few cases of so-called retained placenta, or post-partum will be encountered. Active hemorrhage during the third stage demands prompt action and immediate removal of the placenta, and to attain this end ergot can render no assistance and may greatly delay and impede its removal.

After the delivery of the placenta I believe some agent or agents that secure and maintain a mild, tonic contraction of the uterus are serviceable and for the last six or eight years have been in the habit of administering the following combination, viz:

R. F. E. Ergotæ Grams.
 F. E. Hydrastis canadensis ãã 15.00
 F. E. Hamamelis virginicae qs. ad 60.00
 M. Sig: Teaspoonful three times a day.

But it may be asked why retain the ergot? I am free to confess that this is more of a sop to Cerberus, a deference to long established practice coupled with the instinct of self preservation, than to a well grounded belief in its necessity. The hydrastis stimulates normal uterine action but does not produce continuous contractions like ergot and I have been

much pleased with its action; the hamamelis acts as a synergist and moreover has marked tonic effect on the muscular tissue of the veins. I have thought that the latter remedy given both before and after labor would have a beneficial effect in maintaining the tone of the venous system, preventing engorgement of the veins and thereby guarding against the various phlegmasiæ and last, but not least, help to prevent the formation of hemorrhoids.

For post-partum hemorrhage, I regard prevention of far greater importance than any remedy. Treat every case as though you expected it to terminate in serious hemorrhage and you will very rarely be called upon to face this terrible emergency. In those cases where no precaution can prevent the accident what shall we do? The first and to my mind most important requisite is, *keep cool*, do not get excited but have your thoughts collected and all your resources fully under command. Grasp the uterus externally firmly in one hand and introduce the other previously rendered aseptic into its cavity; turn out the clots and make pressure with the closed fist on the internal walls. The injection of hot water, from 115 degrees F. to 120 degrees F., vinegar, or packing the uterine cavity with iodoform gauze are frequently employed and highly lauded expedients.

There is one other agent, however, which I think should receive more attention than has been accorded to it in the past. I refer to the interrupted electrical current. Here we have an agent that can be applied more promptly than almost anything else, that is absolutely under control, that induces prompt and effective contractions and can be instantly discontinued when the desired effect has been obtained.

THE RELATION OF CHRONIC NASAL AND LARYNGEAL DISEASES TO PULMONARY TUBERCULOSIS.

Read before the Colorado State Medical Society, Denver, June, 1894.

BY S. E. SOLLY, M.D.

COLORADO SPRINGS, COLO.

For the purpose of inquiry into the relation of chronic nasal affections to those of the throat and chest occurring in connection with pulmonary tuberculosis, I have analyzed my last 219 reports of chest examinations. Taking up each report in its exact order, 19 of these, while pulmonary, were apparently non-tuberculous and therefore omitted, leaving 200 to be analyzed. The inquiry was stopped at this number because it seemed sufficient to draw conclusions from and show the tendency of the relationship, and on account of more extended observations requiring more time and labor than could be then spent upon the subject.

There were, therefore, 200 cases of pulmonary tuberculosis to be investigated which were not in any way selected, but taken in the order in which they presented themselves to me for their first examination, running back from a recent date. Of these 200 chest cases, 33 had also nasal disease, 38 also laryngeal, and 23 had both in addition to their lung affection, making 56 with nasal and 61 with laryngeal complications. Only clearly marked cases being noted.

The nasal cases were divided: 1, into those in which the disease was most evident or was known to have commenced, or existed solely or mostly on one

side more than the other, and these again into right or left; and 2, into those in whom the amount of disease or obstruction appeared about equal, and in whom there was no clear evidence of its having begun on one side more than the other, these being grouped for convenience under the head of median.

To enlarge a little on this classification, septal deformities either divergencies or exostoses in the form of shelves or spurs or compensatory buttresses or sigmoid curves, were evidently the most common causes of the stenosis and consequent rhinitis, and therefore the side upon which the stenosis existed, or was most complete, was taken as the one under which the case should be classified even though, as is often the case, the disease of the membrane or turbinated bones was more marked on the other side. Good reasons for this condition are given by Bosworth in his recent and most valuable work upon the nose, in the chapter upon hypertrophic rhinitis, which is well worth reading in connection with this general subject, but which can not be quoted from satisfactorily except at too great a length for the limits of this paper.

The classification was made from the side upon which the chief cause of the disease appeared to be, rather than where its worst symptoms might happen to be exhibited later in its course.

The septal abnormalities referred to were found to be the most frequent initial cause, although there were some cases in which the primary cause appeared to be hypertrophy of the turbinated bodies, or adenoid, or polypoid growths, or an ulceration simple or tuberculous.

Under the head of median there are undoubtedly some in whom the disease had had a starting point on one side but in which the advance of the disease had masked the origin, so that some of these if they could have been traced up should have been classified as right or left.

For the purpose of the inquiry as to the relation of the nasal disease to the pulmonary, the cases were again classified under right, left, and median, with regard to their pulmonary disease. The side of the chest in which the symptoms first appeared, or in which it was most manifest deciding the heading, while those in which the disease was about equal on both sides, or the side of origin was unknown, or had apparently begun on both sides at once, are classified under the head of median.

Defined in this way, it was found that of the nasal cases, in twenty-four the disease appeared to have originated upon the right side and fourteen upon the left. Of the twenty-four cases of right nasal disease the right lung was primarily or chiefly affected in seventeen; the left in one; both equally in 6. Of the fourteen cases of left nasal disease, eight were primarily affected in the left lung, four in the right and two equally in both. So that in the thirty-eight nasal cases where the disease could be classified right or left, 65.8 per cent. had their lung disease primarily or chiefly upon the same side as the nasal disease. It is interesting to note that the case of right nasal disease in which the lung disease was on the opposite side, was one where stenosis of the right nostril had been caused by a fracture of the septum, and of the four cases of left nasal disease where the pulmonary disease was on the right side one also was known to have been a traumatic stenosis.

The causes of this curious symmetry between the

nasal and thoracic affection, are matters of interesting speculation. Interference with nasal respiration undoubtedly influences thoracic disease as will be later discussed, yet it is impossible to believe that the obstruction to the passage of air through one nostril could directly affect the air current entering the lungs through one bronchus more than the other, nor could possible extension of disease along the continuous membrane account for it. Bosworth states his belief that chronic inflammations of mucous membranes are usually local and not general. "Diseases of the Nose," p. 123, W. Wood & Co., N.Y.

With respect to what has been pointed out as the chief cause of nasal obstruction and so of nasal disease, viz: Septal divergencies or hypertrophies, it is assumed by most rhinologists that their chief cause is injury, many of the injuries arising before birth or in childhood and passed over unnoticed. Bosworth ably upholds this view and cites the examinations of Duret, who found the septal growths were composed essentially of plastic infiltration, thus showing their inflammatory origin (p. 290).

While we all know how very much exposed to injury the nose is, we also know how surprisingly it recovers apparently unharmed from many a blow. In the island from whence I came, the successful causing of a bloody nose to one or more of one's fellow students was a necessary portion of the curriculum to be gone through by all who sought distinction in an English school, and many a deed of prowess has been wrought upon my own proboscis and yet I have escaped a diverted or hypertrophied septum. In youth at which time most nasal injuries are received, the elastic resiliency of the parts doubtless prevents permanent deformity, though when the blow is not too violent or one sided and yet there is permanent injury resulting, it may be that the naturally weaker side yields and puts forth callus to afterwards cause an obstruction. In this connection it is interesting to note that the two cases of injury referred to where the obstruction was asymmetrical, were doubtless so because the injury resulted in a fracture by a blow from the same side as the afterwards affected lung. These two cases in not following the apparent rule may be held to give additional evidence of its existence.

The facts would appear to suggest an underlying cause in a common deficiency of resistance to disease or injury on the same side of the body, which was probably caused by a pre-natal or post-natal imperfection of development or growth, either congenital or acquired by circumstance or habit; this developmental deficiency being one of nutrition or innervation, or both.

That there is generally a difference if not an inequality in the portions at least of the two sides of the body is a matter of common observation, as when the beauty at the photographer's has a best side to present to the camera. The difference in the length of the limbs, the irregularities of sight and hearing, and of cerebral action, if such theories as Oliver Holmes, of the squinting brain be correct, are instances of this, while the records of the autopsy table confirming them, make defective development the most plausible explanation of this symmetrical exhibition of disease.

To pass to a consideration of the laryngeal cases and their significance, we find of the 200 cases of pulmonary tuberculosis 30 per cent. had throat disease,

which percentage was made up to 20.5 per cent., tubercular, 9 per cent. simple chronic laryngitis and two cases of syphilitic ulceration.

We do not find in the laryngeal disease any pronounced evidence of one side being attacked earlier or more violently than the other, both being generally or so nearly equally involved as to make any distinction, as in the nasal disease, impossible. This is confirmed by clinical experience, which teaches that the first signs of laryngeal tuberculosis are most commonly found in the commissure and when the arytenoids are involved they are usually simultaneously swollen.

Only six cases in all are noted in which the disease was markedly more severe, or began on one side in preference to the other. Of these, one had the left side of the throat, nose and lung most affected, and one the right side. One the left side of the throat and the right side of the nose and chest. Two the right side of the throat and chest, the nose clear and one the left side of the throat and the right chest. These were all cases of tubercular laryngitis. In the two syphilitic cases, as in the chronic laryngitis cases, the disease was equally distributed on both sides.

The fact that the same side of the throat as that of the nose or chest is not especially involved, would tend to show that the idea of the disease spreading directly from one nostril to the lung of the same side can not be maintained, or that the symmetrical distribution of the nasal and pulmonary disease can be explained by any deflection or obstruction of air currents through one nostril. Thus the theory of developmental deficiency receives additional support by exclusion of these possible explanations.

So far then the facts indicated by this analysis of 200 cases of pulmonary tuberculosis are that 28 per cent. had nasal disease, 30 per cent. laryngeal and 11.5 per cent. both; 20.5 per cent. had tubercular laryngitis, while of the nasal cases it is hard to determine how many were tuberculous; only a very few were noted as positively tuberculous and probably not many more were so, confirming the opinion of most rhinologists that nasal tuberculosis is comparatively rare.

The practical relation of nasal to both laryngeal and pulmonary disease is doubtless chiefly in causing mouth breathing and so catching cold, in diminishing pulmonary expansion and complete aeration; in reflex irritations, and in direct annoyance and consequent mental worry and depression in extreme cases. The moral is to relieve the stenosis by operation when needed, and the rhinitis by cleansing, stimulation or astringency, as radically as the patient's health permits, and the case requires also to examine the nasal and naso-pharyngeal passages, especially whenever the voice is affected or the throat complained of, as the cause of laryngeal symptoms often lies in the nose or naso-pharynx. At the same time it must not be forgotten that rhinitis is frequently kept up, or when there is also a permanent stenosis, aggravated by the patient's general condition, especially with respect to digestive disorders, gout, rheumatism and syphilis.

The practical lesson of the connection between chronic laryngitis and pulmonary tuberculosis is to cure the former as soon as possible, especially in order to ward off danger of secondary tuberculosis by the sputum infecting the diseased mucous membrane as it passes over or lodges on it. The tone and

strength of the voice should always be observed, and it is doubtless best that in all cases irrespective of these warnings a laryngoscopic examination be made, as experience tells one that many cases are overlooked in an early stage when treatment would be most valuable.

In considering the pathologic connection between laryngeal and pulmonary tuberculosis, the explanation is still in doubt among most laryngologists. Many excellent authorities believe that laryngeal tuberculosis is rarely if ever primary, and I myself have never seen a case without accompanying pulmonary signs, though I quite believe in its possibility while some deny it. Further, Heryng and others believe that the laryngeal affection always or commonly results from infection by the bacillary sputum from the diseased lung, through the surface of the laryngeal membrane, while others think, and with them I agree, that while this may occasionally occur it is rare, and that the bacilli attack the membrane from beneath being conveyed often perhaps through the course of the bronchial glands. My reasons for believing this are first, that in Colorado we see very few cases of tubercular laryngitis arising after arrival, yet as the last stage of consumption is especially prolonged in this climate, during which time there is usually a copious and constant stream of bacilli laden sputum being passed through the larynx for a much longer period than usually occurs at sea level, we should naturally expect many cases. Further the ulceration usually follows upon the raising up of the membrane by a tuberculous mass from beneath which is extruded through the ulcer, and then if the patient is fortunate and well treated it will heal. The ulcers rarely presenting the appearance of spreading on the surface like lupus but rather appearing like the necrosed tissue over a boil, through which the contents of the boil afterwards escape.

While recognizing the added danger and so increased mortality from the combination of laryngeal with pulmonary tuberculosis, I am glad to have added my clinical experience¹ to the evidence which shows that laryngeal tuberculosis while always grave is not necessarily fatal, but that it demands and well repays by mitigation always, and occasionally by cure, thorough competent local treatment. My statistics further proving that high climates, when equally good local care is used, are especially suited for the treatment of laryngeal tuberculosis, instead of being contra-indicated as was formerly believed, which is shown by the frequent healing of the throat lesions, even when death ensues from the pulmonary or other tuberculosis.

EMASCULATION AND OVARIOTOMY AS A PENALTY FOR CRIME AND THE REFORMATION OF CRIMINALS.

Read before the Illinois State Medical Society, May 15, 1894.

BY ROBERT BOAL, M.D.

LACON, ILL.

Political and social economists and humanitarians within the past third of a century have spent much time, thought and effort upon the best and most effective means of punishing crime and reforming the vicious and criminal classes of society. The

¹ Therapeutic Gazette, Nov. 15, 1893.

tendency of the present age is to abandon in a great measure the cruel, retaliatory and vindictive punishments for criminal offenses. As we have advanced in morals and a higher civilization the disposition to punish criminals by demanding a penalty in kind, an eye for an eye and a tooth for a tooth, has undergone a marked change, not that crime is more tolerated, or criminals more readily forgiven, but because we have more enlightened and intelligent views of the causes of crime and the antecedents, surroundings and conditions which affect the lives and form the characters of the guilty. We have now a clearer perception of the responsibility of the criminal, vicious and defective classes in their relations to society and in consequence have abandoned our old ideas of retaliatory and compensatory penalties for crime. In thinking upon this subject and upon the efforts that have been made and are now making to solve the great social problem of adequately and effectively punishing crime, of reforming criminals, of bettering the condition and lessening the number of these classes and consequently lessening the burdens they impose upon society, I entertain some opinions which I will present to the Society as briefly and clearly as I can. As a penalty for crime and the reformation of certain classes of criminals, I believe unsexing them to be the most effectual in accomplishing these ends. In my opinion all criminals who indicate constitutional depravity transmissible by heredity should be subjected to surgical unsexing enforced by law. I believe it would cause a diminution of crime and lead to the reformation of criminals. But this penalty should not be inflicted solely upon the male, but should also be extended to the female criminals—for the one emasculation, for the other ovariectomy. The object of all punishment is threefold: 1, to satisfy the demands of justice; 2, to deter and intimidate the criminally disposed; and 3, to effect the reformation of the offenders against the law. Now the punishment for offenses and crimes should be of such a kind and degree as will best subserve these purposes and most effectually protect society from injury and apprehension, diminish crime, and reform the criminal. This is the question over which sociologists and humanitarians have pondered long and earnestly and have not as yet arrived at a satisfactory solution. Prison reformers have accomplished much in improving the sanitary condition of our jails, reformatories and penitentiaries and in causing the adoption of a more humane and considerate treatment of criminals, but have fallen far short of their reformation. In this latter respect their efforts have been crowned with such slight success that it amounts to almost an entire failure. Unless you can change the constitutional depravities transmitted by heredity for perhaps two or three generations, little can be done to reform criminals, diminish their number or protect society from injury. It is my deliberate opinion that if a law was enacted and placed upon our statutes, inflicting this penalty not only upon those convicted of sexual crimes, but extending it to other criminal classes, the paranoiac, burglars, incendiaries, and to other crimes against persons and property, it would answer all the demands of justice and civilized society and vindicate the wisdom of its adoption. In support of these views I beg leave to offer the following considerations:

1. We are taught by both physiology and psychol-

ogy that all human beings are controlled in their conduct, and their actions and appetencies are expressed through their organic structures, or as they are often called, organic instincts. Of these two are of paramount importance and exert an influence over every human being. They are the love of life and sexual love. The first is from birth to death always in active operation in preserving the individual from the various accidents and diseases which tend to deprive him of it. It is the strongest and outlasts all other organic instincts. While it is developed later and does not last so long, next to the love of life, is this love of sex. It dominates human conduct and desires. It has been bestowed upon us for a wise and beneficent purpose, but when uncontrolled it is potent for evil.

2. The greater portion of the crimes characteristic of the criminal and vicious classes of society, may be traced directly and indirectly to the influence of this uncontrolled and dominating sexual love. The rapes, homicides, suicides, defalcations and embezzlements may be ascribed either directly to sexual love or to the influence associated with it. So well is this understood that when we hear of the cashier of a bank absconding with its funds, or a trusted clerk robbing his employer and betraying his confidence, almost the first comment heard is, "Oh, there is a woman in the case." With scarce an exception there are few vices in the calendar of crime—licentiousness, prostitution, intemperance, gambling, and others that are nameless, that are not instigated, associated with and maintained by sexual love.

3. The physical or structural characteristics of the criminal and defective classes of society are produced, reproduced and multiplied and perpetuated by intermarriage or sexual commerce of persons of like defects, and we have accordingly the result of the activities of living matter, or what we term heredity.

4. By the imposition of this penalty, we destroy the capabilities of these defective criminal classes to inflict injury upon society, thus depriving them of the power of reproduction. This, in my judgment, is one of the strongest considerations in favor of the proposed penalty. It has not only an immediate, but a far-reaching effect.

5. For the purpose of intimidating others from the commission of crime, while neither cruel nor vindictive, it is more terrifying and repulsive, next to death, than any or all other modes of punishment. The loss of sexual capability as a mark of manhood is so utterly abhorrent to all men, that it would be avoided if possible by all individuals not hopelessly insane.

6. In unsexing all constitutionally depraved convicts, the most important of all results (which has incidentally been alluded to) is reached, to-wit: To limit the productive capabilities of these classes, thus aiding "natural selection" and insuring if extensively applied the "survival of the fittest." Instead of confining them in reformatories and penitentiaries and trying to reform them by "moral instruction," impose this penalty and they would cease to multiply and accumulate by unrestricted production. In improving the breed of the lower animals, the gentlest, the strongest and best developed and symmetrical are selected for the purpose of reproduction, instead of the deformed, ill-proportioned and vicious. It is "passing strange" that more time and money is ex-

pended in producing and rearing a prize bull, a fast trotter or a race horse, than in applying the same law to man, "the paragon of animals." Many of you have doubtless read the account published a few years ago, of a family of criminals, whose history had been traced through three or four generations—with scarce an exception all were criminals. Of the males, some mounted the scaffold, others were inmates of prisons or penitentiaries a good portion of their lives, some were murderers, some burglars, all of them thieves. Of the women, all were prostitutes as well as thieves and active and efficient coadjutors of the men in every species of crime against society. Starting from the original stock in every succeeding generation there was an increased development and exaggeration of vice and crime. This history of one family is the history of all in like circumstances, conditions and surroundings. Had the reproductive capabilities of this family been destroyed in the first generation, society would have been protected from danger, and the cost of the conviction and maintenance of several generations of criminals saved.

A reporter for one of the Chicago dailies (the *Tribune*) recently visited the prison for youthful offenders at Pontiac, and he gives the number in the prison at the time of his visit as 636, of which 60 per cent. are thieves—some burglars. Seventy are from 10 to 13 years of age; six or seven are over 21 having sworn falsely to their ages. The major portion of these youthful criminals will probably develop into confirmed thieves and burglars and what the law of this State terms "habitual criminals." Investigation would doubtless show that the greater portion of them are constitutionally depraved; in other words there is a hereditary tendency to crime. I do not underrate environment as one of the causes of crime. Vicious surroundings doubtless have their influence, but when you add to that a hereditary taint for two or three generations, you find a criminal utterly oblivious to every moral influence exerted for his reformation. For such, deprivation of their sexual capabilities offers an adequate and effective punishment and so changes their nature, that reformation while not always assured, in my opinion is in most cases practicable.

7. This deprivation of productive capabilities effects well marked modifications in the purposes, actions and characteristics of individuals. They become more gentle; their heretofore ungovernable passions are in a great degree subdued—they are less wayward and obstinate and more effeminate. In short, they are changed and altered beings in more senses than one. This is a matter of every-day observation in animals who have been emasculated or whose ovaries have been removed. In Turkey and other Mohammedan countries, the eunuchs who guard the harems of the rich are said to be inoffensive, gentle and timorous showing conclusively that the altered being has changed in his purposes, actions, capabilities and necessities.

8. If these statements are true, could any other method than the one proposed be more effectual for the suppression of crime and the reformation of the criminal and various classes of society? It may be asked why not inflict the death penalty upon all convicts whose crimes indicate constitutional depravity, and put them out of the way? This would be a more rapid and certain way of disposing of them, but would not the penalty be more severe and unneces-

sary than would be required? Would it not be disproportioned to the crime? When you hang a man you destroy him, while emasculation only changes his purpose and desires and leaves his life intact. Again, I do not believe the death penalty would have such deterring and terrifying power as asexualization, for owing to the technicalities of the law and its delays and the uncertain verdicts of juries, the criminal hopes to escape its extreme penalty. In addition to this, there is a great diversity of opinion in the community upon the propriety of inflicting capital punishment. One portion of it believes it should not be inflicted under any circumstances, while another is in favor of imposing it, only for great and unusually atrocious crimes. It is only when crimes of such magnitude as the murder of Dr. Cronin or the assassination of Mayor Harrison, or of a President of the United States, are committed, that the community is aroused and a demand is made for the execution of the criminals. These are extreme cases, but even in them public sentiment is divided as to the necessity of killing the criminal—so great is this aversion to capital punishment that in some of the States it is abolished and in others greatly restricted. If after conviction, each man or woman, after being deprived of their reproductive organs and subjected to a longer or shorter term of imprisonment was returned to society, it is my belief they would become comparatively harmless. Confinement at hard labor in prisons and reformatories, in nine cases out of ten, fails to reform the criminal. Moral instruction is thrown away upon him—he graduates in crime, and he leaves their walls more depraved, and with a stronger determination to war upon society than when he entered them.

9. This proposed penalty for crime might be made applicable to a large class of offenders; instead of limiting it to such as violate the laws governing the intercourse of the sexes, certain crimes against persons and property might be more effectually punished in this than in any other way. There is a class of offenders against the law, and it seems to be rapidly increasing, called by the people "cranks," by the medical profession monomaniacs or paranoiacs, who escape the penalties of the law upon the plea of insanity and consequent irresponsibility for their acts. It would be cruel and inhuman to hang them, but a deprivation of their reproductive organs might have the two-fold effect of answering the demands of justice, and so changing these desires and purposes as to render them harmless in the future.

In Chicago at the present time an investigation is ordered for the purpose of determining the sanity of the assassin of Mayor Harrison, upon the allegation that his insanity occurred after his conviction and sentence. No one can tell what the verdict of the jury will be upon the question. Suppose they find him sane and he is again sentenced for execution, what is to hinder him before the scaffold is again erected to make another application to a complaisant judge for another trial and stay of execution, on the ground that he has developed insanity since the second sentence was pronounced, and thus indefinitely prolong his life, and in the end escape punishment for his crime. Now, if in this case and that of Guiteau, the assassin of President Garfield, the penalty of emasculation had been imposed, and they had been placed under such legal restraint for a longer or shorter time as might have been necessary to secure

its efficiency, it is my belief that in these instances justice would have been satisfied, society protected from further assaults and the criminals partially, if not wholly, reformed.

In the instances just cited and in all others of like character, experts differ and public opinion is divided as to the responsibility for the criminal acts, and it appears to me that neither justice nor the protection of society requires the infliction of the death penalty.

This subject which I have endeavored to present for your consideration has not to my knowledge been much discussed in medical journals or medical societies, certainly not to the extent its importance demands. Considered in its relation to the well-being of society, the literature upon this subject is meager. With the exception of a paper read by Dr. Orpheus Everts before the Cincinnati Academy of Medicine in 1888, I have been unable to find any mention of it anywhere. Dr. Everts is the accomplished superintendent of the Cincinnati Sanitarium at College Hill, who has given this question a good deal of attention, especially in relation to one of the defective classes of society, the insane. I am indebted to his paper for many of the statements and suggestions I present to you to-day. The late Dr. Agnew of Philadelphia, is credited with the proposal to punish all criminals, who were convicted of rape, by emasculation. He limited this penalty to one crime and to the male. Dr. Everts takes broader ground and would apply it to all sexual and some other classes of crime and to both sexes. In this I fully concur, for I believe the unsexing of both males and females convicted of crime is necessary for their punishment, and reformation by the limitation of their reproductive capabilities. The question may be asked, Why bring this topic before a medical society, and what relation has it to the profession of medicine? I answer that it is the branch of State medicine which deals with crime in its relation to, and its effects upon, the health and well-being of society. The medical profession is in a certain sense regarded as the guardians of the public health. It is their duty to recommend the adoption of proper sanitary measures, to prevent or ward off epidemics if practicable, or if not, to restrict their spread and lessen their violence, and to circumscribe by isolation the area of infectious and contagious diseases. If so, are they not equally bound to ward off and confine within its narrowest limits the infection and contagion of crime, for it is both infectious and contagious and the diseases which it engenders are among the most loathsome and intractable of all which we are called upon to treat. As members of a profession which is one of the highest and noblest of human pursuits we are interested in all that contributes to the welfare of the community. This measure should be investigated and discussed with a view to influencing the public mind in favor of its adoption. When that is accomplished proper legislation will follow. Our criminal jurisprudence needs reform. "There is an increasing want of confidence in the efficiency of the laws and the courts which administer them. Every lynching, every riot, every mob is a protest against the delays and uncertainties in the administration of the laws, and if there is not some reform, there is danger that in the unrest of the public mind human society may be overwhelmed by social and political revolutions brought about by the many ex-

isting abuses." Is not the medical profession interested in this reform, and will they not aid in accomplishing it?

In conclusion, let me summarize the points I have endeavored to make:

1. That the surgical unsexing of all criminals convicted of offenses that indicate constitutional depravities that are transmissible by heredity is both expedient and practicable.

2. This penalty should be applicable to both sexes.

3. That most of the offenses against society by vicious and defective classes originate in sexual disturbance whether in deprivation or excess.

4. It limits the reproduction and transmission by heredity of the defective and criminal classes of society.

5. It inflicts a penalty that is terrifying and abhorrent without destroying life.

6. It is applicable to other offenses against person or property, originating from other than sexual causes.

7. While effective, the punishment is neither cruel nor vindictive.

8. It is more effectual in changing and improving the nature of the criminal than moral instruction, confinement in prison, or houses of correction.

As to when or how the penalty recommended will be carried out must be left to the future law makers. If adopted I doubt not all the details will be arranged and perfected so as to accomplish the desired end. The present century will soon close upon us, and if the same rate of progress is kept up (as I believe it will be) during the coming one, I hope a change will be made in our criminal code in line with these suggestions. The public mind is not yet prepared to accept the change recommended and it would not now be sustained, but if the question is discussed and agitated by sociologists and the medical profession, I believe that at no distant day that change will surely come.

NOTE:—Since this paper was read, the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION of May 19, 1894, published an abstract of a paper read by Dr. S. F. Sim, of Memphis, before the Tennessee State Medical Society upon this subject, in which he substantially agrees with the opinions expressed by the writer. Aside from the coincidence that two papers upon the same subject were read before two State medical societies at different and distant points, it shows that this question is beginning to receive from the medical profession the attention which its importance demands.

War on the Nostrum Venders.—Dr. J. W. Scott, Secretary of the State Board of Health of Illinois, has begun a vigorous warfare on the itinerant nostrum venders who annually fleece the people of this State out of a sum estimated at over \$300,000, by means of brass bands, concert troupes, alleged Indians and other mountebank attractions. Prosecutions have already been begun by several of the State's Attorneys, to whom the Board remits all fines collected as an inducement to vigilance. The law provides that every itinerant vender of medicines shall pay into the treasury of the State Board of Health a license fee of \$100 a month. The penalty for a violation of this act is a fine of from \$100 to \$200, and as the Board refuses to issue such license every itinerant vender is a violator of the law. The Board also has a regulation providing for the submission for chemic analysis of samples of all medicines sold by itinerant venders. This, too, will be rigidly enforced.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

SATURDAY, SEPTEMBER 15, 1894.

THE AMERICAN MEDICAL ASSOCIATION.

Some enterprising persons are unduly exciting themselves about the membership of the ASSOCIATION. Why, asks a certain irregular, should this be called an "American" ASSOCIATION? Solely, our erring brother, because this ASSOCIATION is based upon a representation from the State Societies and the three Public Medical Services. Every regular State Society, except those of New York¹ and Massachusetts, send delegates to the annual meetings; these delegates shape the policy of the ASSOCIATION, and it therefore follows that the total membership of the constituent bodies of the ASSOCIATION, is the actual strength of the ASSOCIATION—with the addition of such local societies as send delegates. On this basis, the adherents of the American Medical are not far from forty thousand.

That they are not all members by the fact of their belonging to the State constituent body is solely due to the failure of one of the proposed amendments. That will come in time as surely as the sun rises in the east. The regular medical profession will not hesitate very much longer, about throwing the weight of their influence in favor of closer union and greater strength. The interests of the profession are too vast and too important to be wasted in divisions and factional differences.

The immense advantages to medical science to be gained by solid adhesion to the representative ASSOCIATION, are too great to justify any other course. While the policy of the ASSOCIATION is thus shaped by delegates duly instructed by their respective State bodies, and by the Medical Department of the Army, the Navy and the Marine-Hospital Service, the scientific features of the meeting are participated in by all members alike, whether serving as delegates or

not. These members control the Sections and the Section work, and there is now no limit.

The technical membership was until the last few years confined to delegates, but now is open to all individual members of any medical society entitled to send delegates.

Every sentiment of professional pride, and as well every sound business precept, should urge every member of the regular profession of the United States to add his name and his active personal support to the great AMERICAN MEDICAL ASSOCIATION, under the auspices of which American medicine has so greatly prospered. Let dissension perish and union prevail.

DEFORESTATION AND AUTUMN FIRES.

Paradoxical as it may sound, there is some ground for the belief that deforestation by the axe is largely responsible for the annually recurring deforestation by fire.

The yearly precipitation of the lake region, including the great timber areas of Michigan, Wisconsin and Minnesota, has diminished since 1886 to a marked degree. For the Chicago region the yearly mean precipitation since 1871 has been 35.6 inches; but for the past eight years the mean is only 29.32 inches, as against a mean of 37.8 inches for the preceding fifteen years.

An examination of the records of the United States Signal Service for the last twenty-three years discloses a grouping of about seven-year periods of plus and minus precipitation. Thus, during the years 1871-1877, the yearly mean was 35.04 inches—a slight deficiency as compared with the yearly mean of the entire period; in 1878-1884 the mean was 39.43 inches—a marked excess; in 1885-1891 the mean was 32.18 inches—a marked deficiency. From this alternation it has been argued that the precipitation is governed by some law not yet recognized and an increased precipitation was predicted for the period beginning with 1891; but thus far this has not been realized and the increasing denudation of the timber lands is again being considered as a possible cause of the deficient precipitation and the prolonged droughts.

Of the regulative effects of forests on temperature and rainfall there can be no question; and, aside from these disastrous forest fires and their destruction of life and property, the conservancy of our timber lands in the interests of public health is yearly becoming more important. The results of MR. GEORGE VANDERBILT'S undertaking at Asheville, N. C.,—which has been characterized by MR. FRED LAW OLMSTED as "the most extensive and important experiment in forest culture ever attempted on the globe"—will be watched with interest by sanitarians and climatologists everywhere.

Meanwhile, the necessity for more thorough gov-

¹ The New York State Medical Association sends delegates to the American Medical Association, so that State is nevertheless fairly represented.

ernmental control of our remaining timber lands has become imperative—a necessity which is atrociously emphasized by the colorable suggestion that the recent fires, with their appalling destruction of life, were the work of “timber pirates” to conceal their depredations.

HERMAN VON HELMHOLTZ.

A dispatch dated September 8, has just announced to the world that one of its illustrious men of science, HERMAN VON HELMHOLTZ, has passed away. He succumbed to a paralytic stroke from which he had suffered for the past six weeks. Advanced as he was in years his unabated mental vigor had still held out the hope that his might yet be years of activity. The shock to the entire scientific world by reason of his death will be all the more keenly felt by his numerous admirers in this country who during his visit one year ago learned personally how little age had dimmed his intellect or marred his genial manner.

Of all men who have left their imprint on the progress of science during this century, the influence of none has extended into as many different lines of knowledge as that of HERMAN HELMHOLTZ. In medicine, particularly, we owe him not merely the numerous additions to our knowledge in physiology and physiologic psychology, but the world is indebted to his genius for that now indispensable instrument—the ophthalmoscope, an invention that will keep his memory alive more permanently than monuments and epitaphs.

His first publication, a thesis on the structure of the nervous system in evertbrates in 1842, gave proof of his ability as an observer. It was the first demonstration of the continuity of nerve fibers with nerve cells. Subsequent to this work he investigated the phenomena of putrefaction and fermentation, but could at that time not decide definitely whether these changes were only of a chemical nature or depended on living microbes. Of greater importance were his studies in animal warmth, in which the application of his thorough knowledge of physics gave to this part of physiology a more precise basis than it had previously possessed. During this time of his life he was army surgeon in the Prussian army, but found or rather made opportunity to have his name spread far beyond the domain of medicine by his essay in 1846 on the conservation of energy. While not the only investigator in this line of thought, for, in fact, he was preceded by several years by ROBERT MAYER, with whose work, however, he was not familiar, HELMHOLTZ was the first to prove irrefutable by mathematical reasoning the correlation and indestructibility of energy in all its different modes of manifestation. To him hence belongs the credit of helping to lay the corner stone upon which the structure of modern theoretical physics rests.

In 1849 HELMHOLTZ was called to the chair of physiology in Koenigsberg, which he exchanged for the same position in Bonn in 1855, leaving that university for Heidelberg in 1858, where he stayed until 1871. The year 1871 ended his career as a teacher of physiology, as he was asked to take the chair of physics in Berlin. He resigned this chair in 1888 and was then appointed Director of the Imperial Physical-Technical Institute at Berlin. His university career was inaugurated by his researches on the velocity of nerve conduction. Accustomed as we are now-a-days to physical methods in physiologic work, we can hardly realize what a revelation HELMHOLTZ's results were to physiologists of those days. One is indeed at a loss which to admire most in those two papers of 1850 and 1852; the surprising revelations concerning the mechanism of nerve-conduction, or the elegance of the methods used in that research.

In 1851 his researches on the path of rays of light in the eye led him to the discovery of the ophthalmoscope. The short precise statement of his work outlined clearly what could be expected of this instrument for clinical purposes, and yet with the full appreciation of what he had accomplished, his essay can forever serve as a model of the modesty of true genius. Continuing his optical researches, HELMHOLTZ next constructed his ophthalmometer, the teachings of which enabled him to compute the course of rays of light in the eye, and led to his discovery of the mechanism of accommodation (simultaneous with but independent of KRAMER). His different optical researches, on the mixture of color sensations, the movements of the eyes and kindred subjects were finally collected in his “Handbook of Physiological Optics,” published between 1855 and 1866, of which a second revised edition is now being re-issued, but is not yet completed. This magnificent treatise in which every fact stated has been verified by the author, unrivalled in philosophic conception and a model in the painstaking accuracy of its historical bibliography is the physiologic foundation of modern ophthalmology.

Comparable to his work on physiologic optics are his contributions to the mechanism of hearing, collected in his “Sensations of Tone,” published in 1862 and in two later editions. It would be difficult to name any other work betraying such versatility in original investigations as HELMHOLTZ showed in his *Lehre von den Tonempfindungen*. The anatomic study of the ossicles and their joints, the physical and mathematical analysis of the timbre of sounds, the inquiries into the psychology of musical perception, broadly philosophical without being speculative, and the literary researches into the theory and practice of music of foreign races stamp the book as the work of an unique genius.

His physiologic researches, however, sufficient as

they were to keep his memory alive in the annals of medicine, were but a part of HELMHOLTZ's work. The prominence which his first masterly essay on the conservation of energy gave him in the ranks of physicists was maintained throughout his lifetime by numerous other contributions all equally characterized by unusual penetrating power guided by mathematical reasoning. Perhaps his best work was in the domain of theoretical electricity. His researches on the time relations of induction currents, and on the oscillations in electric discharges have been the starting point of many of the wonderful extensions of electric knowledge of the last few years.

But he did not confine his physical work to electricity, and indeed with many chapters in the theory of light, sound and hydrodynamics his name will always be associated. Within a few years of his death he began a mathematical inquiry into the movements of the atmosphere, which meteorologists consider as a great advance.

His rare mathematical ability did not prevent HELMHOLTZ from allowing his imagination to soar toward the solution of some general problems not confined to any one narrow line of investigation. His essays on the conservation of energy, the cosmic theory, the relation of electricity to the atomic theory (the Faraday lecture before the London Royal Society for which the COPLEY medal was given him) are all marvels of a versatility, which yet was always controlled by mathematical reasoning. Nor was his safe though far-reaching reasoning any less apparent in his excursions through the treacherous expanse of psychology. Among the great philosophic achievements of the century rank highly his dissertation on the origin of geometrical axioms as well as his discussions on the mechanism of auditory and visual perceptions and their relations to reasoning and the arts.

Not least among HELMHOLTZ's merits are his popular lectures. It is but seldom, that so much genuine knowledge on abstruse subjects has been given to the general public in such palatable shape. For in all his writings characterized by accuracy, preciseness and terseness, HELMHOLTZ was not indifferent to literary beauty. If most of his physical articles tax the attention of the reader to the utmost, they do so only for the reason that he could so easily present his thoughts in strict mathematical garb, and not from want of clearness in the style. In fact, HELMHOLTZ was endowed with rare artistic taste, shown not only by his leaning in psychology towards problems relating to art, but also by the artistic finish of his writings.

His life was an uneventful one, except in scientific triumphs. His seventieth birthday, three years ago, was the occasion of ovations from the entire scien-

tific world, which showed not only the admiration he commanded, but also the personal affection felt by all his pupils towards him. On that occasion the German Emperor recognized officially his merits, by granting him the rank of nobility. But grief did not spare him in his old age by the loss of his son, ROBERT HELMHOLTZ, a promising young physicist.

In the annals of science and progress the name of HERMAN HELMHOLTZ will rank forever foremost as an illustrious example of what man can do for mankind by the conscientious application of intellectual power.

FACIAL CHANGES MEDICO-LEGALLY CONSIDERED.

Is it possible that the face can become so changed as to be unrecognized in a brief time? was the question addressed to a leading physician in a recent trial. His answer was, yes. In an explanation he described the case of a physician who received a dispatch announcing the death of his wife. In half an hour his expression had changed so markedly that he was not recognized on the street, except by those who were most intimate with him. This suggests a field of inquiry that is at least startling. The changes of countenance from disease and injury are familiar to all physicians, but the possibility of similar changes from shock, profound mental emotion or physical disturbances that have no apparent causes are new to the student.

In a recent paper read before the Medical Legal Society of New York, by DR. OSBORNE, "On People Who Drop out of Sight," three cases are given which bring out this fact. Two of the cases were men of some prominence who walked away from their homes in broad daylight entirely unrecognized. They must have been seen by many persons acquainted with them, all of whom did not remember any familiar expression. The most careful exhaustive inquiries failed to trace their movements, and after a long interval both of these cases recovered consciousness of their surroundings and returned, but with no recollection of how and for what reasons they left and what they had done in the interval. In the third case, a man was injured in an accident from a runaway horse; then disappeared in an equally mysterious way, in a place where he was known and apparently under the full observation of many persons. Three days later he appeared at his home in a dazed condition, and very greatly changed in countenance. In these cases the blanks of memory and periods of unconsciousness, or trance conditions, in which another personality existed, was evidently preceded by some profound change in the facial expression.

This, the author asserts, is the key to the cases which so suddenly and mysteriously drop out of sight in broad daylight, and in surroundings where it

would seem impossible. This trance phenomena and double personality is far more difficult to understand than rapid facial changes that would give the appearance of a different person even to those familiar. Practical physicians become experts in reading the changes of facial expression, and rely to a large extent on their knowledge of diseases from this source. Surgeons see signs in the face of early death or recovery without being able to describe or make it clear to others. Many diseases and emotional disturbances are registered in the most profound changes of the countenance; hence it is not improbable that similar changes may come from central brain states at present unknown.

Any one who is familiar with hypnotic phenomena will be startled at the changes apparent in the person who is hypnotized. In one case the sad, melancholy facial shadows, the bowed head, bent shoulders, wearied walk and listless air; in another the buoyant look, flashing eye, erect head, brisk, nervous movements, may be so different from the accustomed appearance of the man as to give the casual observer the impression of a different person. In CHARCOT'S clinic these startling changes of personality and appearance were very clearly illustrated. Many of these so-called hypnotic states are said to be more or less common to persons who are regarded as normal and well. However this may be, it is clear that many and most complex psychical changes of the brain may be registered on the face with such rapidity as to baffle our sense of time. It would be by no means strange that some psychic force should in a brief time transform the face and general appearance so that the person could not be easily recognized, thus making it possible to disappear.

DR. LUKE describes a case of this sudden profound transformation of face and appearance of one who was seized with a suicidal impulse. He was locked up and in a brief time this passed away. Practically this subject suggests the necessity for more accurate observation and study in medico-legal questions involving the possibilities of personal and facial changes. Also that the physiology and psychology of the face, seen at different times and conditions is a practical field of study that will reveal many facts at present unknown. In the very prominent LORN will case, the question was: "Could the testator have left his home at midday, walked down a long street, rode six miles on a horse car and not be recognized by some one, especially where he was so well known?" It was proven that he did this, but that he wore a better hat and suit of clothes than usual; also that he was under great emotional strain of indignation and excitement. On this occasion he must have been seen by at least a hundred persons who were acquainted with him, no one of whom

recognized him. He probably had a totally different expression, due to his mental condition, that with his changed suit of clothes was a complete disguise. In a murder trial at Boston the same question was raised: "Why the murderer was not seen and identified at once, in a town where he was known?" It appeared that he had changed his hat and walked the street and went about for a week or more, then gave himself up. Subsequently it was proven that the act was committed under circumstances of profound grief, and in a state of bewilderment, which finally wore away when he gave himself up. Probably the same alteration of countenance prevented his recognition at the time.

A grouping of similar cases would be of great interest, and throw some new light on many of the perplexing problems of brain disorders.

SEWER AIR AND SEWER VENTILATION.

During the past thirty years a great change has taken place in medical opinion concerning the causation of acute infectious diseases, and particularly of typhoid fever; and it is gratifying to know that every step of this change has been productive of material sanitary improvements. MURCHISON'S pathogenic doctrine became a potent factor in removing filth and giving us the relative cleanliness of the present time, while DR. WILLIAM BUDD'S theory of specifically infected dejecta, with the sewers as a continuation of the diseased intestine, led to the construction of improved sewerage systems. Faulty sewers came to be regarded as hot-beds of typhoid infection and sewer air as the medium by which it was propagated. The efforts made to exclude the latter from our houses educated the plumber, elaborated plumbing regulations and preserved us from many foul emanations. The discovery of the bacillus of typhoid and the infection of water by its presence, led directly to a higher appreciation of the importance of pure water, and in many instances to corresponding efforts to procure it. With the progress of the doctrine of a water propagation of the fever, ordinarily from contamination with specifically infected excreta, sewer air, once considered so deadly, is gradually losing its importance as a pathogenic factor. Some papers illustrative of this were read at the last meeting of the Congress of American Physicians and Surgeons. Chemists have known for years that sewer air differs from atmospheric air only in containing more carbon dioxide and less oxygen, with a little more ammonia and compound ammonias, if the sewage is in a condition of fermentation, which ought not to be the case. To none of these, however, was the deadly character of the sewer air attributed, but to the bacteria raised by evaporation from the foul moist sides of the sewers and the surface of the flowing liquid. But now come the

bacteriologists with the information that pathogenic bacteria and indeed bacteria of any kind are often less common in the air of sewers than in the air of the overlying streets, so that SIR CHARLES CAMERON in his address as Chairman of the Section of Public Medicine, British Medical Association, is fully warranted in his statement that: "The results of recent investigations in reference to the composition of sewer air seem to show that it is superior, bacteriologically at least, to ordinary air. Some of the accounts of its purity are so roseate that one might naturally conclude that a sewer outfall would be an excellent health resort. DR. JOHN BILLINGS, Deputy Surgeon-General, United States Army, goes so far as to doubt that there is conclusive evidence to prove that sewer gases have ever produced disease. PROFESSOR KOCH found only three or four microorganisms in 100 liters of the air of a Berlin sewer, while the atmosphere above the sewer teemed with them. HALDANE detected only 20 microbes per 100 liters of air in a Bristol unventilated sewer."

These and other similar results are accepted by SIR CHARLES CAMERON as obtained from the air of well constructed and well flushed sewers. In discussing the ventilation of sewers he reaches the conclusion that from a health point of view a perfectly open sewer is less objectionable than one ventilated in the ordinary way. This is an open question, but we believe that an *unventilated* sewer is preferable to either of the others. Experiments performed several years ago in the laboratory of the National Board of Health showed that the volume of air contaminated by foul organic matters is the volume of air brought in contact with them. If repeated volumes of 100 liters be drawn over putrescent matter the last volume will be as much contaminated as the first. If no air can be brought in contact with it no air will be defiled. Health officers recognize this and insist upon closed cesspools and garbage cans. In objecting to open sewers, city authorities have acted as if with a due appreciation of the principle, but in fact the action was dictated by the results of observation and experience. The closure of open sewers improved the sanitary condition of the atmosphere by preventing its wholesale pollution by contact with the exposed surfaces. But in constructing sewers of large size, and tapping them at frequent intervals for ventilation, the principle of occlusion seems to have been forgotten or sacrificed to a false idea. Air which has afterwards to be breathed by the thousands of a crowded city is brought by free sewer ventilation into a putrefactive condition. It may not be specifically dangerous, for the bacteriologic tests rarely show pathogenic bacilli, but it is not the invigorating air which should be breathed, and continued exposure to its influence appears to bring about a condition of system favorable to pathogenic developments. Open-

ings are needful to relieve interior pressure, but all communication with the atmosphere other than for this purpose is unnecessary and generally harmful. More particularly should all ventilating grids that exhale foul odors be closed up that the purity of the street atmosphere may be preserved. A lack of sewer ventilation is not a dangerous unsanitary condition. SIR CHARLES CAMERON cites the city of Bristol as having no ventilation for its sewers; but, "if Bristol has made a mistake in not ventilating its sewers it has not paid apparently any penalty, for in the period 1881-90 only one of the large towns had a lower zymotic death rate."

END OF THE PLAGUE.

A cable dispatch announces that the port of Hong Kong has been officially declared free from the plague.

And thus is scored another triumph for preventive medicine in suppressing, within a period of less than four months, an outbreak of a pestilence which, at the beginning of the Christian era and for centuries thereafter, was wont to spread to the ends of the habitable world, causing the most frightful desolation, depopulating cities and towns, turning countries into deserts and making the habitations of men to become the haunts of wild beasts; a pestilence, one epidemic of which, starting, as did this recent one, in the mysterious country of Cathay, spread to Europe and in less than five years swept away 25,000,000 victims, or one-fourth of the total population of the Continent—an epidemic which, to still further adapt the language of HIRSCH, arrested the attention of chroniclers, poets and physicians by its enormous diffusion over the whole of the then known world, by its victims reckoned in millions, and by the shock to the framework of society which it brought with it and left behind it.

The extinction of pestilence in Europe, its cessation in Egypt, Syria and Asia Minor and its infrequent appearance in India and the Far East, have all been attributed to the improvement in hygienic conditions—the greater this improvement the greater the degree of repression of the pestilence, even to the point of extinction. But the unimagined epidemiologist already cited, writing in 1881, was not content to accept this as the sole cause. "There is certainly much that is true," he wrote, "but there is not the whole truth, in the words which AUBERT-ROCHE has chosen as a motto for his work on the plague: '*La civilization seule a détraît la peste en Europe, seule elle l'anéantira en Orient.*' Besides the system of quarantine rules, whose efficacy I can not rate too highly for reasons that I have several times explained, there is no doubt that the improvement in hygienic conditions which has been going on for cen-

turies in the civilized states of Europe, has contributed very greatly to the gradual decrease and final extinction of the plague. But whether that is the whole solution of the problem is very doubtful. Still less can one admit this factor to be the sole explanation of the cessation of the pestilence in the East, although there also, and particularly in Egypt, the good effect of sanitary rules on the remission of the pestilence can not be altogether ignored. These, and many similar questions in the history of national sickness, have no answer to get from science as far as we have gone; and it is well that we should recognize these limitations in our knowledge of the laws that regulate the appearance, the prevalence, the remission and the extinction of pestilences."

We have gone further in science since this doubt was expressed, and PROFESSOR KITASATO'S discovery of the specific cause of the bubonic plague confirms the wisdom of HIRSCH'S judgment. Where the developments of sanitary civilization have advanced sufficiently to destroy the conditions necessary for the existence and growth of the plague bacillus there the plague has been annihilated; where these necessary conditions may occur, or still exist in the unspeakable filth of the lower classes of Oriental habitations, it needs but the introduction of the specific germ to cause a reappearance of the pestilence.

And yet the discovery of the missing factor of HIRSCH'S problem only emphasizes the importance of improved hygienic conditions. Given a good sanitary environment and the bacillus of the Black Death is harmless—even as are the bacilli of other filth diseases. In the paraphrase of SIR BENJAMIN WARD RICHARDSON: *Sanitas sanitatis, omnia sanitas.*

CORRESPONDENCE.

Commissioner Reynolds' Defense.

CHICAGO, Sept. 11, 1894.

To the Editor:—I beg to thank you for your courtesy in sending the proofs of Dr. Bayard Holmes' paper on "The Sweat-Shops and Smallpox in Chicago," together with your suggestion (both received to-day) that, "as he has quoted an official report," you think "it requires a notice at (my) hands."

Permit me to say that I do not see that the quotation of a report requires notice rather than the report itself.

I have not noticed the official report. The State Factory Inspector is avowedly engaged in an attempt to abolish the "sweat-shop" system. I shall do nothing to interfere with the success of that attempt; still less shall I allow myself to be drawn into any controversy over the methods employed in the attempt, since this would involve a traversal of many statements, a denial of imputed motives and a general defense of the Chicago Health Department—neither of which seems to me necessary.

For similar reasons I must decline to notice Dr. Holmes' paper other than to say that, while withholding criticism of his methods, I think I am capable of appreciating his motives and of admiring the zeal he displays in his attacks on social wrongs and abuses, real or fancied.

The lot of the reformer is not a happy lot, and something must be allowed for Dr. Holmes' fervid imagination, impulsive nature and righteous indignation against evils which resist instant correction. These qualities, laudable and even noble as they are, have heretofore in their unrestrained exercise, brought other equally meritorious essays of Dr. Holmes to naught.

I fully believe that if the Doctor had opportunity for further revision of his paper he would strike out much more than he has already done of unfounded and misleading statement and uncharitable expression of opinion. These matters, however, may be safely left with those who know the facts—who know that, "incredible" as it may seem to Dr. Holmes, not a single case of smallpox could be "traced to coats or other clothes made to order," or to any "sweat-shop" made garment; who know that the smallpox mortality in a hospital that "would disgrace Siberia by its management," has been, up to date, a fraction less than 33 per cent. of cases, while the hospital mortality in our last epidemic was 41.3 per cent. of cases; and who know that the city of Chicago, through its Department of Public Health, fought this outbreak by the most effective and economical method known to modern sanitary science, to-wit: wholesale systematic vaccination and re-vaccination—a proposition which Dr. Holmes himself would be one of the first to approve.

There is nothing of profit to the community to be gained, Mr. Editor, by further "notice" of this paper; even what is here said may be construed by some as a violation of the "altruistic" spirit of our profession of which I would not willingly be guilty. Very respectfully,

ARTHUR R. REYNOLDS, M.D.,
Commissioner of Health.

Hydrophobia—Statistics Desired.

To the Editor:—Will you permit me, through your columns, to ask that my professional brethren will communicate to me the occurrence of cases of so-called hydrophobia in their practice for the year 1894, from January 1, and so on until the end of this year?

I would like in all cases to learn: 1, the sex and age of patient; 2a, the kind of animal that is credited with the inoculation; 2b, its state of health; 2c, the provocation to bite (if any existed); 2d, the reasons why the animal was (if it was) deemed rabid; 3, the seat of the bite (or other mode of inoculation); 4, the fact and method of cauterization (if any); 5, the time between the inoculation and the outbreak; the symptoms of the outbreak—the occurrence of mania or imitation of dog actions; 7, the remedies used and doses, with their seeming effect; 8, the issue of the case and when death occurred; 9, the investigations made to exclude the presence of disease other than so-called hydrophobia; 10, the findings on autopsy—if one was held.

I shall acknowledge in future publications aid received in continuing my studies in regard to this subject.

Yours respectfully, CHARLES W. DULLES, M.D.
4101 Walnut Street, Philadelphia.

SELECTIONS.

The Ohio Law—Is It Constitutional?

The following will appear in the *Columbus Medical Journal* September 18:

The recent arrest at Mansfield, of Mr. Ottman, the notorious traveling quack who has his headquarters at Columbus, has precipitated a suit for the purpose of contesting the constitutionality of an ordinance passed by the council of Mansfield, Ohio, during the winter of 1892.

Over a year previous to the passage of this ordinance a petition was signed by nearly every physician, dentist and druggist in the city, and presented to the Health Officer, requesting the passage of a law that would protect the citizens of Mansfield from the designing schemes of traveling charlatans.

In accordance with this petition the writer who was then Health Officer, drew up the following ordinance which was submitted to a committee of attorneys and afterwards unanimously passed by the council on Nov. 29, 1892, and which reads as follows:

REGULATING THE REGISTERING OF PHYSICIANS, MIDWIVES,
PHARMACISTS AND DENTISTS.

SEC. 6.—It shall be the duty of every physician, midwife, pharmacist and dentist practicing in the city of Mansfield, Ohio, to register in a suitable book prepared therefor by the Health Officer, which register shall contain the name, the street address, the college at which said physician, midwife, pharmacist or dentist graduated, and the date of said graduation, and, further, that on and after the adoption of this ordinance no person shall be permitted to practice the art of medicine, surgery, midwifery, pharmacy or dentistry, or sell medicine or drugs from house to house or on the streets, without registering with the Health Officer and furnishing him, when so required, a sample bottle of the medicine to be sold, for analysis, and displaying to him their certificate from the State Board of Pharmacy, in the case of druggists, or their diploma of graduation from a recognized, chartered medical school, in the case of a physician, surgeon, midwife or dentist, and that such persons shall not be eligible to receive a license from any city officer until they have displayed the above mentioned documents or drugs, as the case may be, to the Health Officer and received a certificate from him to the proper city officer, who then shall have the privilege of issuing the said person the necessary license, which shall not be less than ten dollars or more than fifty dollars a day; and further that any person violating this ordinance shall be subject to a fine of not less than fifty dollars nor more than one hundred dollars for each offense. In the selling of drugs this ordinance is not intended to apply to regularly recognized traveling salesmen, who deal directly with the physicians or druggists of the city.

Immediately after the passage of this ordinance it was put into effect and strenuously adhered to by the Health Department which required every physician, druggist, dentist and midwife practicing their profession in Mansfield to properly register with the Health Officer and receive from him a legal certificate to practice within the corporation limits of that city.

By this ordinance, those who were not legally qualified to practice medicine, dentistry or pharmacy were at once shut out and refused a certificate. Those who were legally qualified were granted a certificate by the Health Officer, to the Mayor, who issued them a license for each day they practiced their profession in the city, which license cost them from \$10 to \$50 a day. It will be readily seen that this law practically annihilated the quack business in Mansfield; they gave it a wide berth. Later on other towns followed the initiatory steps taken by Mansfield, until Mr. Ottman found his heretofore lucrative business very greatly infringed upon and finally decided to contest the constitutionality of the law by attempting to practice medicine in the city of Mansfield without a license, whereupon he was promptly arrested by the sanitary officer, brought before the mayor, pleaded not guilty, and placed under a bond of \$100 for his appearance on September 29.

Mr. Ottman has retained the Hon. Thomas E. Powell, of Columbus, and Hon. C. E. McBride, of Mansfield, for his counsel and the case will be hotly contested from start to finish, as the authorities of Mansfield are determined to carry it to the Supreme Court, if necessary, to get a final decision.

This case not only involves many interesting points of law, but is of decided interest to every honorable practitioner in the State of Ohio. If the ordinance is sustained it sets a precedent whereby each city can enact its own laws

for the protection of its own citizens against the nefarious practice of traveling charlatans and quacks. If, on the other hand, an adverse decision is obtained it throws the doors wide open, and invite quacks of all kinds and characters to walk in and help themselves without money and without price. A similar case was tried a few years ago in Kentucky and carried to the Supreme Court which confirmed the authority of a council to pass an ordinance of this character and thus protect its citizens from quackery. It is to be hoped that Ohio will be the next State in the Union to obtain a similar decision.

A Literary Friend of the Doctors.—The versatile Eugene Field writes the following in the "Sharps and Flats" column of the *Chicago Record*:

Just at this time we are interested by the acrimony exhibited by certain medical journals over the crusade which is being prosecuted by a New York publication against the practice of vivisection. We take it for granted that *Life*, the publication referred to, is sincere in the so-called crusade which it has undertaken, and we are free to confess that we have an instinctive horror of the practices of vivisection. The folly into which *Life* has fallen is a wholesale abuse of the medical profession at large; there is equal un wisdom exhibited by the medical journalists in bristling up and scurrying to the defense of a profession that really requires no defense.

Saying sharp things is easy enough when one is indifferent to consequences; this is particularly true when the target for sarcasms is an illustrious one. For centuries the doctor has been riddled with pleasantries and sarcasms; if he had not been good and great he would not have been made a mark for brilliant savageries; if he had not been good and great he would have been swept away long ago by the flood of sharp but not always sincere criticism. Priests and physicians have from time immemorial come in for a large share of what we might call sportive hostility; the world has laughed over these jocularities, yet at the first appearance of spiritual or physical disquietude, the world has sent post haste for the priest or the doctor. This curious perversity is thoroughly understood by the doctores divinitatis and the doctores medicinæ themselves, and it was none other than Dr. Francis Rabelais who embalmed and illustrated it in the immortal couplet:

"The devil was sick, the devil a monk would be;
The devil got well—the devil a monk was he."

We have always thought that in this couplet were most cleverly illustrated the three essentials to the perfect epigram as prescribed by Martial:

"Three things must epigrams, like bees, have all;
A sting, some honey, and a body small."

It is related that Montaigne used to require of his friends that if ever he fell sick they should not send for the doctor until he got better. It was probably about the time of Molière that the story about throwing-away-the-medicine-and-getting-well originated, for when the Grand Louis asked Molière what he did for his doctor, the dramatist answered: "Sire, when I am ill I send for him. He comes; we have a chat and enjoy ourselves. He prescribes; I don't take it, and I am cured." It was probably not until after the evolution of the country editor that the world was apprised, in the very best of faith, that occasionally some people "died without medical assistance." And doubtless there are few of us who have not heard of the man who, having obtained a prescription for insomnia, administered it to his teething baby and enjoyed an unbroken night's rest. These and similar sarcasms upon the medical profession we enjoy, not because of their truth, for we know well enough that they have very little truth in them, but because perhaps, there is a teasing quality in them, and, as Victor Hugo has said, teasing is the malice of good men.

It has been our fortune—our good fortune—to have an acquaintance with many doctors, and we agree with the opinion expressed by the leviathan of English letters when he declared: "I believe every man has found in physicians great liberality and dignity of sentiment, very prompt effusion of beneficence and willingness to exert a lucrative art where there is no hope of lucre." What we particularly admire the doctor for is what he often achieves outside of his profession; the avocations of the physician are notably productive of noble results. Many of the most successful journalists in this country have been doctors; and so have been, or are, many of our most charming writers upon gen-

eral and special subjects. In this city at the present time there is a practicing physician who has made pottery a study and a practice, and he has done more, probably, than any other man toward perfecting the glaze of native pottery. Dr. Oliver Wendell Holmes has done more than simply to adorn and dignify his profession; he has adorned and dignified American literature. The first martyr to the cause of our national liberty was a doctor; the fall of Warren fanned to a blaze the fire of American patriotism. A Dr. Osborn of Massachusetts wrote years ago a whaling song that bids fair to outlive the giant mammal and its adventuresome pursuit which that song celebrated. How largely is not science indebted to Morton, DeKay and Barton, and who that has read his poems and his tales has not acknowledged the literary genius of Weir Mitchell? Akenside was a doctor; so was Cowley, so was Goldsmith; before the days when these literary physicians flourished Sir Walter Raleigh was proud of his fame as the compounder of a cordial and Sir Kenelm Digby was known afar for his recipe for a sympathetic powder which wrought wonders. We remember to have read somewhere that Marat was a doctor, but we have never been able to confirm this story of his earlier life. Arbuthnot was certainly one of the greatest in his profession and his literary abilities and his wit were exceptionally charming. Alexander Pope acknowledged the debt he owed to this physician in ministering to his physical sufferings:

"Friend of my life, which did you not prolong,
The world had wanted many an idle song."

Again, the literary claims of the profession are to be recognized in the poems of James Rodman Drake and in the ever-popular novels of Charles Lever. It was a doctor, Les-tocq, who aided Catherine materially in her struggle for the throne; another doctor, Hamond, was master to the great Racine; Peter the Great cultivated an intimacy with Boerhaave; Hans Sloane provided the nucleus of the British museum; Madden's "Infirmities of Genius" and MacNish's "Philosophy of Drunkenness" are two books that should be in every library. Two other famous books are Dr. Middleton's "Life of Cicero" and Dr. Sir Thomas Browne's "Religio Medici." Rousseau was an invalid all his life. Says he of the physician: "Par tous les pays ce sont les hommes les plus véritablement utiles et savants." The essayist Tuckerman instances the Médecin de Campagne" of Balzac and the "Dr. Antonio" of Ruffini as elaborate and charming illustrations of the testimony given by Rousseau.

Quoth the learned Park: "I hold physicians to be the most enlightened professional persons in the whole circle of human arts and sciences."

But there! we did not intend to say so much upon this subject. The doctor requires no defense, and if he did he could defend himself. We have been led into this idle, desultory chat about him by our sincere affection for him, for we certainly share with all other good folk their admiration and love for this bright, generous, patient, self-sacrificing friend of humanity.

BOOK NOTICES.

Hare's Text-Book of Practical Therapeutics.—A Text-Book of Practical Therapeutics; With Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With special chapters by Drs. G. E. DE SCHWEINITZ, EDWARD MARTIN and BARTON C. HIRST. New (4th) edition, thoroughly revised and much enlarged. In one octavo volume of 740 pages. Cloth, \$3.75; leather, \$4.75. Philadelphia: Lea Brothers & Co. 1894.

When a book has passed to its fourth edition it has passed the point when the written word of the reviewer can help or materially harm. This edition has been largely rewritten, and accounts of several new remedies added.

"Articles on Methylene Blue, Chloralose, Pyrogallol, Condrango, Convallaria, Duboisine and other remedies have been added to the part of the work dealing with drugs. In the part dealing with remedial measures other than drugs, articles have been written on Hypodermoclysis and Enteroclysis, Lavage, and upon Mineral Springs and Climatic Treatment."

In order to conform to the new Pharmacopœia the doses

of drugs are given in the metric system, and for those unfamiliar with that system the old dosage has been also retained. A posologic table has been added in both the old English system and the metric.

We are pleased to note that Dr. Hare has, in this edition, given especial prominence to American climatic health resorts, and although very brief it is a good beginning.

Chemistry: General, Medical and Pharmaceutical, including the Chemistry of the U. S. Pharmacopœia. A Manual on the General Principles of the Science and their Applications in Medicine and Pharmacy. By JOHN ATTFIELD, F. R. S., etc. Cl., pp. 794. Fourteenth edition. Philadelphia: Lea Brothers & Co. 1894.

Attfield's Chemistry in its latest dress, is again upon our table, and it is like looking on the familiar face of an old friend. The changes that have been made in this edition are such as are necessary for the demonstration of the latest developments of chemical principles, the latest applications of chemistry to pharmacy, and to make it conform to the last revision of the U. S. Pharmacopœia. The book has always been a favorite text-book with students in medicine and pharmacy, and if the publishers keep it up to the date of each successive revision as well in the future as they have in the past, it will continue to be the favorite for very many years to come.

NECROLOGY.

RAMON TAQUIMETTO, M.D., of Brooklyn, N. Y., died August 26, at Bensonhurst-by-the-Sea, in the forty-second year of his age. He was a native of Havana, Cuba, of Spanish parentage. He had been sick for several months, having become the subject of both renal and cardiac disorders. He was a man of high intelligence and much culture.—Henry Worthington Webster, M.D., at Baltimore, Md., August 29.—J. W. Campbell, M.D., at Ottumwa, Iowa, August 26.—W. D. Chase, M.D., at Peterboro, N. H., September 2, aged 57. He represented Peterboro in the New Hampshire Legislature in 1889.—Hilborn T. Cresson, M.D., of Philadelphia, at New York City, September 6.—Henry James Brown, M.D., at Detroit, Mich., September 6, aged 81.—A dispatch from Tiffin, Ohio, September 8, says: The body of Dr. William B. Seymour, the Tiffin physician who left here last Christmas and whose disappearance from New Market, Va., was noted last June, has been found in the mountains four miles from New Market with both arms broken. The indications are that the old man, who was in his 85th year, had fallen over a ledge and afterward starved to death. Dr. Seymour had no relatives here, and was supposed to have been quite wealthy.—C. E. Wasson, M.D., at Spruce Creek, Pa., September 7.—S. B. Merrill, M.D., at Chicago, September 11.

ASSOCIATION NOTES.

The Journal and Abbreviations.—Abbreviations are things we do not like, as previously announced in these columns. But our exchanges do not all agree with us, and a few still insist in crediting extracts to the "*Jour. Am. Med. Ass.*" As the *Journal* has but one resemblance to the long-eared animal, in that its voice is heard for a very long distance, we can see neither propriety or sense in continuing such reference. As there is but one *Medical Record*, and as there is but one *Medical News*, so there is but one *Journal*. It is *The Journal* of the great medical profession of this country. We do not speak of the *Medical Record* as the *Medical Record* published by Wm. Wood & Co., and edited by Dr. Geo. F. Shrady. We simply say the *Medical Record*, and that is all. Therefore, let us speak of *The Journal*, and drop all superfluities.—*National Medical Review*.

SOCIETY NEWS.

Seventeenth Annual Re-union of Pennsylvania and Maryland Physicians.—The physicians of the Counties of York, Lancaster, Cumberland, Dauphin, Lebanon and Berks, Pennsylvania, and Cecil and Harford Counties, Maryland, held their seventeenth annual re-union at Chickies Park near Columbia, Pa., on Thursday. About one hundred and fifty physicians with their families and friends were in attendance and spent a most delightful day. The heavy smoke filling the atmosphere prevented a full enjoyment of the magnificent scenery from the celebrated Chickies Rock, but otherwise the day was greatly enjoyed.

At 12:30 o'clock the party was brought to Columbia on special electric cars and taken to St. Paul's Protestant Episcopal Church. They then adjourned to the parish building in the rear, where they partook of a dinner, which was served them by the ladies of the church.

After dinner the members with their families and friends boarded the special and returned to Chickies Park, where the business meeting and election of officers of the Society was held, presided over by President Frey, of York.

Following are the present officers of the Association:

President—Dr. Levi Frey, York.

First Vice-President—Dr. George R. Welchans, Lancaster.

Second Vice-President—Dr. J. W. Trabert, Annville.

Secretary—Dr. Roland Jessop, York.

Treasurer—Dr. George M. Stump, Perryville.

Executive Committee—Dr. Alex. Craig, Columbia, Chairman; Dr. George W. Gillespie, Oxford; Dr. A. C. Wentz, Hanover; Dr. R. A. Bromwell, Port Deposit; Dr. T. R. Bucher, Lebanon; Dr. W. Murray Weidman, Reading; Dr. H. A. Hare, Philadelphia.

Following is a list of physicians in attendance, each one being accompanied by one or more persons:

Drs. Bacon, York; Mowery, Letort; Morris, Baltimore; Wentz, New Providence; Foster, Pittsburg; Gillespie, Oxford; Ritchie, Harrisburg; Welchans, Lancaster; Musser, Lampeter; Gable, York; Berntheizel, Columbia; Trabert, Annville; Bromwell, Port Deposit; Small, York; Daxe, Rising Sun; Potteiger, Harrisburg; Shellenberger, Philadelphia; Gillespie, Pleasant Grove; Ulrich, Chester; Alexander, Marietta; Livingston, Columbia; Deisinger, Hellam; Middleton, Steelton; Weidman, Reading; Miller, Bird-in-Hand; Seitz, Harrisburg; Quickel, Manchester; Spangler, York; Rohrer, Lancaster; Lehman, Mountville; Frey, York; Wentz, Hanover; Black, Strasburg; Cleaver, Reading; Leaman, Leaman Place; Mowery, Marietta; Netcher, Lancaster; Carfield, Baltimore; Stover, Chester; Bucher, Lebanon; Marshall, Shippensburg; Morton, Philadelphia; Landis, Reading; Jamar, Elkton; Reynolds, Baltimore; Yost, Bethesda; Guilford, Lebanon; Harter, Maytown; Zeigler, Mt. Joy; Warrell, Elkton; Davis, Lancaster; Simmons, Baltimore; Kirk, Oxford; Craig, Markel, Backius and Lineaweaver, of Columbia.

PUBLIC HEALTH.

Typhus Fever in Paris.—From January 1 to July 4 of this year, forty-seven cases of typhus fever were recorded in Paris, with twenty-two deaths. In June there were twenty cases and nine deaths and in the first four days of July, six cases and four deaths. This increase led the Advisory Committee on Public Hygiene of France, to issue a circular requesting the authorities of Paris to take steps toward disinfecting in the most thorough manner those "shelters for the night" established by private munificence.

Disinfection by Ammonia Vapors.—Dr. von Rigler, of the Hygienic Institute of Buda-Pesth, proposes (*Concours Médical*) a new method of disinfection. He suspended threads impregnated with microbial cultures in a room 100 cubic meters in size, 1000 grams of ammonia being placed in numerous flat dishes on the floor. At the end of one hour 100 grams of the ammonia had evaporated; in two hours, 250 grams; in four hours, 350; at the end of eight hours 450. The bacilli of cholera and of typhoid fever were killed after two hours; of anthrax, with or without spores, after three hours; the Löffler bacillus only after eight hours. This

method is cheap and has the added advantage of not being injurious to furniture, drapery, hangings, etc. It is to be hoped that the results of these experiments may be corroborated; effective disinfection by ammonia vapors would remove many existing difficulties in the way of quarantine practice.

Ammunition of the Anti-Vaccinist.—In a circular recently issued by the London (Eng.) Society for the Abolition of Compulsory Vaccination, it is asserted that the death rates in the smallpox outbreak in Leicester in 1892-93 were as follows: "Death rate from smallpox of the re-vaccinated, 270 per million living; of the vaccinated, 159; of the non-vaccinated, 109 only." These figures are made the basis for the usual argument against vaccination and it may be expected that they will shortly be reproduced by the anti-vaccinist on this side of the Atlantic. That they are absolutely false will not prevent their citation by the propagandist of free smallpox nor their unhesitating acceptance by his dupes. Nevertheless it may be worth while to say that there was no death of a re-vaccinated smallpox patient in Leicester and that the actual death rate of the three classes of the population of that city, during the outbreak of 1892-93, were as follows:

| | |
|--------------------------|------------------|
| Re-vaccinated | 0.0 per million. |
| Vaccinated | 5.4 " " |
| Non-vaccinated | 102.7 " " |

The circular and its unblushing mis-statements are fair specimens of the ammunition furnished to the "anti's" for their warfare upon vaccination.

Typhoid in Buffalo.—The recrudescence of typhoid fever in Buffalo is attributed by Health Commissioner Wende to the use of water from the 400 old wells remaining in the city, many of which are found on examination to contain the typhoid bacillus. The people persist in the use of these wells because they say: "The water was good enough for our fathers and our grandfathers, and it's good enough for us." Dr. Wende anticipates trouble in securing the abandonment of these polluted wells and fears a renewal this fall of the epidemic of last spring.

Sanatorium for Tuberculosis.—The Municipal Council of Paris has decided to establish a sanatorium for consumptives in one of the suburbs, a few miles from the city. The report of M. Paul Strauss, (*Gaz. Méd. de Paris*) which led to this action, gives the following reasons for its establishment: The first advantage which will be gained is the cleaning out of the general hospitals, which are too often occupied by the chronic consumptives at the expense of the acute; this alone would not justify special hospitals, but, unhappily, the great number of consumptives do not gain access to hospitals—they are habitually refused, and if they are received in the wards they do not receive the particular care they need, and there is risk of transmitting the germs of their disease to the other occupants of the wards. General hospitals are not adapted to the treatment of this class of cases, which are of long duration; they are not built or situated for that purpose; the unfortunate patients have not the privilege of wintering in a suitable climate; distress weakens their chances of survival and the disease has, so to speak, a clean field. Such noted authorities as Bouchard, Cornil, Brown-Séquard, Grancher, Jaccoud, Peter and others have proven beyond a doubt the curability of tuberculosis and the efficacy of its hygienic treatment. The experience of the sanatoria of Falkenstein, Gorbisdop and Hohenhonnef shows the value of the results obtained by permanent aeration, forced alimentation and hydrotherapy. In ten years the sanatorium at Falkenstein has a record of 24.2 cures per 100, and Dr. Neisser at Hohenhonnef shows 27 per cent. of cures.

Epidemic Diseases.—Asiatic cholera continues to spread in Europe, especially in Russia and in the provinces of East and West Prussia. During the week ended September 11 there were reported 6,376 new cases and 4,192 deaths in all Russia; the disease is most virulent in Radom where there were 1,238 new cases and 617 deaths; in Kielce there were 1,138 new cases and 565 deaths, and in Warsaw 1,100 new cases and 532 deaths. The disease has also appeared at Riga, a fact which derives importance from the extensive communication of the port both by water and rail. For this season, however, the disease is fast losing interest so far as this country is concerned. The suspicious death of a Bavarian immigrant at Cumberland, Md., on the 5th inst., hardly caused a ripple of excitement; a bacteriologic examination by Passed Assistant Surgeon Geddings, M. H. S., showed that death was due to ptomaine poison from improperly cooked food. Suspicious sickness on the *Werra*, from Genoa at New York, September 10, also proved to be non-contagious.—Some alarm was occasioned at Baltimore on the arrival of a British steamer from Havana on the 8th inst., with alleged cases of yellow fever on board, supplemented by the arrival on the following day of an American bark, infected with the disease, at the Cape Charles (Va.) quarantine station. The season is too far advanced to make any extension of the disease probable.—The prolonged drought has caused an increase of typhoid fever in many localities, owing to the increased density of pollution of water courses and the resort to old disused wells as a source of supply. The Passaic River at Jersey City is so low that the pollution from the cities of Newark, Paterson, Passaic, the Oranges and other towns, and from the many factories, dye houses, gas works, slaughter houses, sewers, etc., that drain into it, has made it wholly unfit for drinking purposes. The nuisance has become so intolerable and the menace to public health so great that it will probably compel the city government to provide a new and more wholesome water supply.—Smallpox threatens more seriously than any other of the epidemic contagious diseases. Correspondence of health authorities with the *JOURNAL* indicates considerable apprehension for the coming winter on this account. During August there were 117 cases of the disease in Chicago; the situation in Milwaukee can hardly be said to have improved recently; an increase is reported in New York; Indianapolis is threatened with a general outbreak through a mistaken diagnosis, and at Walkerton, Ind., several well-developed cases have appeared as the result of the deaths of the wife and mother of a local physician from a disease, which is now pronounced to have been smallpox. Health officers in other localities are also in a state of mind over the situation, similar to that of "Hosea Biglow's" during the war—

"all one teeter, hopin', dreadin'."

Extension of Glanders due to Public Water. The Brooklyn Board of Health issues a Circular of Information.—Not only in Brooklyn, but in several of our Eastern cities, there has been a recrudescence of glanders and farcy. The sanitary authorities of the former city seek to bring about a diminution of the disease by enforcing a full reporting of cases by veterinarians and others, and also by causing the non-use of public watering troughs that are possibly infective. The following are selections from an article that has recently appeared in a Brooklyn daily journal:

"The Department of Health is measurably responsible in the matter of checking the progress of contagious disease among animals. For this reason it is one of the requirements of the city ordinances that the Department shall be notified of all cases of glanders or farcy. Section 31 of the Sanitary Code, is as follows:

SECTION 31.—That no cattle shall be killed for human food while in an overheated, feverish or diseased condition; and all such diseased cattle in the city of Brooklyn and the place where found, and their disease shall at once be reported to the Department of Health by the owner or custodian thereof, and it shall be the duty of every veterinary surgeon, owner or person having the charge, care or custody of any horse, ass, mule, colt, ox, milch cow, calf, sheep, or

goat, or any other animal affected with glanders or farcy, pleuro-pneumonia, tuberculosis or other disease infectious, contagious or pestilential, among such animals, to report the same to the Department of Health within twenty-four hours of their knowledge of such disease, stating where located.

"The early coöperation of all veterinarians will have the effect of restricting the progress of the disease.

"Furthermore, doubtful or suspicious cases may be reported and the assistance of the Department in this way be obtained as to diagnosis and sanitary precautions; and 'mallein,' a new substance prepared at the Bureau of Animal Industry, Washington, D. C., is at command of the Inspector of the Department for the settlement of suspicious cases at an earlier stage of the disease than can be otherwise reached.

"This is the circular of information to the owners of horses:

"Notice is hereby given that glanders is a disease among horses manifesting considerable prevalence at the present time, and that no little loss has lately been experienced by those so unfortunate as to have animals affected by this disease. It is the belief of the veterinary inspectors of this and other Departments of Health that the disease is spread among horses by means of the public watering troughs situated on many of the public thoroughfares. It is expedient therefore, that all persons owning horses and all drivers of teams should be cautioned against this danger from watering their horses at these public troughs. All drivers who are compelled to remain away from their private sources of water supply for any considerable period of time are advised that a safe course for them to pursue will be to provide a pail which can be carried in the truck or vehicle, or hooked under the wagon body. Into such a pail running water can be given, freshly drawn and clean, whenever the animals are in need of water.

"All veterinarians and horse-owners are required by Section 31 of the Sanitary Code to report to this Department all cases of glanders. Any person having a horse or other animal suspected of being affected by an infectious disease may, on application at this Department, have the services of our Veterinary Inspector for the purpose of promptly determining the diagnosis."

MISCELLANY.

Physicians' Protective Association.—The first annual meeting of the Physicians' Protective Association of Detroit, was held September 4. Reports of officers showed a prosperous year, \$9,916 in outstanding accounts having been collected. Officers for the ensuing year were elected as follows: President, L. J. Lennox; Vice-President, Dr. R. H. Stevens; Secretary, Dr. P. M. Hickey; Treasurer, Dr. S. H. Knight.

International Congress of Gynecology and Obstetrics.—At the second session of this Congress, to be held at Geneva this month, the following topics will be discussed: The treatment of eclampsia; the surgical treatment of retro-deviations; the relative frequency of the various pelvic contractions in different races; the best method of suturing the abdominal wall to prevent ventral hernia; treatment of pelvic suppurations.

Mysterious Disappearance.—Cassopolis, Mich., has had a sensation similar to that caused in Chicago a few years ago by the murder of Dr. Cronin, in the disappearance of Dr. A. B. Conklin. He was to have been a witness in an insurance case trial at Traverse City, Mich. He is believed to have been abducted and perhaps murdered. The abduction occurred September 4. A reward of \$2,000 has been offered for his body.

Quills from the Fretful Porcupine.—Dr. Gagen, of Heppner, while out gunning last Sunday, shot and fatally wounded what he supposed to be a badger. Fearing that the animal would get away from him, he ran and seized it with both hands,

but immediately let go again. It proved to be a porcupine instead of a badger. It took him about two hours to pick the quills out of his hands and arms.—*Ellensburgh* (Wash.) *Localizer*, September 1.

Medical College Opening.—The College of Physicians and Surgeons of Chicago held its opening exercises September 5. There were 200 matriculates in attendance. The introductory was given by Dr. W. S. Christopher.

Doctors' and Lawyers' Fees Again.—In Brussels, during 1893, twenty-one medical men received 8,745 francs for services rendered to the *personnel* of the railway, postoffice, telegraph and telephone departments of the government. For services rendered to the railways alone, *three* lawyers received 18,000 francs.

Medical Journalism in Russia.—There are, according to the *Journal de Médecine de Paris*, thirty-eight medical journals in Russia at the present time. Of these twenty are published in St. Petersburg, five in Moscow, four in Warsaw, two in Odessa, two in Charkov, and one each in Kasan, Kieff, Saratov, Varsovege and Poltova. The oldest journals are the *Medizinskoie Obozrenie* (Review of Medicine), twenty-first year; the *Rousskaia Medizina* (Russian Medicine), nineteenth year; and *Wratch* (The Doctor), fifteenth year.

An Electric Ambulance.—An ambulance, moved by electricity on the street-car lines of St. Louis, made its first trip in that city recently. The experiment was so successful that it is proposed to place these ambulances on every car line in the city to make trips at stated intervals. It is anticipated that when the plan is perfected, patients can be removed to the City Hospital from any part of the city in less than an hour, and that the service will save thousands of dollars annually as compared with the present ambulance service.

Distribution of the Sexes.—In the population of the whole earth the number of females is very nearly equal to that of the males; but, according to the *Journal de Médecine de Paris*, there are marked variations in different countries. Of all the countries on the globe, France is the one where the sexes are most nearly equal, there being 1,007 females to 1,000 males. For the same number of defenders of their country we find 1,064 females in Sweden and only 933 in Greece. In the French island of Réunion 547 Creoles or brown mulatresses can choose between 1,000 Frenchmen—including those with black skins. In Hong Kong for every 1,000 males there are but 366 females.

Oldest Physician in the Country.—Since the recent death of Dr. James Kitchen, of Philadelphia, Dr. Hiram Corson, of Montgomery County, Pennsylvania, is declared by Philadelphia papers to be the oldest physician in the United States who has been in continuous practice. He will be 90 years old next October, and has been in active practice since 1827. He is still in excellent health, with astonishing preservation of his physical and mental powers. Dr. Corson is now writing his personal recollections of the anti-slavery movement, in which he took an active part, having assisted many a fugitive slave to escape by the "underground railroad." He has frequently contributed to the *JOURNAL* and we hope soon to have an article from him.

Fighting the Diploma Trade.—Dr. C. T. Metcalf, Secretary of the Indiana State Board of Health, has instructed the county boards of health to notify clerks of court to refuse licenses on the diplomas of the "Marion Physico-Medical School of Indiana and Marion." This institution does not appear in the list of existing medical schools in the Illinois Report on Medical Education—either among the "reputable" or "fraudulent" institutions—and it is alleged that it grants degrees after three weeks' study and issues diplomas for the sum of

\$25 each. Application has been made in the Delaware County (Ind.) Circuit Court by the holder of one of these diplomas for a mandamus to compel the clerk to issue a license thereon. The Indiana State Board will resist the application on behalf of the clerk.

Illness of Prominent Persons.—Professor Aoyama, who, with Professor Kitasato, was dispatched by the Imperial Japanese Government to Hong Kong to study the plague, has had a serious attack of the malady, from which, although reported on the 1st inst. to be convalescent, he is suffering pyemic complications. Dr. Aoyama was making a special study of the pathological and clinical features of the disease while Kitasato is investigating its bacteriologic character.—Robert Koch is suffering from the effects of overwork and has had to resort to the famous water cure at Woerishofen of Father Kneipp, the Bavarian priest and preacher of hydrotherapathy. On a recent visit to Rome, it is said, that this advocate of the "wet pack" and the douche was consulted by Leo XIII. for the relief of certain ailments, due to advanced age, from which his Holiness is suffering. The Pope was advised to apply cold compresses to his knees and to the back of his neck, and did so with rather disastrous results. He caught quite a severe cold, and both knees became so swollen that he was forced to call upon his own physician to combat the consequences of the experiment.—It is recalled that the diagnosis of the case of the Comte de Paris, who died last week of cancer of the stomach, was made by the electric illumination of that organ, by means of which, we are told by a European correspondent, the operator was "able to detect through the skin an incipient cancer or ulcer on the left wall of the organ. The doctors then discussed the desperate expedient of the excision of the entire stomach and the substitution of the same organ from a lamb, an operation which has been successful in one case in French surgery. The risk was deemed too great, and the patient was not informed of the real nature of the disease until recently." The Marquise de Fontenoy says (*Chicago Record*): "It is curious how prevalent this particular affliction has been among the members of those houses that have reigned over France," and cites the late Comte de Chambord, the first Emperor Napoleon, his nephew "Plon-Plon," the late Prince Jerome, as well as his brother, King Louis of Holland, as victims of the malady. King Louis XVIII. was carried off by the same insidious disease, while his successor, King Charles X., although he fell a prey to cholera, was found after death in exile at Coeritz to be similarly afflicted. Louis XII., Louis XIII. and Louis XIV., as well as Francis I., also succumbed to abdominal troubles of a cancerous sort.—A Berlin dispatch of the 1st inst. says that it is reported there that the Czar Alexander, was recently examined by Professor Sacharin, the specialist, who discovered a renal calculus as the cause of the sufferings which have previously been attributed to the sequelæ of influenza.—Queen Victoria suffers so much from rheumatism, confined almost exclusively to the knees, that she has abandoned her proposed trip to Italy, and will go instead to Aix les Bains or Wiesbaden for a course of the waters and to undergo massage. The Princess of Wales is a victim of the same painful malady. The Crown Princess Victoria is dying from consumption.—The *Medical Record* of September 8, mentions that the Shah of Persia is troubled with his eyes and is in poor general health; that Signor Crispi, the Prime Minister of Italy, is slowly recovering from injuries received in a fall; that the Queen of Italy is suffering from nervous shock occasioned by the sudden death of one of her attendants in her presence; that the wife of Prince Bismarck is ill, and it is feared that should she not recover the Prince himself will break down entirely; that Mr. Gladstone was recently operated on for cataract; that the young King of Spain is very delicate, though no definite disease has yet declared itself; and that President Cleveland is reported to be suffering from malaria and the effects of overwork.—Finally, to round out the week's budget of this sort of news, the *Pall Mall Gazette* publishes a long letter from Bangkok, in which are explained the recent rumors that the King of Siam was dead. It appears that he is a victim of the chloral habit, and his illness, from which there is little prospect of recovery, is the result of the use of the drug for many years.

Washington Notes.

PUMP INSPECTION.—Four pumps have been condemned during the past week and ordered closed.

RULES FOR DISINTERING BODIES.—Regulations have been prescribed by the Commissioners, governing the disinterment and transfer of bodies from Graceland Cemetery, as provided by an act passed at the last session of Congress. Written application must be made to the Health Officer, bearing the signature of the secretary of the cemetery association, giving name, age, date, and cause of death. No disinterment will be permitted during the months of June, July, August and September, and no body of a person under 12 years of age may be disinterred within a year from date of burial.

Upon disinterment, all articles of any description found in the grave, together with the remains of the coffin or casket, must be inclosed in an air-tight box and transferred at once to the place of re-interment, and re-interment must take place within twenty-four hours from the time the remains were exhumed. Bodies of persons who die of diphtheria must be saturated with a solution of chlorid of lime before removal, and the grave must remain open for a period of twenty-four hours.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ending September 1, shows: Number of deaths, 86; white, 55; colored, 31. Death rate per 1,000 per annum: white, 14.66; colored, 17.9. Total population, 15,69. Thirty-two were under 5 years of age, 17 were under 1 year old and 15 over 60 years. Eighteen of the deaths occurred in hospitals and public institutions. The deaths by classes were as follows: Zymotic, 25; constitutional, 11; local, 41; developmental, 6, violence, 3. The principal causes of death were: Croup, 1; diphtheria, 1; consumption, 5; diarrheal, 9; erysipelas, 1; typhoid fever, 7; malarial, 1; scarlet fever, 1; pneumonia, 2; congestion of the lungs, 1; whooping cough, 2; kidney disease, 9; cancer, 1. Births reported: 25 white males, 24 white females, 19 colored males, 20 colored females. Marriages reported: 4 white, 5 colored.

As favorable as was the last health report there was a still further improvement in the mortality of the city during the past week. There was but one death from scarlet fever and one from diphtheria reported. While the total mortality during the last week was 86, there were 116 deaths in the corresponding period of last year and 110 in the year preceding that.

Hospital Notes.

THE CORNER STONE of the Julia F. Burnham Hospital at Champaign, Ill., was laid with appropriate ceremonies August 23.—Dr. Gillies, of Winnipeg, has been appointed Medical Health Officer of the Brandon Insane Asylum, to take effect Jan. 1, 1895.—The New Emergency Hospital at Milwaukee has just been completed at a cost to the city of \$60,000. Drs. Frank, French, Farnham, Brown, Wahl, O'Brien, McDill, and Wingate constituted the original Board of Trustees.—The Sioux Falls, (S. D.) Hospital will be opened soon. Drs. H. Hoide and Arne Zetlitz are the chief promoters of the enterprise.—St. Mary's Church at Omro, Wis., is to build a cottage hospital to cost \$15,000.—The will of J. V. de Lavaga, of San Francisco, provides for the erection of a hospital for the deaf, dumb and blind to be located at Santa Cruz, Cal., and to cost almost \$1,000,000.—The Jefferson College Hospital of Philadelphia, has undergone extensive alterations and repairs, under the personal superintendency of Dr. E. E. Montgomery.—The Cincinnati City Hospital is to have improvements in lighting and ventilation at a cost of \$8,427.—A hospital for epileptics is to be built at Rochester, Pa., after the Bielenfeld plan, as a memorial to the late Dr. W. A. Passavant.—The physicians of Oshkosh, Wis., held a meeting August 28, and adopted the following: We the undersigned, at a meeting held at the Athearn Hotel Aug. 28, 1894, to consider the matter of establishing a hospital in the city of Oshkosh for the general good of the city, do hereby agree to do all in our power, financially and by personal efforts, to aid in the establishment and maintenance of such enterprise. (Signed) T. P. Russell, B. C. Gudden, G. M. Steele, W. A. Gordon, J. C. Noyes, L. P. Allen, Fred W. A. Brown, S. Buck Ackley, Burton Clark, W. Treptow, H. B. Dale, Willard H. Titus, A. Roos, Harvey Dale, D. W. Harrington, S. T. Lewis, E. M. Wilson.

MANAGING A FLOATING HOSPITAL.—The *Springfield Republican* (Mass.), says: "The floating hospital which has made five trips down Boston harbor this season, carrying 1,100 children, is a charitable enterprise paying quick and large returns to those who have made its ministrations possible. When the passengers arrive, gathered from the north, south and west ends of the city, they are met at the gang plank by two doctors, two assistant superintendents and a policeman. The physicians inspect the children to see that none with contagious diseases are taken on, and they also examine the packages carried by the mothers to confiscate green fruit, sausages, bananas, cold potatoes, salt pork, beer, brandy and whisky, all of which are found and thrown overboard. Then something better is provided for the babies. As soon as the boat starts the upper and lower decks are divided into wards, with a doctor and a nurse for each. The patients are then examined, and the most serious cases sent below for special treatment. The diet and medicines necessary for each child are prescribed, no charge being made if the home diet is correct, and each mother is given a ticket which is punched when she receives the first meal for the baby, and taken up at the second feeding, at 3 o'clock. The doctor and nurse are responsible for the ward under their direction.

In the meantime, preparations are made for lunch, and when the boat anchors off Hull, at noon, the food placed in neat boxes, is carried to the decks in baskets and served to the mothers, with tea, coffee or milk, tickets for these having been distributed just before the lunch time. In this way the rush is avoided, and all attention is given to the mothers. At intervals throughout the day pitchers of milk are distributed to the larger children and the mothers who wish it. The milk is sterilized in the bottles, thirty-five being prepared at once and then a spoonful of lime-water is added to each bottle before the milk is given to the little ones. On the five trips made 650 mothers were carried with the 1,100 children."

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Sept. 1, 1894, to Sept. 7, 1894.

Major W. H. GARDNER, Surgeon, relieved from duty at St. Paul, Minn., and ordered to Ft. Custer, Montana, for duty.

Major HENRY McELDERBY, Surgeon, relieved from duty at Omaha, Neb., and ordered to Ft. Robinson, Neb., for duty.

Major GEORGE W. ADAIR, Surgeon, relieved from duty at Ft. Robinson, Neb., and ordered to Washington Bks., D. C., for duty.

Major JOSEPH H. CORSON, Surgeon, relieved from duty at Washington Bks., D. C., and ordered to Ft. D. A. Russell, Wyo., for duty.

Major JOSEPH K. CORSON, Surgeon, is granted leave of absence for one month, to take effect when relieved from duty at Washington Barracks, D. C., with permission to apply for an extension of fifteen days.

Major WASHINGTON MATTHEWS, Surgeon, is granted leave of absence for four months on surgeon's certificate of disability.

Capt. CHARLES B. EWING, Asst. Surgeon, is granted leave of absence for one month and fifteen days, to take effect on or about Sept. 10, 1894.

First Lieut. JAMES M. KENNEDY, Asst. Surgeon, will be relieved from duty at Ft. Custer, Montana, and will report in person for duty at Camp Merritt, Montana.

Capt. JEFFERSON R. KEAN, Asst. Surgeon, is granted leave of absence for twenty days, to take effect Oct. 10, 1894.

The Journal of the American Medical Association

VOL. XXIII.

CHICAGO, SEPTEMBER 22, 1894.

No. 12

ADDRESS.

ADDRESS OF THE CHAIRMAN.

Read in the Section on Laryngology and Otology at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY E. FLETCHER INGALS, M.D.
CHICAGO.

I congratulate you upon gathering together on this occasion under such favorable auspices. Notwithstanding the deplorable circumstances which separate us from a large part of our *confrères*, your officers have secured a large number of papers for this occasion, which will be found of great interest, and which I hope will receive the thorough discussion they merit. Knowing that the meeting of the American Congress of Physicians and Surgeons in Washington would keep from us some who would like to attend, and that many of the best laryngologists and otologists in the country are, out of self-respect, absolutely precluded from membership in this ASSOCIATION by the antiquated and narrow policy which unfortunately still prevails, your officers have urged their friends to contribute to the success of this meeting by sending papers, even if they could not attend in person. We have, however, required that all such articles should be accompanied by abstracts that may be read, provided there is not sufficient time for the whole paper. When a few years ago some of us attempted to organize this Section, it was opposed strenuously by some of the members of the ASSOCIATION on the ground that there was too great a tendency to specialists in medicine, and also that the various Sections would tend to detract from the interest in the general meeting. These objections seemed well founded, but the progress of events enabled us after two or three years to overcome the opposition and the Section was organized with Dr. Wm. H. Daly, of Pittsburg, as Chairman and myself as Secretary. The following year we had about forty papers in this Section. This again brought down upon us the criticisms of some of our friends in the ASSOCIATION, but it did not dampen the ardor of those engaged in our specialty, and during the succeeding years this remained one of the strongest Sections in the ASSOCIATION, both in character of the work performed and in the number of men interested.

We must, however, regret that many of those who could furnish us results of most valuable scientific work are kept aloof by the traditional policy, which, although the best which could be devised in the bitter hostility which existed fifty years ago, has been the very means of perpetuating an absurd pathy which would have long since fallen into the shadows of oblivion, if the regular profession had not afforded its misguided adherents the constant opportunity to pose as martyrs.

This ASSOCIATION has done much for the cause of medical science in this country, but it has failed to engage the active coöperation of a large majority of the medical profession, and it has thus fallen short of accomplishing the magnificent possibilities which seem open before it.

A wide breach has occurred between this ASSOCIATION and some of our best friends in the regular profession; and this has been thoughtlessly laid largely to the men who are devoting their whole energies to some of the special departments of our art and science. This, I am entirely satisfied, is a mistaken idea. Indeed, I fully believe that the great relative falling off in the ranks of the pathists within the past few years which amounts to about 30 per cent. of the number of students graduated from the homeopathic schools, has been due to the greater wisdom coming largely from those same men, that has caused the profession to recognize honest work wherever found, and to ignore absurdities without raising them into prominence by discussion.

While fully realizing all that has been done, we can not help asking ourselves whether we are doing all that can be done to promote harmony and good will in our own ranks. The answer must be in the negative. Under the present policy of our ASSOCIATION it has been impossible to greatly increase our membership, and as a result we have to-day only about one-fourth of those who should belong to the ASSOCIATION and who, by a wise policy, might be induced to stand with us for all that the profession needs. I hope the members of this Section will by their acts refute the charge that specialists are trying to disrupt the profession, and that they will aid in every honorable way to secure the new order of things which some of us believe will make our calling more useful, which will bring our friends together with us, and which, I fully believe, would, within a quarter of a century, practically wipe out the pathies that now fret the earth.

ORIGINAL ARTICLES

ON TUBAGE AS ACCESSORY TREATMENT IN CERTAIN CASES OF SEPTAL DEFORMITY.

Read in the Section on Laryngology and Otology at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY PRICE BROWN, M.D.
TORONTO, CAN.

Deviations of the nasal septum are of such frequent occurrence among all civilized races that we need not wonder at the number and variety of methods practiced for their removal. Each method of operation is often eulogized by its advocates as superior to all others, and histories of cases are cited

as direct evidence of the truth of the statement. Still, while granting all that can be said in favor of the many ways of treatment, every operator will admit, I think, that cases sometimes occur in which mere operative measures are insufficient, unless supported by accessory treatment of a more than ordinary character. Judging from personal experience, I think this is particularly true of that class of cases, characterized by extensive adhesions between the septum and middle and inferior turbinated bones.

I do not refer to cases where synechiæ or cicatricial bands, due to inflammatory action, are stretched across the central nasal cavity binding the two sides together; but to those cases usually traumatic in their origin, in which the anterior end of the vomer, the lower part of the perpendicular plate of the ethmoid, and the triangular cartilage, unitedly forming the central portion of the septum are crowded over, and pressing directly against the turbinated have produced osseous and cartilaginous union. These are cases in which the patency of the entire nasal cavity, subsequent to operation and during the process of healing, becomes a subject of the greatest importance.

In another class of traumatic cases the injury is confined chiefly to the nasal cartilages. The vomer and the ethmoid may be unaffected; but the crushing of the external nose may be so severe that during the process of internal repair the mucous membrane is extensively destroyed—the resulting cicatrization producing almost complete stenosis.

In both classes of cases we have in tubage a most valuable aid in the way of accessory treatment; and with the hope that other rhinologists will give it a more extensive and thorough trial I append the histories of several cases, which have during the last two years fallen into my hands for treatment. I am satisfied that in these cases, had I resorted after operation simply to sprays, the use of the cotton tampon, the ordinary rubber plug, brushing and similar procedure, the results either to patients or operator would not by any means have been of so satisfactory a nature.

Case 1.—November, 1892, Miss F. McD., aged 17 years. Her father and sisters had large Roman noses, and during childhood her own is said to have been of a similar type. At the age of 10 years, she had a severe fall, lighting on the bridge of her nose and effectually depressing it. This was followed by an abscess, which discharged a great deal of pus and eventually healed. Five years later she was taken to a surgeon in Vermont to have the nose elevated. He made an incision from the left inner canthus, down the angle of the nose adjoining the cheek and across the left ala. Then dissecting the soft tissues back, he transixed the nasal bones with needles, and attempted to raise them to the normal position. The nose was returned and sutured, and the transverse needles left *in situ* for a time. Probably owing to the length of time which had elapsed between the periods of injury and surgical treatment, the result was not very satisfactory. The cicatrix had almost disappeared, but the bridge was only slightly raised.

When she came to me two years later it was largely on account of nasal stenosis. On examination I found the cartilaginous septum crushed down and completely distorted. Its position instead of being vertical had become irregularly diagonal. On the right side there was still sufficient mucous membrane to make a fairly free passage after sawing off the projecting cartilage. But on the left, which contained the bulk of the septum, there was almost complete stenosis. The cicatrization had destroyed the mucous membrane to such a degree, that a cocaineized cotton probe could only be passed through the center of the choana, and that with difficulty. Posterior to the stricture, the lumen did not seem to be defective.

Retaining that portion of the septum which still acted as support to the depressed bridge, and preserving what little mucous membrane remained, I cut out the balance of the cartilage with saw and bistoury; as it was the cause of part of the obstruction, and was too unshapely to be utilized. On its removal, however, the soft alar tissue collapsed, closing in some measure the space produced by the operation. This difficulty was met for a time by the use of a hard rub-

RHINAL TUBES.—Anterior ends of tubes to right; posterior to left B is vertex of a, d is vertex of c.

ber plug; but whenever it was removed the choana would at once collapse. Dr. Grant's vulcanite tubes would probably have suited this case. Unfortunately I did not possess them; and so as a last resort, had a silver one made of a shape to suit the nares. It was narrower in the center than at either end, to secure it in position after insertion. During the time that the young lady remained in the city for treatment, I had the tube modified in form so as more

accurately to fit the passage; and for cleaning purposes instructed her how to remove and return the tube at regular intervals.

In March last after an interval of more than a year, the patient's father called upon me to report progress. He said that for several months his daughter continuously wore the tube I provided. But as it became loose, she took it to a jeweler and had another made after the same pattern. This she was now wearing. The choana was becoming more open, but she still required assistance in nasal respiration; and before having any further alterations made in the tube he would bring her in for examination. This, however, up to the present he has not found necessary.

Case 2.—February, 1893. Mr. N. McM., machinist, age 38. Mr. McM. has had chronic nasal and throat catarrh for years. He dates his trouble to a blow, breaking and deflecting the nose to one side, which he received in boyhood. The right nasal cavity was unusually wide, the septal cartilage presenting a deep concavity. The left naris was tolerably clear in upper portion, but not enough so to allow of respiration, except when the walls were held ajar; while the lower half of the front portion of the nasal cavity was obliterated by cicatrization. It was evident that it would be impossible to afford relief to respiration, without removing a portion at least of the dense cicatrix; the cicatrix removed, would be followed by another, unless a suitable instrument could be adjusted to the part and worn continuously for a long time. My first operation in this case was the reverse of successful. I excised sufficient of the dense fibrous tissue to make a free nasal opening, and adjusted an improvised silver tube. For a time it worked well, and the patient attended to it regularly and efficiently. By-and-bye he disappeared and I saw nothing more of him for a number of months. When he came back in December he said he had spent the summer and fall in Winnipeg. The tube after a time had been troublesome to insert, and for two months he had not tried to put it in. On examination I found that the whole wound had filled up again with cicatricial tissue. On consideration, I concluded to operate again the second time in a somewhat different manner. Instead of excising down to the floor of the inferior meatus, and making a wound so extensive as to prohibit the possibility of extension of mucous membrane over its surface, I excised only the upper part of the cicatrix, with the hope that the healthy mucous membrane of the superior meatus would have sufficient vital power to gradually cover the raw surface of the middle region.

After the operation, I inserted a part of a gum elastic catheter until I could get a suitable tube made. I had this variously modified until it assumed the shape of the accompanying Fig. 2, a and b. Through it the patient breathes more freely than he has done for years. He takes it out, regularly cleans it, and returns it. The concave side is the lower one. The bulge on the tube was placed to insure retention and at the same time to give width to the passage; while it presses towards the concavity mentioned as existing on the right side of the septal cartilage. The hope is that by wearing this or a similar tube for a year or two, the passage will become so open and the parts so endowed with new mucous membrane, that the patient will be able to breathe normally without any artificial assistance whatever. His throat catarrh has already disappeared.

Case 3.—August, 1893. Mr. T., medical student, age 21 years. Had originally a Roman nose. Ten years ago it was broken and depressed by a blow from a cricket bat; now it is straight with thickened bridge. Nasal breathing difficult, chiefly on left side; nasal tone of voice; catarrhal throat attended by constant hoarseness. Upper septum on left side, except at the summit, has united with external wall of the nasal cavity and is solidified. Lower portion has been broken and protrudes as a sharp upright spur—the two filling up the lumen and almost occluding it. Under cocaine, I sawed out the spur, and removed a segment of the septum, cutting both sides of it, up to the free mucous membrane of the superior meatus. The parts were kept open by use of albolene tampons replaced daily. During this period several projecting nodules were touched by galvano-cautery or removed by chisel. After the first few days I substituted silver tubes in place of the tampons. They served a good purpose, but when in Washington in September, I succeeded in securing one at the surgical instrument exhibit of the Pan-American Medical Congress, which was much better suited to the case. I regret that I could not obtain the name of the originator. The photograph, Fig. 3, exact sign is here given. It was worn daily by the gentleman for several weeks. Then for a few hours only at regular intervals. Subsequently the intervals became

longer, and when I last saw him, he had finally laid it aside—considering its further use unnecessary. His respiration was unobstructed while the throat catarrh, hoarseness, and nasal intonation had all been relieved.

Case 4.—February, 1894, Mr. P. B., age 18 years, was brought to me by his father, a leading physician of London, Ontario. He had a large prominent nose—the whole organ being turned somewhat toward the left side. The left nostril was freely open and the transverse diameter, opposite the central portions of the middle and inferior turbinateds, exceedingly wide. The right side of the columnar and triangular cartilages filled up the anterior naris, and pressed against the right ala. On separating the sides of the choana a probe could be passed easily along the floor of the inferior meatus; and also, when curved, from the front to the back of the superior meatus. The whole central part of the passage was, however, completely solidified by cartilaginous and bony union between the septum and the middle and inferior turbinated bones, for a horizontal length of about an inch, and height of half an inch. The naso-pharynx was covered by thick, tenacious, ropy mucus, which was very difficult to remove. The youth was pallid in color, and had been troubled with a harassing bronchial cough all winter. The only possible cause that could be assigned for the deformity was a severe blow from some hard substance, which he remembered to have received on the left side of his nose, a number of years earlier.

Dr. B., the patient's father, was under the impression that the best relief that could be obtained was by septal perforation. It is needless to say, however, that with such extensive adhesions, such an operation, to say the least, would be impracticable. After thorough examination it seemed to be a case in which, owing to the youth of the patient, advantage might be taken of the comparatively soft condition of the vomer and plate of the ethmoid; and hence, admirably suited for treatment by tubage after operation.

Under 15 per cent. solution of cocaine, I sawed out as wide a section of the triangular cartilage as I could without producing perforation. Then with a thick saw cut through the bony adhesions between the septum and turbinateds, completely severing them. After hemorrhage had abated, I applied cocaine again, and forced into the chink a flattened, thin, but somewhat wide silver tube. For the first twenty-four hours there was a good deal of maxillary neuralgia, but the tube retained its position. The second day it commenced to loosen and slip forward. Another tube was made somewhat larger, with a bulge on its outer surface, near the posterior end, to help to retain it in place. Before its insertion, a portion of the lower part of the middle turbinated had to be removed by galvano-cautery, as it threatened to fill up the passage. The lumen of the tube was narrow, not sufficient for full respiratory purposes. Still albolene could easily be forced through it by atomizer, and also along its superior and inferior sides. After remaining under treatment for several days, the patient went home with instructions to remove the tube for cleansing purposes, as often as required.

Three weeks later he came back for further treatment. For the last few days he had been unable to get the tube fully back into position. On examination I found some parts of the cut surfaces healing satisfactorily, and being gradually covered with mucous membrane. Some granulation tissue in the center required removal, but the general lumen was all that could be desired, and breathing through the nostril when the tube was out was easy. I had the same tube lengthened somewhat, its lumen slightly increased and the bulge for retention made a little larger. After removing the granulations it was again placed in position. It is represented in Fig. 4, c and d. When Mr. B. returned home I expected that in a few weeks he would be able to dispense with its use, and breathe almost if not entirely as well through the restored nostril as through the other.

April 27. I have again had a visit from Mr. B. There has been continuous improvement, free respiration, and cessation from suffering; but as healing is not yet perfect he will continue to use the tube at stated intervals for some weeks to come.

Besides these, there are a number of other cases, in which during the early periods of treatment I have used silver tubes to advantage; but as they

¹ I do not think the perforations are of any advantage, and they might possibly produce sepsis.

² Subsequent note: August, Mr. B. has not required to use the tube for the last two months. Healing and respiration are now normal, and the throat catarrh has ceased.

bore no distinctive marks they are only worthy of a passing notice.

On looking over my case-book of private practice, for the year and a half covered by the history of the cases mentioned, I find a record of forty cases of deviation of nasal septum, sufficiently severe in character to require operation. Hence the number of cases requiring tubal treatment has been limited to 10 per cent.

In conclusion, I would like briefly to emphasize two points: 1, that our cases of septal deformity, whatever their origin, should not be treated according to any cut-and-dried rule; but that each case be dealt with distinctively upon its merits; 2, that in irregular cases, having their origin chiefly in traumatism, we have no better adjunct to successful treatment than that afforded by careful and discriminate use of silver tubage. Any good silversmith can mold that soft, non-corrosive, pliable metal into the required shape. Its smooth polished surface will give cool aseptic support and compression to the incised tissues, eminently favoring epithelial repair; while the lumen of the tube will allow a free passage of air, so essential to thorough cleansing as well as respiration. The possibility of the slipping of the instrument through the posterior choana can be guarded against by a proper oversight in the construction of the tube, and by duly warning the patient. In the number of times, which number must amount to several hundreds, that the tubes have been inserted, collectively, by all my patients, this accident never occurred but once. On this occasion it slipped a little too far into the passage; and while the family physician was attempting to extract it, the tube glided over the palate and out of the mouth.

37 Carlton Street.

THE CAUSATIVE RELATION OF NASAL OBSTRUCTION TO LUNG DISEASE.

WITH THE PRESENTATION OF NEW MECHANICAL DEVICES FOR TREATMENT.

Read in the Section on Laryngology and Otolaryngology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY CHARLES DENISON, A.M., M.D.

DENVER, COLO.

The mechanics of respiration, in conjunction with the varying degrees of blood pressure within the thorax, have for some time greatly interested me. I must refer you to my address ("Abnormal Intrathoracic Air Pressures," September, 1890) read before the American Climatological Association, for the considerable amount of details which would make this paper too long to introduce it here.

Briefly summarized, sphygmographic tracings were there presented of various pulses under varying conditions of intrathoracic pressure, together with certain facts and measurements of air pressure by the manometer and of air quantity by the spirometer, so as to make plain the following general conclusion, namely, that the blood and air within the nose or less rigid walls of the thorax, may be considered as two reciprocally acting fluids. If one can not get in, in normal pressure, the other will to a certain degree take its place. It was under the influence of this reasoning that what I believe was an original discovery was made, namely, that marked decrease of pulse tension during inspiration and increase dur-

ing expiration can be utilized as a positive diagnostic sign for immediate intubation of the larynx or for tracheotomy in membranous croup or laryngeal stenosis. A delicate tactile sense in feeling the pulse and a slowly breathing child are great helps to this important conclusion. Out of thirty cases intubated by me, I have demonstrated this diagnostic sign and followed its indication for immediate interference in I believe the three last of the ten successful cases.

A logical mind needs no stronger proof of the value of this sign or of the importance of the subject I have chosen for this paper, than that which may fairly be drawn from the combined tables of all the intubations or tracheotomies which have been performed, to-wit: That children operated upon die more from a previously or coincidentally started *aspiration pneumonia* than they do from the disease or blood state which caused the laryngeal stenosis. Some of my cases have been wonderful illustrations of this suction power exerted upon the blood, because of the vacuum produced in the thorax by the interference with the ingress of air through the constricted larynx.

All the above is an argument by way of illustration, for the nose, though it is at the extreme end of the breathing tube, is as important a part of respiration as the air cells of the lungs. Because the mouth is interposed on the way is no proof that these two openings are normally supplementary to each other. They can not be, their functions and construction are so unlike.

Dr. J. A. Thompson (*Lancet-Clinic*): "Patients who are confirmed mouth-breathers or in whom the respiratory function of the nose is from any cause abolished, are sure to be the victims of laryngitis, trachitis and bronchitis. The membrane chronically inflamed, with its resistance to infection lowered, is much more apt to be the seat of tubercular disease than in those persons whose respirations are carried on normally through the nose." He further shows that the absence of the moisture contributed to the inhaled air in the nasal passages diminishes the absorption of oxygen in the lungs, which, to his mind, explains why patients with atrophic rhinitis, hypertrophics, etc., are so poorly nourished.

Bosworth attributes three functions to the nasal passages: 1, that of respiration; 2, an aid to phonation by acting as a resonant chamber; 3, as an olfactory organ.

There is evidently a purpose in the large expanse of the membrane lining those passages, in the generous blood supply to the same and in the abundant exudation of mucus from the rich glandular structures situated therein. That purpose is accomplished in the warming and softening of the air, in the sifting of all dust out of it, and so equalizing the air introduced in respiration. We used to believe the large amount of moisture ordinarily thrown off from the lungs in twenty-four hours was mainly from the lungs. Now comes an experimenter, Aschenbrandt, who claims to have demonstrated the source of this moisture to be largely in the nasal chambers. Just how much of the 7,000 or more grains of moisture daily thrown off come from this source, I will not pretend to decide. I simply give this evidence to show the great importance of the nasal passages as an essential part in the respiratory tract.

The effect of prolonged inflammatory action, such as catarrhal colds neglected, or one attack succeeding another, is not very different from similar congestions elsewhere; namely, an increase of connective tissue, except that the resulting obstruction tends to augment this effect locally and the blood once drawn into these affected parts is not normally expelled because of the suction in that direction. There is no doubt about the fact that obstructions at the nasal end of the breathing tract produce this suction influence in the naso-pharynx, and the perpetuation of a slight obstruction may in time produce more or less permanent injury in all connecting cavities or tubes, such as: 1, engorgement of the middle-ear space causing a certain amount of deafness with more or less closure of the Eustachian tubes; 2, the same hypertrophic influence in the lining of the ethmoid cells and lachrymal ducts with adenoid growths and polypi which flourish in the other unventilated parts of the pharyngeal and nasal cavities.

One has only to experiment with himself to get an idea of the varying conditions of air pressure to be noted in the naso-pharynx. For instance, after a full inspiration, while holding the nose go through the operation of swallowing, then do the same with the lungs as nearly emptied as possible; the impaction of the air through the Eustachian tube and in the middle ear is felt to be much stronger during the first part of the swallowing act with the lungs distended than when empty, and then during the last part of the act the descent of the pharynx, trachea and esophagus seems to give less of the suction influence when the lungs are distended than after a complete expiration.

This is an experiment with the nose entirely closed, but with lesser stoppages of the nasal tract even the frequent act of swallowing must correspondingly affect the naso-pharynx, for then the mouth must be closed. If one attempts to measure with the manometer the approach to a vacuum possible in the nose, he will find that a pressure represented by a very few millimeters of mercury, say three to ten, will seem sufficient to hold together the sides of the nasal passages at the outer orifices. So the stuffed-up head due to a "cold" or a series of them can be clearly understood as leading first to the hyperemia of the pharynx and nasal fossa and then to chronic pharyngitis and enlarged tonsils.

When we come to apply the same kind of reasoning to the farthest recesses of this respiratory tract, we find that the larger spaces, the trachea and bronchial tubes, are held open by their form of construction, and the fortification of connective tissue around, that by the manometer the suction or inspiration power is equal to about fifty millimeters, *i. e.*, about half of the expulsive or impactive power. Is it not reasonable, however, to believe that even though so evenly and minutely divided as this suction power is in the air cells, an equal resistance to closure does not exist in the periphery of the lung? I have had the following experiment tried on myself, which any of you can verify, to show that it is the flexible air cells which must of necessity compensate for any obstruction to the entrance of air, via the trachea during inspiration; namely, breathe out all the air possible, *i. e.*, the *complemental*, the *tidal* and the *reserve* or *supplemental* air, leaving only the *residual* air in the lungs; then while the nose and mouth are

closed make a powerful effort at inspiration. Meantime some one is percussing and listening with the stethoscope in the axillary space. Percussion will give a slight elevation of pitch and auscultation will show the movement of air away from the periphery during this inspiratory effort, the normal gradually returning so soon as the straining is relaxed and air allowed to enter the thorax. What has occurred? The more pliable and consequently more compensative alveoli have given up this residual air to supply the vacuum created in the stiffer and unyielding tubes within by this ineffectual effort at inspiration. Here it is that the compensative and equalizing influence of the blood circulation shows itself, which compensation is aided by the active capillary circulation—five times more so as I understand it, in the capillaries of the lungs than in the surface of the body. The sphygmographic tracings, previously here referred to, show how the blood is held back from being sent out of the thorax into the extremities. The pulmonary arteries not anastomosing while the veins do, the red oxygenated blood in these pulmonary veins is drawn back into arterial capillaries by such suction influences, whether due to cough or exaggerated inspiration or to obstruction anywhere in the respiratory tract above.

This explanation of Niemyer's, why a pulmonary hemorrhage, from an embolic or other plugging of a pulmonary artery, always gives the bright red, freshly oxygenated blood, serves well to impress the mind with an important fact pertinent to our present study, namely, that lesser causes, obstructive to the free entrance of air into the lungs, will produce proportionately less severe forms of congestion or engorgement. In fact, the pulmonary lesion may be in almost exact proportion to the obstruction to respiration. The determining cause being that obstruction, it follows that even slight degrees of constriction of the breathing tract, as in the nose, when perpetually operating, as deviated septa and hypertrophies of turbinated bodies do, may be the deciding causes of chronic pulmonary engorgements in the lung periphery. Especially will it be recognized that such a cause may be operative when, during the relaxation of sleep, lung resistance has been lessened by the existence of unresolved pneumonias—influenzas and catarrhal bronchitis. I have been of late so much impressed with the fact that nasal obstruction, with or without mouth breathing, is promotive of a large portion of the non-tubercular chronic diseases (especially asthma, fibrosis and pleurisy, with adhesions), that I will risk the assertion that these abnormal states in the lungs are very largely, in say 90 per cent. of them, perpetuated or caused by the nasal obstructions. As to the tubercular cases, tuberculosis may be a cause or a secondary effect, and the existence of nasal hindrance to free and healthful inspiration seems to me to be largely in excess in all this class compared with the average of healthy persons.

There are no statistics available, that I know of, to settle this question, but the experience of those of us who have dealt largely with lung cases and especially of you, gentlemen, whose duty it often is to straighten the "crooked paths" in nasal passages, ought to count for much in lieu of numerical data, toward the causative effect of this nasal obstruction to breathing. I shall be glad to learn if your experiences are confirmative of my impressions.

Through the kindness of Dr. Andrew H. Smith, of New York, I am enabled to present his "mechanical device for illustrating the movements of the lung in penetrating wounds of the chest," which may also serve two purposes here, namely: 1, to illustrate the compensating service of the circulating blood in the thorax, to take the place as I have before pointed out, of the deficient air inspired because of respiratory obstruction; 2, to illustrate the reverse effect, needed as a means of relief, *i. e.*, mechanically produced increased intrathoracic air pressure.

This apparatus of Dr. Smith's is a bellows divided to represent the right and left of the thorax. In each half of this is a thin rubber bag connected by a tube with a joint trachea. The suction of the bellows upon the bags (lungs) within, is uniform and causes them to fill with its expansion. If the glottis is partly closed it takes more strength to expand the bellows, and under these conditions if air is let into the side, but outside the rubber bag, the other rubber bag only will expand, except during compression some air will come round from the unaffected or fully filled lung. Now, supposing we agree that the air which is let into one side of the thorax, outside the lung, shall represent the blood circulation, and that it gets there because it is drawn in to take the place of the air which ought but does not get into that lung. It is seen at once that the relative amount of blood in that side bears a direct relation to the non-entrance of air in that lung. There is a reciprocal relation between the inspired air and this induced congestion. Now we come to the second illustration, the method of relief. The above defect having been recognized and the opening being left, which allowed the air (or blood?) to enter the thorax outside the bag (lung); then increase the pressure of the air which the weak lung does contain by stopping up that bronchial tube and at the same time compressing the bellows. You thus see every part of this lung brought into use, and all the air inside the bellows and outside the bag driven out. This is the office of regularly increased intrathoracic air pressure during expiration. It is the principle in correct respiratory gymnastics which I have advocated for a long time—in perfect accord with the greater use of air in the high altitude climatic cure—and the principle which is used in several breathing tubes, notably the "Howe tube." But it has been only recently that I have succeeded in combining the automatic control of both an *inspiration* and an *expiration* valve in combination with a chamber for medicated vapors and in the convenient little pocket device I have here presented.

The office of this instrument is not only by its steady, vigorous and continuous use, to drive the surplus or stagnant blood in the thorax onward in its proper channels, but by pressure on the hypertrophied linings to bronchioles and alveoli, to compel the reception of oxygen from the air once inhaled, as well as to produce such antiseptic or healing effects in diseased areas as can be done by vaporizable oils and salts conveyed in the inspired air.

The pressure used is or should be the utmost which is agreeable for a given individual, enough to close the entrance valve with a click at the beginning of expiration and to redden the face with the effort. The results in pulmonary fibrosis and all these obstructive conditions are very gratifying.¹

Reference can be made in corroboration of the

above to the article of Dr. George F. Hawley in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, May 12, describing "A New Apparatus for Nebulizing Non-volatile Medicaments, for administering the same through impacted air as a medium by the process of forced dilatation instead of inhalation, spray or douche." The effect of such increased pressure within the cavities treated is so much

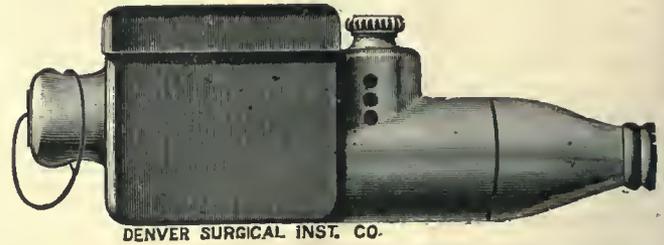

Figure 1.

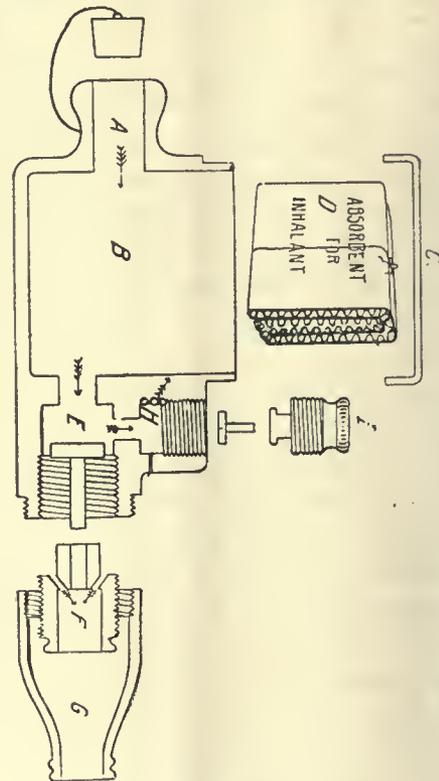

Figure 2.

DESCRIPTION OF MECHANISM.

The air enters the inhaler through nozzle "A," which is purposely made for the possible attachment of a rubber tube connected with an oxygen tank, any desired vaporizer or gas generator. In the box "B" covered by cap "C" is the Absorbent "D," made of corrugated blotting paper a little smaller in size than the inner caliber of the box. The inlet valve "E," governed by screw head "F," may be reached by unscrewing the mouth-piece "G," from the instrument. This inlet valve closes with expiration so that the inhaled air has to go off through the exit valve "H," which in turn is made adjustable by screw top "I." This constitutes the most important feature of this device. By the control of the exit valve, from 1-10 to 6-10 open, the tension of the air in the lungs may be increased at will from an easy to a difficult use, according to the need and ability of the user.

DIRECTIONS FOR USING.

After the adjustment of the valves, according to the case, (or as usually used, with inlet valve "E" $\frac{3}{4}$ open and outlet valve "H" $\frac{3}{4}$ shut) the Absorbent "D" in inhaler box "B," being semi-saturated with the Inhalant, and the plug to entrance nozzle "A," being removed, draw long full breaths through the mouth-piece "G," the chest meanwhile being expanded and shoulders thrown well back. Then, without removing the instrument, exhale into it with force so that the entrance valve "E" closes with expiration, and so continue to exhale till all the air possible is removed from the lungs. Repeat same way for three to five minutes during each of eight to twelve hours of the day. Vary the renewal of the remedy once or twice a week in chronic tubercular or fibroid lung cases, or as indicated by the use of other remedies than this Inhalant, if such are prescribed by the patient's physician.

¹ This expiration pressure will vary from twenty to seventy millimeters as gauged by the manometer for different invalids or healthy persons.

opposed to the suction influence, due to obstruction of which we are now speaking, that there is nothing surprising at all in the good resulting from such method of treatment. It is in exact accord with the proper use of the inhaler and exhaler described above. But simply to get rid of the results of obstructed inspiration, some one will say, is not doing what we ought to do, *remove the cause—the nasal obstruction*. Exactly, and that is the reason I am not going to say much about another little device I here present called the "Spirodom," made in Bridgeport, Conn., and calculated to compel the wearer to breathe through his nose while asleep. One is not required to undergo the discomfort and vexation of wearing such a thing if, as is possible in nine out of ten cases, the obstacles to nose breathing are removed.

A whole discourse could be written upon the etiology of septum deviations. But I have neither the time or intention to try to exhaust that subject or speak of their various treatments. The object here is rather to deal with the pulmonary results. Suffice it to say that, according to Zuckerkandl, the superior

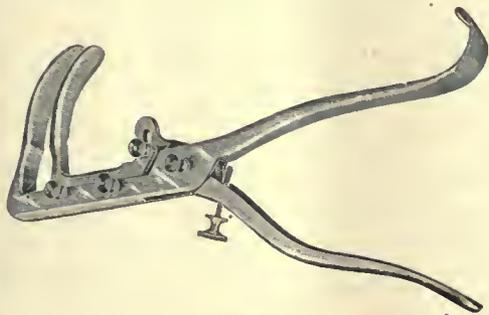

Figure 3.

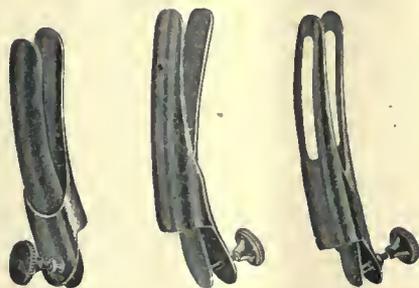

Figure 4.

racers show more deviations than the inferior. Again, the cartilaginous deviations probably exceed the bony, and Morell Mackenzie (p. 300, "Manual of Diseases of Throat and Nose") found in 2,152 skulls in the museum of the Royal College of Surgeons, that in 77 per cent. of them there were more or less unsymmetrical positions of the septum. In these athletic times, with base ball, foot ball and boxing so popular, it is no wonder that there is a considerable predominance of nasal deformities among men. The five cases I had chosen to present to you of lung disease referable to nasal obstruction were none of them from the gentler sex. I will not tax your patience by giving detailed histories. They were characterized by hemorrhagic tendencies to start with, a tendency to flat chests or retraction from pleuritic adhesions, they were non-tubercular so far as microscopic examination of the sputum could show and in one case the non-tubercular nature was thought to be proven by the high power microscopic

study of the blood according to Dr. Ephraim Cutter's method. They were all mouth breathers during sleep at some time during the course of their illness. Two had nearly total occlusion of one nostril (bridges across the cavity) while all had hypertrophied turbinates and deviated septa sufficient to make these lesions causes of the fibroid and atalectic tendencies in the lungs. As is usual in these cases the spirometrical record fell a little short of the healthy average while a pretty good manometer record was shown; and in two of these cases the respiratory sound at the apices, as heard with the stethoscope, was decidedly influenced as to quality, by the nasal obstruction. The removal of that hindrance to normal nasal breathing, the employment of compensatory lung gymnastics with climatic treatment were and are still the means being successfully employed in the cure of these cases.

The time already consumed prevents the discussion here of the various methods of surgical or topical treatment of these obstructions. I will simply add my mite to the already multitudinous surgical armamentarium for this purpose, and present the accompanying *vomer straightener* and the *right and left nasal dilators* which I have lately devised and which have been made for me by the Denver Surgical Instrument Company.

I had never seen the Adams' forceps and did not know of Gouley's septum splint when I devised this vomer straightener. However, they are all enough dissimilar to be considered unique. This instrument I present has curved nostril bars of steel, which easily fit the average of nasal canals and whose arms are controlled for any desired approximation by a screw in the handle to limit the closing. The power is the same lever principle used in my rib-cutter and is sufficient to overcome any obstacle or deflection which may be present. Oval side curvatures, displacements from fracture, or unusual hypertrophies may all be crushed to the desired normal thickness, which in many cases is considered preferable to the tedious, and to the patient, vexing and painful process of sawing or drilling away these obstructions.

Afterward the right and left nasal dilators come into use, designed to hold the passages open, till that openness becomes patent. These are made long and of light strong material and with side-screw adjustment, so that a patient can both introduce them daily for a while and gauge their pressure to what he can stand.

I have also had these dilators made with fenestrated sides (see single illustration of the right one) for the separate use of guarding other tissues than those intended to be cauterized when deep-seated hypertrophies are sought to be exposed to view.

The use of these devices as septum splints, substitutes for some forms of plugging and to obtain desired room for deep cauterizing, it is hoped will be as satisfactory in the hands of others as it has been for a limited period in those of the writer.

An Argument against the use of Boiled Water in Times of Cholera.—The Russian moujik, or peasant, is very much of a fatalist in respect of measures for the prevention of epidemic diseases. A recent letter from Minister White, on cholera at the Russian capital says, in effect, that "the moujik is in the habit of remarking, when advised to use boiled water only, as a beverage, that if Almighty God had intended him to use boiled water all the rivers and lakes would have been filled with water of that sort."

THE USE AND ABUSE OF COCAIN.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY D. BRYSON DELAVAN, M.D.

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY, NEW YORK POLYCLINIC.

According to the law which requires that every positive must have its negative, and every high light its shadow, it appears that all good and useful things must have their antithesis. Of nothing is this statement more true than of drugs. Thus, alcohol is at once a life-saving stimulant and the curse of the world. Opium, the salvation of thousands—the destruction of the power and progress of nations. Probably no drug has ever been discovered of which this is more true than of cocain. Mild in action, seductive in influence, treacherous in effect, it weaves a network of silken threads about its willing victim and leaves him of all men the most helpless.

When the discovery of Köller was first made known, it was natural that the desire for new information regarding the effect of cocain should have led to much self-experimentation and more particularly so because of its apparent harmlessness. The number of cases among physicians in which the habit was formed and the victim ruined from this ignorant use of cocain was startling. Later, the drug was prescribed by physicians for their patients. It was especially popular as a cure for coryza and a panacea for hay fever. Placed in the hands of a neurotic patient it is not strange that it should soon become indispensable to him. The strangest episode in the whole history of cocain is that certain medical men who have become its victims have been the very ones to disclaim its harmfulness, to freely prescribe it, and to recommend its use in their published works. As to this charge the rhinologist has much to answer for. Under his advice the patient has used it as a nasal spray, and has continued it, until the habit has become established and the spray has been exchanged for the hypodermic needle.

More recently cocain has been used by the manufacturers of patent medicines. Catarrh snuffs, throat lozenges and various other preparations containing it are urged upon the willing public. The general consumption of the drug has become very large and its use extensive. There seems to be no section of the country where it has not penetrated. Institutions for the reform and cure of the alcoholic and opium habits now advertise to cure the victims of cocain. The testimony of intelligent physicians generally, and the writer has questioned many from all parts of the United States, is to the effect that the evil has grown to serious proportions. I have, therefore, thought fit to bring the subject before this meeting, in the hope that an earnest protest might be made by the representative association of this country, against the abuse of the drug cocain. It is not necessary to go into the details of the question, for these are already painfully familiar. We all know the story of cocain from beginning to end. We know the great value of the drug when properly used, the peculiarly delightful effect which it seems to have upon many persons, the recklessness with which it has been prescribed and the baleful effects which have followed its over use. Is it not time, then, that we who have in part been the cause of this state of things should give our attention to the subject?

In view of the present state of the matter, the following propositions are offered:

1. Cocain, one of the most useful of drugs, is capable of being more harmful than even alcohol or opium.
2. The use of cocain is increasing to a serious extent.
3. For this the medical profession is largely responsible.
4. It is the duty of the profession to guard the public by every proper means against the dangers arising from the use of cocain.
5. To this end, it is desirable that this ASSOCIATION place itself on record as distinctively discountenancing the careless use of cocain: *a*, by the manufacturers of proprietary medicines; *b*, by the general public; *c*, by the general profession; *d*, and, lastly and particularly, by the Department of Rhinology, which we represent.

PSEUDO-HYSTERICAL APHONIA.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held in San Francisco, June 5-8, 1894.

BY F. B. EATON, M.D.

PROFESSOR OPHTHALMOLOGY, OTOTOLOGY AND RHINOLOGY MEDICAL DEPARTMENT UNIVERSITY OF OREGON; OPHTHALMIC AND AURAL SURGEON, GOOD SAMARITAN HOSPITAL, PORTLAND, OREGON.

Typical hysterical aphonia is described in our treatises as a form of bilateral adductor paralysis of the larynx, usually of neurotic origin; sometimes more exactly, as paralysis of the lateral crico arytenoid muscles. As such, its etiology, symptomatology and treatment, as generally accepted, are familiar to all laryngologists. Some writers describe associated laryngeal conditions, such as hoarseness from acute cold; others loss of power of articulation. The inference is that the neurotic feature is not the only etiologic one. Indeed, many cases of this affection appear to be the result of a number of abnormal factors, though the prominent indication to be met and the one most influencing the physician in his attitude toward the complaint is the functional, hysterical, nervous one; it overshadows all the others, and treatment is directed toward its removal too often without due consideration of other important constitutional and local conditions. I am satisfied that the chief cause of many of these cases can be found in the upper respiratory region without doing violence to facts, or giving a disproportional prominence to the influence of any abnormal conditions of the nose or naso-pharynx. In other words, such cases may be regarded as primarily of nasal origin, the aphonia being the result of reflexes which are not fully understood though recognized. The term, pseudo-hysterical aphonia, is not scientifically correct, but I have ventured to employ it as descriptive of the main idea I wish to convey in this paper. Such a case I have had exceptional opportunities of studying, and I shall therefore give its history somewhat in detail:

Miss L., age 18, a relative of my own, came under my care in April 1892. Had always enjoyed robust health, parents healthy, good family history. When 13 years old she had severe coryza and much nasal discharge. A year later her voice began to "break" in singing high. Later on she lost her singing voice, "note by note," and had to sing alto. Finally she gave up singing, but made frequent efforts to regain her high notes; and as she expressed it, "one day I found another voice, but could use it only very weak and very high." About this time she experienced difficulty in

talking. At first it was only an effort; she had "to try to get the words out," and at school in order to avoid this effort she purposely allowed questions to go by without answering. She could make a loud sound easier than a soft one. When she tried to speak with little sound, her "voice would not come," and when she tried to sing in the new high voice this made the talking voice more difficult to produce, and whistling had the same effect. There was no pain, and speaking gave none, but the voice broke and there was a helpless feeling of inability to use it. When 16 she began to have "a falling down feeling in the throat" with some aching, and she then told her sister that these sensations were in the palate.

All this time she could talk by making great effort, and at school she obtained permission to speak very low. The nasal trouble was less than when she was younger.

Shortly after she was treated by a specialist who pronounced the trouble to be located in the vocal chords, though she told him she was sure it was in the palate. He cauterized the larynx daily, later every alternate day, and after each application she was better for some hours. But now aching referred to the palate became a prominent symptom, in spite of the treatment the voice steadily deteriorated and in six months she ceased to attempt to talk and returned home. Here, the family physician cauterized the throat for a follicular pharyngitis.

She now came under my care. I found a strong robust young woman of placid temperament. She had not made a vocal sound but on one occasion for three months. Patient admitted that cold in the head always made the voice worse, as well as nervousness, but thought she breathed easily through the nose. The larynx appeared perfectly normal with one exception, the chords could be approximated closely but the left lagged slightly and was further from the middle line during respiration. There was chronic post-nasal catarrh and moderate chronic swelling of the turbinated bodies, the middle ones being moderately enlarged. The vestibules were very small, and breathing moderately obstructed.

I made a diagnosis of hysterical aphonia and gave strychnia and quinin, the former in gradually increased doses, and applied a mild solution of zinc chlorid to the larynx at intervals. Later I applied a twelve cell current to the pneumogastric and larynx externally, and touched the chords with closed forceps, evoking thereby a cough with vocal sound. The use of a faradic current externally enabled her to use her voice moderately, but it would come and go, always being restored by the current for a day or two, but lost if wearied at all. Still later, after a month of treatment, the voice remained moderately strong. I learned, however, that menstruation occurred every three weeks, and uterine treatment was carried out by a brother physician. During the summer the condition became worse, the aching pain in the palate returned, and my patient rebelled against the strychnia, insisting that while it stimulated her larynx, its after effect was bad, and that the only way she could regain any use of her voice or relief from pain was to rest the larynx. In this she was undoubtedly correct.

Upon my advice, when in San Francisco, she consulted Dr. Thos. F. Rumbold, who gave as his opinion that while there were some hysterical symptoms, the main cause of the aphonia was the catarrhal inflammation of the nose and naso-pharynx, the effect of which had been to produce reflex anemia and paresis of the soft palate, and inhibition of the action of the laryngeal muscles. Paresis would hardly be a correct term to apply to the observed condition of the palate, except in reference to the vasomotor influence resulting in marked anemia. As far as motor reflex is concerned, there was no absence of distinction between the anterior and posterior pillars of the fauces, such as seen in some nasal cases. There seemed rather to be an increased motor reflex, a *quasi* spasm of the palate, referred to the levator palati muscles which with the azygos uvulæ are innervated by a descending palatine branch from Meckel's ganglion, which also supplies branches to the middle and inferior turbinated bodies.

His prognosis as to recovery of the voice was favorable, and he advised treatment mainly directed to the nasal passages. This he began himself with the spray of warm vaselin, which, however, had to be used with very little air pressure, the nasal fossæ being in a very hyperæsthetic condition. This treatment I carried out myself later, but during the chilling humid Oregon winter which followed, my patient was in every respect worse. The mucous membrane of the fossæ, especially in the upper portion, was acutely painful on the occasion of every fresh coryza, as was also the

aching "pain" in the palate. More than a very moderate use of the voice resulted in the necessity of whispered conversation, and for a time there was complete aphonia. At times there were attacks of chilliness, followed in about an hour by a condition of stupor which lasted about half an hour. During such an attack the patient appeared to know nothing of what was going on about her, nor could she be roused. When questioned, she declared that the pain in the nose and palate caused the stupor and chilliness.

There were clear symptoms of hysteria some of which, while intensified by, could not be attributed to, her ailment, such as capriciousness, rapid changes from depression to cheerfulness, lack of healthy interest in her surroundings, inability to apply herself usefully, and little self resource. Knowing the nature of her early training, the indulgence of her parents and her disposition, I state advisedly that the young woman was hysterical, using the term as descriptive of a psychosis and of mental habit. She had some dysmenorrhea, and for this the uterine canal was curetted and otherwise properly treated with no beneficial effect as far as the nasal and vocal symptoms were concerned. The use of the vaselin spray, however, had to be stopped, since it appeared to aggravate the nasal inflammation.

In the meantime the patient's brother, aged 24, applied to me for treatment of his long standing asthma. I found some hypertrophy of the turbinated bodies, a hyperæsthetic condition of the mucous membrane similar to but not so marked as that of his sister. With the advent of spring, 1893, treatment of the young lady by vaselin spray was cautiously renewed by Dr. Rumbold, who also applied the galvano-cautery and counseled me as to future treatment. During the summer I lightly cauterized the middle and inferior turbinated bodies, thoroughly, the result being in three months a restoration of normal breathing on the left side, and nearly normal on the right. All the symptoms now gradually improved, so that my patient has had little trouble during the past winter, being able to talk easily, but liable to suffer still from prolonged use of her voice, which will probably never be perfectly strong.

It is worthy of remark that while she can sing without words, very softly, and obtains relief thereby, talking is more difficult, even in a low voice. This she attributes, and correctly, to the necessity of using the palate in articulation more, and in a different manner than when singing in alto register. A coryza will still produce some aching of the palate, and she says that if she worries over this, slight symptoms of stupor sometimes come on. She also informs me that when her voice "is strong, it feels strained; when weak, it is easy;" a paradox which has some weight, for she is sure that "when my voice is strong but feels strained, if I practice my voice softly, singing low 'breathing' notes, this relieves the strain."

What I wish to emphasize concerning this case is: 1, the over-use of the voice in childhood; 2, the gradual onset of the aphonia, which has been partial rather than complete, truly adynamic, since the power of speaking by effort is present; 3, the evident objective and subjective symptoms of anemia and paresis of the soft palate; 4, the existence of mild hysteria; 5, the improvement of all symptoms when nasal stenosis was relieved, while all nerve stimulants aggravated them. Hence I conclude:

1. That over-use of the voice, nasal and post-nasal catarrh, together with hysteria, may collectively cooperate to cause aphonia.

2. That cases of so called hysterical aphonia may result chiefly from disease of the upper respiratory region, the neurotic features being subordinate, and that grave injustice and injury may be done the patient in such cases by the ordinary stimulating and irritating local treatment of the larynx.

To Dr. Rumbold, through whose experience and counsel the true nature of the case was rendered apparent, I take this opportunity of expressing my obligations.

DEFLECTION OF THE NASAL SEPTUM AND ITS SURGICAL TREATMENT.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY E. A. SPILSBURY, M.D.

LECTURER ON LARYNGOLOGY AND RHINOLOGY, TRINITY MEDICAL COLLEGE; SURGEON TO THE THROAT AND NOSE DEPARTMENT, TORONTO GENERAL HOSPITAL.

Deflections of the septum, either as a result of traumatism or inflammatory action, are probably the most frequent of the exciting causes of catarrhal inflammation in the nasal mucous membrane. Consequently, it becomes a matter of considerable importance that we should thoroughly appreciate, not only their method of development, but also the nature of their action upon the lining membrane of the nasal cavities, as well as their influence upon its respiratory functions. In health, we find the nasal septum presenting simply as a bony and cartilaginous wall, dividing the nasal passages into two symmetrical cavities. In diseased conditions, we find present in this structure certain abnormalities of contour, which undoubtedly have a marked influence in the production of an ordinary catarrhal inflammation. The earliest investigators attributed deflections to excessive growth of the septum, as a result of which it became too large to fit in its bony framework, thereby becoming warped. This theory may account for a certain number of cases, but the great proportion of cases requiring surgical interference that have come under my care, have had a clear traumatic history. Sir Morell Mackenzie in an examination of 2,152 skulls, with the bony septum entire, in the museum of the Royal College of Surgeons, found 76 per cent. presenting more or less deviation; 38 per cent. to the left side, 28 per cent. to the right, while in the remainder it was irregular. When it is remembered that a large proportion of cases as seen in practice present the deflection chiefly confined to the triangular cartilage we see that the percentage must be even larger than that given by Mackenzie. Delavan has found among European races well marked deflection in 50 per cent. of several thousand crania examined. In cases of deflection the cartilaginous or bony septum, or both portions are simply bent to one side, the cartilaginous portion usually being the most involved; the deformity causing enlargement of one nasal chamber at the expense of the other. In most instances of deflection of the septum there is also thickening, especially at the lower part of the convex surface. The deflections are sometimes double, the convexity of one bend presenting in front on the one side, and the convexity of the other bend presenting further back on the opposite side, thus forming a double deviation resembling in shape the letter S.

In cases of fracture I have found that the cartilage is the part of the septum most frequently broken. Next in order comes the perpendicular plate of the ethmoid, its articulation with the vomer being the usual seat of fracture. The vomer is very rarely influenced by the concussion, its anterior edge being posterior to the bones of the face, and the cartilage yielding to the force of the blow. The causes of this deformity are obscure, and various theories have been advanced to account for its occurrence. In regard to those deflections which are due to fracture of the septum, of course there can be no question, they are due to a direct blow upon the nose. When we undertake, however, to inquire into the causes of the

S-shaped or unilateral deviations from the middle line, a wide field for discussion is placed before us. Morgagni was the first to advance the view that these deflections are due to excessive development of the vomer. This theory was subsequently advocated by other investigators and I think it would account for a great proportion of these cases. With every regard for the various theories, I think clinical observation teaches us that traumatism is by far the most frequent direct cause of septal deformities. Where the patient is conscious of obstruction in one side of the nose, the trouble is not infrequently dated from a severe blow or fall on the face. This coupled with the fact that men are three or four times as frequently affected as women and that boys are more liable to blows on the nose than girls, indicates very strongly the probability of a traumatic element oftener than is usually supposed. I have observed, moreover, that women relate more precisely the history of a bad blow or fall upon the face, as if, the event being comparatively rare among them, they took more notice of it; while with men, a frequent answer to the interrogation is that they had the average amount of knocking about the face at school. In these cases I consider it sufficient to assume a fracture of the septum to account for all the appearances. When the deflection is great, the most prominent symptom is twisting of the nose to one side, usually to the side opposite from that affected. This deformity is sometimes very marked from bending to the side of the anterior edge of the cartilage, even though there is but little deflection farther back. More or less difficulty in nasal respiration is experienced according to the amount of obstruction. Interference with the free passage of air through the obstructed side causes the secretion to collect behind the convex portion and in the nasopharynx, giving rise to post-nasal catarrh, and I have frequently observed that pressure upon the external wall, especially when associated with exostosis, induces atrophy of the turbinated body of that side while the inferior turbinated body of the other side, is usually found to be hypertrophied; and thus it often happens that patients find respiration easier through the cavity which upon inspection seems most obstructed.

As a further consequence of this obstruction, the voice acquires a nasal twang, and mouth breathing becomes necessary with all its attendant evils. There is no disease with which deflection of the septum is liable to be confounded if a careful rhinoscopic examination is made. Most of the evil results of the obstruction can be remedied by a suitable operation, and the external deformity may be largely removed if the nasal bones have not been crushed so as to cause depression of the bridge of the nose. As to the kind of cases requiring surgical interference, it is undoubtedly bad surgery to hold that every deviation from the middle line in the position of the septum demands treatment, and it is probably equally faulty to assume that surgical means always be adopted, even when one nasal fossa is almost completely occluded. I have found by clinical experience that many individuals tolerate partial and sometimes nearly complete nasal obstruction on one side without any inconvenience whatever. It is only when actual symptoms are produced in consequence of pressure on contiguous surfaces or interference with nasal respiration that operation is demanded. Whenever, for instance, there is a chronic laryngitis,

with enough nasal stenosis to cause even a partial buccal respiration; whenever there is paroxysmal sneezing or hay fever, even though there be but little interference with nasal breathing; whenever there is post-nasal catarrh or Eustachian occlusion; whenever there is dry rhinitis of the open fossa, we may operate with perfect propriety, and with the best hope of success. The essential feature of deflections of the nasal septum which demands treatment is the stenosis, as from this arises all the sequelæ and complications which accompany them. Where the deformity has occurred as the result of a fracture, this may be accomplished either by removing the projecting portion of the deviation, or by restoring the fragments to their normal plane. The earliest effort (1750) in this direction is the method of treatment by which the patient is advised to push the septum firmly over to the opposite side several times daily; but unfortunately this simple plan is seldom capable of accomplishing any good. About a century later (1845) Dieffenbach advised that the projections be sliced off with a knife, but this proved rather unsatisfactory. In 1851 Chassaignac recommended a form of treatment especially applicable to deviations with thickening of the cartilaginous septum. This consisted in dissecting up the mucous membrane and paring off the superfluous tissue. It is not easy of accomplishment, but in certain cases no better operation perhaps could be devised. Blandin, of Paris, first advocated punching out a portion of the septum and establishing free connection between the two nares, but this operation rarely affords the desired relief and can not be recommended. An easy operation, and one which has given me great satisfaction in several cases of simple cartilaginous deflection, is an incision through the projection following its long axis. Considerable hemorrhage takes place as soon as the incision is made, but it soon ceases. The end of the finger being introduced into the nostril, the septum is forcibly pushed beyond the center and maintained there, by packing the previously obstructed nostril with carbolized oakum. The cut edges over-ride each other, and after a couple of weeks are firmly united.

The oakum plugs should be changed daily and the cavities sprayed with Dobell's lotion or a solution of permanganate of potash, gr. i—3i. Dr. Roberts, of Philadelphia, devised an operation in which a long incision is made obliquely or horizontally, as required, through the septum from back to front along the line of deviation or projection. This is done with a knife introduced into the occluded nostril. If the bony septum is deflected, it is divided by a chisel in the same direction. A long steel pin is then introduced into the normal nostril, and its point passed, with about two-thirds of its length, through the septal cartilage, a short distance above and in front of the incision. This brings the pin into the occluded nostril. Pressing the end of the nose and septum, according to the character of the case, into its proper position, the "head-end" of the pin is brought close to the anterior part of the septum, thus causing the "point-end" or portion in the occluded nostril to lie across the incision and adapt itself lengthwise along the surface of the septum beyond the incision. The pin is then pushed in up to the head, and its point is thus deeply imbedded in the soft tissues of the septum, and upper and posterior part of the occluded nostril. It doesn't make much difference where the point is fastened so that it is firmly fixed and holds

the incised septum straight. Sometimes two pins will be required to correct the deformity. In such cases the second one is inserted, not from the mucous surface within the nostril, but from the cutaneous surface of the dorsum of the nose just below the nasal bone. The operation is a bloody one, because of the vascularity of the parts and because it will be useless unless the incisions are very free, so as to take away all resiliency of the cartilage. The pins are left in position two weeks. I have operated in several cases by this method with favorable results. The patient is subject to but little inconvenience, and the cavities can resume their functions at once with no disfiguring apparatus apparent. A small square of court plaster will cover the end of the external pin, which should have a flat head. The other does not show, as its head lies within the nostril. Another method of rectifying deflection of the septum is to forcibly return it to its normal position by means of heavy forceps, as devised by Adams of London, but never having looked upon this instrument with favor I have not given Adams' operation a trial. In those forms of comparatively slight deflection with considerable thickening of the prominence causing partial stenosis, the simplest method I have found, in dealing with such cases, is that devised by Bosworth of New York. It consists in cutting off with a saw specially constructed for the purpose, the protruding portion, together with its covering mucous membrane.

The saws are two in number—one cutting downward and the other upward. The steel portion is about five inches long, the anterior half serrated and beveled, while the other carries a large wooden handle at the proper nasal angle. By this means the hand is kept away from the field of vision during the operation. The mucous membrane having been well cocaineized with a 20 per cent. solution soaked in a tampon of absorbent cotton, the saw is introduced either above or below the protrusion as may appear more convenient, and rapidly cut through, care being taken to make a straight cut without bending the instrument. The bleeding is sometimes very profuse, though it generally ceases as soon as the operation is completed. It is of great importance, in removing these projections, that a thoroughly smooth surface should be left, for when a jagged uneven surface remains the result is unsatisfactory, and the period of healing occupies an unnecessarily long time. Recently, I have adopted a new operation for the worst cases of deflected septum, whether cartilaginous only, or bony and cartilaginous combined and with very favorable results. The operation is that of Delstanche, of Paris, and the set of instruments consists of strong crushing and cutting stellate septum forceps, septum clamps, and handle or tightener. The clamps are three in number, each consisting of two blades lined with rubber, and sliding on a square bar. The handle is also used to separate the blades of the clamp when removal is required. The patient being under the influence of chloroform the stellate blade is passed into the open nostril to the required position, and the flat blade passed into the obstructed nostril to a point opposite; the blades are then locked as with obstetric forceps and pressure exerted, thus crushing and cutting the septum. This is repeated in two, three or more places, until all resiliency of the septum has been overcome, when the index finger can easily be passed up the occluded side, and the clamp then adjusted in position. In tightening

the clamps, care should be taken not to exert too much pressure as it would interfere with the nutrition of the seat of operation and probably give rise to sloughing. Frequent cleansing should be carried out by means of a spray of Dobell's solution or other antiseptic wash. The clamp should remain in position for three or four days, after which I use plugs of carbolized oakum, as they are more cleanly than hard plugs of ivory or wood and exert sufficient pressure to hold the part in the required position. They should be changed at least once daily. In some cases it will be sufficient to plug only the formerly obstructed side with the oakum, after removal of the clamp. The evening temperature may rise above 101 degrees on the second and third days after operation, but soon subsides. The three following severe cases of deflected septum, all in male patients, and of traumatic origin, which I have recently operated upon by Delstanche's method with the most favorable results, both as regards the nasal stenosis and the facial deformity, have satisfied me as to the efficiency and value of this operation:

Case 1.—A. W., age 21, consulted me, Oct. 26, 1892, for complete obstruction of the right nostril and catarrh, and expressed himself as desirous of undergoing any operation that would give him relief from the distress he experienced at not being able to breathe through the right side of his nose. At about 5 or 6 years of age a severe fall upon the face had broken the nose, nothing having been done at the time to set it, so that from that time he could not breathe through the right nostril properly, and this difficulty increased in after years, until almost complete obstruction existed. Upon examination I found the right nasal chamber almost entirely occluded by deflection of the septum in both its cartilaginous and bony portions, and of undoubted traumatic origin. The left inferior turbinated body was greatly enlarged by puffy hypertrophy, yielding easily to pressure of the probe, and it almost filled the large concavity caused by the deformity of the deflected septum. In this case as there was so much inflammatory thickening of the projecting portion into the right nostril, I removed a piece about an eighth of an inch in thickness with the saw, in order to obtain space for the introduction of the flat blade of the forceps, as well as with the view of obtaining a better result after crushing. The blades of the forceps being placed in position in their respective nostrils, the anterior portion of the deflection was crushed and cut; this was repeated in two or three places back to the posterior part of the deviation, after which all resiliency was overcome, and the finger could be passed into the occluded nostril. The clamp was then placed in position and firm but not tight pressure exerted. The temperature rose to 101.2 degrees on the evening of the second day after operation, but soon fell to normal. On the morning of the fourth day I removed the clamp, and plugged both nares with carbolized oakum which was renewed daily. After two weeks' treatment the plugs were abandoned, firm union having taken place, and the patient could breathe freely through both nostrils. The facial deformity was also markedly reduced, the nose being now fairly straight. This patient returned by appointment in about a month from date of discharge when the relief of the stenosis was found to be permanent, and the catarrhal condition had nearly subsided. At this time the left inferior turbinated body was cauterized two or three times by galvano-cautery and the patient has since remained free from any obstruction or inconvenience from catarrh.

Case 2.—F. M., age 30, consulted me Feb. 3, 1893, for almost complete obstruction of the left nostril, very marked facial deformity and catarrh. About seven years previously he had received a severe blow on the right side of the nose. Upon examination I found the left nasal chamber almost entirely occluded, and post-nasal catarrh. The deviation was both cartilaginous and bony, and of unmistakable traumatic origin. I operated by Delstanche's method with the result that in two weeks the patient was breathing as freely through the left nostril as through the right, and upon inspection there was almost as much space. In this case also the deformity of the nose externally was decidedly improved and now, in appearance, is comparatively straight.

Case 3.—G. H., age 17, consulted me, April 6, 1893, for ob-

struction of the left nostril, which was causing him great discomfort. About five months previously, he had received a heavy blow on the right side of the nose. Upon examination I found marked deflection of the cartilaginous portion of the septum to the left, causing partial stenosis, and there was also post-nasal catarrh. The facial disfigurement consisted of rather an abrupt turning of the tip of the nose to the right. I did Delstanche's operation in this case with the most satisfactory results in regard to both the nasal stenosis and the external deformity. During the past year I have treated several additional cases by means of this operation and with equally good results.

A CASE OF RETENTION CYST OF THE FRONTAL SINUS.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY F. B. EATON, M.D.

PORTLAND, OREGON.

In January, 1893, an Italian aged about 26 years, consulted me concerning what appeared to be an osteoma at the upper and inner angle of the right orbit. Three years before, the skin over the right brow and upper lid became red and swollen. The redness disappeared in three weeks; the swelling remained. Six months later a soft swelling appeared where the tumor is. Sometimes there was pain over the right brow. Nose used to run before the swelling but has "dried up" since. The hard swelling has increased slightly in the past year. No specific history.

Objectively the right eye was pushed downward and outward and there was some proptosis. The hard tumor, about the size of a hickory nut, was not tender to the touch. Nasal respiration was impeded by a very large polypoid in middle turbinated bodies, the right being fully one-half inch wide. Believing this condition might be connected with that of right frontal sinus, I snared off with a powerful instrument the anterior portion of the right middle turbinated bone, the piece being the size of a hickory nut. That night a large amount of fluid escaped from the right nostril. Later I used a small electric light and found I could illuminate the left, but not the right frontal sinus when it was placed under the brow.

In consultation I made a small incision over the projection, ten millimeters above the tendo-oculi, and with an electric drill perforated the bone which proved to be thin. The drill entered a cavity which could be probed to great depth.

Two weeks later at the Good Samaritan Hospital I made an incision parallel with the eye-brow joining it by a vertical one at the inner end, exposed the bone and with a beak-shaped bone knife removed a piece of the bony shell one inch long and one-half inch wide. The sinus was found completely and tightly packed with a fatty granular substance, which was removed with a curette as rapidly as possible, there being profuse hemorrhage. There was no capsule. The sinus was as large as a good sized egg, extending far back, and its outer and lower wall was very thin. This cavity was packed with iodoform gauze, which could not be changed for several days, owing to the free hemorrhage which returned on each attempt. I decided later on to endeavor to obliterate the cavity by keeping it packed with gauze, since there was a continued tendency to mucopurulent discharge, owing to infection from the nose. I made an attempt to secure free drainage into the nose by passing a long slender silver probe by way of the infundibulum into the sinus. To the end I attached a bit of silk suture tying it to a strip of gauze which I drew into the nose. On the following day I found the gauze caused so much irritation that I withdrew it, and continued the daily packing with gauze, which, in about four months, resulted in obliteration of the cavity. The projection of the outer wall remained, however, as well as the displacement of the eye.

The substance removed, examined under the microscope, proved to be composed mainly of fusiform cells of an epithelial character, with some amorphous fatty substance.

DISCUSSION.

DR. MANSFIELD—I have had a case of a gentleman under my observation for the past five or six years with about the same amount of aphonia as the case reported by Dr. Eaton. He has not had catarrh, and being a vigorous male can not

be suspected of hysteria; he is also able to make a much louder and better voice when he sings in a high key than when speaking. He has paresis of the left vocal band probably of cerebral origin.

REPORT OF CASE OF TOTAL ADHERENT SOFT PALATE; OPERATION AND RECOVERY.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY J. E. SCHADLE, M.D.
ST. PAUL, MINN.

Eighteen months since, James S. consulted me in reference to complete stenosis of the nasal passages and deafness which had existed for a period of seventeen years. On examination of the nasal passages they were found to contain polypoid growths varying in size, which by their presence seemed to annoy considerably the patient by creating a continuous flow of serous fluid from the nostrils and bringing on attacks of violent sneezing, which condition ceased soon after the tumors were removed.

Inspection of the throat revealed partial obliteration of the pillars of the palate, entire loss of the uvula, and total adhesion of the velum palati to the posterior wall of the pharynx. What still remained of the soft palate consisted chiefly of cicatricial tissue as was evidenced by the firmness and density of the structure. After explaining to the patient the character of his trouble, informing him of the difficulty surrounding such an operation and advising him against one being performed, he left me, determined to seek advice elsewhere. Two months ago he returned to me and insisted on my giving him relief, if it be possible.

The patient is a book-keeper by occupation, was born in Manchester, England, and came to the United States in 1885. As to family history; mother died early in life from the effects of puerperal septicemia and the father three years ago from an attack of gout. The subject of this sketch is the eldest of six children all of whom except himself are in the enjoyment of good health. The history is negative, so far as tubercular or malignant diseases are concerned. Mr. S. is now 32 years of age, married, weighs 140 pounds, is in a general way robust and healthy and complains of the local malady only, on account of which he seeks advice. He denies ever having had acquired syphilis. When 10 years old he developed a sore throat which continued to disturb him for some months when the family physician was consulted, who pronounced the disease "an ulcerated sore throat" and made repeated applications of lunar caustic. The morbid process of the throat seemed to have remained unarrested as is shown by the fact that at the age of 14, interference of nasal respiration was markedly experienced, and at 16, the sense of smell was lost, the function of the ears was impaired and the power to breathe or blow through the nose was totally abolished.

Cocainizing the parts to be operated upon as thoroughly as possible, I divided the adhesions by the use of an angular probe-pointed knife and curved scissors such as are employed in gynecologic work.

After puncturing on either side of the adherent parts with a sharp-pointed bistoury, I insinuated through the opening thus made the probe-pointed

blade of the angular knife and severed the attachments by first cutting downward to the lowest point of adhesion, thence upward to the median or uvular line where the adhesions were freed with the scissors.

These different procedures effected a communication between the naso-and oro-pharynx of sufficient spaciousness for me to introduce my index finger into the post-nasal cavity for purposes of exploration. By means of this manipulation, numerous bands of adhesions extending from the superior surface of the palate to the vault of the naso-pharynx were discovered, which bands I divided with the knife guarded by the finger. The loss of blood was slight. The patient was at once enabled to blow his nose with entire freedom and nasal respiration was restored. In a few days after the performance of the operation, a sense of smell in a measure returned and hearing without any other aid became perceptibly improved. Regarding after treatment which I deem most essential, the plan adopted to keep the denuded surfaces from reuniting, was as follows:

A piece of iodoform gauze, two inches wide, fifteen inches long, was in half its length divided, which parts were respectively drawn through the nostrils from behind the palate forward, thus by means of slight traction bringing the crotch of the tape to rest firmly against the posterior extremity of the septum narium. The broad or oral end of the tape was brought forward through the mouth, and united with the ones passing through the nose over the upper lip. This appliance was well borne by the patient, its presence interfering somewhat with the acts of deglutition and phonation. Apart from this inconvenience no demurrer was made. The dressing was changed every twenty-four hours for two weeks, after which it was omitted during the day and worn through the night only. Mono-chloroacetic acid (Smith and Delavan) was applied occasionally to the raw surfaces to insure if possible a favorable issue. Whenever a point of adhesion would show itself, it was immediately broken up. The nostrils and post-nasal cavity were kept clean by the employment in spray form of antiseptic washes.

REMARKS.—1. The cause of the ulcerative processes of the soft palate followed by adhesions, was inherited syphilis. This opinion is confirmed by the fact that the patient had typical Hutchinson teeth.

2. The operation is justifiable and made successful by effecting a thorough division of the points of adhesion, and devoting most zealous attention to all details of after treatment until recovery takes place.

TREATMENT OF HAY FEVER.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY A. C. WOLFE, M.D.
COLUMBUS, OHIO.

Bostock, himself a sufferer from hay fever, gave the first detailed account of this disease in 1819. In 1869 Helmholtz held that the symptoms were produced by vibrios existing in the nasal passage. In 1873, Blackley, by carefully conducted experiments, was led to believe that the pollen of grasses and flowers was the exciting cause of hay fever. In 1883, Roe advocated that hyperesthesia is associated with, or occasioned by a diseased condition, either latent or active, of the naso-pharyngeal mucous membrane. Harrison Allen attributed the disease to permanent

or temporary obstruction to one or both chambers. McKenzie claimed that the disease is dependent upon some functional derangement of the nerve centers as its predisposing cause. Sajous advanced that the affection was due to an idiosyncrasy on the part of certain individuals to become affected by certain emanations and that hypertrophy of the nasal mucous membrane increased its irritability and the intensity of the symptoms, and that three conditions are essential factors in the production of hay fever: 1, an external irritant; 2, a predisposition on the part of the system to become influenced by this irritant; and 3, a vulnerable or sensitive area through which the system becomes influenced by the irritant.

One of the conditions necessary to produce an exacerbation is the presence of pollen in the atmosphere; another, and very important, is the neurotic habit; and another, a local morbid condition of the nasal mucous membrane. Clinical experience teaches that these three conditions are present in all cases, and that a person in whom one or more of these conditions are absent is not susceptible to an exacerbation. I regard the neurotic condition as the most important factor in the etiology of the disease. Neurotic tendencies increase with the advance of civilization; due perhaps, to the constant worry and bustle characteristic of the American people.

The sufferers from this malady nearly all belong to the active, energetic class of so-called nervous organization. A singular feature is that it is almost exclusively confined to persons of some education, and generally to those of a fair social position. Heredity has a powerful influence. In Wyman's experience there was heredity in 20 per cent., and in Beard's 33 per cent. In forty cases recorded by Sajous, 35 per cent. have near relatives who present a clear history of hay fever, and 42 per cent. have asthmatic relatives. Beard also established the fact that the prevailing family tendency was in the direction of nervous affections, such as chorea, epilepsy, asthma and other kindred disorders. It is a matter of constant observation that the disease runs in families. The pathologic lesion in these cases is found in the lack of vasomotor control which characterizes the neurotic manifestations, and that the affection is closely allied to asthma, in which the essential lesion is due to a vasomotor paresis of the blood vessels of the bronchial mucous membrane, while in hay fever the condition is due to a vasomotor paresis of the blood vessels of the nasal mucous membrane. An investigation of the origin of the premonitory symptoms will show that a neurotic element is an essential part of the affection. The following have been observed: A tickling in the roof of the mouth, dull pains in the head and back; another experiences chills and shuddering; and a large proportion complain of palpebral pruritus some days before the symptoms begin: The symptoms may be those of a mild coryza and last only a few days, or they may assume such a violent form as to cause the patient great suffering. There are two well marked types of the disease, the catarrhal and the asthmatic. In the former the onset is usually very sudden. The attack usually begins with a sensation of itching in the nostrils, which soon becomes very intense and causes violent and prolonged sneezing; a burning sensation in the inner canthi, followed by profuse lachrymation, may accompany this symptom, or constitute the first evidence of the access. Very soon the nose becomes

occluded through turgescence of its lining membrane, and respiration through it is practically impossible. A watery discharge appears, which soon becomes very profuse. Violent sneezing may begin at once, or occur when the watery discharge begins to trickle down along the intra-nasal walls. The asthmatic form of the complaint may be superadded to the disorder just described, or may constitute the entire affection. The only disease with which it need be mistaken is an ordinary acute rhinitis; but hay fever differs essentially from the ordinary cold in the head, in the fact that the latter is marked by several stages, namely: 1, a dry stage, lasting about twelve hours; 2, a stage of serous discharge, lasting from two to three days; and 3, a stage characterized by a profuse muco-purulent discharge, which lasts from five to ten days. In hay fever, on the other hand, the discharge is a serous discharge from the onset, and is practically so during its whole course. An examination of the mucous membrane should always serve to establish the existence of a morbid condition which is due purely to a vasomotor paresis. The appearance of the membrane is characteristic, and resembles in no respect an inflammatory process. It is markedly swollen, giving rise to more or less complete occlusion of the nares, but is of a bluish-gray color, which in every respect differs from the appearance of the membrane in a state of acute inflammation, which is of a bright red color. The mucous membrane in hay fever is covered with a thin, slightly viscid, watery serum, which gives it a glassy and semi-transparent aspect. The prognosis is not a grave one, but the tendency to the development of a periodical asthma and eventually of a perennial asthma is one that should always be borne in mind. A spontaneous disappearance of the disease has been observed in children, perhaps due to increase of nervous stability, consequent upon their growth and development. As there are three factors which we regard as essential in the production of an attack of hay fever, the treatment will consist in measures for the correction of the same. The object of this article, thus far, has been to demonstrate that the experience of different specialists and writers warrant the belief that the neurotic element is the prime factor in the etiology; and I am thoroughly convinced, beyond a doubt, from my own experience in fifteen cases, that this is the correct theory. Therefore I deem it of the utmost importance in the treatment of this disease, that our main attention be given to the nervous system; although the treatment of the other factors should not be neglected.

That the disease can be cured can not be questioned. That all cases can be cured is very questionable. We can only assure our patients that a majority of cases are curable, and that much relief certainly can be afforded in the larger proportion of cases. Many internal remedies have been recommended for the neurotic habit. The most successful ones are belladonna, zinc, arsenic, phosphorus, strychnin, valerian, assafetida, bromids, iodids, chloral, opium, quinin and various preparations of iron. In my treatment of five cases last year with belladonna and phosphid-zinc combination, two of the cases commenced treatment about two months before the attack was expected, one three weeks, one two weeks, and the other during the attack. The two cases in which I began treatment early, almost entirely escaped the attack. In the two that took

treatment so short a time before the expected attack, the severity of the symptoms and their duration were very much lessened. The case which commenced treatment during the attack, was also a sufferer from perennial asthma from childhood. I continued the treatment through the attack and during the three succeeding months, during which time he had no symptoms of asthma. After he had stopped taking medicine for about a month, an attack of asthma came on, but much milder than before. I again put him upon his former treatment which he is taking at the present time, and has been exempt from further attacks since renewing treatment. Previous to commencing treatment the attack would come on once a month and last for a week or more. This leads me to believe this to be the treatment, not only for hay fever, but also for purely asthmatic patients, and I think it best to give the remedies as Bosworth has recommended in his formula. In all cases a careful inspection of the upper air passages should be made, and if any morbid lesion exist, it should be corrected and the normal patency restored as nearly as possible.

It is very essential to begin the treatment at least two months before the annual attack is expected, thus building up the general system, and bringing it thoroughly under the influence of the medicine in order that the coming attack may be warded off, or at least very much ameliorated. Blackley found that the greatest relief was afforded by the exhibition of iodid of zinc in doses of one two-hundredths of a grain. Beard and McCullough advocated the use of quinin. Good results are sometimes obtained from the administration of belladonna in connection with opium. It is best to begin the drug about three months before the attack is expected and to continue it until the end of the period. McKenzie speaks very highly of valerianate of zinc in combination with assafetida. He gives 1 grain of the zinc with 2 grains of compound assafetida pill. Bosworth regards belladonna as exercising a more specific and thorough control of the disease than any other drug, and next to this he places reliance in the therapeutic value of some preparation of zinc. He claims most excellent results from the following formula:

R. Zinc phosphidi. gr. viij.
Ext. belladonna gr. x.—M.
Fiat mass. in pill No. xl. div.

Sig: One pill three times a day, after meals.

If there is impairment of the general nutrition he adds 1 grain of arsenious acid to the above prescription.

For the local treatment of the exacerbation of hay fever, no remedy equals cocain, in relieving the local manifestations. The value of its action is in contracting the blood vessels rather than in its anesthetic action. It should be used as a spray, and in the hands of patients, the solution should not be stronger than 2 per cent.: to the solution I generally add sodic bicarb. and the borate. Another good combination is to add albolene; this not only affords the controlling action of the cocain, but also coats the membrane with the albolene in such a way as notably to protect it from the impact of pollen. The sleeplessness and nervous irritability necessitate the administration of anodynes to secure rest; for this purpose I give sulphate of morphia, one-eighth grain every two hours until relieved.

DIPHTHERIA; ITS ETIOLOGY, CHEMIC PATHOLOGY AND TREATMENT.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY M. M. JOHNSON, M.D.

HARTFORD, CONN.

ETIOLOGY.

The century which has just passed has been fertile in scientific researches. The etiology of diphtheria has engaged the attention of many of the ablest workers of our profession. Atmospheric conditions, peculiarities of soil, miasmatic conditions and filth have each in their turn been investigated to account for the origin of this most fatal disease.

The symptoms accompanying this disease as conditions of the throat, with all its clinical peculiarities; the onset fever; the sequelæ of paralysis, have long been known and accounted for by a poison absorbed in some way into the system.

In 1841 Henle expressed his belief in a contagium animatum. Schwann demonstrated the presence of lower organisms in fermentation and putrefaction. The teachings of Pasteur, "concerning the conditions under which putrefaction occurs, all tend to explain the various contagious and infectious diseases by analogy, and stimulated the search for a vegetable organism in diphtheria."

Huter found these in the diphtheritic membrane of the pharynx and larynx, inoculated them into the mucous membrane of animals and described them as dark, round active little bodies. Ortel found them in diphtheritic membrane and lymphatic glands and kidneys and other organs. He considered them as constituting the contagious element. Thus we see that the trend of scientific investigation was in the line of a microorganism as the specific cause.

It was reserved for the last decade to fully demonstrate the etiology of diphtheria which places little if any, doubt upon the subject. Paralysis is the constant and dangerous symptom following diphtheria. The problem before the investigation was to fully account for this condition.

Klebs first discovered the bacillus diphtheria; Löffler first isolated it in pure culture; Roux and Yersin were the first to show that, when introduced into the circulation of a rabbit, this bacillus produced paralysis.

Löffler, in his article published in 1884, in his histologic examination of a large number of cases of diphtheria, concluded that a specific of bacillus found by him in diphtheritic membranes, and whose morphology and biology he carefully studied, was identical with the one described in the previous year by Klebs, and is the only one present which is of any pathogenic importance. These investigations were verified by Babes, D'Espine, v. Hoffman, Artmann, Roux and Yersin, and others.

The question was considered as practically settled that the Klebs-Löffler bacillus was the cause of diphtheria, and was present in all the primary cases of this disease in the diphtheritic deposits. When inoculated into susceptible animals it produced the disease in all its features, even to the characteristic paralysis. This would have settled the question beyond a doubt had not Prudden, of New York, come to a different conclusion from the examination of twenty-four cases of diphtheria, (*American Journal*

of the *Medical Sciences*, April and May, 1889) in which he failed to find a single instance, either by microscopic examination of membrane, or by culture of the Klebs-Löffler bacillus. As Prudden was a competent bacteriologist, Löffler said: "I do not believe that in North America a form of diphtheria prevails different from that with us."

Prof. W. H. Welch, M.D., and A. C. Abbott, M.D., (Bulletin of the Johns Hopkins Hospital, Volume ii, No. 11) review Prudden's cases. All but two of the twenty-four cases occurred in children's asylums or hospitals, sixteen being in a large foundling asylum, in which measles and scarlatina were prevalent. In seven cases the diphtheria was complicated or preceded by measles, in three by scarlatina, in one by whooping cough, in four by phlegmosis or erysipelas inflammation, and in only nine was the diphtheria uncomplicated by previous disease. Of these which were apparently uncomplicated, it is uncertain how many developed in the hospitals, under the same epidemic influences as the majority.

It is evident that the cases examined by Dr. Prudden, taken as a series, could not be regarded as primary diphtheria but rather as diphtheria secondary to measles, scarlatina, erysipelas, or as developing where these diseases prevailed.

Professors Welch and Abbott further state that it is remarkable that in not a single instance in the apparently primary cases of diphtheria did Prudden find the Löffler bacillus. His observations can not be considered contradictory to others who had studied primary diphtheria. They wisely concluded that more bacteriologic examinations should be made of primary diphtheria occurring in this country.

In May, 1890, these two eminent bacteriologists commenced the examination of membranous exudations in cases of diphtheria in Baltimore. In all the cases examined by them, clinical diagnosis was positive and all were primary cases of diphtheria developing in healthy children in private practice in various parts of that city. Their examinations were made from bits of membrane removed by sterilized forceps, during life. After separating the bacillus in pure culture its virulence was tested in each case by the inoculation of guinea-pigs; they had for comparison pure culture of the Löffler bacillus obtained from the Hygienia Institute in Berlin. The identification of the bacillus in their cases was based upon a study of its morphology, its behavior in various culture media and its effects when inoculated into guinea-pigs and other animals. In all respects they found it identical with the Löffler bacillus in the culture obtained from Berlin. This series of experiments removes all doubt that the Klebs-Löffler bacillus is the veritable bacillus diphtheria.

The location of the bacillus diphtheria in the membrane is thus stated. Most superficially are various kinds of bacteria, among which the Löffler bacillus is recognized; beneath comes a feebly-stained layer, rich in cells, but containing little or no fibrin; in this layer the Löffler bacillus, both singly and in groups, are made out. In the deeper layer the Löffler bacillus is abundant. In the layer resting on the mucous membrane no Löffler bacillus are seen. The bacilli are never found in the mucous membrane nor in sections of internal organs. The Löffler bacilli therefore not only do not invade the mucous membrane, but they usually do not extend through the diphtheritic membrane.

Dr. William Hallock Park, of New York, in a careful review of the etiology says: "The toxic albumins produced by the diphtheria bacilli have been especially investigated by Roux and Yersin, Fraenkel and Brieger. This toxic substance is of a proteid nature precipitated by alcohol and soluble in water. Nearly pure it is a white amorphous mass of specific gravity and keeps its properties for a long time unchanged. With Roux and Yersin's experiments four-tenths of a milligram of the substance when inoculated killed eight guinea-pigs. The long continuance of the toxic power of the poison in the body and its slow absorption from the locally affected tissues account for the deaths which occur some time after the entire disappearance of the bacilli from the infected throats.

"Experiments with the Klebs-Löffler bacilli show that an agar tube culture in the laboratory is still alive after seven months, and bits of membrane kept in cloth still alive after six months. In dark, damp or dirty places life remains much longer, but under unfavorable conditions the bacilli might live only a few days."

Dr. Park concludes that there are two great divisions of pseudo membranous inflammations; one caused by the Klebs-Löffler bacilli and the other by some form of streptococci. The name, diphtheria, will probably be agreed upon by all for those cases in which the Klebs-Löffler bacilli are present, alone or associated with other bacteria. For the other, some name will have to be agreed upon.

Further investigation only can determine whether streptococcus diphtheria will be acceptable for the present pseudo-diphtheria. In June, 1893, Dr. W. T. Councilman, of the Harvard Medical School says: "We now regard those pseudo membranous inflammations as belonging to diphtheria in which the Klebs-Löffler bacillus is found. When that is not present, no matter what the extent and the character of the local lesions, no matter what the severity of the symptoms, the disease is not diphtheria. The Klebs-Löffler bacillus is a small organism not much larger than the tubercle bacillus. Its most striking feature morphologically is its variation in form and its irregularity in staining, the ends of the organism are frequently clubbed, sometimes at one end and sometimes at both ends and when stained it shows a series of clear spaces along with intensely stained particles. The diphtheria bacillus is not a pus producing organism, and varies greatly in virulence.

"The danger in diphtheria lies chiefly in the absorption of the virus which is produced locally, and this does not take place with anything like the same readiness in adults as in children, due probably to the more delicate tissues of a child, its greater vulnerability and possibly a greater facility of absorption."

Dr. Louis Fischer, of New York, in a series of experiments, found true diphtheria bacilli in sink traps of houses where diphtheria had prevailed.

Pseudo-Diphtheritic Bacillus.—The status of the so-called pseudo-diphtheritic bacillus can not be considered as settled. Löffler finds such a morphologic and biologic difference between it and the true bacillus diphtheria, as to lead him to regard it as a different species.

Roux and Yersin consider it as a modification of the bacillus diphtheria, from which it only differed by absence of virulence. They claim that the pseudo-diphtheritic bacillus is identical in its morphology

and its behavior in culture media, with the diphtheritic bacillus. The former is only an attenuated form of the latter.

Dr. Abbott, after conducting an extensive series of experiments, (Johns Hopkins Hospital Bulletin, October-November, 1891) is unable to finally settle the question. Clinically the practitioner can not distinguish the one from the other; both should be treated the same.

Abbott has so recently given an exhaustive review of this subject that Dr. Park in his articles gives but a brief summary.

It has been established that bacilli with all the characteristics of the Klebs-Löffler, except their virulence, are to be found exceptionally where pseudo-membranes are absent. These are never numerous, only a few scattered colonies being found on plates or tubes. Roux and Yersin found gradations in virulence. As the result of a large number of experiments these investigators hold that the morphologic and cultural difference between the diphtheria and the pseudo diphtheria bacilli are inconstant, and when present are insufficient to establish that they belong to different species. In this country the pseudo diphtheria bacilli have been infrequently found. Prudden in a large number of cases in New York did not find them once. Koplik has found them a few times and Abbott in fifty-three cases, in four. In these studies the pseudo diphtheria bacilli were met with but once as proved by animal experiments, (159 cases by Dr. Park).

Councilman says of pseudo diphtheria: "Too frequently in practice every sort of white deposit and discoloration in the membranous inflammation is perfectly distinct anatomically, whatever may be its etiology. It is always dense and firm and is made up of fibrin and degenerated cells. In the pseudo diphtheroid inflammations are masses of bacteria collected on the surface of the mucous membrane, consisting of cast-off epithelium, mucus and masses of bacteria of varied forms. In the absence of a definite diagnosis made by bacteriologic investigation, the only safe way is to consider every case in which pseudo membranous inflammation of the throat is found, whatever its character, however mild the clinical symptoms may be, as a case of true diphtheria.

The foregoing history is interesting and of great value: 1, as showing the extreme care taken to logically eliminate every element of error in this most brilliant line of discovery; 2, that the bacillus diphtheria, when subjected to culture media and inoculated into susceptible animals, not only produces the characteristic membrane at the site of inoculation; but further, is the cause of the paralysis following, a symptom observed to be characteristic of diphtheria for so long a period; 3, upon these results we can consider the etiology of diphtheria as fully settled.

THE CHEMIC PATHOLOGY.

There is a beautiful harmony existing between the etiology, as embodied in the bacillus of Löffler being the veritable cause of diphtheria, and the chemic pathology, which is the next step in the line of accounting for the tissue changes which exist in diphtheria.

Sidney Martin, M.D., F.R.C.P., in his Gulstonian lectures on the chemic pathology of diphtheria, (*British Medical Journal*, March 26, 1892) has, in his mas-

terly way, given us the most recent status of this most important study. In these lectures he demonstrated in what the diphtheritic poison consists. His exhaustive study upon the pathology of anthrax, infective endocarditis and tetanus, are applied to diphtheria. Anthrax and infective endocarditis he groups as eminently febrile; while diphtheria and tetanus manifest symptoms referable to the nervous system.

In diphtheria and tetanus the primary infective agent is found only at the point of inoculation; hence the study of its morphology does not account for the symptoms which follow. A chemic investigation is necessary, not only for the explanation of the symptoms, but for a scientific treatment of the disease. Leaving the study of the pathology of anthrax, familiar to you all, we will direct our attention to the methods described in the chemic pathology of diphtheria.

Dr. Martin conducted his experiments on eight cases dead of diphtheria. His method of separating the poisonous products from the tissue was as follows: The spleen and other tissues, with the blood, are finely minced and placed in rectified spirits and allowed to stand until the proteids are coagulated; they are then filtered and the residue is then extracted by cold distilled water until nothing more is dissolved. The extracts are evaporated at 35 degrees C., to a small bulk and placed in absolute alcohol. This precipitates most of the albumoses. After standing the alcohol is poured off, the precipitate evaporated to dryness at a low temperature and extracted by absolute alcohol, until nothing more dissolves. The process of dissolving in water and precipitating in alcohol is continued, until all traces of bodies soluble in alcohol and excess of mineral salts is removed. After the last precipitation, the precipitate is allowed to stand under absolute alcohol for about two months, after which the alcohol is poured off and the precipitate dried in a vacuum.

The resulting product is a light yellowish brown powder, which yields nothing to alcohol, ether or chloroform, and which keeps indefinitely if put in a dry atmosphere. It is soluble in water, cold or boiling. The alcoholic extract of the tissues is strongly acid and contains an appreciable amount of free fatty acid. Another acid is separated from the first by its solubility in chloroform.

The chemistry of the tissues in diphtheria results in two classes of substances, which are abnormal to the body—one belonging to the digestive proteids, namely, albumoses; the other an organic acid.

The albumoses of diphtheria can not be distinguished from those of anthrax; their physiologic effect, a test more delicate than any chemic action, is the only mode by which their specificity is made evident. It is the injection of this substance which causes the symptoms of paralysis.

The fever following the injection of albumoses is very variable, as is the case in the course of diphtheria. In the first animal injected, the fever lasted during the seven days that the animal lived. In subsequent injections the fever lasted from one to three days, varying from 3 to 4 degrees.

The symptom of paresis is more definitely marked following the injection of albumoses. In the first animal injected, paresis of the left leg appeared on the second day; it was not used so much in jumping. The paresis was more marked on the seventh day, both legs were affected on the fifth day,

and on the seventh day there was paresis of all the legs. From the injection of these substances a paresis is produced which may be more marked in one limb but always progressive and general. The paresis is not accompanied by any wasting of the muscles; when one limb is more paretic than the other it does not waste to a greater extent. The slowness of the coagulation of the blood was also characteristic of this condition of diphtheria.

Examination of the Nervous System.—Martin next makes an examination of the nerves supplying the paralyzed muscles. His method of studying the peripheral degeneration is to stain the fresh nerve with osmic acid, so that the white substance of Schwann is stained black, and counter-staining with carmine to bring out the nuclei and axis-cylinder. In all animals the same changes were found. After staining the motor nerve with osmic acid and following its course, the upper part of the fibers are normal. A little lower down they show a breaking up of the white substance of Schwann, which is thin and but little stained by the osmic acid, while lower down the white substance disappears entirely. Below the point at which the white substance disappears, the axis-cylinder is in many instances broken. After the rupture of the axis-cylinder, the nerve fibers below the rupture undergo the Wallerian degeneration.

The part of the nerve primarily affected is the white substance of Schwann, which breaks up and finally disappears. The different branches of the motor nerve are affected in a varying degree, so that in an individual motor nerve there may be fibers which can still innervate the muscle owing to the integrity of the axis-cylinder. This is the reason why the condition observed throughout life is a paresis and not a paralysis. In many nerves the change only affects a few fibers lying side by side, or a single bunch of fibers. This is well seen in many specimens of the phrenic from these animals.

Martin says that the heart is found in an advanced state of fatty degeneration; on what it depends, it is difficult to say, as there is no degeneration of the vagus nerve. It may depend upon the changed condition of the blood or the diphtheritic albumoses may have a special action on the heart. The sensory and sympathetic nerves show a similar degenerative process, oftentimes segments of degeneration. These changes thus described are produced by the inoculation of diphtheria into previously healthy animals. Martin next considers the relation of the nerve degeneration to the changes in the nervous system in diphtheria palsy in man.

Many observers, both before and after the appearance of De Jerine's work in 1878, in which he recognizes that paralysis following diphtheria is due to a parenchymatous degeneration of the peripheral nerves, have described changes in the cells of the anterior cornua of the spinal cord, and some have gone so far as to ascribe the symptoms to a mild form of poliomyelitis. The symptoms are not those of an affection of the anterior cornua of the spinal cord, as there is an absence of the wasting of the affected muscles. These are phenomena due to changes in the peripheral nerves. The poison which produces changes in these nerves and fatty degeneration of the heart may after a time affect the nutrition of the nerve centers causing a fatty degeneration and atrophy of the cells.

Action of the Organic Acid.—When the organic acid found in diphtheria is injected in a watery solution into the circulation of a rabbit, it produces a moderate degree of fever which may last two or three days. The animal wastes a little but has no paralysis following the injection of the acid even after a dose of 0.1559 per kilo of body-weight. The blood coagulates normally. Fatty degeneration follows the injection. The phrenic nerve when examined in its upper half was found normal, while the nerves to the semi-membranosus, the vastus and gastrocnemius, show different stages of the characteristic degeneration already described. Organic acid, therefore, found in the body of diphtheritic patients is like the albumoses, a nerve poison capable of producing the same anatomic changes in the nerves.

The Diphtheritic Membrane.—The chemical examination of a diphtheritic membrane was conducted, as already described, from the tissues of the body of a diphtheritic patient. Thirty milligrams were injected into a rabbit weighing 560 grams. The result of this injection was the characteristic paralysis of the muscles of the limbs, as was described in previous injections. The blood coagulated as already described. The result is important, as it shows that in the membrane there exists a poison which produces exactly the same results as the albumoses found in the spleen and blood of diphtheritic patients, only being much more virulent. There was entire absence of microorganisms in the tissues of the body.

The Bacillus Diphtheria.—All observers agree that the bacillus diphtheria is limited to the superficial layers of the membrane and is not found in the tissues of the body. When inoculated into the body it kills the animal, but its growth is limited to the site of the inoculation.—(Sidney Martin's "Conclusions.")

From the facts under consideration it is clear that: 1, "the bacillus diphtheria forms from proteid products of the same chemic nature as those found in the bodies of patients dead of diphtheria, albumoses and organic acid;" 2, "the albumoses formed by the bacillus diphtheria in artificial cultivation have in single and multiple doses the same physiologic action as those found in cases of diphtheria in man; this action is the production of fever, of diarrhea, of loss of body-weight and of progressive paresis of muscles, dependent upon degeneration of the peripheral nerves;" 3, "the bacillus diphtheria is therefore the primary infective agent of diphtheria." "That this liberates in the membrane a ferment which, when absorbed, digests the proteids of the body forming albumoses and an organic acid." "These digestive products are the agents producing death, in causing fever and the depression and paralysis which follow diphtheria." "The diphtheritic product found in the body does not all come from the membrane."

In the case where there were but a few specks of the membrane found in the larynx, yet in the body a large amount of diphtheritic products was present, it is probable that the ferment absorbed from the membrane digests the more or less stagnant products in that organ. We know that the spleen contains a proportionately greater quantity than the blood of bodies formed from proteids such as uric acid, etc.

TREATMENT.

There is no disease which is subject to such a

latitude of random treatment as diphtheria, some believing diphtheria to be first a local disease, others that it is primarily a constitutional disease and treat accordingly. Still others give no attention to the nature of the disease, whether it is local or constitutional, but administer one drug for a few hours and if there is no improvement try another, and so on, meanwhile having no clear conception as to just what is to be accomplished. When death occurs there is a great feeling of satisfaction that all was done that could be done, because the doctor did not fail to use every remedy possible.

J. Chalmers Cameron wisely says: "If there is one disease more than another in which man should have the conviction, and courage to act upon it, it is diphtheria."

From the etiology already given, based upon the researches of Klebs, Löffler and Welch, and the chemic pathology of Roux, Yersin and Sidney Martin, the question may be considered as settled, that diphtheria is first a local disease caused by the bacillus diphtheria, with the membrane at the site of inoculation and should be treated as such; also, that the bacilli diphtheria liberate a ferment which, when absorbed, digests the proteids of the body, forming albumoses and an organic acid. These are the agents producing death; fever and paralysis following diphtheria. This is the secondary or constitutional stage of the disease.

In diphtheria we have to deal with the same condition, whether the primary site of inoculation is nasal, tonsillar, pharyngeal, laryngeal or elsewhere. Hence these local divisions are unnecessary. We should treat the disease and not the location.

We would emphasize the fact that every practitioner should have a clear conception of the condition which he is to treat, and a well-defined outline of his methods based upon scientific knowledge. The first or local stage of the disease is necessarily of short duration. If seen in time, treatment should be directed to the destruction of the bacillus diphtheria at the site of inoculation; this done, further treatment is unnecessary.

Ruling out a thousand and one pet nostrums which physicians use without reason, we will confine our discussion to two methods. The first is known as the tincture of the chlorid of iron treatment, which has constituted the standard treatment by the medical profession for over a century. Second, the bichlorid of mercury treatment, which has been in use for about fifteen years, although used by some for a longer period.

Chlorid of Iron Treatment.—Prof. J. E. Winters, writing on the use of iron, states ("Diphtheria and its Management," p. 36): "If we are to obtain the decided effect of the drug in a case of septic diphtheria, at least 1 dram of the tincture should be administered every hour to a child from 2 to 5 years old. We have given 2 drams every hour for forty-eight hours to a boy 8 years old." This may be taken as a sample of using the iron treatment as a method. Yet Professor Winters states to his class that with this treatment he loses about 50 per cent. It is safe to say that during the last century the iron treatment has been used by the ablest men of the profession, with a death rate of about 40 per cent. and upward, recording as death from diphtheria those who died before the membrane had disappeared from the site of inoculation. Of the large number who have died

within a few days to a few weeks from paralysis and heart failure the per cent. is unknown.

It is the undoubted experience of all the practitioners that a large number of those treated with iron have paralysis, more or less extensive, following the disappearance of the local symptoms in the throat. This is the point to bear in mind in judging of the final value of any form of treatment. The fact that paralysis follows the use of iron as a treatment so frequently, means that the drug does not exert a controlling influence over the liberation and absorption of the ferment, and its farther action in digesting the proteids of the body and the formation of albumoses and organic acid, which are the cause of the degeneration of the white matter of Schwann in the peripheral nerves, causing the paralysis. It is here that the physician makes the great error in considering the patient cured and recording it as such, as soon as the membrane has disappeared from the location of inoculation, when in fact the most serious trouble is in progress, viz.: Paralysis and death. The lesson is that we should not too early abandon the treatment.

The Bichlorid Treatment.—The corrosive sublimate treatment, used some fifteen years ago by Billatti, is highly esteemed by many. Dr. Jacobi says ("Practical Therapeutics," Hare): "Diphtheria can not be treated by any other drug as well as by the bichlorid, as it is readily soluble and counteracts the specific poison."

(*Berlin Klin. Woch.*, August 26.) . Rennet recently reported his year's treatment with the bichlorid, the result of which was sixty-two consecutive cases of diphtheria, all of which recovered. In none of his cases was there mercurial poisoning.

His formula is:

Hydrarg. chlorid corrosive 1 part.
Acid tartaric 5 parts.
Aque 1000 parts.

He applies this solution to the membrane thoroughly every six to twelve hours.

In England the bichlorid treatment as advocated by Dr. C. R. Illingworth, has been highly praised. The membrane disappeared in from two to five days. O'Dwyer, in speaking of emetics in laryngeal diphtheria says by their aid he has succeeded in getting many cases through; especially those which were put on the bichlorid treatment at the commencement of the disease, that would otherwise have required intubation. In the practice of the writer he has used the bichlorid treatment for nine years. During this time he has carefully recorded *one hundred and eighty-five cases of diphtheria with six deaths*, making a loss of 3.2 per cent. (One hundred and twenty-eight consecutive cases without a death). Fourteen were nasal, eight laryngeal. Paralysis appeared in but one case.

The following table shows the death rate from diphtheria in Hartford from 1886 to 1891:

| | Reported | Deaths | Per Cent. |
|----------------|---------------|---------------|-----------|
| 1886 | 94 | 17 | 19.14 |
| 1887 | 66 | 28 | 43.42 |
| 1888 | 148 | 43 | 29.00 |
| 1889 | 348 | 111 | 32.00 |
| 1890 | 130 | 63 | 48.40 |
| 1891 | 271 | 92 | 33.50 |
| | 1,057 | 354 | 33.39 |

During six of the nine years in which he has used the bichlorid treatment, the death rate from this disease in Hartford has been 33.39 per cent. The aver-

age death rate in New York City from diphtheria from 1880 to 1884, was 42.405 per cent.

In the epidemic of diphtheria in Bridgeport, there was reported to the city clerk from March, 1885, to March, 1886, 131 cases of diphtheria, with 68 deaths, making a death rate of 51.90 per cent. (Proceedings of the Connecticut Medical Society, 1886.)

In this epidemic 99 per cent. of the physicians in Bridgeport used the iron treatment with chlorate of potash locally.

The writer can better illustrate his method of the bichlorid treatment by giving a detailed history of a few cases where corrosive sublimate was the only treatment and milk the exclusive diet:

Cases 37 and 38 are interesting and instructive, as the history shows.

Nov. 8, 1884, I was called to see a child in consultation with Dr. Coogan, at 34 South Prospect Street. The child had been sick five days. When the Doctor first saw the child he said there were small spots on the tonsils which he thought of little account. A day or two later, he said the child was hoarse and croupy; still he thought there was no danger. On the fifth day he saw the child who was suffering from extreme dyspnea. I expressed the opinion that it was laryngeal diphtheria as there was a diphtheritic membrane covering one tonsil. I was of the opinion that treatment would be of no use. The child died a few hours later.

Nov. 24, 1884, two weeks later, was called to see Joseph N. and William H. F., aged two years and three months, and one year and two months, respectively, in the same building. The older child had a rough croupous respiration, dyspnea well marked. Bearing in mind the fatal case in the same building, I lost no time in putting the child under treatment. I ordered the wash-boiler put upon the stove, the room well filled with steam, and gave one twenty-fourth grain of corrosive sublimate every two hours, with milk between each dose. I returned in a few hours later and found the treatment had been stopped by a meddling old woman, on the ground that it was useless to torment the child, as it would die any way. Treatment was resumed and at my next visit again stopped; but a few positive words settled the matter and treatment was not interrupted again.

The next day the younger child, one year and two months old, was taken in a similar way and similarly treated. The breathing in both cases became alarmingly stridulous. They were typical cases of laryngeal diphtheria. Dr. Woods kindly assisted me by making several calls daily to see that the treatment was faithfully continued; I made three visits myself. Four days later, November 28, the breathing became somewhat easier. There was a steady improvement until the 30th inst., when both children were breathing freely. All obstruction was removed and treatment stopped. The older one had taken one twenty-fourth grain every two hours for seven consecutive days and nights. He showed slight symptoms of gastric irritation, which soon subsided when treatment stopped. The younger one showed no signs of gastric irritation.

Cases 53 and 54—I was called to 17 Chapel Street, May 18, 1885, 10 p.m., to see George W. P., and George L. L., who were sick with a very malignant form of diphtheria. The third child had just died with diphtheria within two weeks, under the treatment of a clairvoyant and magnetic healer, who had applied blood-root and other "purely vegetable" remedies to the throats; also gave them Dr. Conant's compound vapor baths, etc., until three died and two more were very sick. The cause of the outbreak was the cleaning of a very large privy vault, which had not been disturbed for many years. George W. P. had been sick four days with diphtheria. Posterior nares, pharynx and both tonsils were covered with diphtheritic membrane; patient was restless. The fatality that had occurred in this house was good evidence that it was genuine diphtheria. I ordered one twenty-fourth grain of corrosive sublimate every two hours, with milk between each dose. Second day, constitutional symptoms were improved; less restless; less fever. Third day, there was an improvement in the appearance of the membrane. It began to thin out and granulations began to appear. The treatment was continued every two

hours for five days. The improvement was such that I gave it once in three hours for two days longer, when the membrane had entirely disappeared and the treatment stopped. I then gave an iron tonic. He made a good recovery.

George L., who was sick in the same room, underwent the same treatment eight days and recovered. The clairvoyant doctor seemed less satisfied with the results of these two cases than she was with those that proved fatal. There was quite an epidemic of diphtheria in the neighborhood, resulting from the disturbance of this cesspool.

Case 94.—Master Eddie C., aged 4 years.

This case furnishes the most valuable study in the use of the bichlorid treatment of any I have had to this date.

The following is the history of diphtheria in this family:

Jan. 7, 1887, I was called to see a case of diphtheria in consultation with Dr. Welch, a girl aged 11 years, whom he had treated for about five days with one-twentieth of a grain of the bichlorid every two hours. The diphtheritic membrane had, the previous day, extended to the larynx. We increased the medicine to one-twentieth grain every hour. The next day, January 8, the dyspnea was so great that there was nothing to be done but to relieve the patient's suffering by tracheotomy. At my suggestion Dr. Wainwright was called in to perform the operation of intubation which was not satisfactory, and later I performed tracheotomy. The child was put on one-twentieth grain every hour, with milk and stimulants. Dr. Root stayed with the patient three nights and administered the medicine, which was continued three days with fair prospect that the patient would rally. We then gave the medicine every two hours for twelve hours; then every three hours which was followed by decided failure of the patient who died Jan. 13, 1887. In reviewing the case it seemed to me that if the medicine had been given every hour for a longer time there would have been a greater chance of saving the patient. With my subsequent experience I am more firmly convinced that my conclusions were right. I have detailed this case, which I saw in consultation, to show its relation to Case 94, which I treated from the beginning in the same family, to which we will return.

January 8, Eddie C. (brother of the one just referred to) was sick; examination revealed a large membrane on one tonsil. Dr. Welch asked me if I would take charge of the case. He said he would render me any assistance he could, but wished me to direct the treatment, which I did. One-twentieth grain bichlorid of mercury was given every hour from 11 A.M., January 8, until January 9, 7 P.M., thirty-two hours; one and one-third grains. The improvement was such that I gave one-twentieth grain every two hours until January 11, 7 P.M.; forty-eight hours, one and three-fifths grains. The medicine was then given every three hours until January 12, 11:30 P.M. The next morning the membrane had rapidly extended through the entire nasal passages so that it could be seen in the interior nares. I then returned to the one-twentieth grain every hour, which I continued for seventy-two consecutive hours; three and three-fifths grains were given. There was sufficient improvement to again warrant my administering the medicine every two hours, which was done for twenty-four hours; three-fifths of a grain was given. The medicine was given one-twentieth grain every three hours until January 17, 9 A.M., when treatment was stopped; seven and three-twentieths grains were given in nine days.

Dr. Wainwright saw the case several times. He came in just as I had stopped the one-twentieth grain every hour, which had been given seventy-two hours. The Doctor was surprised to see how bright the little fellow was after this treatment. He said our theories must be wrong as to the use of the bichlorid of mercury. The Doctor related the case in the Hartford Medical Society at the next meeting. The two cases acted similarly; one suddenly becoming laryngeal and the other nasal. As the vigorous and long continued use of the medicine in the latter case resulted so favorably, I believe it would have been equally successful in the former had we pushed the treatment as persistently.

I will further add that the same family lost a child by diphtheria a few months previously in the same house. The teaching of my successful case in this family is that it is necessary to give the large dose and continue it until there are signs of im-

provement, and that there is great safety in so doing.

Case 121.—Laryngeal diphtheria. I was called to Wethersfield in consultation with Dr. Fox, Jan. 15, 1888. The patient, aged 15 years; Dr. Fox gave the following history: Thursday, January 12, he was called to see the patient, who was suffering from a sore throat. Complete aphonia and marked dyspnea. He was put under treatment and there soon appeared a diphtheritic patch on the pharynx, which spread to the tonsils. When I saw the patient there was complete aphonia; pharynx, tonsils, palate and uvula were covered with a solid diphtheritic membrane. The boy lay on his back, mouth wide open, breathing heavily; the case looked doubtful.

I advised the giving of one-tenth grain of corrosive sublimate every hour and milk one-half hour later, with stimulants. The first dose was given at 6:30 P.M., January 15. I saw the patient next day—condition about the same, only that the membrane was softening a little. I advised the same treatment continued until January 17, 7:30 A.M. Patient had now taken one-tenth grain of corrosive sublimate every hour for thirty-five hours; three and one-half grains had been given; a marked improvement in the patient; medicine was given less frequently; at the end of five days treatment was stopped; five and seven-tenths grains of corrosive sublimate had been given.

The first movement of the bowels was in forty hours after treatment commenced, the second fifty-six hours after treatment commenced, the third sixty hours after treatment commenced, the fourth eighty-one hours after treatment commenced. No paralysis following, he made an excellent recovery.

Those who have used the bichlorid treatment intelligently get the most satisfactory results, as far as the prompt disappearance of the disease is concerned. The important point is that the cases so treated not only make a satisfactory recovery immediately, but are exceptionally exempt from paralysis and heart failure, following the disappearance of the throat symptoms.

This one fact of the absence of paralysis would leave ground for a legitimate conclusion, *that the bichlorid of mercury has a controlling influence over the production of albumoses and an organic acid*; known to be the direct cause of death, paralysis and heart failure, as previously stated. If this be so, we have in the bichlorid of mercury a remedy, which, when properly used, will prove of incalculable value in the treatment of diphtheria.

As has been seen from Case 94, I have administered one-twentieth grain of corrosive sublimate for seventy-two consecutive hours with most beneficial results. In Case 121 I used one-tenth grain for thirty-five hours with no constitutional symptoms.

The best results are secured when no cathartic effect follows the administration of the medicine. In case of looseness of the bowels, I usually give a little morphin to control the movements. The more completely the mercury is retained in the system the more rapidly is the disease controlled.

The treatment should be administered according to the severity of the disease, irrespective of the age or weight of the patient. A malignant case of diphtheria is just as hard to control in an infant as in an adult. In my experience it requires just as heroic treatment in one case as in the other. The sooner the patient is brought under the control of the mercurial, in the infant or adult, the shorter will be the duration of the disease and less of the drug will be administered.

ABUSE OF THE GALVANO-CAUTERY IN RHINOLOGY.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY W. H. DALY, M.D.

PITTSBURG, PA.

Since I may justly be considered by the profession to have been one of the founders of the school of intra-nasal surgery in America, I trust I may be pardoned if I speak briefly upon some of the abuses that have grown, with the tremendous advance of the special work of this branch of surgical practice.

There are unfortunately always zealots who are ever ready to out-Herod Herod in any field of work; indeed there have been Christians, who have destroyed their fellow beings for the love of God. But it is of the modern, indeed the very latest crop of rhinologists about which I here, with some hesitation ask permission to speak, and in doing so beg to disclaim any intention of personal offense, but none the less I have an ardent desire to hold our excellent special branch of medical practice safe from the wild and injurious vagaries of the injudicious ones who are liable to do us as well as their patients serious harm, by their well-meaning but excessive zeal.

I do not hesitate to say that where positive hypertrophies exist within the nasal cavities they ought to be reduced or removed, with due regard to safety, and the securing of ample and sufficient breathing capacity for the nose; such as Nature intended the individual to enjoy.

But to endeavor to cure half of the fleshly ills, including chronic diarrhea, by the cauterization of turbinates that do not in any way encroach upon the lumen of the nasal canal is beyond doubt a foolish, if not a most reprehensible practice. What I shall say may do little or no good, but I shall nevertheless do what little I can to prevent obloquy cast upon a most useful branch of medicine, to which I have devoted the best years of my professional life.

In 1880 I read a paper before the AMERICAN MEDICAL ASSOCIATION, entitled: "An Analysis of the Value of the Galvano-Cautery in the Treatment of Diseases of the Upper Air Passages." Therein I spoke of the possibilities of this instrument, pro and con, and I supposed that the admonitions of one who had already then used the galvano-cautery in more than two thousand operations might be of some use to the profession as a warning to be careful in its employment, but it proved like the admonition to children "not to put beans in their noses"; they go straight away and do it.

There was an increased demand for galvano-cautery batteries, and the thousands of poor noses and throats that have since been mercilessly burned will probably never be told of, but we hear of many nevertheless, and now and then I have heard of a case where some one has had their nasal interior freely cauterized and gone home, had a chill and died within six days, from intercurrent inflammatory disease traceable to the operation. True, patients will sometimes die from the result of a trivial operation; if this be granted then more's the need that every possible precaution be taken.

Professor Bosworth, has, I believe, always agreed with me that the galvano-cautery ought to be used only by the expert and cautious rhinologist.

I am always in the habit of looking with consider-

able apprehension for inflammatory complications of the middle ear, so that I rarely allow a patient to go from under my immediate care, after the employment of the cautery, until such danger is passed. I much regret this care is not more generally observed; as I have seen as consultant, in the practice of others, serious inflammatory mischief follow the employment of the galvano-cautery, the evil consequences of which were only counteracted by prompt measures, which are in themselves sometimes fraught with quite dangerous possibilities to the hearing; such as perforating the membrana tympana, which must be resorted to for the relief of acute otitis; media purulenta, a not uncommon liability following intranasal cauterizations.

I am sometimes appalled by what I have heard concerning the abuse of the galvano-cautery within the nasal cavities, and I have been sometimes subjected to feelings of chagrin when called upon as consultant, to help bear the responsibility encountered in accidents following the unwise if not cruel and needless cauterizations within the nose.

In conclusion, I do not desire to be understood as making a wholesale condemnation of the employment of the galvano-cautery, in cases where the removal of hypertrophies and growths interfere with the breathing capacity through the nares, pharynx or larynx; but I do most earnestly ask that those who use the instrument will not resort to its employment needlessly, and when they do let them ever bear in mind that the most watchful care is needed to prevent and meet damaging inflammations that may follow to the middle and internal ear, and possible damage, even to the life of the patient.

ABSTRACT—A LARYNGEAL NEOPLASM SIMULATING THE EVERTED VENTRICLE.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY S. K. MERRICK, M.D.

PROFESSOR OF DISEASES OF THE NOSE, THROAT AND CHEST IN THE BALTIMORE MEDICAL COLLEGE.
BALTIMORE, MD.

[Patient, male, age 48, in good general health presented himself accompanied by his physician, May 12, 1893, for laryngoscopic examination. Had impairment of voice and breathing since November 1892, growing steadily worse, until he fell on the street and became unconscious from laryngeal stenosis and over-exertion. Laryngoscope revealed a soft ovoidal, inflamed tumor filling up the left ventricle, concealing left and part of right, and occupying three-fourths of the glottic space. Patient's breathing loud and stridulous. Syphilis denied by family physician and the case diagnosed as probably everted ventricle associated with laryngitis. Later, patient confesses he has had syphilis and the neoplasm is diagnosed as a gumma and treated successfully as such. Comparative rarity of the two affections and the instructive features of the case.]

Mr. W. G. W., age 48, height 6 feet, weight 175 pounds, occupation capitalist, was brought to my office May 12, 1893, by his physician, Dr. Wilmer Brinton, of Baltimore, Md. Dr. Brinton said his patient had been suffering with dysphonia, (he feared from some laryngeal growth) since November 1892; that his condition had steadily grown worse, until his breathing had become so seriously embarrassed, that he had fallen on the street a day or two previously in a state of asphyxia, becoming cyanotic and unconscious. After restoratives were administered freely, the patient slowly regained consciousness. No doubt over-exertion precipitated this attack. Up to this time patient had declined to consult a throat specialist, although frequently urged to do so by his physician. He now gave his consent. Nothing in the family history was elicited which had any bearing on his case, except that his father at this time was suffering with a carcinoma of the face. With this information, furnished

by his physician and the assurance of the latter that he was sure there was no specific taint in the patient's constitution, as his children were all healthy, I began the examination.

The man's breathing was stridulous and there was both inspiratory and expiratory dyspnea and marked dysphonia. His condition was such that he was not permitted to come to my office without an attendant, and his wife did this service for about ten days after treatment was instituted.

The laryngoscope revealed a diffuse intense laryngitis and an ovoidal inflamed tumor, filling up the left ventricle and concealing the anterior three-fourths of the left cord to which it was attached either by adhesive inflammation or as the site of the neoplastic formation. On adduction the growth overlapped the right cord, covering its anterior two-thirds and on quiet breathing about one-half. The ventricular bands were so inflamed and infiltrated that they met at their anterior thirds and covered in the growth at its anterior attachment, thus concealing a considerable portion of the tumor. I now made a careful drawing of the laryngeal image which I kept for comparison in the future progress of the case.

After some days of mild astringents and antiseptic sprays and nightly inhalations of medicated hot vapors, without any very marked benefit therefrom, a consultation was had with Dr. Jno. N. MacKenzie. He was inclined to believe the tumor was an everted ventricle, associated with a severe laryngitis.

While the tumor was compressible and yielding and could be made to occupy largely the ventricular cavity by means of the probe, the left cord could not be exposed by this manipulation, and it was evident that the cord was the primary site of the tumor as the adhesions had been so uniform that it was bound down firmly to all parts of the concealed portion of the cord. I myself inclined to the opinion, that the growth had its origin in the cord, and as it grew it filled up or encroached upon the ventricular as well as the glottic space.

A few days later, Dr. MacKenzie saw the case again with me and affirmed his former diagnosis. Up to this time no change had been made in the treatment; there was possibly some improvement in the laryngitis and the patient was permitted on his own request, to come to the office alone in the future.

May 25, I saw the patient for the first time when his wife was not at his side. Not being fully convinced that I had to deal with an everted ventricle, and yet unable to account for the presence of a soft tumor of the cord, I determined to question the patient myself as to his past history, this being the first opportunity in the absence of his wife, who had always followed him into my operating room. I asked him if he had ever had syphilis at any time during his past life. He confessed at once that he had a chancre fifteen years ago and that he had gone through a course of treatment for six months or a year and was pronounced well. He said he had withheld this information from his physician, and feeling sure his throat trouble was in some way caused by this disease he shrank from a laryngoscopic examination which he believed would lay bare this part of his history; this he said explained his reluctance to consulting a throat specialist.

Believing now that I had to do with a gumma of the cord and a specific laryngitis, I began at once to give iodid of potash cautiously. The drug was well borne and after consulting with Dr. MacKenzie and making known the result of inquiry, it was agreed that the agent should be pushed to iodism, unless contra-indicated. Improvement began in less than a week, and in two weeks Dr. MacKenzie saw the case again and agreed with me that the improvement was great, and that the tumor was doubtless a gumma.

A rapid amelioration in all the symptoms took place and on July 22, 1892, I made another careful drawing of the laryngoscopic image and by comparing it with the one made May 21, it was estimated that two-thirds of the growth had been absorbed and the diffuse laryngitis and infiltration of the ventricular bands had nearly disappeared. Local and constitutional treatment were continued for about six weeks without any marked change for the better, and Dr. MacKenzie suggested that pure lactic acid be applied to the remains of the growth, with the view of destroying it or stimulating its absorption. Undiluted lactic acid was now applied twice a week to the growth and the iodid continued internally. Very slow absorption under the use of the acid took place, but at no time ulceration.

By Oct. 20, 1893, only a slight local bulging of the diseased cord could be seen, and the patient visited the World's Fair at Chicago, where he took cold and had a decided set-back. A

severe laryngitis set in resulting in some swelling of the growth and ulceration of the right cord. It took the remainder of the year to get my patient back to the condition he was in, before he went to the Fair. Improvement has gone on steadily since Jan. 1, 1894, and I now see him once or twice a week—he is practically well. The cord has not quite regained its normal pearly white appearance, and I shall keep the patient under observation until I see no trace of the disease left, knowing the liability to relapse.

I have reported this case somewhat minutely in view of its being a rare affection and one simulating another affection which is equally rare; at the same time presenting difficulties in diagnosing to so competent a laryngologist even, as Dr. Jno. N. MacKenzie is acknowledged to be.

The first to recognize the everted ventricle during life was Lefferts who reported his case in the *New York Medical Record*, June 3, 1876. Since then a number of cases have been reported, but the rarity of the condition may be inferred when such observers as Cohen, Elsberg and Semon each have been unable to report but one case.

The gummy tumor of the larynx doubtless occurs much more frequently than the everted ventricle, but owing probably to the great activity of the structures when it is likely to form, it breaks down so readily and forms an ulcer so quickly that the latter process is fully established before the lesion is observed. The rare instances where the tumor does not break down for some unknown reason constitute the class to which my case belongs. Such cases have been reported by Luca, Delie, Charozoc, Fischer, Cardone, Schech, Massie, Sewin and Mandl, which will not probably outnumber the cases of everted ventricle reported.

The foregoing case emphasizes:

1. The difficulty of differentiating the gummy tumor from the everted ventricle, when the former fills up the ventricular cavity.
2. The great importance of excluding syphilis in all laryngeal tumors if possible.
3. The brilliant results which follow specific treatment, although tracheotomy may appear to be necessary, for the stenosis.

A NEW APPARATUS FOR THE TREATMENT OF FRACTURE OF THE INFERIOR MAXILLA.

Paper read before the Colorado State Medical Society, June 23, 1894.

BY CLAYTON PARKHILL, M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE UNIVERSITY OF COLORADO; SURGEON TO ST. LUKE'S AND ARAPAHOE COUNTY HOSPITALS, ETC., ETC.

Last October I was consulted by Mr. C., who gave the history of having been sandbagged the night before. The right side of his face and the parotid region presented evidence of serious contusion. The mouth was open and fixed, giving him the appearance of having a dislocation of the jaw. The incisors were separated about three-quarters of an inch, the posterior molars being in contact. There was no lateral displacement. On examination under an anesthetic, I found a fracture of the neck of the jaw. Crepitus was marked. There was apparently no displacement of the upper fragment. Reduction was effected very easily, the teeth coming into perfect articulation. A gutta-percha splint was molded to the jaw, and attached by tapes to a cap covering the head, making an apparatus similar to what is known as the French Dressing.

No sooner had the influence of the anesthetic passed away than the deformity returned. I then

Fig. 1.

applied in turn the various bandages which have been recommended, only to be met by failure with each one.

On the following day I requested Dr. H. P. Kelly,

Fig. 2.

an expert dentist of this city to see him with me, and make a model for an inter-dental splint. It was

found impossible to separate the molars sufficiently to get the plastic material between them. I then

Fig. 3.

applied the Hamilton Dressing, only to suffer another defeat.

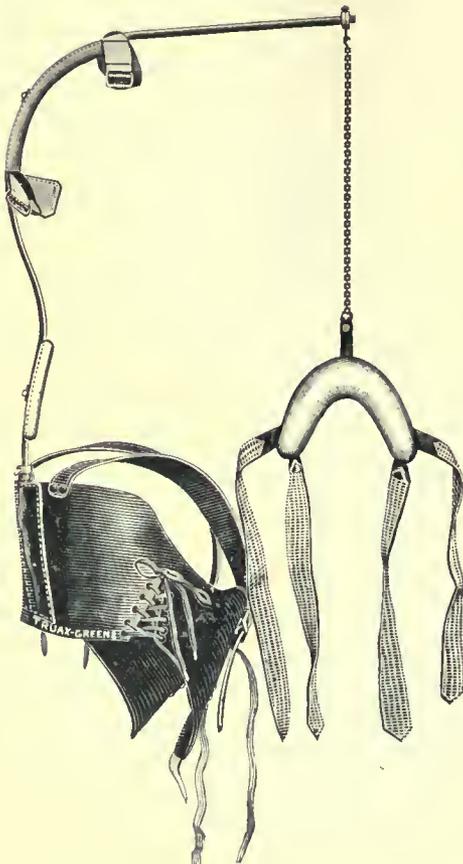

Fig. 4.

It was evident that the displacement was due to the action of the temporal and masseter muscles on the

side affected, and that a dressing capable of holding the jaw in place must be one having an upward and forward pressure, antagonizing this force.

I had the Denver Surgical Instrument Company make for me the apparatus shown in the accompanying cuts. The corset is made of heavy leather and has a socket fitted in it at the back to receive the spring. The spring is in shape similar to the ordinary jury-mast, and is made of steel. It has attached to it an inter-scapular pad and an occipital pad. On its anterior extremity there is an adjustable ring fastened by a set screw. This is intended to regulate the tension by shortening or lengthening the spring. The jaw-piece is made of copper, molded to the shape of the maxilla. The horizontal and vertical tapes attached to the jaw-piece posteriorly are self explanatory. The small chain attached to the jaw-piece anteriorly ends in a hook. This chain is intended to pass through the sliding ring, and when the proper tension is attained, to hook back into one of its own links.

This apparatus was applied with the patient under an anesthetic. The deformity was completely corrected, and there was never the slightest tendency towards its recurrence. The patient expressed himself as feeling no discomfort. He removed it contrary to my directions at the end of twenty-one days. I had intended that he should wear it four weeks. The result, however, was perfect.

A fracture through the neck of the jaw, is a very rare injury, but I believe this apparatus will prove equally good for other forms of fracture of that bone. I propose to have made another jaw-piece which will extend upward around the maxilla and afford a lateral support. With this addition I think the instrument will apply as well to either simple or multiple fractures of the body of the bone, as it does to the neck.

The results obtained in fracture of the lower jaw are far from satisfactory in many cases. Within the last three years I have operated on three cases which were sent to me suffering from ununited fracture. This number of failures to get union in a fracture of no greater frequency seems to me to indicate that present modes of treatment are not entirely satisfactory, and affords me encouragement to present this new method of treatment to the profession for its approval.

THE BUBO PLAGUE IN CHINA, WITH A BRIEF ACCOUNT OF THE GREAT PLAGUE OF LONDON.

BY BURNSIDE FOSTER, M.D.

SURGEON TO THE SKIN AND VENEREAL DEPARTMENT OF THE ST. PAUL CITY AND COUNTY HOSPITAL; DERMATOLOGIST TO ST. LUKE'S HOSPITAL; DERMATOLOGIST TO ST. JOSEPH'S HOSPITAL; VISITING PHYSICIAN TO THE ST. PAUL FREE DISPENSARY, ETC.

ST. PAUL, MINN.

Although the possibility of there being in this country an epidemic of this terrible disease is a very remote one, it would not be at all surprising if an occasional case should be brought to the Pacific coast from China, where it has been raging so recently, and where it still exists. In view of these facts I have thought that some account of this, by far the most fatal and horrible of all epidemic diseases might be of interest—as well from an historical as from a medical point of view. The first extensive epidemic of the plague, of which history has recorded any definite account, occurred in the sixth century, A. D.,

and is usually described as the Plague of Justinian, since it existed during nearly the whole of that emperor's reign.

Although there are some discrepancies in the various accounts which I have consulted, the epidemic seems to have had its origin in Lower Egypt in the year 542. From its starting point it traveled up the Nile, and then leaving that stream it swept with increasing fury into the interior of Asia Minor. Constantinople was visited, with the result that for some days the people died at the rate of 10,000 daily. In the next year it traveled over Greece and Italy; in 545 it extended into Gaul and in the following year reached the cities of the Rhine. During the seventy years of its existence this fearful disease visited all parts of the known world and its victims were numbered by millions. In several instances historians have recorded that more than half the population of many of the cities perished, and that scarcely people enough were left alive to bury or destroy the bodies of those who died. In the words of a recent German historian (Baas): "For long years this plague endured, intermixed at the close with small-pox, sweeping away in its devastating course the bloom of manhood and youth and destroying the greater part of women, maidens and children in all the then known world. It loosened too, almost all the rootlets of the ancient civilization, so that the withered stem was able to maintain for centuries only a feeble and sickly existence."

During the succeeding years of the Middle Ages we have no knowledge of any very extensive plague epidemics until the sixteenth century. In the year 1500 it raged in Germany, Italy and Holland for seven years; in 1534 in southern France; in 1562 for six to eight years it was pretty general throughout Europe. During these epidemics we find it recorded for the first time, that to some extent epidemics were considered preventable, and that there were attempts at disinfection and isolation. Sulphur, arsenic and alcohol were among the earliest disinfectants; and the plague physicians, "Pest Medici" as they were called, wore special gowns and masks, and anointed their hands and arms with medicated oil before coming into contact with the sick. During this and the seventeenth centuries a number of severe and fatal epidemics of this dread disease occurred in all parts of Europe, but the one of which I will make special mention is the Great Plague of London which occurred in the year 1665.

There came by chance into my possession recently two curious old books which were written, the one by a layman and the other by a physician; both inhabitants of London at that time. I refer to De Foe's "History of the Plague," and to the "Works of Dr. Thomas Sydenham," a very eminent physician of that time. These two books give, from their different points of view, such a comprehensive and interesting account of the events of that dreadful year that I shall quote from them both in some detail:

In September, 1664, there began to be rumours in London that the plague was again raging among the Dutch and in the latter part of November two men said to be Frenchmen died of the plague in a house at the upper end of Drury Lane. During the next few months there were occasional cases in the same part of the city, but it was not until early in the following May that there began to be any serious apprehension. With the warm weather the cases became more numerous and in the second week in June about one hundred died of the plague in the out parishes and the disease began to appear in the city, and by July 1 the pestilence had

become so general that business of all kinds was suspended and many of those who had the means to do so shut their homes and places of business and fled to the country. The panic among the people became so great that many went mad through fear and others deliberately committed suicide to avoid the infection. Great numbers of quacks, mountebanks and impostors seized the opportunity to prey upon the fear and credulity of the people.

De Foe records that the posts of houses and corners of streets were plastered over with doctors' bills and papers of ignorant fellows quacking and tampering in physic and inviting the people to come to them for remedies.

"Infallible, preventive pills against the plague. Never failing preservatives against infection. Sovereign cordials against the corruption of the air. Anti-pestilential pills. Incomparable drink against the plague. The only true plague water. The Royal Antidote against all kinds of infection, and such a number more that I can not reckon up, and if I could would fill a book of themselves to set them down."

Others assuming specious titles summoned people to their lodgings by such bills as these:

"An eminent High Dutch physician, newly come over from Holland, where he resided during all the time of the great plague last year in Amsterdam and cured multitudes of people that actually had the plague upon them."

"An ancient gentlewoman having practised with great success in the late plague in this city, Anno, 1636, gives her advice only to the female sex."

"An Italian gentlewoman, just arrived from Naples, having a choice secret to prevent infection, which she found out by her great experience, and did wonderful cures with it in the late plague there, wherein there died 20,000 in one day."

"There is no doubt," says De Foe, "but these quacking sort of fellows raised great gains out of the miserable people, for we daily found the crowds that ran after them were infinitely greater, and their doors were more thronged than those of Dr. Brooks, Dr. Upton, Dr. Hodges, Dr. Berwick, or any, though the most famous men of their time."

The Lord Mayor and Aldermen adopted very sensible and very stringent measures for the separation of the sick from the well, and for general disinfection, which doubtless had a considerable effect in controlling the disease. An infected house was at once shut up and a watchman appointed to guard it day and night, to see that none entered or left it without special permission. By this means, harsh and cruel as it was in many instances, the infection was to some extent confined and localized. During August the deaths became so numerous that it was impossible to give decent burial to the bodies. Great ditches were dug, and the bodies, without discrimination were cast into them. It was estimated that above ten thousand houses in London were deserted and that about two hundred thousand people left the city. From August 8 to October 10, according to the mortality bill there died in London 59,810 people, of whom 49,605 died of the plague. The total number of deaths from the plague during the epidemic is placed by De Foe at 100,000. From November 1 the number of cases began to diminish, the death rate of those attacked became smaller and as winter came on, people returned to London, resumed their business and by February of the next year the Great Plague was over.

A very accurate clinical description of the disease is given by Sydenham, and I will presently refer to it. In regard to the nature of the infection by which the disease is spread, De Foe, after discussing various opinions says: "Others who talk of infection being carried through the air only, by carrying with it vast

numbers of insects, and *invisible creatures*, who enter into the body with the breath or even at the pores with the air, and there generate, or emit acute poisons, or poisonous ovæ which mingle themselves with the blood and so infect the body." Strange that the actual discovery of germs and of the ptomaine theory should have been delayed for two centuries!

The symptoms of the disease are thus described by Sydenham:

"Its first approach is almost always accompanied with shaking and shivering like the fits of an ague; presently violent vomiting, a pain about the region of the heart, a burning fever with the usual concurrence of symptoms perpetually afflict the sick till either death itself or a happy eruption of a bubo discharges the morbid matter and so frees them from that deplorable condition. It does now and then happen that it comes without any sense of fever before and suddenly kills men; the purple spots which are the forerunners of death breaking out as they are about their business. But this sudden death scarce ever happens but at the beginning of a dreadful plague. It sometimes also happens that swellings appear when neither a fever nor any violent symptoms went before. The victims sometimes died within a few hours of the first symptoms, and rarely lingered beyond four or five days. If the buboes suppured it was considered to be a favorable circumstance and they were therefore treated by incision or by caustics."

The other local manifestations were carbuncles, furuncles and ecchymoses. A peculiar and characteristic stench was emitted from the bodies of the sick. At the beginning of the London Plague upwards of 90 per cent. of those attacked, perished. Towards the end of the year the disease seemed to become milder and the mortality was much less.

I have gathered from various sources a pretty accurate description of the epidemic now devastating China, and its identity with the above is undoubted.

The disease first appeared in the Province of Kwantung in the latter part of March and spread principally among the poor and filthy, with frightful rapidity. More than half a million people perished in two months and the great commercial centers, Canton and Hong Kong were soon attacked. In the former city with a population of 1,000,000, the number of deaths exceeded 100,000!

The symptoms are thus described: With or without premonitory warning in the shape of malaria or chill there is a sudden onset of fever, rising to 105 degrees F. or over; there is much headache and cerebral disturbance, accompanied by stupor. In from twelve to twenty-four hours glandular swellings occur in the neck, armpits or groin, rapidly enlarging to the size of a hen's egg; these are hard and exceedingly tender; with or without a decline of the fever the patient sinks into a deeper condition of coma and dies usually at the end of forty-eight hours or sooner. If six days are reached recovery is hopeful. The glandular swelling shows no signs of suppuration, in some cases epistaxis or vomiting of blood occurs. Petechiæ appear in a few but there is no regular eruption. The mortality is about 90 per cent.

In the latter stage of the disease, when the local manifestations are most apparent, the fever usually diminishes and there occurs a sticky and very offensive perspiration. The inguinal and femoral glands are those most commonly affected, although those in the axilla and neck are often involved at the same time. The carbuncles are of less constant occurrence than the buboes and are usually seen on the lower extremities, the buttocks and the back of the neck. Among the sequela in those who finally recover, are

continuous suppuration of the buboes, abscesses of the skin and muscles, pneumonia, dropsy, partial paralysis and mental disturbances.

The malady is undoubtedly a filth disease and caused by a bacillus. Indeed, Professor Kitasato, a competent bacteriologist and a pupil of Koch, claims to have discovered the specific germ. There is no doubt and it has been repeatedly demonstrated during the last one hundred years, that efficient quarantine gives absolute protection from the disease, and that modern sanitary means can rapidly stamp out an epidemic should a few cases be imported into a well ordered community. It has been well named, "the disease of barbarism," from the fact that it only occurs among the semi-civilized. There is little to be said concerning treatment. There is no known specific and the treatment, like that of all acute fevers, must be supporting and symptomatic. Should there be given sufficient opportunity to study this disease scientifically, which is not at all likely, I am convinced that the only specific medication would be found in the development of the antitoxin theory. It is also probable that immunity might be given by inoculation of an attenuated virus. Fortunately our shores are so well protected by quarantine and our communities are so well ordered from a sanitary point of view that it would be impossible for this plague to make much headway within our borders, even should a case or two find their way through the gates of commerce.

THE DESTRUCTION OF CONJUNCTIVAL GROWTHS BY ANIMAL FERMENTS.

BY T. O. SUMMERS, M.A., M.D., F.S. Sc., LOND., ETC.
WAUKESHA, WIS.

Having been for some time past engaged in the work of experimentation upon the therapeutic uses of the animal ferments in surgical diseases, I desire among many remarkable instances of the powerful digestive action of these agents upon the neoplastic structure to call the attention of the profession to a case of cauliflower excrescences upon the conjunctiva of the lower lid, which are well known to the ophthalmologist and have hitherto been considered amenable only to surgical treatment—complete excision. In the case referred to, the lower lid was covered with a number of these growths, columnar in structure and of rapid growth. The removal of them by escharotics was not for a moment to be considered on account of the danger of injury to the normal structures in which they were imbedded. After thoroughly cleansing the surface and applying cocain to relieve the pain I covered the surface thoroughly with a paste of glycerin and peptinzyne (Reed & Carnrick's preparation from the gastric, splenic and intestinal glands). To my great satisfaction I saw that the growths were immediately attacked and after three or four applications they were completely removed without the slightest injury to the surrounding tissues. I consider this a triumph of therapeutics over surgery and heartily recommend the use of these ferments in all these abnormal neoplastic growths which spring up like mushrooms from mucous surfaces. I shall have more to say of the action of the dialytics upon false membranous deposits in another paper upon this subject.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 96 FIFTH AVE., CHICAGO, ILLINOIS.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

SATURDAY, SEPTEMBER 22, 1894.

THE JOURNAL OF THE AMERICAN MEDICAL
ASSOCIATION.

By the time this number of the JOURNAL reaches our readers, the goods and chattels of the ASSOCIATION will have been housed in more commodious quarters. It has long since outgrown the little space in the Wabash Avenue building in which for the last decade the business of the JOURNAL has been done and the faithful compositors have worked. The erection of the new city library building cut off the light and air to a great extent. The gas has been lighted continuously during business hours for the last six months, and owing to the cramped space the editorial work had to be done elsewhere.

The editor was last year authorized by the Trustees to secure other and better accommodations, but it was thought best, owing to the unsettled outlook of business matters generally, to wait another year. The year passed, and finds the ASSOCIATION once more with a sufficient balance in the treasury to warrant it, and new offices are being fitted in the Times Building, 84-86 Fifth Avenue, where the members of the ASSOCIATION, and the subscribers to the JOURNAL, will be made welcome should they visit the office.

For the first time in its history, the JOURNAL will in one week from the date of this issue, be printed on its own presses, the best and fastest that can be purchased at this date, while the remainder of the machinery is of the latest and best pattern. No fault can be found with the excellent press work so long furnished by MESSRS. BLAKELY & ROGERS, but it has not only seemed to the Committee on Management, more economical but vastly more convenient, to have all the work done under the immediate supervision of the editor. The experienced foreman, who has been with the JOURNAL, with slight interval ever since its foundation, will continue in that capacity for many

years we hope. While the first outlay will be considerable, the ASSOCIATION will be the gainers in having the office fully equipped, probably better than any medical journal in the world. In business matters it is an axiom that to do business one must be prepared for it. The preparation has now been made and the Trustees confidently appeal to the medical profession at large, scarcely less than to the members of the ASSOCIATION to approve of the great advance in medical journalism by renewed and active interest in the ASSOCIATION, and its JOURNAL, which is published in the interest of the *entire* profession.

In the face of this great improvement in the material interest of the JOURNAL we trust we may be pardoned, if we refer with pride to the steadily onward progress the JOURNAL has made since its commencement. The wisdom of its founders has been made apparent, and the broad lines of development laid down by the first Board of Trustees are bearing their fruit. Carping critics have not infrequently amused themselves by predicting the downfall of the JOURNAL, but supported by the ASSOCIATION, it has continued to prosper beyond the most sanguine hopes of its best friends. With the increase in its subscription list that must follow, the JOURNAL will soon be able to enlarge its scope, by adding new departments from time to time, as its support justifies.

IS SMALLPOX A SPOROZOAN DISEASE?

Smallpox belongs to that class of acute exanthematous diseases like scarlet fever, measles and chickenpox, in which, notwithstanding the patient efforts of bacteriologists, a specific microbe has not been demonstrated. From time to time, since bacteriologic methods have been employed, the report of the discovery of the specific bacterium of one or another of these diseases has appeared, only to be refuted by more extended studies. That smallpox, for example, with its well-marked typical course; its pronounced infectious character; and the long-known possibility of preventive inoculation should escape the most searching analysis of the bacteriologist, is indeed singular. Reasoning from the analogy with other infectious diseases, nothing would apparently be more simple than to isolate from the vaccine virus, the bacterial parasite of smallpox. It is scarcely to be wondered that the few remaining critical scoffers against pathologic mycology have pointed to these negative results with vindictive emphasis.

These failures indicate one of two conclusions: 1, either smallpox is not a parasitic disease; 2, or, being caused by a parasitic organism, this organism is one which does not yield to any of the methods employed in the ordinary bacteriologic technique. To admit the first postulate would be to undermine the whole foundation of modern parasitology. Obvi-

ously, in the still comparatively new state of bacteriologic science, such an inference would be premature. The only reasonable attitude, therefore, toward the unsolved problems of the etiology of that class of diseases of which smallpox is a type, is that indicated by our second postulate—an attitude of patient expectancy.

Recent studies in parasitology, however, tend to stimulate us with the hopes that ere long we may be rewarded by the discovery of specific organisms for many of those diseases which still baffle our investigations. These hopes are kindled by the progress made in the past few years in the study of a class of lowly animal parasites which do not respond to the usual methods of investigation employed by the mycologists. The current literature of micro-biology bears witness to the eagerness with which the work on the protozoan parasites of man and the lower animals is being pursued. The remarkably prolific discussions on the protozoan theory of cancer have furnished the attentive medical world much information concerning this hitherto overlooked (in human pathology) class of parasites. Along this same line is the work that has given us the specific parasite of malaria—a protozoan microorganism* with well defined characters.

The large proportion of the studies on the sporozoa as disease-producing organisms have been confined to the lower animals, especially to the lower vertebrata—fishes, amphibians and birds. The coccidia disease of rabbits and other mammals has long been known. The probable identity of a sporozoon organism residing in the blood of infected cattle, with the parasite of Texas fever, has been established by the investigations of THEOBALD SMITH (Texas Fever, U. S. Department of Agriculture, Bureau of Animal Industry, Bulletin No. 1, 1893; and preceding communications herein referred to).

With these introductory researches on the sporozoon diseases in view, it is not surprising that the presence of the protozoan parasites should have been suspected in those infectious diseases which had escaped the investigations of the bacteriologists. In fact, KOCH predicted more than ten years ago, (*Deutsche Medicinische Wochenschr.*, 1890, p. 757) that in measles, scarlet fever, variola, typhus, etc., which had resisted mycologic study, animal parasites would be found. Doubtless with these predictions in mind, a number of investigators have undertaken the study of the non-bacterial diseases—including smallpox.

For a long time careful observers have noted peculiar bodies ("inclusions") lying in the substance of the epithelial cells of the vesicles of variola and vaccinia. These bodies have been described, and in part, illustrated, by POHL PINCUS, WEIGERT, KLEIN, BAREGGI, PLAUTH, ZÜRN, ISIDOR NEWMAN, BIRCH-

HIRSCHFELD, HELFAUT, CORNIL and BABES. These pioneers did not, however, suspect the parasitic nature of these cell inclusions.

L. PFEIFFER (*Monatshefte f. prak. Dermatologie*, Bd. vi, Nr. 10-15, 1887; and *Die Protozoan als Krankheitserreger*, 1890, and 1891) was the first observer to ascribe to these intra-cellular bodies in variola and vaccinia a parasitic protozoan character. VAN DER LOEFF (*Ibid.*, Bd. vi, Nr. 5 u 10) published his observations almost simultaneously with PFEIFFER. The reports of PFEIFFER and VAN DER LOEFF were confirmed by the studies of GUARNERI (*Archivo per le Scienze Mediche.*, Vol. xvi, Nr. 22, 1892) on smallpox.

Recently, RUFFER and PLIMMER (*British Medical Journal*, No. 1748, page 1412, 1894) have reviewed the previous work and have, in their personal researches, been able to substantiate the claims of the foregoing authorities who regard as protozoa the cell inclusions of smallpox.

PFEIFFER describes the sporozoa of smallpox as existing in two forms—a free flagellate organism residing in the blood plasma; and an amœba-like inclusion in the epithelial cells. In a case of vaccinia in a child he found the free flagellate protozoa in the blood at the fourth day after vaccination and marked their presence until the sixth or seventh day had expired. When stained by the Biondi Ehrlich reagent the organisms exhibited a small central nucleus; and in preparations stained by the Biondi-Ehrlich reagent, and followed by Löffler's flagella stain, distinct flagella were noted—a single flagellum to each organism. PFEIFFER found similar organisms in the blood in cases of varicella and zooster. He was rarely able to discover these amœbæ in segmentation stages as observed in the plasmodia of malaria. Similar forms to those just described, but minus the flagella, were found in the contents of newly formed vesicles of zooster, varicella and vaccinia. The amœbæ were never found in the substance of the red blood corpuscles, and the investigator concludes that the free parasites in the blood represent but one stage of the infection.

With the disappearance of the organisms in the blood in smallpox, a secondary cell infection makes its appearance in the epithelium of the epidermis. A similar phenomenon occurs in the *stratum lucidum* in scarlet fever, zooster, varicella and measles. The intra-cellular bodies increase in size, pushing the nucleus of the cell to one side. Bodies similar to these cell inclusions also appear in the cellular interspaces of the epidermis. Eventually these inclusions, after increasing greatly in size, undergo a multiple segmentation with the production of countless, very minute spores.

This is, in substance, the description given by PFEIFFER of the sporozoon parasites of the acute exanthematous diseases, and it is, in the main, sub-

stantiated by the more recent investigators above cited.

The whole subject of sporozoon parasitology is still in its infancy; and we have much to learn ere we can definitely discuss any of the interesting problems suggested by this line of work. The knowledge of the morphology and biology of these parasites is still largely undetermined, even in the case of the best known sporozoa of comparative pathology. Notwithstanding repeated efforts, we are still practically unable to isolate and cultivate in artificial media, these peculiar organisms. Thanks to the patient work of comparative pathologists, however, we are coming to a better understanding of the life history of the pathogenic sporozoa; and the immediate future doubtless has in store for us a method of artificial cultivation. What OGATA has accomplished in the cultivation of certain of the larger protozoa will soon be applied to the sporozoa.

With these facts in mind we must regard as very suggestive and very promising the researches into the sporozoon character of the acute exanthemata. When it is remembered, for instance, that such a well known protozoan as *Heteromita* has been repeatedly observed, in its multiple fission, to form spores so minute as to be almost beyond detection with the most powerful lenses of the present day, then it will not appear so remarkable that many of the protozoan parasites have escaped detection. With this well established phenomenon in mind it would not be difficult to account for the fact that up to the present time no visible organism has ever been detected in the vaccine virus, with the clinical effects of which we have been so long acquainted. The "resisting spores" of smallpox doubtless exist in so minute a form as to be ultra-microscopic.

HAS VACCINATION ANY THERAPEUTIC EFFECT?

PROFESSOR COMBEINALE furnishes the *Bulletin Médical du Nord* his conclusions as to the necessity of re-vaccination and, incidentally, as to the effect of vaccination performed during the incubative stage of smallpox. These conclusions are founded upon his observation of 330 cases of the disease during the epidemic of 1891-92 at Lille—89 of the cases being children under 12 years of age. He concludes that: 1, it is necessary to re-vaccinate children every five years; 2, adults can be assured of real and continued immunity only when they, too, are re-vaccinated every five years; 3, in case of failure of vaccination in children it must be repeated every year until successful; 4, re-vaccination during the stage of incubation does not influence the course of the disease any more favorably than a primary vaccination—meaning, it is assumed, that the vaccination performed on a previously vaccinated person after

the disease had been contracted, would have no influence. Unhappily, the subjects involved in these conclusions promise to be of more than passing interest to the profession in this country during the next few months. As indicated in last week's JOURNAL, there is a general apprehension among health authorities of an epidemic prevalence of smallpox this coming winter.

Passing over his conclusions with regard to the necessity of re-vaccination, it may be worth while noting that COMBEINALE's fourth conclusion as to the inutility of re-vaccination during the incubative stage of smallpox does not accord with that of the late DR. RAUCH on the same subject. In an argument advocating the use of humanized, rather than of bovine, virus—on the ground of the greater promptness and certainty of action of the former—DR. RAUCH asserts most positively the therapeutic value of vaccination as well as its prophylactic power¹. His language may be profitably quoted in this connection, when opportunity for the application of its lesson may be afforded in the near future. "Thus," he says, "if a patient be vaccinated during the febrile stage and the vaccination progress normally—there being nothing antagonistic between the two diseases, variola and vaccinia, to prevent such normal progress—the areolar stage of vaccination will be reached before the dangerous tenth day of the variolous disease; and, as has been repeatedly witnessed [during the epidemic of 1881-83] the graver disease will be aborted, jugulated or materially modified." As an illustration of this abortive power of vaccination he cites an instance (MARSON'S?) which, he asserts, was almost exactly paralleled in the epidemic under his observation: Of three children, equally and simultaneously exposed to a case of smallpox, one had been vaccinated and the other two were unprotected; the former escaped entirely, but the others in due time exhibited the usual symptoms of the disease; one of these was vaccinated immediately on the appearance of the symptoms, but the other remained unprotected; the disease seemed equally severe in both up to the eighth or ninth day, when the vaccinated child began to improve, the pustules dried up, no secondary fever followed and the case went on to convalescence; "in the unvaccinated child the disease runs the usual course of unmodified smallpox, and during the tenth to twelfth days—the period of greatest mortality, and when the other child is entirely out of danger—this one has about equal chances for and against recovery."

Finally, in a study of 1,931 cases of the disease during the epidemic of 1881-83—nearly six times the number observed by the French writer—DR. RAUCH found that, whereas, the average duration of all cases

¹ The Relations of Smallpox and Vaccination. By John H. Rauch, M.D., Springfield, Ill., 1884.

non-vaccinated, vaccinated and re-vaccinated, was 20.8 days (rising to 29.8 days in the non-vaccinated), the duration was only 13.8 days in those re-vaccinated after exposure, *i. e.*, during the stage of incubation. Not only this, but the veteran American sanitarian has shown that, while 93.18 per cent. recovered of those who were vaccinated or re-vaccinated *before* exposure only, 94.20 per cent. recovered of those vaccinated *after* exposure only; and all cases—sixty-eight in number—recovered who were vaccinated both before and after exposure. It was upon these results that DR. RAUCH based his apothegm: *It is never too late to vaccinate.*

CORRESPONDENCE.

Cataract Extraction, an Office Operation.

Reply to Dr. Kollock's Letter.

Sr. Louis, Mo., Sept. 18, 1894.

To the Editor:—I do not usually take public notice of such an article as the one by Dr. Kollock, of Charleston, S. C., in the JOURNAL of September 1, condemning the methods of dealing with cataract patients as practiced more or less by Drs. Cheatham, Le Mond, myself and others. I might add, *many* others; but the wide circulation of our JOURNAL and the severity of the criticisms calls for a word of defense for myself, as well as for the other gentlemen named, for the quite large number who have not as yet published their experiences with this method and are conscientiously and satisfactorily making use of it. Dr. Kollock openly condemns the procedure without offering any well founded reasons for so doing beyond mere opinion.

Such a course as this is not conducive to the advancement of science in any of its departments, but rather is the spirit that checks progress. According to the views expressed by Dr. Kollock any one who departs from the "well beaten path" should fall under the condemnation of all "conservative surgeons;" and, he suggests, become liable to suit for malpractice,—a spirit of uncharitableness in the profession that we had hoped was long since extinct. It is that spirit which has in all times opposed true progress. Any procedure in surgery that is fraught with danger is sure to bring its own condemnation and lead to its abandonment. If I am a "progressive and intelligent ophthalmologist," as the gentleman gives me the "honor" (?) of being, I certainly would not tenaciously hold to and advocate a method that contained any essential elements of danger. About eight years' experience with the method in question on my part, and fully nine years by Dr. Cheatham certainly ought to have shown us the danger, if danger there be, in it. Every operation on the eye is attended by some risk, and we can not always foresee where the point of danger lies, but we usually see it afterward.

I have shown in former articles on this subject that the great secret of success in cataract extraction lies in a well performed and smooth operation done under strictly aseptic rules, and followed by a careful adjustment of the lids over the globe (for which I prefer a strip of plaster), and interfering as little as possible until the corneal wound has united. Hardly any one will gainsay this proposition. As to the control of the patient after the operation the views of men of large experience radically differ, but one thing must be noticeable to every one who has followed this subject, and that is, the old method of bandages, dark rooms and strict confinement in bed are being rapidly abandoned

by the ophthalmologists of to-day. Nothing ever brought me more expressions of gratitude from my patients than the abandonment of dark rooms. Next to this came the omission of bandages; and last, the greater liberty allowed my patients after extraction. In my hands these departures from the stereotyped methods have proved blessings to the afflicted, but they each and severally have suffered opposition and criticism by the profession.

Ours is an experimental science, and the conservative experimenter, not the reckless adventurer, is the one who makes valuable improvements in our methods of dealing with disease without sacrificing his patients.

In adopting cataract extraction as an office and dispensary operation I led up to it by very cautious steps and well matured convictions. My several contributions on this subject show it. When fully convinced of the safety of the procedure I began to advocate it on the ground of its many advantages. The first question to determine its claims for adoption is, *Is it safe?* To whom should we look to answer this question? To the men who have made repeated and fair tests of it, or to those who have never tried it, perhaps never saw it used, and who, as the Western politician would say, are "constitutionally agin it?" For information on this subject I would refer Dr. Kollock and all who think as he does to the reports of Dr. Cheatham, myself, and to the experience of others whose names I could give. No man who has had the courage to rise above "popular opinion" and make a test of it has ever after had any fears of performing an extraction in his office and allowing the patient to go home. The invariable experience has been, in so far as I know, *it is eminently satisfactory and the results are as good as are obtained when the operation is performed on the bed where the patient is to lie.* Dr. Cheatham reports better results with his fifty-three cases, and I have certainly had better results since adopting it, but I attributed it to greater dexterity in operating. If the method is safe, then what are the advantages that can be claimed for it?

First, the appointments of a well arranged office or dispensary furnish much better facilities for performing a neat and skilful operation than the home of the patient. These advantages are of much importance. This is particularly the case with poor people who constitute the great majority operated on. As has been already suggested, a well performed operation is far more important to success than the pose of the body afterwards. The element of time can not be ignored by the busy surgeon, and the saving in this particular is very great, especially in a large dispensary practice. The extent of territory from which dispensary patients are often drawn in our large cities makes this a very important item. The chief surgeon can do the operation and one of his assistants can visit the patient and render the necessary after attention. Such important work should not be given out to inexperienced operators. The poor are entitled to the same skill as the rich, for their sight is just as valuable, and to them more important. See what Dr. Baker has to say in his address as President of the Section on Ophthalmology, on the subject of who are qualified to operate for cataract. Many dispensary patients will not suffer any one but the chief surgeon to operate on them, and his services become necessary. Certainly by far greater opportunities for success are given the patient skilfully operated on at the dispensary and permitted to go home, than would be given him if some unskilful operator were to go to his home and perform the operation. By carrying his parody of reasoning a little further, Dr. Kollock would render every surgeon liable to suits for malpractice in the legitimate pursuit of his calling. Every operator has some methods peculiar to himself that others object to, but which he honestly prefers. Why not grant him the privilege of exercising

his personal judgment and discretion if he is so entitled by reason of his experience, learning and observation?

In conclusion, I will only say: If I have sown "dangerous seed" I may look out for thorns and thistles, but so far it has been my observation, and the observation of many others who have adopted the procedure, that the extraction of cataract as an office or dispensary operation has borne only good fruit. I would humbly request Dr. Kollock to make a test of it before he writes another criticism. If he does a neat operation, other conditions being favorable, I guarantee a good result.

T. E. MURRELL, M.D.

Emasculation and Ovariotomy.

HAMILTON, OHIO, Sept. 17, 1894.

To the Editor:—The article on this subject by Dr. Robert Boal, in your issue of September 15, leads me to think that the belief in castration for crime is orthodox in the medical ranks. In the Cincinnati *Lancet-Clinic* of August 25, I protested against that proposed punishment, and up to date I have not found an article or editorial on that question which was at all heretical.

The castrationists seem to forget that after castration society deals with a eunuch, not with a man; and while lauding the virtues of the lazy, fat, oriental eunuch, whose ideas of individual rights are almost *nil*, they overlook the fact that our emasculated product, before deprived of virility, was a desperate, vicious person who had a very clear conception of rights, even though he had no regard for them. It is very doubtful if the American eunuch would be the docile, useful thing that his Asiatic prototype is. On the contrary, there are many reasons why he would become a dispenser of dynamite. There seems to be some causal relation between over-government and explosives. At least they are found together.

If castration and ovariectomy are begun, where will be the stopping place? If the morally weak and undeveloped are to be unsexed, is it not consistent to do likewise to the physically deranged—the puny, the weak, the tuberculous? If an affirmative answer is given, then it may be asked who can pose as the infallible arbiter who will say when operation is needed? Difficulties would here arise which no mortal judge could cope with. It would be impossible for a supreme court made up of Galtons and Ribots to say what would be the offspring of any given parents. This nice old couple has been sorely troubled by a vagabond son. Should that couple have been sterilized? Remember the proverbial wickedness of preachers' sons. On the other hand, remember that Australia was partly colonized by convicts; and that waifs from the metropolis often do well when taken to the country.

Rights imply duties. My right to talk, to move, to live, in short to exercise my faculties, provided they do not interfere with the like faculties of others, implies that it is the duty of all men not to infringe on my rights. It may therefore be questioned on the grounds of equal freedom, the alleged right of the community to hang, to imprison in some barbarous place, or to castrate. That the criminal should be restrained, and that society should be protected, no sane man will deny; but no humane man will for a moment think of anything but ultimate reformation of the evil-doer, and that, without the destruction of a faculty.

If the criminals' rights are denied, one can consistently say that one has no duties to them. Such an attitude is not fair to the criminal; while to free men it is demoralizing, inasmuch as it tends to make them oblivious to the great ethical law—the law of equal freedom to all. That castration would not accomplish what is expected of it, and that it

would encourage cruelty, despotism and anarchy, I have attempted to show in my article mentioned above.

Now if castration *must* be tried to see how it works, may the official castrator not forget some prison officers, skilled in torture; some policemen, who believe their efficiency proportionate to the number of their arrests; some judges, who stupidly say, "thirty days," and who really imprison for poverty; some commissioners, who perpetuate our vile county jails—"compulsory schools of crime at public expense"; and last but not least, some tenement-house owners.

Castration and ovariectomy as penalties for crime, can not be reconciled to any ethical system worthy the name. It savors of the ethics of the forest, the sea, and the air, best shown by the wolf, the shark, and the dragon-fly.

Many crimes have been committed in the name of law and religion, but here is a proposed one under the guise of science. That science will do more than religion or law to make men better, I really believe; but it does not appear to me to be scientific to attempt reformation by deformation; or to try to insure the survival of the fittest by blunting the moral sense of the whole community. Surely it is a greater triumph to guide the morally diseased to health, or even to try it, than to change their natures by destroying hopes and powers.

Some day the story of humanity's struggle with brutal punishment will be written, and I fear that it will not reflect the credit on the present medical profession that the history of most reformers has.

In conclusion let me call attention to the writings of that much maligned man, Gov. John P. Altgeld. His criticism of the penal machine would not inspire the castrationists.

Yours very sincerely,

MARK MILLIKIN, M.D.

The Oldest Doctor.

PULLMAN, ILL., Sept. 17, 1894.

To the Editor:—I observe that in the *JOURNAL* of September 15, Dr. Corson, of Montgomery County, Pa., is declared the oldest physician in the United States, which, if the date of his birth given is correct, is doubtless true.

Dr. Lewis Dyer, residing in Du Quoin, Ill., was born Feb. 24, 1807. He graduated in medicine in 1828, was Surgeon of the Eighty-first Regiment Illinois Volunteers from August, 1862, to the close of the war, and is doubtless the oldest army surgeon living in the United States, unless Dr. Corson was in the army.

Dr. Dyer is in full possession of his mental faculties, does some consultation practice, reads the journals, and takes great interest in the current events of the day.

I called on him a month since, and found him reading the history of the late war, and on his table were maps and charts of campaigns and battlefields, which he was consulting.

JOHN McLEAN, M.D.

Objects to Animal Extracts.

CLINTON, IOWA, Sept. 12, 1894.

To the Editor:—In the issue of August 25, appears an advertisement of the Columbian Chemical Company setting forth the virtues of "Ovarine," presumably an extract of pigs' ovaries, with quotations from Professor Hammond and others, having reference to the healing qualities of animal extracts in general, and this one in particular. Then follows a letter from E. Houston, M.D., who has boldly put "a highly intelligent lady, aged 26 (presumably married) on ovarine as a steady diet, which he proposes to 'continue till she becomes pregnant,' when he promises to report further.

In the same issue, Armour & Company offer to send to

any member of the profession samples of desiccated thyroids which the enterprising firm claim has produced most gratifying results. Then follows some unscientific and misleading statements asserted to have been made by Prof. Solomon Solis-Cohen.

I would suggest to the Columbian Chemical Company, and Armour & Company to enlarge their field of usefulness by furnishing the regular profession with tr. uteri, testicular fluid, tablet triturates of perineal gland, elix. gray matter (avoiding an infringement on "cerebrin") granulated liver, dosimetric granule of appendix vermiformis. Finally, I would ask the publishers if it is not time to expunge such "rot" from the advertising columns of a journal which claims to be an exponent of the best there is in scientific medicine to-day?

Very truly yours,

ALBERT REYNOLDS, M.D.

A Case of Abortion.

WHEELING, W. VA., September, 1894.

To the Editor:—The following case terminated so happily that I feel like recommending the method as much more safe than that employed in a case recently before our court, in which the fundus of a pregnant girl had been punctured by a sound with fatal result.

Mrs. A., age 25 years, mother of two children, last menstruated August 5-8. At 10 A.M., September 14, thirty-seven days after last date she introduced the closed end of a common wire hairpin into the cervix, in the effort to produce an abortion. It slipped from her fingers and disappeared beyond her reach. Eleven hours later I saw her, and no sign or symptom of local disturbance was present. My index finger, inserted as far as possible into the cervix, felt no foreign body. I concluded that the woman was so agitated during her criminal effort that the pin had dropped into the vagina, and afterwards escaped; or, that she was lying to me in the hope of inducing me to explore the uterus in search of a hairpin and to deliver her of a fetus instead. I, therefore, concluded to defer action and instructed the woman to send for me if certain symptoms presented.

September 25 at 10 P.M.—Twelve days after the hairpin was said to have been lost I was called again and found that an abortion had occurred an hour before. This history was elicited: In the afternoon of each day since my former visit, a little bleeding had occurred, but none at other times. No pain had accompanied this. Bleeding was continuous on the 23d, 24th and 25th. On the last day patient walked three-fourths of a mile to spend the day with a friend, and walked home in the evening. Bleeding was free during the afternoon, and at 7 P.M. pain set in for the first time. Two hours later the abortion occurred.

On examination, I found the cervix just sufficiently open to admit the index finger. A portion of the ovum remained and lying perpendicularly I felt the hairpin, the open ends downward. After several failures, I at last grasped both ends of the pin with a uterine dressing forceps, and removed the instrument of death. From the rounded end to the open extremities, it measured two and a quarter inches. No damage to the uterus seemed to have resulted from a twelve days' presence of its unusual tenant, and the patient had an uneventful convalescence.

S. L. JEPSON, M.D.

BOOK NOTICES.

Young's Orthopedic Surgery; A MANUAL OF ORTHOPEDIC SURGERY, FOR STUDENTS AND PRACTITIONERS. By JAMES K. YOUNG, M.D., Instructor in Orthopedic Surgery, University of Pennsylvania, Philadelphia. In one octavo volume of 446 pages, with 285 illustrations. Cloth, \$4; leather, \$5. Philadelphia: Lea Brothers & Co. 1894.

There will be found little that is new in this book; it is apparently a book written as a text-book for students, from which they may memorize the general principles of the orthopedic art. What is in the book is clearly stated, the arrangement is excellent, and as a rule the teaching is sound

and conservative. The author in speaking of the severer operations on the foot, such as Ogston's says, p. 393: "These severe operations should only be resorted to when milder measures, after due trial have failed; for comparative relief will in the majority of cases be obtained by the milder remedies in about six or eight weeks, whereas several months are required after any cutting operation upon the tarsal bones before the foot may with impunity be freely exercised." The same wise conservatism is seen in speaking of erosion, p. 125: "The operation as thus performed substitutes in many cases the graver operation of excision, and where the bone destruction has been small it offers great advantages over the latter operation." In the treatment of pes planus the steel spring arch for the sole is commended. The use of iodoform emulsion injection is not mentioned nor are many operations described; as for all major operations the reader is referred to works on general surgery.

The Science of Vital Force; Its Plan, Division of Functions and Operative Methods in Health and Disease, an involuntary agent of nature that can be harnessed and utilized. By W. R. DUNHAM, M.D. CL., pp. 198. Boston: Damrell & Upham. 1894.

The author says: "The object of this volume is to designate and demonstrate the fundamental principles of the science of vital force—a department of natural science that is directly applicable to the preservation of health and the treatment of disease. It is implied in fundamental principles and laws of Nature not yet recognized and presented for consideration, and is a department of science that will require a large amount of literature to illustrate its practical application to individual and national affairs. It also implies a revolution of the recognized plan and principles of a department that has been erroneously presented; a revolution as significant as was effected in the ideal change of the solar system, and the principles involved as being as capable of a positive demonstration. We allege that medical practice both regular and irregular is based on imaginary fundamental principles as unreal as was the Ptolemaic system of astronomy on theories that are as insufficient for the safe guidance of treatment, and dangerous in their application."

After this introduction the reader is at once prepared for a startling demonstration, but the author soothes us on page 16 by saying that "this whole matter is easy of comprehension when considered from a correct standpoint." The author then gives various definitions and divides vital force into four ultimate vital properties, namely, *sensibility, instinct, sensation and contractility*. No one can seriously disagree with the definitions and interpretations the author gives under these divisions, but there may be serious differences of opinion as to the extent and degree of "revolution" that may follow acceptance of them.

The book should be read carefully, and when so read can not fail to be appreciated. It is entertaining, novel and instructive.

Fundamental Problems, THE METHOD OF PHILOSOPHY AS A SYSTEMATIC ARRANGEMENT OF KNOWLEDGE. By DR. PAUL CARUS. Pp. 373, paper. Chicago: The Open Court Publishing Company. 1894. Price 50 cents.

This is a work, somewhat remarkable for its makeup, and as it is intended to occupy a new field in literature, it is filled with definitions of terms old and new.

Its chapters on Ontology and Positivism; Sensation and Memory; Cognition; Knowledge and Truth; the foundation of Monism; Form and formal Thought; with its survey of Kant, etc., goes to show we have to deal with an independent thinker, whether we accept his premises or not. These papers have been previously published in the *Open Court*.

There has been added an appendix in which the critics from various quarters have received an appropriate answer. How far the author has succeeded we must leave our readers to judge, simply reminding them of the words of Solomon that "of the making of books there is no end," while as a matter of fact there is nothing new under the sun. The effect of the word, "unthinkable," as used by our author is the same as inconceivable, and it seems as if much of the new philosophy consists in the invention of new forms of speech rather than the expression of new ideas. Metaphysics and psychology seem drifting into the hands of mere word jugglers.

The New Sydenham Society's Treatise on Malaria.

This volume consists of two parts, the first giving a translation of the monograph of Marchiafava and Bignami, the translation having been done by Dr. J. H. Thompson, formerly of Washington, D. C., with revisions by Dr. T. E. Charles, of Rome; the second part comprising an essay by Dr. Julius Mannaberg, translated by Dr. Felkin of Edinburgh. The original work of Bignami, in 1890, in aid of the differentiation of the forms of parasite in the different manifestations of malarial fever forms an important part of the first monograph. His opportunities led him to a study of the morbid appearances met post-mortem in malarial diseases, and he endeavored to interpret the ante-mortem systems by the knowledge gained from those phenomena. Quartan fever was found to be due to an amœba whose cycle of life is three days. The sporulation or segmentation of the amœba is complete at the time of febrile paroxysm, and much pigment forming is incident to the development of the parasite. After the paroxysm, the young amœbæ without pigment, may be seen in the red corpuscles. Tertian fever has for its parasite one whose life cycle is two days only. The amœbæ of the quartan variety discolors the red corpuscles less rapidly and less thoroughly than that of the tertian. Their movements are less lively in the quartan form. The quartan parasite has more sharply defined outlines than the other. The granules of pigment in the quartan amœbæ are coarser than in the other. The two varieties, also, exhibit differences as to the manner of their sporulation. There is a plasmodium of the quotidian intermittent, also, whose life cycle is a day. This is to be seen especially at the height of the paroxysm, one or two of the parasites occupying the red corpuscle and manifesting a power of lively movement; in shape sometimes annular and sometimes discoid. The amœbæ of the malignant forms of fever are peculiarly active in propagation and lively in movement. This malignancy is more often a sequel to the quotidian and tertian fevers, and is probably an expression of the cerebral complications created by the amœbæ and their hematic changes. In reference to malarial melanemia, Dr. Mannaberg's treatise advances the idea that the melanin is an undigested residue of the nourishment, exacted by the parasite from the corpuscle; and may, with propriety, be described as a parasitic fecal matter, although it has not been extruded or voided. The anemia of the fevers appears as an inevitable result when it is seen how largely the red corpuscle is fed upon and demolished by the parasite. The compensating power of the blood-forming organs of the system is still the unknown factor which must next be wrought out by these or other expert observers. Until this shall have been done, we will still be unable to explain why it is that certain of our malarial patients resist the anemic and melanemic symptoms so much more readily and steadily than do the other and easier victims to paludal poisoning. Regarding the laboratory work done with quinin in connection with the plasmodium, the earlier monograph gives the best summary of expert opinion and investigation.

The above facts regarding this new publication are drawn from an early notice of the book, appearing in the *London Lancet*, pp. 258-260, for August 4, 1894.

Transactions of the Texas State Medical Association.—Twenty-sixth annual session held at Austin, Texas, April 24 to 27, 1894. Pp. 450. Galveston. 1894.

The volume contains a list of the officers and members, constitution and by-laws, the minutes of the meeting, and the papers read at the session with the discussions thereon. The resolutions passed by the Association, include a resolution in favor of a Secretary of Public Health, and a Department of Health, and by formal vote it accepted the invitation of Chairman Holland to attend the meeting of the Mississippi Valley Medical Association which will meet at Hot Springs in November next. In addition to the usual section divisions, this society has a section on microscopy and pathology which judging from the printed papers is doing excellent work. The Texas transactions are yearly growing more interesting.

SOCIETY NEWS.

Mississippi Valley Medical Association.—The twentieth annual meeting of this well-known organization will be held, as previously announced, at Hot Springs, Ark., November 20, 21, 22 and 23, 1894.

The general committee of arrangements held their final meeting on September 1, in the city of St. Louis, there being present, in addition to the committee, President Scott, of Cleveland, Vice-President Strauss of St. Louis and Secretary Woodburn, of Indianapolis. Dr. T. E. Holland, of Hot Springs, presided. All of the preliminary arrangements for the meeting of the Association were completed.

Owing to the hearty coöperation of the railroads, the arrangements in this direction will surpass those of any previous meeting. On motion of Dr. I. N. Love, of St. Louis, a committee of five railroad officials was appointed to secure the desired reduction of rates. This committee consists of Messrs. Townsend, Crane, Snyder, Wishard and Ives.

The interest and enthusiasm manifested in all parts of the country concerning the meeting in November, is certainly remarkable. The fact that Hot Springs is to be the meeting place is probably an inducement for many to attend. From the large number of favorable responses to his preliminary announcement, the Secretary feels justified, even thus early, in predicting an attendance double that of any previous meeting of the Association.

Let every doctor who can possibly leave home for a few days go to Hot Springs in November. Let him take his family and his friends and not only a profitable meeting, but a royal good time will reward him for the exertion.

FREDERICK C. WOODBURN, M.D., Secretary.

399 College Avenue, Indianapolis.

Tri-State Medical Society of Iowa, Illinois and Missouri.—The third annual session of the Tri-State Medical Society will be held at Jacksonville, Illinois, Oct. 2 and 3, 1894. The Secretary is authorized to announce that papers will be read by the following gentlemen: J. H. Kellogg, M.D., Battle Creek, Mich.; Joseph Eastman, M.D., L.L.L., of Indianapolis, Ind.; A. H. Ohmann-Dumesnil, A.M., M.D., of St. Louis, Mo.; W. B. LaForce, B. S., M.D., of Ottumwa, Iowa; J. J. M. Angear, A.M., M.D., of Chicago, Ill.; Sarah Vasen, M.D., of Quincy, Ill.; Charles W. Adams, A.M., M.D., of Kansas City, Mo.; E. H. King, M.D., of Muscatine, Iowa; Heine Marks, M.D., Louis, Mo.; John Punton, M.D., of Kansas City, Mo.; Boerne Bettman, M.D., of Chicago, Ill.; F. B. Dorsey, M.D., of Keokuk, Iowa; J. F. Binnie, M.B., C.M., of Kansas City, Mo.; Anne H. McFarland, M.D., of Jacksonville, Ill.; James H. Etheridge, A.M., M.D., of Chicago, Ill.; A. A. Henske, A.M., M.D., of St. Louis, Mo.; M. P. Hatfield, M.D., of Chicago, Ill.; Ellet Orrin Sisson, M.D., of Keokuk, Iowa; B. B. Griffith, M.D., of Springfield, Ill.; Jacob Block, M.D., of Kansas City, Mo.; James A. Close, M.B., M.R.C.S., of St. Louis, Mo.;

James Moores Ball, M.D., of St. Louis, Mo.; W. M. Catto, M.D., of Decatur, Ill.; J. Fred Clarke, B.S., M.D., of Fairfield, Iowa; Geo. D. Purinton, A.M., M.D., P.H.D., of St. Louis, Mo.; S. G. Gant, M.D., of Kansas City, Mo.; D. C. Brockman, M.D., Ottumwa, Iowa; Frank Parsons Norbury, M.D., of Jacksonville, Ill.; Robert H. Babcock, M.D., of Chicago, Ill.

It is expected that Professors Senn and Murphy, will both be present and read important papers. The second day's session will be held in conjunction with the Capital District Medical Society of Illinois.

It is expected that reduced rates will be obtained on all railroads, and no doubt the meeting will be the best yet held in the history of the Tri-State Medical Society.

The Address on Medicine will be delivered by N. S. Davis, Jr., of Chicago. The Address on Surgery will be by Dr. A. V. L. Brokaw, of St. Louis.

JAMES MOORES BALL, M.D., Secretary.

810 Olive Street, St. Louis, Mo.

PUBLIC HEALTH.

Anthrax in Hides Again.—M. Lancereaux has recently made a communication to the Council of Hygiene of Paris (*Progrès Médical*) concerning three cases of malignant pustule resulting from handling foreign hides which should have been disinfected before being touched. Unfortunately, all agents hitherto employed for this disinfection, especially the sulphate of copper, cause a deterioration of the hides, so that there is a disposition to evade this requirement whenever it can be done. Schutzenberger has proposed the use of formal which is to be tried.

Deforestation as a Cause of Mortality.—Descourtis claims (*Revue d'Hygiène*) that deforestation of a given region increases the death rate. His argument is founded on the investigations of Dr. Jeanel, who reports that the mortality in the woodless departments of France, is 1.64 per 100, while in those with forests the mortality is only .18 per 100. The proportional loss then is nine times greater in the thirty treeless departments than in the fifty-seven wooded departments. If deforestation is really the cause of the disproportionate death rate and of the diminished population in many parts of France it must be regarded with as much solicitude as the contamination of water supplies, unhealthy dwellings or the contagion of zymotic diseases.

Insanitary Condition of Havre.—Prof. Brouardel, in a lengthy paper of some thirty pages in the *Annales d'Hygiène*, reviews the general sanitary state of the city of Havre, the hotbed of typhoid fever in the south of France. He does this by discussing the memoir of Dr. Gibert, in which it is contended that pollution of the under soil of the city is the only cause of the defective sanitary conditions which exist, while Prof. Brouardel attributes the prevalence of typhoid and other zymotics to the polluted water supplies. It is very evident that Havre is in great need of thorough sanitary regeneration, which the discordant views of these two savants only emphasize.

Source of a Typhoid Fever Epidemic.—Another outbreak of typhoid fever is traced to the dairy as its source. The little village of Montlignon near Paris has had a visitation of the disease for some months past. Dr. Hourlier, one of the attending physicians, undertook an inquiry with regard to the method of spread of the infection and communicates to *Progrès Médical* the following conclusions: The first case, origin unknown, occurred in a child May 15, who recovered. The clothes of this child were washed in a brook which flowed past a milkman's place and this milkman was in the habit of washing his milkpans in the brook. Dr. Hourlier is con-

vinced that this man carried the disease in the milk served to his customers and directly traced to this source one case in the person of another dairyman who, being out of milk for his own use, borrowed some from the first milkman and was subsequently attacked. The village authorities have instituted vigorous prophylactic measures.

Epidemic Diseases.—Although the cholera continues to spread in Russia, Galicia, Bukovina, in certain parts of Germany and in Holland there is no uneasiness felt except as to Marseilles, the sanitary state of which, *re cholera*, causes much anxiety in the south of France. Simultaneously with the announcement in consular reports of the presence of the cholera at that port, the municipality suspended the publication of statistics as to the number and the causes of deaths usually issued. The *British Medical Journal* says there was undoubtedly choleraic disease in Marseilles early in August, and the reticence of the authorities encourages the belief that matters have not improved and that the disease is really Asiatic cholera. Elsewhere, except as mentioned, the disease gives no serious concern and the danger for this country for the present season is steadily subsiding.—Thus far the development of the smallpox incidence in the United States is mainly in the interior, and in the States of Indiana, Illinois and Wisconsin. Secretary Metcalf of the Indiana State Board of Health reports to the *JOURNAL*, since August 16, four cases in Kosciusko County; one in Whitley County; two in Indianapolis, Marion County; one in Marion, Grant County. The case in Whitley County and the four new cases in Kosciusko County were the results of exposure to the original case in the latter county. The first case in Indianapolis was in the person of a negro tramp who said that he had recently come from Chicago. The case in Marion was that of a lady who recently came from North Dakota and, on her way to Indiana, stopped over for a short time in Milwaukee and Chicago. The origin of the Walker-ton outbreak has not been satisfactorily determined. There is a gradual increase in the number of new cases—including arrivals from other infected places—in Chicago, and an occasional case appears in the State at large. During the week a case was reported at Toluca (?) said to have been contracted in Chicago. The City Council of Chicago will be asked, immediately on its re-assembling, for an appropriation for a permanent contagious-diseases hospital. The situation is not materially improved in Wisconsin, although the Health Commissioner of Milwaukee has been sustained by the courts. A dispatch from La Crosse, dated the 17th, announces that Dr. Charles Marquardt of the State Board of Health is down with the disease at his home in that city; the disease was contracted in Milwaukee while there on official business. The disease has also been imported from Milwaukee into Racine County. There are a number of cases in Leavenworth, Kan. In Detroit, Mich., the outbreak has almost entirely subsided. New cases continue to occur in New York city, chiefly in one locality. The Newark, N. J., City Board of Health has applied for an extra appropriation of \$25,000 to defray expenses incurred in suppressing the smallpox outbreak in that city.

Diphtheria at the Congress of Hygiene.—At the recent International Congress of Hygiene, at Buda-Pesth, Prof. Oertel proposed an international investigation for the better understanding of the origin and spread of diphtheria. He sketched a form which will entail an exhaustive inquiry into the whole subject, regarding feeding, exposure, climate, dwellings, surroundings, etc. He urges that by comparing the results of such an investigation, carried on in Europe and in America, some more satisfactory knowledge may be obtained than that which we now possess.—Prof. Löffler said that the specificity of the diphtheria bacillus and

the value of its recognition as a means of diagnosis in doubtful cases are now generally recognized, and he strongly advocated the appointment of bacteriologists in every district, to whom should be committed the duty of making the necessary examinations.—Dr. J. S. Billings, for the American Committee, showed by a series of maps that in 1880, out of every 1,000 deaths from known causes 78 were due to diphtheria, whereas in 1890 only 49 per 1,000 were ascribed to that disease. In the rural districts of America the proportion in 1880 was 83 per 1,000, and in the cities and towns it was 57 per 1,000; but in 1890 these figures had fallen to 49 for the country and 50 for the city. This diminished mortality was attributed chiefly to the recognition of the contagious character of the disease and the consequent enforcement of disinfection and isolation. The results of the system of bacteriologic examinations instituted in certain cities of the United States showed that 80 per cent. of the cases usually returned as croup were true diphtheria.—The report of the British Committee, submitted by Dr. Edward Seaton, dealt with the increase of the disease in the United Kingdom during the twelve years ending in 1892, certain features of which suggested that the spread of diphtheria was governed mainly by the habits of population. The great change to be noted in these habits is the influx of country population into towns and the collection of children in schools. It was urged that the education of the public in systematic encouragement of scientific observations and research in matters connected with the public health is the most pressing need of the day.—The importance of the early recognition of the disease, which could only be attained by the systematic observation of the throats of children, was the theme of the report of the French Committee. M. Roux, of the Pasteur Institute, spoke strongly in favor of the antitoxin treatment of the disease and of prophylactic inoculations; he stated that the use of Behring's serum had reduced the mortality from diphtheria in one of the Paris hospitals from 40 to 25 per cent.

NECROLOGY.

CHAS. H. DARE, M.D., Bridgeton, N. J., died August 25. He was for seventeen years County Physician, and was Surgeon of the Fourth New Jersey National Guard.—Jacob Newkirk, M.D., Binghamton, N. Y., died August 13, aged 89.—Charles H. Williamson, M.D., formerly a surgeon in the U. S. Navy, died at St. John's Hospital, Brooklyn, N. Y., in the sixty-ninth year of his age. He was a native of Portsmouth, Va., and a graduate in medicine from the University of Pennsylvania. He had served at several stations as naval surgeon, prior to the breaking out of the late war, but he went with his State when Virginia dissolved her allegiance to the Union. He received a Confederate commission and served as naval surgeon, upon the *Charleston* and in other capacities. After the war Dr. Williamson took office under the Pacific Mail Steamship Company, not only as surgeon on the vessels sailing to and from New York, but also as a resident employé of the company at the harbor of Panama. In this latter relation he spent nearly the whole of the last ten years of his life. A widow and two daughters survive him.

MISCELLANY.

Frontier Medical Association.—The Frontier Medical Association of Canada, which embraces the Counties of Huntingdon, Chateauguay and Beauharnois, held their annual meeting at Valleyfield the election of officers resulting as follows:

President, Dr. Sutherland, of Valleyfield, reelected; First Vice-President, Dr. Wells, of Huntingdon, reelected; Second Vice-President, Dr. A. G. Hall, of Ormstown; medical Council, Dr. Groulx, of Valleyfield; Dr. Monk, of Rockburn, and Dr. de Moulpied, of Hemmingford; Secretary and Treasurer, Dr. C. Marshall, of Huntingdon.

Latest Quotations in the Diploma Market.—A London correspondent says the trade in bogus American academic degrees, which Labouchere broke up by his exposures in London *Truth*, is again booming. "England is a peculiarly rich field for this sort of swindle, for John Bull's pet weakness is his ambition to write a long string of letters after his name. The latest quotations for degrees from the bogus American University are M.D., or LL.D., \$150; any other degree, \$125."

Actinomycosis in Finland.—Dr. Borsdorff has been able to collect only eighteen cases of actinomycosis occurring in Finland up to the present time. Of these, ten occupied the face and neck; one, the lungs and thorax; seven, the abdomen, including two of actinomycotic perityphlitis. Nine of these cases were cured, seven died and two are still under treatment. Borsdorff thinks that operative treatment is the most effective and, perhaps, the only certain means of cure—at least in the more chronic cases.

Statue to Marion-Sims.—On November 13, prox., the anniversary of his death, a massive bronze statue of James Marion-Sims, M.D., LL.D., will be unveiled in New York city. The statue will be erected on the north side of Bryant Park, where a completed pedestal of dark granite marks the site. In making this announcement it is said that this will be the first instance of such a tribute being paid to a member of the medical profession in this country; "but even this monument will not be as fine as the Woman's Hospital of which he was the founder."

Poisoning by Crayfish.—Crayfish poisonings must now be added to the long list of those caused by lobsters, mussels, shrimps, crabs and oysters. Cases have recently been reported in *Progrès Médical* from four different localities in France—the most serious at Geaudeize, where forty guests at a wedding feast after partaking of a bisque of crayfish were seized with vomiting and violent colic. Although medical aid was soon at hand many of those attacked succumbed. The supplies in all cases had been obtained at Cologne, which is the chief market for this article of food.

Conviction Can Not Stand.—A corollary to the decision of the Supreme Court of Montana in the case of *State v. Kellogg*, referred to in the *JOURNAL* of August 18, pages 288 and 289, is found in another decision of that court, entitled the same, but rendered June 4, 1894. Here the court holds that when a physician's license is revoked by the State Board of Medical Examiners, and, pending an appeal, through the district court, to the Supreme Court, the physician is convicted of practicing medicine without a license, the latter judgment will be set aside after the Supreme Court has reversed the one revoking the license, for the reason that there is nothing to support it.

Flies as Contagion Carriers.—Travelers in Egypt notice the large number of blind persons and those afflicted with diseases of the eye. In pus collected from the conjunctiva, gonococci or other microbes are frequently found—sometimes both. A very potent agent in the dissemination of these diseases is to be found, according to Lucien Howe (*Rev. Int. de Bibliog. Méd.*) in the flies which infest Egypt in myriads. He has observed that when these flies walk over gelatinous bacteria develop in their tracks, and notes that the Bedouins of the desert, where few flies are found, rarely

have any disease of the eyes. Dr. Howe neglects to mention, however, another important cause of this class of diseases, namely, the irritation of the conjunctiva from fine particles of sand.

An Ambulance Surgeon Murderously Assaulted.—Dr. Thomas Garvey, ambulance surgeon to the Harlem Hospital, New York City, came very nearly losing his life while removing a desperate patient to the hospital for treatment. The man, who was partially intoxicated, and suffering from a dislocation of the humerus, drew a pistol and fired on his surgeon while they were in close quarters in the removal wagon. The bullet took effect in the right shoulder of Dr. Garvey, causing a painful but not serious wound. Before the man could follow up his murderous attack, the surgeon threw himself forward on the man and disarmed him. The man subsequently stated that he mistook the surgeon for an officer who had him under arrest. Whatever the motive of the man may have been, his missile went very near to blotting out the life of a worthy young surgeon.

To Abolish the Coroner.—The Constitutional Convention now in session for the State of New York has voted to strike out the office of coroner, as a constitutional position, by a vote of ayes 97, naves 43. This is one step in the direction of giving to New York the system of medico-legal experts, such as has been possessed by Massachusetts for many years. The ratification of the action of the Convention must be obtained, at the polls, by the general vote of the people of the State. There seems to be a strong presumption that the revised constitution will be adopted; at all events, the medical societies, such as the Academy of Medicine, the medico-legal organizations and others, that have been fighting for years to do away with this relic of barbarism, will have their sympathies warmly enlisted to work for the new constitution in order to secure this reform, if none other.

Surveillance of Mineral Waters.—The growing consumption of mineral waters in this country and the entire absence of official surveillance of the business lend interest to the recent action of the Academy of Medicine of Paris, in the adoption of the following resolutions: 1, the Academy is still of the opinion that certificates for all mineral waters that are charged and bottled should be withheld; 2, certificates should be granted only when the water in question contains no pathogenic bacteria; 3, the Commission on Mineral Waters shall be furnished all the apparatus in the laboratory of the Academy necessary to study any water for which a certificate is asked, to ascertain its freedom from microbes and the stability of its composition. In times of epidemics, when the populace has recourse to mineral waters instead of the usual supply, the Academy will assume the additional duty of pointing out the danger of drinking these waters indiscriminately and of insisting that none be sold unless they have been examined and certified to be innocuous.

The Earliest American Symphyseotomies.—Dr. R. P. Harris, of Philadelphia, writes to the *New York Medical Journal*, August 25, that he has found three unreported symphyseotomies that antedate that of Dr. Jewett, of Brooklyn. These were done in 1880, 1884 and 1889, the two latter operations being supported by sworn evidence. He has reason to believe that the earliest American symphyseotomy was done in 1880. These three early cases will be duly reported so soon as he is convinced that they were actually performed as alleged. In not less than two cases studied out by Dr. Harris, he has been compelled to certify that the claims of operators have been factitious. One of these had been publicly, though mistakenly, credited as the first of its kind. Dr. Harris will continue his detective work until the truth

shall have been brought to light. The operation of Dr. Jewett will probably prove to have been not earlier than the fourth.

A City Home for Epilepsy.—The ideal location for a retreat for the care of epileptics is in the country rather than in the city. The satisfactory working of certain colonies or farms, both abroad and in America, has been abundantly proven. These charitable undertakings are, for the major part, in their infancy and are not sufficiently numerous to make it possible to do away with city homes for the unfortunates of this class, and it will be a long while before they can all be provided with ideal protection. A new charity has been organized at Brooklyn, known as the Non-Sectarian Hospital and Home for Epileptics, having accommodations for forty inmates. The medical staff is large and competent, embracing among others the names of Drs. D. Simmons, C. H. Schapps, Charles Shepherd and W. G. Preston. The support will be entirely that yielded by charitable citizens and physicians. The Home will be located at 1038 Green Avenue.

Neutralizing Serpent Venom.—M. Tricard, of Martinique, has lately experimented on the effects of different agents in neutralizing the venom of serpents. The experiments were made on the smaller animals—rabbits, rats and pigeons—he not having been able to obtain any dogs. The drugs used were a solution of iodine, permanganate of potash, chromic acid and chlorid of gold. He concludes (*Arch. de Méd. Nav.*) that we have drugs capable of completely neutralizing this venom and that chlorid of gold is the most efficacious and the most easily managed. Many injections must be made and it does not suffice to make them in the subcutaneous cellular tissue alone; some must be made in the muscles at a point below where the fangs have penetrated. It will be remembered that Prof. Daniel Brainard, of Chicago, many years ago proposed tr. iodine as an injection in cases of snakebite. Successful experiments on animals were repeatedly made in the surgical amphitheater.

Anecdote of Von Helmholtz.—Although the late Prof. von Helmholtz was among the most popular instructors of the University of Berlin, he was not the kind of man of whom many anecdotes are told. The following, however, has found circulation: A number of years ago the Professor attended a celebration in honor of the birthday of Prof. Bunsen at Heidelberg. The toast of the evening was responded to by Prof. Kirchhof, one of the best known men at the time in Heidelberg, and the associate of Bunsen. He ended his address with, "Long live Bunsen." The cheering had not ended when Prof. Helmholtz stood up and said: "Bunsen must indeed be immortal when even the graveyard (Kirchhof in German means graveyard) wishes him long life." Von Helmholtz was a man of remarkable appearance and his eyes are said to have been among the most beautiful and penetrating ever set in a human head. A few years ago his favorite daughter was married to Dr. von Siemens to the great joy of von Helmholtz, thus uniting two famous houses. She is an unusually clever woman.

CO₂ and Mental Activity.—Elaborate atmospheric determinations, made four times daily during the last nine years in the various rooms of the Walker building of the Massachusetts Institute of Technology, have now been tabulated and made public. An increase of about 0.5 parts over the ordinary proportion of carbonic acid in the outer air is found in 10,000 parts of the air in the rooms when empty, and this increase is attributed to decomposition of the organic matter present in the flues, floors and walls. The air of those parts of the building which are open and in which people are constantly moving about shows about five parts of car-

HYPERTROPHY OF THE PHARYNGEAL OR LUSCHKA'S TONSIL.

Read in the Section on Laryngology and Otology, at the Forty-fifth
Annual Meeting of the American Medical Association, held at
San Francisco, June 5-8, 1894.

BY E. FLETCHER INGALS, A.M., M.D.
CHICAGO, ILL.

Hypertrophy of the pharyngeal or Luschka's tonsil, by some authors termed adenoid growths, consists of an abnormal enlargement of the glandular tissues normally found in the vault and walls of the pharynx. It is characterized by obstruction of nasal respiration, with catarrhal symptoms and in many cases partial deafness, with alterations in the voice partially due to obstruction of the resonant chamber in the posterior nares, and partially to changes in the larynx caused by mouth-breathing. There is also more or less deterioration of the general health, and frequently deformity of the chest; in many instances mental hebetude and imperfect physical development are very pronounced. Attention was first directed to this condition by Meyer, of Copenhagen, in 1860, and later by Loewenberg, of Paris, who reported three cases in 1865. The same author subsequently published a complete *résumé* of the subject in 1879. A thorough discussion of the subject was brought out by Meyer's paper at the International Medical Congress in London in 1881; since which time so many articles have been written upon the subject that it has been worn almost threadbare. Nevertheless it appears to me that an analysis of a considerable number of cases occurring in private practice may furnish some new items of interest concerning the affection, or at least aid in settling some of the uncertain points in its clinical history.

Notwithstanding the many cases that have been reported by laryngologists, the disease is not so common as would at first appear. I find among my records of private patients since 1881, histories of between 11,000 and 12,000 persons, of whom about 90 per cent. or in even numbers 10,000, came to me because of some disease of the chest, throat or nasal cavity. Of these, 203 or in even numbers, 200, equaling only 2 per cent. of the whole, had hypertrophy of the pharyngeal tonsil. It is impossible to determine the relative frequency of diseases of the chest, throat and nose, but as only 2 per cent. of these special cases suffer from enlargement of this gland, it is clear that the percentage must be infinitely smaller when all classes of disease are considered.

I find in 10,000 consecutive cases of diseases of the chest, throat and nasal cavities, 200 cases of hypertrophy of the pharyngeal tonsil. Of these 65 per cent. were residents of the city, and 35 per cent. came from the country or smaller towns. As only 27 per cent. of the whole number of my private patients

within the last decade have come to me from out of the city it would appear upon the face of these statistics that the disease is about 50 per cent. more frequent in the country than among residents of the city. This does not agree with my deductions when considering the influence of sex, where I state that because of their living more out of doors boys seem less liable to the disease than girls. Possibly the disparity in this respect is due to the relatively larger number of city physicians who would treat this affection, thus diminishing the number of such patients who would consult any one specialist.

Out of the 200 cases of hypertrophy of Luschka's tonsil that have consulted me, in some the condition was of so little importance that it had not attracted the patient's attention, and was only discovered incidentally in making the ordinary examination; in many others I was consulted merely for diagnosis, and in still others for various causes the history has been imperfectly taken, so that the records are worthless for purposes of study. Excluding most of the foregoing I have selected 100 cases as nearly consecutive as possible, not from any special feature which the case might present, but simply because of the completeness of the history, and I have excluded a considerable number of cases similar to these, not from any peculiarity of the history, but because it is more convenient to deal with an even hundred. These cases therefore, ought not to be considered as selected cases in the ordinary acceptance of this term; though it is probable that patients presenting the most pronounced symptoms were most carefully interrogated by my assistants who took the histories.

In my further consideration of this subject I shall confine myself to a study of these 100 cases which I think fairly and honestly represent the cases of well developed hypertrophy of the pharyngeal tonsil who would present themselves to a physician in private practice in this country.

The affection nearly always develops in infancy or early childhood. From the ages of the patients recorded, it appears that the disease is most frequent in children between the ages of 2 and 15; 54 per cent. being observed between the second and eighth year and 37 per cent. between the ninth and sixteenth. But the affection is also seen in older persons. Seven cases were found between the ages of 18 and 25, and one each at the ages of 26 and 37 respectively. These results differ widely from Meyer's, who observed less than 37 per cent. under 10 years of age, and less than 62 per cent. all told under 15. They differ even more widely from Bosworth's statistics which show less than 30 per cent. under 15 years of age. The difference is probably to be explained by the fact that I have ignored cases in which the growth had not attained sufficient size to cause the patient inconvenience, or had atrophied to such an extent as to have become unimportant.

A more critical examination of the histories in the endeavor to ascertain when the symptoms first appeared, indicates that the disease was certainly developed in 90 per cent. of the cases in infancy or very early childhood. Many of these cases were said to have had difficulty in breathing since birth, and it is probable that in some of these the growth was congenital. I doubt very much whether the disease is ever developed after puberty.

From my statistics the affection appears to be more frequent in girls than in boys, 41 per cent. having been recorded as males and 59 per cent. females. This is possibly due to the fact that boys being so much more out of doors than girls are apt to be more vigorous and consequently less liable to hypertrophy of the adenoid tissues.

In Meyer's cases a little over 51 per cent. were males, but in Bosworth's cases only 36 per cent. were males. When it is remembered that in Copenhagen and its vicinity, the girls live more as do the boys than in this country, and are consequently more vigorous, my explanation of the influence of sex seems partially substantiated and it appears probable that under the same hygienic conditions there would be no difference in the frequency of this affection in the two sexes. Militating against the correctness of this view is the fact that Greville Macdonald and Sir Morell Mackenzie found the disease considerably more prevalent in males. This, however, may have been due to their considering many cases in which the gland had dwindled into insignificance; for it would appear reasonable to suppose that as puberty occurs at an earlier age in girls than in boys and as these glands usually atrophy at that period, the hypertrophy among girls would be noticed less frequently among them after the age of 11 or 12 than among boys of similar years. The fact that Woakes, also of London, found this affection about equally in the two sexes suggests that there must have been some radical difference in the method of analyzing the cases by different observers. Keeping in view the fact that 90 per cent. of the cases I am considering were observed before the age of puberty, and that all of them were well marked, there seems little room for doubt that, in this locality, at least, the disease is more prevalent among girls than boys.

The anatomic and pathologic characteristics of this affection have been so thoroughly described by Meyer, Loewenberg, and subsequent writers that I will pass them by.

Etiology.—In an affection which has generally existed for years before the physician is consulted, it is impossible to obtain any very accurate idea of the causation; but this analysis seems to prove that enlargement of Luschka's tonsil in the great majority of cases is due to the same causes as hypertrophy of the faucial tonsils. It is attributed by various authors to hereditary influences, to the strumous and rheumatic diathesis, to diphtheria and the exanthematous diseases, to catarrhal troubles and to frequent colds.

I find among my cases several that appear to be congenital, though in none of these could this be stated certainly. Ten per cent. were apparently of hereditary origin as shown by the occurrence of two or more cases in the same family; 3 per cent. appeared to follow immediately after measles; 4 per cent. after scarlet fever; 1 per cent. after diphtheria; 3 per cent. were attributed by the parents, or

the patient, to pneumonia or influenza; and a large number, amounting to 16 per cent., were attributed to frequent colds, or to what is doubtless included in the classification of some authors as a catarrhal condition. In 63 per cent. nothing could be discovered which appeared in any way to account for the origin of the disease. I find in the same connection that 35 per cent. of these patients were subject to frequent diseases of the throat.

In 76 per cent. one or both of the faucial tonsils were also enlarged in the same case; in 7 per cent. one, and 69 per cent. both. This coincident enlargement of the faucial tonsil occurs in such a large number of cases as to indicate that the two conditions are commonly dependent upon the same causes, and it leads us to suspect that many of the results formerly attributed to enlargement of the faucial tonsils, more especially affections of the eye and ear and alterations of the voice, were in reality due to enlargement of Luschka's tonsil. In the great majority of cases where any of these symptoms just referred to appear with enlargement of the faucial tonsils, excision of the latter will be found to have but little influence, unless the pharyngeal tonsil is also removed. Scrofulous affections or enlargements of glands in other parts of the body were noted in only 2 per cent. of the cases.

Symptomatology.—The symptoms which are most commonly noticed by the parents or friends are: Snoring, loud breathing at night, restlessness, poor sleep with bad dreams, mouth breathing and general debility. The most frequent objective symptoms are: Impairment of the voice, deafness, and partial loss of the sense of smell. The patient's strength as indicating his general condition is noted in 65 cases, in 80 per cent. of which it was found to be good, in 18 per cent. only fair, and in 2 per cent. poor. The general debility apparently resulted in most of these cases from the imperfect aeration of the blood in consequence of obstructed respiration. Pains in various parts of the body were complained of in a few instances. The sense of sight was affected in 1 per cent. of the cases, and the sense of smell in 11 per cent. Frequent headache was complained of in 27 per cent. of the cases. Deafness is a common result of hypertrophy of Luschka's tonsil, the sense of hearing having been found impaired in 33 per cent. of these cases. In only 38 cases has any reference been made to the patient's mental condition, but because of the frequency with which these patients appear to be dull, I am surprised to find that in only one case is it noted that there was any impairment of the mental condition, and in this case it is stated that the patient appeared to be idiotic, a condition which seemed to have had no relation to the obstruction of the naso-pharynx. The condition of the voice is noted in sixty-five cases; in 30 per cent. of these it is said to be normal, but in fifteen muffled, impeded or thick; in forty nasal, and in fifteen hoarse or husky, showing that it was affected in 70 per cent. of the cases where the condition of the voice was mentioned.

The condition of the respiration was noted in forty-six cases, in 60 per cent. of which it was found to be unaffected, but in 40 per cent. there was decided dyspnea. In only 8 per cent. of these the dyspnea was said to have occurred at night or during sleep, while in the remaining 32 per cent. the dyspnea was also noticed during the day.

More or less cough is a frequent symptom, with

regard to which I find notes in seventy-three cases; of these 60 per cent. had no cough; in 12 per cent. it was described as slight or inconsiderable, in 12 per cent. as hacking to clear the throat, and in 12 per cent. as severe. In 6 per cent. of these seventy-three cases the cough occurred especially at night, or in the early morning.

The condition of the nasal cavities is noted in eighty-six cases, in 30 per cent. of which they were described as free or normal; in 12½ per cent. they were obstructed by exostosis from the septum, and in 50 per cent. by hypertrophy or swelling of the inferior turbinated bodies. Excessive secretion or other catarrhal symptoms were also noted in 60 per cent. of the cases. This would appear to sustain the theory advanced by MacDonald ("Diseases of the Throat and Nose," 1890), that a majority of cases of enlargement of Luschka's tonsil are due to obstruction of the nasal passages consequent upon rarification during inspiration of the air in the naso-pharynx. However, as my records do not enable me to determine whether in these cases the obstruction of respiration preceded or followed the enlargement of Luschka's tonsil, the evidence for or against this proposition can not be considered conclusive; but there has always been a question in my mind whether the obstruction of the nasal cavities from swelling of the soft tissues in such cases was not the result rather than the cause of the hypertrophy of the pharyngeal tonsil.

The excessive discharge in nearly all of these cases is clearly the result of obstruction in the naso-pharynx, which independently of its influence on the congestion of the mucous membrane, prevents evaporation of the secretions and causes their collection in the nasal fossæ.

In many cases, enlargement of the pharyngeal tonsil may be suspected from the appearance of the follicles in the lower portion of the pharynx. I find the condition of the pharynx noted in eighty-one cases, in 25 per cent. of which the follicles were found decidedly enlarged.

Deafness is noted in forty cases; the right ear was affected in twenty-four, the left in twenty-one, but there seems to be no relation between deafness upon one side and enlargement of the corresponding faucial tonsil; indeed, deafness appears to have been present quite as frequently when the faucial tonsils were but little enlarged as where these latter organs were greatly hypertrophied: therefore, so far as these statistics go they would seem to substantiate the statement already made, that affections of the special senses formerly supposed to have resulted from hypertrophy of the tonsils, have doubtless in most cases been caused by enlargement of the pharyngeal tonsil. In twenty-two of these the deafness was entirely cured or greatly improved by the treatment.

The form of the chest walls has been noted in only fifteen cases, but it is fair to suppose that in a majority of the others it was in a normal condition, otherwise it would have attracted the parents' attention and have been mentioned in the course of the examination. In the records where the condition of the chest walls is referred to it was normal in twelve and more or less deformed in only three of the cases.

Diagnosis.—The diagnosis in these cases was usually made by inspection of the posterior nares with the rhinoscope, aided sometimes by anterior rhinoscopy and the nasal probe, but in young or unmanageable children in whom the throat mirror could not be

properly used, it was verified by the finger passed into the naso-pharynx.

Treatment.—Many of the cases that have come under my observation were brought to me simply for diagnosis and suggestions for treatment, the patient subsequently having been placed under the care of some other physician. In some instances where the parents feared an operation, internal treatment has been recommended and carried out for a greater or less period of time, sometimes with advantage but in others with no effect. In still other instances surgical procedures have been carried out by other physicians, and I have been unable to obtain information of the results.

In the whole 200 cases, removal of the gland by operation was recommended in only 120 or 60 per cent., and in the 100 cases I am now considering it was recommended in only 90 per cent., and performed by me in only 76. In a considerable number of the patients upon whom I have operated, the records of treatment are very imperfect for the reason that speedily after the gland was removed the symptoms disappeared and the patient was considered well, so that I have heard nothing more of the case.

The records show that in fourteen cases internal treatment consisting of syrup of the iodid of iron or syrup of hydriodic acid, was suggested, and that in ninety cases surgical procedures were recommended. By consulting my records and the replies of parents or friends to my letter of inquiry, I find that the hypertrophied gland was removed in 76 of these 100 cases; that it was treated by local applications of chromic acid in 11 cases, but that the patient received internal treatment only in 13 cases. In fifty of the cases operated on, one or both of the faucial tonsils were also found more or less enlarged and in twenty-two cases they were removed at the time of the operation on Luschka's tonsil.

One of the most notable results of freeing the naso-pharynx from this obstruction has been its effect upon the general condition. It is not uncommon for young children within six months after the operation to gain from 20 to 40 per cent. in weight and correspondingly in vigor and endurance.

Although in very few cases was the mental condition noted when the record was first made, I find by inquiry of parents or friends of the patient that the mental condition has been improved in 12 per cent. of cases in which an operation has been performed.

Deafness was noted in only forty cases and the effects of treatment upon the sense of hearing was recorded in only thirty-seven. In 30 per cent. of these there had been no improvement; in 4 per cent. there has been slight improvement, and in 66 per cent. the deafness has been greatly ameliorated or cured; the latter result being noted in 33 per cent. of the cases.

In the whole number of cases the voice was noted to have been affected in forty-five. In three of these no improvement was observed as a result of treatment; in some no subsequent history could be obtained, but in thirty-five, or 77 per cent., great improvement has been observed.

Of these 100 cases, 56 complained of catarrhal symptoms. Eighty-six per cent. of these have been greatly improved by the treatment, though 14 per cent. seem not to have been benefited. This appears to justify the opinion, already expressed, that the obstruction of the nasal passages is often the result

instead of the cause of hypertrophy of the pharyngeal tonsil.

There is an undoubted tendency for hypertrophy of the pharyngeal tonsil to disappear by atrophy about the time of puberty; but an analysis of these cases, of which 9 per cent. were over 16 years of age, shows that this fortunate result is not so common as generally supposed. There appears to be a common impression among laryngologists that unless such growths are removed by surgical measures the condition of the patient is almost sure to go from bad to worse, until the twelfth or fourteenth year, when atrophy usually begins. In twenty-seven of these cases, for various reasons no radical operation has been performed. Eleven of these were treated by applications of chromic acid through the nostril, and I find that eight of them were apparently cured by this treatment. In the remaining sixteen cases we have relied entirely upon internal treatment, consisting of the syrup of hydriodic acid or of the iodid of iron, the latter being given when anemia was apparent. I have been unable to obtain the subsequent history in four of these. In 50 per cent. of the twelve whose histories are completed there appears to have been great improvement or complete recovery, apparently as a result of the treatment. Four others were somewhat improved from various causes, and two appeared to have made no gain. This goes to show that although the most brilliant and satisfactory results are obtained by surgical procedures, constitutional remedies are adequate to the removal of the disease in a considerable number of cases, but this should not be made an excuse for allowing the patients with well marked hypertrophy of this gland to go on from year to year in the hope that internal remedies or time may effect the cure; because in the meantime in very many cases, inflammation of the Eustachian tube and middle ear will have caused deafness, or the voice may have become permanently altered, while deprivation of the patient of the amount of oxygen to which he is normally entitled will have stunted his growth, impaired his constitution, and possibly will have left a permanent impress upon his mental faculties from which nothing can ever relieve him.

An analysis of these cases leads to the following conclusions:

Hypertrophy of Luschka's tonsil is comparatively infrequent, occurring in only 2 per cent. of the patients with diseases of the chest, throat and nasal cavities, and probably in not more than one-half of 1 per cent. of all cases.

In this locality the disease is apparently 50 per cent. more frequent in the country than in the city, and it occurs more frequently in girls than in boys.

The disease is observed in 90 per cent. of the cases before the fifteenth year of age and is probably always developed in infancy or early childhood, some cases appearing to be congenital.

Ten per cent. of the cases are apparently hereditary. Sixteen per cent. may be attributed to frequent colds; but in 63 per cent. no etiologic factor can be discovered.

In the great majority of cases the affection is apparently due to the same causes as enlargement of the faucial tonsils, and in 76 per cent. of the cases the faucial tonsils are also hypertrophied.

In a considerable number of cases, amounting to 18 per cent. the general health is materially injured by this affection.

The sense of smell is obtunded or lost in 11 per cent.

Hypertrophy of Luschka's tonsil is a frequent cause of headache, it being present in 27 per cent. of the cases.

It is a frequent cause of deafness, the hearing being affected in one-third of the cases. The deafness so caused may be benefited in a large majority (70 per cent.) of cases by operative procedures, 66 per cent. being greatly ameliorated and about half of these being completely cured.

The disease causes much alteration in the voice in about 70 per cent. of the cases. In nearly eight-tenths of these the voice may be greatly improved as the result of treatment.

In about 40 per cent. of the cases there is decided dyspnea, resulting from partial closure of the nasopharynx.

Forty per cent. of these patients have more or less cough, in about one-third of which it is quite severe.

The pharyngeal follicles are enlarged in about one-fourth of all the cases. The nasal cavities are more or less closed by swelling or hypertrophy in 50 per cent. of the cases, and 56 per cent. complain of catarrhal symptoms, but in about nine-tenths of these the symptoms are removed by extirpation of the glandular tissue.

Although deterioration of the general health is not usually complained of, it is found as the result of operation that in many cases great improvement occurs immediately, the patient often gaining 30 per cent. in weight within six months.

THE THROAT APPEARANCES IN MYXŒDEMA.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY H. HOLBROOK CURTIS, M.D.

NEW YORK.

One year ago a patient presented herself at my office to have her throat examined, in order to undergo treatment for difficulty in speaking distinctly. Her history from my note book was as follows: Age 48, weight 190 pounds. Had five children. Menstruation stopped two years ago. Suddenly became very stout about ten years ago, after a prolonged and exhaustive experience with nursing a sick relative, at the same time undergoing intense mental agitation from other sources. Has had no perspiration for ten years. Water always very distasteful as a drink. Partakes sparingly of tea and coffee. Six years ago legs became glazed and waxy, the small hairs disappearing from same. Some edema of ankles but no pitting on pressure. Had been twice to Carlsbad for jaundice within seven years. Much brown pigmentation on abdomen. Had to stop playing piano some six years ago, because great weakness developed in her arms. Walking became very distasteful. Commenced at this time to become partially deaf. Could only hear in theater in the front rows. Eyes also commenced to appear small by reason of swelling of the lids. Speech became thick every afternoon at 5 o'clock, but without hoarseness. Often disinclined to talk and became sad and morose. Eighteen months ago throat symptoms became more marked. Often in talking "a spasm would choke her." Patient likened it to a cramp of the throat. Far back on the sides of the

tongue a marked stiffness was complained of, and the point seemed thick and difficult to control. The end of her tongue was always "in the way." During this time patient always slept well. Pulse 72, temperature slightly subnormal. Patient was always cold, and very anemic. Ears presented a waxy appearance. More recently the gums were swollen and deficient in nutrition. The lips had recently become difficult to manage easily; they felt very thick and stiff. Was apt to say bore for more, etc. The last two years mental symptoms had commenced to develop. Patient would frequently use the wrong word but always corrected it herself. It was very often a great effort to think quickly. A sudden surprise would make speech almost impossible. Coming into a room where there were strangers would confuse ideas and speech. Upon examination of the nose, the mucous membrane appeared bluish and pale, the turbinate bodies enlarged and very soft, (inflated) making nasal respiration wellnigh impossible. The uvula was very thick, very pale with a yellowish tinge, and the pillars of the fauces were thickened and of the same general hue. The posterior pharyngeal wall was yellowish, with the blood vessels prominent and very red. There was atrophy of the glandular tissues of pharyngeal vault, and also at the base of the tongue. The arytenoids were enlarged but had a fatty yellowish appearance, instead of the bluish edematous look they present in laryngeal phthisis. The interior of the larynx was full and flabby, the tissues intruding into the caliber, while partaking of the yellowish hue of the rest of the membrane of the throat. The false cords seemed especially thickened. The vocal bands were normal, as was also the epiglottis with the exception of the pallor. In October last, the patient suddenly developed edema about her eyes, and the characteristic appearances of myxœdema. At the same time loss of hair under the arms and on the head was commencing. I had not seen the patient for four months, and the difference in appearance was quite striking. There was no albumen found in the urine. Suspecting that it was an undoubted case of myxœdema, I commenced treatment by giving 5 drops of the extract of thyroid gland in glycerin (Gibier) morning and night after meals, increasing the dose to three times a day at the end of a week. Patient was living on a simple diet but not restricted. At the end of two weeks a marked change appeared to manifest itself in the general comfort of the patient, and the spirits commenced to improve; at the expiration of three weeks the tongue began to become more manageable and breathing was easier upon exertion. In six weeks the patient began to lose flesh rapidly, had to get smaller gloves and shoes and commenced to have clothing taken in. The dose meanwhile had been reduced to 5 drops twice a day, and two weeks afterward to 4, at the same interval. At the end of six months there had been a loss of twenty pounds in flesh. The speech is fluent. No disturbance of ideas. Tongue perfectly free; thickening disappeared from the folds of fauces. Uvula, pharynx and larynx healthy. Color of the mucous membrane changed from the yellow waxy look to normal, and there persists but slight injection of the blood vessels. The measurements of one of the extremities taken by Mr. Riker for an elastic stocking before and after taking the thyroid extract show the following differences, and may be of interest:

Ankle, 9½; 8½. Calf, 16; 14½. Knee, 15½; 14½. Thigh, 21½; 19. In the corset measure the hips appear to have decreased five inches, the waist three, and the bust four inches.

The above case is interesting in that it presented itself to a laryngologist. The difficulty with enunciation antedated the loss of hair and brittle finger nails by a year. Absence of albumen in the urine, no previous loss of hair, and no facial edema accounted for a late diagnosis of the true condition. However, to-day the patient is restored to apparent health, looks younger by ten years, is as bright and cheerful as possible, and thoroughly enjoying life.

NOTE.—Patient is taking 3 drops of thyroid extract twice daily, and is in excellent health, Sept. 22, 1894.

THEORIES AND FACTS CONCERNING DEFLECTION OF THE NASAL SEPTUM.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY W. A. MARTIN, M.D.
SAN FRANCISCO, CAL.

That the major portion of nasal troubles is caused by the deviation of the septum, I think will be admitted by those who have devoted much time to the treatment of nasal troubles and have investigated the causes of these troubles. As a nation the Americans may be said to be universally afflicted with deflected septa, and to this cause alone we may safely attribute 75 per cent. of the nasal affections that are so frequent among them. I have been unable to find any extensive statistics concerning this trouble in the United States, but from my own observation I will venture to place the percentage of deviated septa as high as 90 per cent.

The only reliable statistics of any extent furnished on this subject are those of Mackenzie among the English and of Zuckerkandl among the Austrians. The first taken from the skulls in the museum of the College of Physicians and Surgeons in London and the latter principally from the cadaver. Other statistics have been published by Semeleder, Theile, Allen, Potiquet and others, but all in smaller numbers than the first mentioned. In this country, statistics so far as I have been able to find, have been limited to those who have applied for the treatment of some nasal trouble and consequently are of no value in determining the frequency of its occurrence, as there are untold numbers to whom it causes no inconvenience and a large proportion of the population who suffer in silence and never consult the specialist.

The statistics of Mackenzie show that in 2,152 skulls examined, 76.9 per cent. of the septa were more or less deflected. Those of Thiele, Semeleder and others taken in Germany differ only 1 or 2 per cent. from Mackenzie. Statistics of Zuckerkandl show that in 370 skulls examined in Vienna, 53.2 per cent. of the septa were deflected.

The most diverse theories have been evolved to account for this frequent condition of the septum, some of them most amusing when one considers the source from which they emanate. A few of the many I will quote are:

"Blowing the nose habitually with the same hand. Habit of sleeping with the same side of the face to the pillow. Habit of putting finger in one side of the

nose. Action of astringents, rickets, syphilis. These causes I simply mention and do not consider it necessary to give them any further thought as causal factors in producing deflections of the septum. The following causes are the ones accepted by the leading specialists of to-day: Traumatism, over-development of the septum, obstruction in one or both nostrils, heredity, evolutionary and devolutionary changes." The first mentioned of these causes, viz: Traumatism is the one accepted by Bosworth, who seeks to defend it in his text-book, "Diseases of the Nose and Throat," as being the most frequent source of the trouble.

It is remarkable how readily a patient will recall some cause for the deformity, when informed that such a condition exists, in the shape of a blow on the nose fifteen years ago; a tumble down stairs, a frequent cause given by mothers is a blow from the baby's head, and numerous other causes are assigned too numerous to mention, but with which you are all familiar. It is peculiar how sensitive individuals are concerning any deformity which is congenital, or for the source of which they have no natural or physical cause to offer. They seem to consider it a blight cast on their lives by nature, but if they can offer a cause in the shape of some physical force, the defect is regarded as of little consequence or even as an insignia of glory, showing the prowess of the individual or the martyrdom through which he has passed. Now deformities of the nose are no exception to this rule. There is no feature about which people are so sensitive as the nose; reference to the shape will give offense, and many individuals who are perfectly satisfied with the external appearance of that organ will doubt the ability of the specialist, who informs him that the interior is twisted and contorted. He immediately recalls some manufactured or almost forgotten reason for the existing condition, but the patient is willing to retract somewhat after being informed that his nose does not differ materially from the general average.

Bosworth informs us that "an injury to the nose need not necessarily give rise to the immediate development of a notable deformity as in fracture, but it may set up a low grade of morbid action which going on through a number of years will develop a condition by which the normal function of the nose is seriously hampered."

Why this low grade of inflammation should continue for years, without causing any inconvenience excepting the resultant deformity and having caused the deformity should cease is not apparent. One might give it some little consideration if we had only nasal spines and crista to deal with, but we know these are dependent on a curvature of the septum, and that condition would have to be first accounted for and could not be accounted for in this way. The frequency with which we meet with this deformity is the strongest argument against the theory of trauma. Certainly 90 per cent. of Americans and 75 per cent. of the European population have not suffered sufficient injury to their noses to produce this almost universal defect in this particular portion of their anatomy.

In a neat little brochure, Mr. Mayo-Collier distributed broadcast throughout the land his idea of the real cause of this deformity. I quote here the introductory notice: "The ready and full acceptance of my views on the causation of deflections of the nasal septum by the very competent tribunal to

which I submitted them has lent some warrant for my placing this small monograph before the profession."

The tribunal referred to is the British Laryngological and Rhinological Society. Certainly, if such a competent tribunal has passed favorable judgment on Mr. Mayo-Collier's views I can not ignore them.

The sum and substance of Mr. Collier's conclusions is, that the deflection of the septum is caused by a stenosis of one or both nostrils and the resultant atmospheric pressure acting on the unoccluded side, thus pressing the septum toward the opposite side. The theory is pretty, but it does not work in practice. In the first place most specialists agree that the septum is seldom if ever deflected in the posterior third, and that the curvature is almost exclusively confined to the anterior two-thirds. If the deflection is the result of atmospheric pressure, the posterior third would certainly be more exposed to such pressure than any other portion of the septum. In every case of stenosis, where we find a curvature in the middle or anterior third, the posterior third would be exposed to the same or greater pressure than the part affected.

One of the favored points of deflection is in the cartilage. Jurasz asserts it is always there; now certainly a stenosis never occurs anteriorly to the cartilage; it may occur as far forward as the cartilage, but then this would not furnish the necessary condition for a deviation that is confined mostly to that portion.

Artificial stenosis, as in the case of foreign bodies retained in the nose, furnish conditions most favorable for the production of a deflection if Mr. Collier's views are correct. Since reading his monograph I have had five such cases under treatment where the foreign bodies had been *in situ*, periods ranging from three months to five years; in each and all of these cases, the deflection was toward the unoccluded side. The cases were all children of from 3 to 9 years of age; a time of life when the septum is most pliable and when it would be most easily affected by such pressure.

Mr. Collier lightly disposes of polypi in "one breath." Certainly they deserve some consideration as one of the causes of stenosis. At the time of writing I have under my treatment a boy 9 years of age, who has had the right nostril obstructed for a year or more. The entire right side of the face is undeveloped. The septum, however, is very little if at all deviated.

Because 80 per cent. of savages and aborigines have symmetrically placed septa, Mr. Collier reasons that civilized people are more prone to colds and injuries, etc., that produce stenosis, which leads ultimately to the deflection of the septum. A great many scientists hastily conclude, that because civilized people are subject to affections from which the uncivilized are free, that the manner of living must necessarily be the cause. Civilization and refinement I admit are accountable for some of the minor ills from which mankind suffer, but there are great laws that control the human race and which are unaffected by the manner of living, and certainly there is no law that produces a deformity that has such serious consequences as the deformity under consideration, that does not have some more reasonable explanation than that it is simply a result of civilization.

Certainly, we do not live under any more unfavor-

able conditions than the Chinese, and again take the statistics of the American negro as stated by Allen. Here is a race living in the same country and climate and under more unfavorable conditions than the majority of Americans, and still the statistics show that only about 20 per cent. are affected with deviation of the septum.

As a "liqueur" to the feast, Mr. Collier quotes the results of Ziem's experiments on animals as proof of the efficacy of the great cause for which he contends. No one attempts to dispute the effect of stenosis of long standing, but unfortunately Mr. Collier has mistaken the cause as an effect. The most frequent and most permanent form of nasal stenosis is the deviation of the nasal septum and it is secondary to no other form of stenosis; it is the form that produces asthenopia, and assymetry of the face.

Over-development of the septum as first mentioned by Morgagni and later by Chassaignac, and accepted as a satisfactory explanation of the cause of this deformity by numerous specialists of to-day is decidedly unscientific. If there is a tendency to over-growth of the nasal septum we must have an explanation of the cause of this over-growth.

We are willing to admit that in the case of a deflected septum there is a profligacy of Nature in supplying such an abundance of material, but it is the wherefore we are seeking and not the fact that it is there, which is palpable to every observer.

Heredity as a cause is equally unscientific. It is no cause; it is merely a law that perpetuates the deformity. I can relate a circumstance where three brothers and one sister were all affected with exactly the same form of deviation. The external appearance of the noses was so much alike that one could call any of them by name, having been introduced to one of the four. It was a family nose inherited from their father. Heredity explains it thus far; are we to be satisfied with the explanation, or shall we seek farther and find that it descended from one generation to the other until the original of this type of the family nose is found?

Evolutionary or devolutionary changes. Here is the field in which our researches are most likely to be rewarded. There have been several searchers in this field working mainly in the same direction. Among the more prominent are Potiquet, Bendelack Hewetsen and Zuckerkandl. They commenced with the same theory, namely: That the condition was the result of a change from prognathism to orthognathism. Zuckerkandl merely suggests it without offering any particular reasons.

The paper read by Bendelack Hewetsen a few months later than the monograph read by Mr. Collier, shows that there was at least one member of the British Laryngological and Rhinological Society who did not accept the latter gentleman's theory as absolutely conclusive. Hewetsen in his paper discussed "The Relations between the Various Forms of Nasal Stenosis and Deafness." He found that nasal stenosis was associated with a narrowness of the jaw, crowding of the teeth and an elevation of the palate. This narrowing of the modern face, "the ultra refined face", as he terms it, he attributes to the fact that civilized men partook habitually of a much softer food than that which fell to the lot of savage man. He had examined large numbers of natives of the Zanzibar coast, of Hindoos, and lastly large numbers of Arabs in Morocco. In none of these people did he find any nasal

stenosis. It is to be presumed that there being no stenosis in these people examined, that the septum was quite or nearly symmetrically placed. Mr. Lenox Brown very correctly observed in the discussion of the paper that "the diet of lentils and curries which Hewetsen said formed the principal food of the people examined, did not seem as difficult of mastication as the average specimen of meat, which the modern European was called upon to masticate. The Mongolians certainly subsist on softer food than the Europeans.

Dr. Potiquet gave the result of his researches on this subject to the Paris Society of Laryngology, Otology and Rhinology in July, 1892. His researches were conducted on the 400 skulls in the museum of the amphitheater of the hospitals. I quote from a report in the *Journal of Laryngology*: "His conclusions are that in the Parisian, the osseous nasal septum tends to incurve so much the more, as the movement of rotation of the pre-maxillary around the point of junction, of the posterior extremity of the vomer with the body of the sphenoid taken as a center, is more marked. This conclusion may be regarded as a verification applied to a very limited group, of a law common to the whole series of primates, to-wit: That the nasal septum has so much the greater chance of lateral incurvement as the axis of the face is itself the more inflected in its antero-posterior direction. As this axis is more and more inflected as one rises from the anthropoid to the European male, the septum tends to incurve laterally more and more as one follows this ascending series. Lateral curvature of the septum therefore appears to be an evolutionary phenomenon related to the degree of antero-posterior inflection of the axis of the face." Farther along in the same article the writer remarks: "It would not be extravagant to say that a man has only exceptionally the septum which belongs to him."

It is difficult to argue this point without fuller statistics at one's disposal. For my own part, however, I do not believe that the rotation of the axis of the face in the European male is greater than in the case of the Hindoo and Arab, who Hewetsen claims are seldom if ever troubled with stenosis, but Potiquet says: "It is a law applied to a very limited group," and I judge that in this way he excludes all except the Europeans and their immediate descendants, but Nature's laws are not elective. If this condition is the result of evolutionary changes pure and simple, a change produced simply by the progressive or retrogressive state of man to accommodate him to a new condition of things, then it is the only instance I have been able to find where there has been such a marked assymetry of development as to impair the usefulness of the organ. We have instances where parts have atrophied when they were of no more use or left in disuse, but as far as I am aware none where there has been a hypertrophy.

It is possible that the nose, as an organ of sense, has not the magnified function that it had when man was in a less civilized state, but the peculiar shapes that characterize different races are probably not so much a result of the increased or impaired functions of that organ as a result of sexual selection. The nose, one might say, is the center of attractiveness in the determination of beauty in the eyes of most races. This being the case it is not strange that in the development of the different races we find in

their perfect development a type of nose that varies very little in the different individuals of the same race.

There is no feature or characteristic of a race that is so typical as the nose. The features of the purer races as the Mongolian, African, or Polynesian are so much alike that it is with the greatest difficulty that even the most skilled physiognomists are enabled to distinguish between individuals without a close acquaintance with them. This fact is aptly demonstrated by the difficulty we have had in finding some positive way of excluding our Mongolian brother from the confines of our country.

From the statistics at our disposal of Mackenzie, Zuckerkandl, Adams, Hewetsen and others, we find that the nasal septum of these different races, namely, Chinese, Japanese, Malay, Hindoo, Arab, American Indian and Polynesian varies as little in shape as does the external appearance of the nose.

Among the Europeans and their immediate descendants we find that there is no characteristic type of nose. In Paris, in the classification they have adopted for the recognition of criminals, they distinguish nine distinct types of noses and with subdivisions have as many as twenty-seven. These distinctions are from—the outline of the nose, convex, rectilinear, or concave—base of nose, ascending, straight or descending; these in the different combinations make nine varieties, and either of the combinations may be either thin, medium or broad. The interior probably offers greater variety than the exterior in so far as the septum is concerned. There are distinct types of noses, however, preserved in limited areas of Europe that were originally typical of a grand subdivision of the Caucasian race, as for instance the Roman, the Grecian, the Semitic; and again the other subdivisions as the Teutonic, Slavonic and other tribes that at one time had distinctive noses. The same law that produced the Mongolian or African type was effective in shaping the nose of the Roman, the Greek or the Teuton. It was the outcome of centuries of exclusiveness, and I venture to make the assertion that these people were no more troubled with the deflection of septum and the resulting stenosis than the Mongolian and other purer races of to-day. Their noses were the outcome of natural evolutionary changes.

How about the European population of to-day? The modern European and the immediate descendant to a greater extent represents a composite anatomy. The work of centuries in building up and fashioning tribes of distinctive types of features has been undone in a comparatively short period by the commingling and mixture of these distinct tribes. The commingling has not been limited to the people of the Caucasian races, but other races of a distinctive type, as the Mongolian and African, the American aborigines and others equally as distinct, have all united in lending characteristics to the modern European and American. I need not enter into the genesis of the European. It is a matter of history and accessible to all. The mixture, the result of conquest and slavery in ancient times and in later years of emigration and intermarriage between persons of different nationalities has equalized to a greater or less extent the distinctive type of features.

If we could examine the skulls of the purer ancient types as the Roman, the Grecian or the Semitic, I dare say we should find the deflected septum as rare

among them as among the purer races of to-day. If we should take the septum from the skull of one of these people and attempt to fit it into a Chinese or negro skull we would assuredly find a misfit, but this is the condition imposed on Nature by the mixture of races and a condition that is not likely to be modified for centuries to come, as the evolutionary changes necessary for Nature to accommodate herself to this innovation will be slow; as all evolutionary changes are.

We might accept it as a law that the straight or symmetrical septum is distinctive of a pure race, while the deviated septum is characteristic of a mixed race.

Such being the case, where would we expect to meet with this deformity most frequently? I think that you will all agree that the people of the United States are the greatest sufferers in this respect. In England, Mackenzie's statistics show that 76.9 per cent. of the population suffer with this deformity. If we could have statistics from Russia where there has been less of a mixture of races than in other European countries we would probably find the straight septum more the rule. Zuckerkandl's statistics show only 53.9 per cent., as we would naturally expect, as the farther east we travel the nearer we approach to original racial types. In the purer races as the negro and the Mongolian, we find the same shape to the nose in the child that we find in the adult, and other things equal we see no variation from the original type. The child resembles both its father and its mother, and in fact the whole race as far as features are concerned. In the European and American, however, the case is quite different; here there is apt to be a reversion to ancestral type. The offspring may resemble any progenitor as far back as its simian ancestors and excite no particular comment. An American with a Roman nose who takes for a spouse a woman with a *retroussé* nose may find in his several children as many different shaped noses. The only fact he can safely predict is that one and all will have a deflected septum. In a well regulated Roman, Grecian or Semitic family I venture to remark that if any of the children had had a *retroussé* nose that there would have been an investigation set afoot.

That deflected septa are as frequent as 20 per cent. in non-European and non-American people is readily accounted for by the fact that even in the most isolated races there is a certain percentage of mixture. There are few people whom we have the opportunity of examining among whom the whites have not mixed. Missionaries, adventurers, travelers and shipwrecked persons have gained a footing in even the remotest corners of the earth and their imprint is found stamped in the nasal septa of the inhabitants.

Another important factor must not be overlooked as accounting for a certain percentage of the deflected septa both in the civilized and uncivilized races, that is owing also to a disparity in the development of the cranial and facial bones. We find not infrequently that the cranium is small in proportion to the development of the facial bones, owing to the too early ossification of the cranial sutures. This need not be sufficient to bring the individual within the limits of cretinism, but sufficient to be an important factor in causing a deformity of the septum. The most deformed septa I have ever seen were in

individuals belonging to this class. Three cases I recall where the individuals escaped only with their reason. Two had the peculiar facial expression of those affected with pharyngeal adenoids, but they were in no way improved either as to facial expression or as to mental condition by the removal of septal spines, crests and enlarged turbinates which furnished free breathing room through the nostrils, thus proving rather conclusively to my mind that the disparity in development in these cases was the cause of the nasal stenosis, and that the latter condition had very little effect on the mental condition; as one might infer on first thought.

The deviation of the septum resulting from anomalies in development occurs during the time of the second dentition from the seventh to the fourteenth year; it may become more pronounced from then up to the eighteenth or twentieth year when ossification in the skull is completed. It rarely if ever occurs before the fifth and *never* after the twentieth year, unless from pressure or traumatic causes. It occurs during the years of greatest development of the brain, and consequently with the greatest expansion of the cranial and facial bones. Whether during this period the space between the ethmoid and the superior maxillary is abridged, or whether there is a greater development of the septum than the space admits, or whether both these factors come into play, I am not prepared to state. Up to the time of the second dentition there is a similarity in the facial appearance of European and American children, but at this time there commences a variance in the nasal shapes that does not occur in the children of unmixed races. The mixed races seem to be affected by other anomalies in development of the facial bones that occur principally during the same period, namely, the narrow and shortened jaws and the high arched palate, the latter more apparent than real, as the nearer approach of the alveolar processes makes the palatal arch seemingly higher. These anomalies all seem to be more clearly explained by the blending of different racial types than by evolutionary or devolutionary changes from a prognathous to an orthognathous type. The whole matter is one of theory, but the weight of the evidence is in favor of the former, because we know it has been and is occurring continually while the latter supposition is purely theoretical.

FIBRO-LIPOMA OF THE PHARYNX.

Read in the Section on Laryngology and Otology at the Forty-fifth Annual Meeting of the American Medical Association held at San Francisco, June 5-8, 1894.

BY JOHN O. ROE, M.D.

ROCHESTER, N. Y.

REPORT OF CASE.

Benign tumors of the oro-pharynx, involving the posterior wall alone, are of comparatively infrequent occurrence. Judging from the cases reported, and from my own experience, lipomatous tumors located in this region are the rarest of all. The following exceedingly interesting case, that of a large fibro-lipoma of the pharynx came under my observation last January, and is quite worthy of record:

Mrs. R., 49 years of age, began nine months before I saw her to experience a sensation of roughness and fullness in her throat, attended with difficulty in swallowing, and associated with pain extending to both ears. While remaining quiet she experienced no special discomfort in her throat,

but on attempting to swallow, the sensation of constriction about the throat and the pain in her ears would be frequently quite severe. This difficulty in swallowing began with the taking of solids, particularly in large pieces, and gradually increased until the time she came under my observation, when she could swallow liquids only and these only in small quantities. Owing to this great difficulty in swallowing she had become emaciated, and was rapidly losing flesh and strength. An examination of her throat revealed a large swelling projecting forward from the posterior pharyngeal wall, nearly filling the pharynx. It extended vertically from a point opposite the base of the uvula to a point opposite the arytenoid cartilages, and laterally from one posterior pillar to the other. This enlargement was somewhat ovoid in shape, the larger portion being above, and covered with mucous membrane, indicating the existence of a growth located behind the pharyngeal wall. The mucous membrane covering the swelling was somewhat pale from the pressure of the growth beneath, but otherwise presenting no unusual appearance; and there was no evidence of previous ulceration or disease of any nature.

On palpation, this swelling had a soft doughy feeling, similar to that of an abscess, but the history and appearance gave no suspicion that this swelling was of that character. There was no history of a specific disease, and the patient had met with no injury to the pharynx of which she was aware. Thinking, perhaps, the swelling in her throat might be a collection of enlarged post-pharyngeal lymphatics, due to some unknown specific trouble, I placed her on vigorous specific treatment for a time. This treatment, however, had no effect upon the swelling in her throat, therefore, without doubt, the swelling was not of a specific nature. The growth to all appearance was a lipoma, and I accordingly advised its removal, which was done the following day. Local anesthesia with cocain injected and applied to the surface was quite sufficient to relieve the pain. An incision about an inch and a half long was made along the median line down to the tumor, which lay encysted just beneath the submucous connective tissue. I then endeavored with a thin curved elevator to separate the tissues from the growth and thereby to enucleate it. This I succeeded but partly in doing and, owing to the fact that the thin portion of the anterior wall of the growth became ruptured, a portion of the contents escaped. This was preserved for further examination and found to be composed of fat. In conjunction with this substance other tissue of a firm character was found, which was afterward shown on examination to be fibrous connective tissue.

It was with some difficulty that the growth was separated from the surrounding connective tissue, and along the posterior surface it was attached and firmly adherent to the pre-vertebral fibrous tissue. The attachment of the growth extended throughout the posterior surface from a point opposite the base of the uvula to a point opposite the arytenoid cartilages, being the area that the growth occupied externally as indicated during the first examination. It was with considerable difficulty that this attachment was removed from the vertebrae, requiring careful dissection. The removal of the growth was attended with very little hemorrhage, no vessels requiring ligation, and capillary oozing soon subsided.

The whole cavity, after being thoroughly cleansed with a solution of bichlorid of mercury (1 to 5000) was completely packed with iodoform gauze, not only to render the parts thoroughly aseptic, but also to prevent food from entering the sac. Notwithstanding the fact that the sac was as completely filled with the iodoform gauze as it had previously been with the growth, the patient could swallow much more easily than before the operation. She was placed upon sterilized milk diet which was maintained until the parts had healed.

The cavity left by the removal of the growth was allowed to fill with granulation, requiring about two weeks. At one spot there was a portion of the attachment of the growth to the posterior wall that had not been completely removed; this was destroyed by the galvano-cautery. At the end of three weeks the surface was completely healed, leaving only a slight scar along the median line, and since that time there has been no evidence of any return of the growth.

This growth was evidently a combination of a lipoma-molle and a fibro-lipoma, in which the fatty portion had become liquified by the heat of the body and by the motion and pressure to which it was subjected. A case similar to this one, in nearly all par-

ticulars, is reported by Taylor¹. In Taylor's case, the tumor was mistaken for a post-pharyngeal abscess and incised. It passed down so far behind and projected so far on each side of the larynx as to cause dysphagia and dyspnea from pressure on the larynx. Tracheotomy gave no relief. In the case I have described the patient suffered from dyspnea, although not from pressure upon the larynx but from partial obstruction of the larynx, and also of the pharynx by the growth interfering with the ingress of air.

DIPHThERITIC CRICOID PERICHONDRITIS AND NECROSIS.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY PROFESSOR RAMON DE LA SOTA Y LASTRA, M.D.
SEVILLE.

The idiopathic inflammation of the laryngeal cartilages is considered a rare affection by the greater part of the authors; who instead affirm that the laryngeal perichondritis and chondritis, as manifestations of certain constitutional illnesses, pocken, typhoid fever, syphilis, lupus, cancer, tuberculosis and mercurial intoxication, are sicknesses which are observed frequently. I think that the idiopathic perichondritis appears many or more times than the symptomatic, and if we do not take notice of it with more attention, it is because it terminates generally by resolution, and passes without being noticed, and we believe it to be an inflammation limited to the mucous membrane, and to the immediately sub-mucous tissue, which penetrates into the same cartilage. For which it is called intense inflammation of the arytenoid mucous membrane, that which not only invades the immediately submucous tissue, but that which reaches the crico-arytenoid articulation, beginning in many cases the phlogosis by the same articular surfaces; after that it goes on to attack the mucous membrane, this being the consecutive inflammation, and the arthritis the primitive one.

Among the causes of the consecutive perichondritis only two authors notice the diphtheria, Gottstein and Bosworth; the first saying, speaking from the etiology of the perichondritis, that this "can appear as joined to an ulcerative process already existent of a diphtheritic character; but without stating if his affirmation is purely rational or deducted from the experience; and the second cites the diphtheria as a cause of the inflammation of the laryngeal cartilages, because one of the 33 cases of perichondritis observed by him was produced by the diphtheria. Volume II. of the *Journal of Laryngology*, pages 366 and 367 contains an extract of a case published by Jacoborvitsch, from St. Petersburg, in the *Archives für Kinderheilk.*, Vol. 10, No. 1: "It was a child a year and three months old, which suffered the scarlatine. The diphtheria of the throat appeared several weeks after, and the diphtheritic membranes persisted on the tonsils and upon the pharyngeal vault during two months. There was also increasing stenotic respiration. Tracheotomy was performed, and the child died. In the necropsy was discovered perichondritis of the cricoid. The pharyngeal mucous membrane was covered with pus and membranes."

The *Internationales Centralblatt für Laryngologie*, published at Berlin from 1889 till 1890, page 189, copies from the *British Medical Journal*, Sept. 22, 1888, a case of the necrotic perichondritis observed in a pig by Proctor S. Hutchinson, of London: "The animal suffered from symptoms, which resembled those of the croup. It was not founded on motives to diagnose the acute illness. The animal died, and necropsy was performed. It was found with an inflammation, which was extended around the cricoid cartilage with partial necrosis of the same. A very great part of this cartilage fell down, and only remained a little part of the lower and anterior portion. The suppuration was insignificant. The necrosed piece was buried in a tissue of soft granulations. At last existed a general edema of the larynx, which explained the dyspnea."

This is all that I could find in the medical literature, which says anything with regard to the appearance of laryngeal perichondritis produced by the diphtheria; not even Knight, (who, in the eighth annual meeting of the American Laryngological Association, held at Philadelphia in May, 1886, with motive of a case of perichondritis, studied the causes of this affection in a splendid work) mentions diphtheria.

I have recently had occasion of observing the fatal consequences of this complication of diphtheria (which I think is not very rare) and by it have been many deaths attributed to other different causes. But before making more reflections, I will refer to the history of an interesting case for more than one reason:

February 4, 1894, I was called in consultation by the well-known physician, Reyero, on a child of 23 months, whom he found with all the symptoms of diphtheritic croup, and he recommended me to take the necessary instruments in case of necessity of performing the intubation, as he supposed.

At 8 o'clock in the evening we assembled at the house of the little invalid, who six or eight days before had shown symptoms of the bronchial catarrh, according to the statement of the parents; who had not been alarmed and had not called in the physician until that same afternoon, because they did not think it was fever, and notwithstanding that he did not like to eat, because he felt a pain in swallowing, coughed frequently, was hoarse and was unable to get up, but breathed well, they had confined themselves to have him protected from the cold, poulticed in the neck, and giving him some warm milk. They gave him also two emetics of ipecacuanha, one every second day: the latter one that same day; and notwithstanding the two operated well, as the illness not only remained, but increased until the difficulty of breathing inspired the parents with some dread, they resolved to call the physician.

The state in which Dr. Reyero found the little invalid five hours before the consultation, was a little more or less the same in which we found him when we joined for the consultation, and believing the child to be in a very grave condition, Dr. Reyero had the consultation immediately. I noticed that it was a larger child than its age seemed to warrant, and seemingly vigorous. He slept in his mother's arms, with difficulty breathing noisily in the inspiration and in the expiration; the forehead was covered with a cold and viscous sweat, a livid line existed around the eyes and the mouth; the cheeks were very high

¹ Lancet, London, 1876, Vol. II, p. 685.

colored, but the ears, the lower part of the face and the nose were pale; the wings of these latter moved when he breathed; the supra and infra-clavicular, and supra-external fossæ, and the epigastrium fell down profoundly during the inspiration; the scapular, sterno-cleido-mastoides, pectoral and abdominal muscles concurred with their contractions to introduce the greatest possible quantity of air in the lungs. The respiration was shallow and hasty (38 every minute); the pulse was feeble and quick (112 every minute); the skin of the extremities was cold; the nails were blue, and the axillar temperature arrived to 38.9 degrees. Examining the mouth, appeared a white and large false membrane, which covered the soft palate, the uvula, the two pillars and the two tonsils. The rest of the mucous membrane of the palate and the pharynx was very red and friable, and to the least light friction bled. From the excoriated nose flowed a bloody ichor, but the false membranes were not seen there. At auscultation we noted a noise of large bubbles as much in the anterior part as in the posterior part of the chest. Our diagnosis was pharyngeal and laryngeal diphtheria in the asphyxia period, and complicated with intense and extensive bronchitis.

We made a very dangerous prognostic, not only by the advanced and extensive suffering, but because the gripe was existing in Seville at that time. We feared that the bronchial catarrh would assume an infective character, if by chance it had not yet assumed it. Notwithstanding, we agreed that it was necessary to perform the intubation immediately, in order to free the child from the imminent asphyxia; to separate the false membrane with a ball of very firm sterilized cotton; to irrigate the throat and the nose with a solution of carbolic acid (1 to 100); to touch the sores of the diphtheritic plaques with another ball of sterilized cotton moistened in a solution of the absolute phenol in the sulpho-vicinat of soda (20 to 100); these three latter were to be done every hour. The following mixture:

R. Hydrargyri bichlorid .01 gram.
Tinct. ferri chloridi, 8 cc.,
Potassi chloratis, 4 gram.
Glycer., 60 cc.,
Aqua, 120 cc.,

was given, a teaspoonful every hour, and we advised that nourishment should be often taken, taking care to place the invalid with his head downwards, whenever he took any fluid. Moreover the bed was surrounded with sheets, making like a tent, and burning within the sheet two grams of calomelanos every four hours.

All was performed as we ordered. The intubation was made very easily and promptly, putting the tube, No. 2, of the scale of O'Dwyer, corresponding to the two years which the child had. But at the first fit of coughing after having placed the tube, this was expelled with force and to a great distance; which showed me the necessity of placing another and larger tube, and without difficulty I put that of the No. 3, and the little invalid remained breathing, coughing and discharging mucosities by the tube with great facility, and without showing any grievous symptoms.

The first night he was very agitated, the tracheal râle was heard outside the room, and the temperature was raised to 39.8 degrees. The succeeding days at 9 o'clock in the morning the fever went down suffi-

ciently, for it descended to 38 degrees, but it rose again during the night, the child did not wish to eat, it was sorrowful and did not speak. Notwithstanding, the respiration was performed easily, and the false membranes were every time reproduced with less vigor.

On the sixth day I determined to take the tube away, that I had hesitated to take away before, watching the bulk of the introduced instrument. The child passed the day better than the anterior days; he had sat down at table with his parents and had wished to eat what he saw, though he suffered much in swallowing it; the diphtheritic sores of the throat had totally disappeared, but the respiration (a condition that should not be forgotten, by what happened after) was noisy, notwithstanding that it was performed easily, as the tracheal rattle and the axillar temperature was raised to 38.7 degrees. The extraction of the tube was performed quickly and well, but in the moment that it was taken away from the larynx, and when I believed that by its friction against the posterior laryngeal wall, the violent fits of cough commenced which expelled the materials lodged in the trachea, I observed with great disgust that they were carried down by the current of inspired air, and afterward the child began to suffer the peculiar paroxysm, precursor to the asphyxia. I expected that this dyspnea would disappear by degrees, as I have had occasion to observe it in other operated persons, and examined the tube, which was completely obstructed, and saw a piece of the macerated false membrane formed a cap or a capsule in the inferior extremity of the instrument. I introduced the obturator of the tube and there came out a dense mass in shape of a cylinder, a veritable mold of the lumen of the tube, composed of detritus of false membrane, by semi-coagulated mucus and probably by some food. I called my learned colleague's attention to all, and he asked me from what time this material had filled the tube. I could not tell him; by the consistency of the plug, which did not break when it fell to the floor, I ventured to say that the tube had been obstructed from twenty-four to forty-eight hours.

When I was occupied in these examinations the state of the child grew rapidly worse. I observed it by the noise which the air made in passing the glottis, and my friend Reyero advised me of it, at first with tranquillity and the second time with exigency, because the little fellow was suffocating. I was already trying to place a thread in the tube in order to repeat the intubation, but the moisture of the instrument and of my hands made it very difficult to slip the delicate thread of silk in the small hole of the tube. I could not do it. Reyero was alarmed, and with reason, because the face of the child was violet, and he told me again of the danger; and for that reason I left the silk, because there was not a moment to lose, and, placing my confidence in God, without silk and without gag, I performed the intubation, doing it with great facility and at the first attempt, and beginning immediately the artificial respiration; because the child could not get breath and all its skin was covered with a cold and viscous perspiration, and the muscles completely relaxed. We obtained in three or four minutes of the artificial respiration the natural one well restored. The child slept after the danger which he had run, and we were smiling after having been in such great anxiety.

We attributed what happened to the aggregation upon the wing of the trachea of layers of the false membranes and of a great quantity of semi-concrete muco-pus, and we decided to leave the tube for two days more, holding same medication, but stopping the painting with the solution of phenol, because the diphtheritic sores had disappeared.

Thirty-eight hours were passed without any accident, the temperature had been normal since the following day; the same in the morning and evening. The child wished to eat, but the deglutition was always painful, the respiration was accomplished without noise and suddenly at a fit of coughing the tube was expelled. I was called and went with the haste which was natural after what happened two days before, and when I arrived at the house of the invalid, which is very far from mine, I had the consolation of finding the child respiring, though with great pain. I was surprised that the tube was expelled so soon, because it was much larger than usually used in a child of that age. The dyspnea reappeared the moment the tube was extracted, and increased until nearly asphyxiated, although the lumen of the instrument was clean and we could not hear the tracheal rattle, but we could hear the whistle which the air made in the glottis, as much in the inspiration as in the expiration. I performed intubation for the third or fourth time, and all remained as if nothing had happened; but I was very displeased, because I thought that it was caused by a post-diphtheritic paralysis of the posterior crico-arytenoid muscles, and so I told Dr. Reyero, who coincided with me in the diagnosis and also in the prognosis; we then left the house sorrowfully thinking of the paralysis in such little muscles where perhaps it had never been before. Knowing how rebellious and long are these fits of paralysis, we did not dare to say how long we should have to leave the tube in the larynx, and the inconveniences that were present by the paralysis of the dilating muscles of the glottis. Notwithstanding, as that day the dyspnea had not been as early and as severe as two days before, I hoped that the tube inciting the part would determine the contraction of the postici muscles. In thinking of these things we arranged for a new consultation in two days, in order to take away the tube, besides he did not expel it as before, and resolving to carry one of the shortest tubes and of a great diameter to substitute for that placed, in case it were necessary.

On these two days nothing happened worthy of mention, and to the disgust of the parents I took away the tube; and the scene of the latter day was repeated. I then placed the third tube of the short ones, and left the child all right.

Two more days were passed with tranquillity; the only unpleasant phenomenon was the pain in the larynx sustained, in my opinion, by the long permanency of the tube in the larynx; and so great was my desire of taking away the instrument, that I extracted it in the hope of finishing my task that evening; but if there was a moment in which it seemed that the respiration was performed easily, that passed, and the peculiar respiratory whistle was repeated. With disgust I listened to it; but I did not wish to repeat the operation. Reyero looked at me and said: "I do not wish the child to remain like this; I have very much to do and can not lose the time. I beg you to repeat the intubation." He was right, and I obeyed.

The child resisted all our maneuvers; thus as soon as he saw the gag he closed the teeth, and there was no human force that could separate his jaws; we vexed and annoyed him every time that the gag was applied. On this occasion the maneuver was something more tedious than the anterior ones; and a tooth was knocked out; the little invalid shook the head in the moment of nausea, so notwithstanding our efforts to subdue him I was only able to place the gag in an imperfect manner. So I performed; but when I put my finger upon the head of the tube in order to withdraw the obturator, I observed that the larynx fell down until I could not touch it with my finger. I stopped in suspense. What had happened? Where had the tube fallen down? That tube of which the diameter was triple, that which corresponded to the age of the child? To the subglottic part? To the trachea? Impossible, because the shortest tube placed by Brothers in the larynx of the dead body of a child could not be made to go down to the trachea, far less could this large tube fall down so small a larynx and with so light an effort. Guided by this reasoning I took away the thread. Notwithstanding so nervous a person, as I, can not rest under the power of the imagination without suffering dreadfully, and for that reason I decided to take away the tube. I introduced the extractor and putting it well down I managed to seize the tube and take it away. I had nothing to dread, but it was necessary to repeat the operation, and as the child had the mouth open, and recollecting what I had done a few days before in very exacting circumstances, I wished to repeat the operation; that is, I wished to introduce the tube without putting in it the thread of silk; but the tube, large and short, was separated from the obturator, and before I could seize it, the tube fell down the esophagus lengthwise, and penetrated into the stomach. A similar contrariety bothered me very much, though I knew already that the tube would sooner or later be expelled by the ano, and in the same instant I seized another tube of the largest and shortest, put in it the silk, and placed it in the larynx. The tube was larger than that which had been slipped by the esophagus, and, notwithstanding, I felt it slip under my finger, just as the other one had done when it fell down, but yet I did not trouble myself, because I knew that it was upon the vocal cords; notwithstanding I was not able to explain what happened; for the paralysis of the abductor muscles was not sufficient reason for this rare phenomenon. That happened February 23, and we agreed that the parents should carry the little invalid to my home on the 26th, in order to begin the application of electricity to the paralyzed muscles.

By misfortune, I woke on the 25th with a great superciliary neuralgia, which obliged me to remain in bed. On the evening of this day the child expelled the latter tube, so extraordinary large for its age, and the father called me in order to help his son, who was suffocating. As I could not rise from the bed, so I besought my dear disciple and expert laryngologist, Gallegos, to go and do what he believed necessary for the child.

My friend went instantly, found the child in asphyxia, and introduced the tube which had been expelled two hours before. In introducing it he observed what I had observed already; that is, that the tube under the pressure of the finger slipped by

the larynx to a place where it could not be touched by the finger. That surprised him as it had surprised me; but he had not time to pre-occupy himself, because he had scarcely taken away the thread than a fit of the cough expelled the tube out of the larynx. This scene was repeated six times; on the third, after the issue of the tube was a moment of imminent asphyxia; a whitish body appeared between the teeth in the middle of thick and sanguineous mucosities, which Gallegos seized, believing that it was a tooth, as the anterior, separated. When he had it in his hand he saw that it was not a tooth, but a white opaline substance, from two millimeters of thickness by ten and seven of length and nine of breadth; irregular, concave on one of its surfaces, convex on the other; with two even and round borders, one superior and the other inferior, and with two dentated extremities. He considered what it might be. At first he thought it was a piece of epiglottis, but when he examined this with the finger, on making a new intubation, he observed that it was intact. He thought then if it might be a substance thrown from the stomach, but none of the food that the child had taken could contain anything of that size and form. Believing that it was gristle he wrapped it carefully in a paper and continued attending to the patient. Tired and weary because the tube was always thrown out by the cough which the extraction of the thread caused, he decided to leave it, reminding the mother not to loosen the thread at all during the night, so that the child could not pull it with his hands and extract the tube.

On the following morning Gallegos went to see the patient and found that he could take the thread without the tube being expelled, and he came to tell me all that had passed and to give me the tube which had fallen into the stomach, and that before twenty-four hours it had been expelled by the ano. Also gave me the strange body taken between the teeth on the preceding night. I staid in bed suffering from neuralgia; heard the relation of my friend, seized that which he gave me, and looked at it carefully. It was already dry, and was transparent and hard, rolled upon one of its surfaces, and had all the appearance of a large psoriasisic scale. "I do not know what it is," said I to him.

"Nor I either," he replied, "but I believe that it is a piece of gristle." "It does not appear to be so," I answered; "it resembles more a dried false membrane, or a piece of loosened and dried vocal cord." "You did not see it when it was fresh; then it was like a necrosed cartilage, and by its breadth I believed that it was the epiglottis, but then I have touched it with my finger, and observed that it was complete." "If it is cartilage, as you believe, it will be a piece of the cricoid gristle by its form; but leave it, for I can not speak. Please put it on my cabinet table." Observing the bad state in which I was Gallegos departed; and two hours after the parents of the child arrived at my consultation room with the little patient. He had expelled the tube; and I told them to take him to Gallegos, who performed the intubation, but three hours after another fit of coughing threw out the tube. The child remained without it all that afternoon and all the following night.

In the morning they called me, but as the neuralgia did not permit me to go, and knowing that the child was choking, that he could not swallow more than

fluids, and that his general state had grown much worse since I had last seen him, I advised them to perform tracheotomy; for it was seen that the paralysis of the vocal cords was so great that they wanted the necessary tension to retain the tube. I indicated this to the parents the day before, but they did not wish to have a bloody operation performed; yet at last, knowing that if the trachea was not cut their son would die, they asked of me the cannule of tracheotomy corresponding to the age of the child, and with it they went to call Reyer. Unfortunately, he could not go to the child until 12 o'clock; half an hour before this, died, asphyxiated, that fine child who during fifteen days had passed through so many vicissitudes.

As soon as I was relieved from the neuralgia, I begged of my dear friend, the illustrious Dr. Roquero, Professor of Histology in the School of Medicine of Seville, to make a microscopic examination of the body held by Gallegos. Roquero then immersed it in pure distilled water, and examined with the microscope a section, and saw that it was a hyaline cartilage, and that the piece would correspond to more than the posterior half of the cricoid cartilage. Effectually, after having soaked it in the water, the figure shown in the annexed photograph appeared clearly. The surfaces A and A correspond to the

articular facets upon which the arytenoid cartilages turn round; in the middle of the plate one can distinguish the projecting line that shows the union of the two halves of the seat of the ring, and in the sides you can see some rugosities indicative of the insertions of the posterior crico-arytenoid muscles. This anatomic piece I conserve in a solution of hydrate of chloral; for it is equivalent to an necropsy, because it explains the phenomena observed during life, and puts out of doubt the existence of diphtheritic laryngeal perichondritis and necrosis.

If these affections are not quoted as frequently as they ought to be, without doubt we must impute that to people not thinking about more than the inflammation of the mucous membrane and the submucous tissue; as if further than that there is some insurmountable barrier to the simple inflammatory or specific process. As there is no such barrier, it will be permitted to suppose that in many cases the diphtheritic process advances to the perichondrium, and into the same cartilage; and if we do not observe its greater frequency the expulsion of the necrosed pieces, as in the present case, it is due to death happening before there was time for the cartilage to be carious in all its thickness, or that either a large or small sequestre could come out. Neither is it risky

to suppose that there have been cases of expulsion of the cartilaginous pieces, but unknown or not seen by the assistant persons.

I have said that the piece taken from our patient is worth as much as an autopsy or more. It explains to me why the child was choked as soon as he expelled the tube. I imputed it the first time to the mucosities and detritus of the false membranes accumulated upon the spur of the trachea; the second time to a paralysis of the dilator muscles of the glottis of diphtheritic nature. This second time I was right about the paralysis, but I was wrong in its cause. The perichondritis must have appeared in those first eight days in which the child did not have the necessary medical attendance as proven by the intense dysphagia manifested by the little patient. In the moment of the first operation the cartilage must have been immersed in a bag of pus, formed under the perichondrium, the lateral parts of which were probably grown carious. During the first six days of the permanence of the tube, the perichondrium and cartilage stopped ulcerating and then the crico-arytenoid posterior muscles were lost in a great part of its extension. For this reason the vocal cords united as soon as the tube was taken away, and the air whistled in passing through, as much in the inspiration as in the expiration. For this reason the first tube, larger than was convenient for a child of that age was expelled in a fit of coughing, and the same happened with the second and third tube, and this fell down in the larynx, when it was pressed by the finger, because the larynx lacked resistance, the soft parts and the hard parts had lost the base of their support for it is well known that the cricoid cartilage is the fundamental cartilage of the larynx, and that all other parts of this organ rest upon it. When so considerable a part of the cricoid ring gives way as gave way in this case, all the posterior laryngeal wall is put out of its place, the soft tissues are flattened or are united with those of the anterior part of same organ, the arytenoid cartilages necessarily sink and fall in the laryngeal vestibule, and the thyroid cartilage remains without control, through failure of its inferior adhesions.

But the case also obliges us to think that it is possible that one of the ordinary tubes of O'Dwyer can descend in the trachea; for Doctor Brothers, after his experiments, which prove the impossibility of the tube falling down by its own weight in the trachea, tells us that what principally impedes this descent is the enlargement or prominence of the cricoid cartilage in the anterior part of the larynx. If that is so, then if a considerable part of the ring is separated, the retentive enlargement is wanting, and as the soft tissues are elastic, it is possible that the tube may penetrate to the tracheal conduit. If in this child this did not happen, it must be without doubt that when the sequestrum lost its relations with the anterior part of the ring, the diameter of the tube was too large. I, a decided partisan of the method of O'Dwyer, show this contrariety, which is neither little nor insignificant, because the fall of the tube in the trachea would oblige the operator to perform tracheotomy immediately in order to extract the strange body; which would place the physician who had already told the parents of the little patient that he knew a proceeding that would free the child from asphyxia without cutting, in a very delicate situation. Until now I never thought that I should

find myself in such a difficulty; for the future I shall have to dread it, although it may be rare, and I shall so tell the family.

But if this case has given me a motive for fear, at the same time it has given me another motive for confidence. All the authors, when writing about the serious accidents of intubation tell us about the obstruction of the tube by the false membranes or by other cause. In this child I found the tube completely obstructed when I took it away the first time, and notwithstanding the child breathed perfectly; and more, the dyspnea began as soon as I extracted the tube. How do you explain the phenomenon? I believe it very easy. Place two thin bands of caoutchouc of five millimeters in breadth by twenty in length in form of ribbons upon a tube, so that they are touched by its borders, but are not very tight. Between two bands is placed a little tube of O'Dwyer, and it will be seen that the ribbons remain separated two or three millimeters in front and behind the instrument. What more suffices for the respiration to be made with relative ease? A similar thing happens in the larynx. The vocal cords are relaxed as in the present case by the loss of resistance of its posterior insertions.

Finally, this history also teaches us that we must never try to extract a tube without having another prepared to introduce, if it were necessary, as happened the first time I took away the tube. If, then, I have the misfortune, which I had in my latter intubation, that the tube gets out from the obturator, and instead of falling into the larynx, it falls into the esophagus, the child would be asphyxiated with all certainty. I do not know if any one of those who have written upon intubation of the larynx have improved upon this precept; if none have previously indicated it, I now show it.

RETRO-PHARYNGEAL LYMPHADENITIS.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held in San Francisco, June 5-8, 1894.

BY W. E. CASSELBERRY, M.D.

PROFESSOR OF THERAPEUTICS AND OF LARYNGOLOGY AND RHINOLOGY IN NORTHWESTERN UNIVERSITY MEDICAL SCHOOL (CHICAGO MEDICAL COLLEGE); LARYNGOLOGIST TO WESLEY HOSPITAL, ETC. CHICAGO, ILL.

It is now well established that retro-pharyngeal abscess arises ordinarily not in caries of the cervical vertebrae, but in the inflammation of the lymphatic glands which are imbedded in the posterior pharyngeal wall. Of 204 cases analyzed, Bokai placed 187 in this class, in contra-distinction to only 7 cases, secondary to caries of the vertebrae. Children are especially prone to inflammations of the lymphatic system. Cervical lymphadenitis is common among them. Frequently it is tuberculous, but often it is not, and usually the acute variety whether suppurative or non-suppurative, results from infection by a previously existing tonsillitis. So also with retro-pharyngeal abscess; it is most reasonable to regard it as a secondary infection of the pharyngeal lymphatics from inflammation of exposed and associated muco-lymphoid glands, like the faucial and naso-pharyngeal tonsils. In rare instances the source of infection may be rhinitis communicated through the nasal lymph channels or, still more rarely, a suppurative otitis; but as previously mentioned, follicu-

lous and suppurative forms of tonsillitis, as well as those forms of tonsillitis and pharyngitis which are symptomatic of the exanthemata, may reasonably be regarded as the most frequent causes of retro-pharyngeal lymphadenitis.

Whatever the source of infection, the initial stage of retro-pharyngeal abscess is retro-pharyngeal lymphadenitis, and moreover the lymphadenitis may be of a non-suppurative type, or the disease become arrested in this stage, undergoing resolution without the formation of an abscess. This simple lymphadenitis has been but rarely observed in this country, but Bokai, in addition to 400 cases of abscess, mentions 112 cases of simple retro-pharyngeal lymphadenitis as having passed under his observation in the Pester Kinderspital.

I would report the following instructive case:

A female babe 4 months of age, was convalescing from acute follicular tonsillitis, probably of the variety which I have elsewhere described, under the name of infectious pseudo-membranous tonsillitis, which was prevalent at that time, and which in several other cases, under my observation, had occasioned pronounced cervical lymphadenitis. As the tonsillitis subsided dyspnea commenced and increased for two weeks, at which time I saw the case in consultation through the courtesy of Dr. E. J. Kuh. Suffocation was imminent, cyanosis marked, respiration irregularly stertorous and only possible when the child was held in a certain position. The voice was unimpaired and inspection of the fauces negative, but careful palpation disclosed a hard tumor which projected from the posterior pharyngeal wall in the median line, extending downward sufficiently to press upon the opening of the larynx. I made three punctures into this tumor but failed to evacuate pus, and being otherwise satisfied by its hardness to the touch and the absence of fluctuation that it was not an abscess but a case of simple lymphadenitis, tracheotomy was advised. The recovery which ensued from this operation in a child so young as 4 months, is to be largely attributed to the skillful manner in which Dr. L. L. McArthur opened the trachea without an unnecessarily large external wound, without delay and with antiseptic precautions. The tumor underwent gradual resolution without suppuration, or at least there was no perceptible discharge of pus in any quantity. At the end of two weeks the tracheotomy tube was withdrawn, and the child recovered.

The successful management of such a case would depend first on a correct diagnosis. Dyspnea is the most prominent symptom, the cause of which must be precisely determined. It is easy to exclude diphtheria by inspection of the fauces, and equally easy to exclude both spasmodic and membranous croup by the presence of an unimpaired voice; but I have seen identical symptoms of suffocation produced by a large collection of "adenoids" in the naso-pharynx, which by pushing the velum palati downward and forward, caused it to impinge on the dorsum linguæ and thus impede respiration. This condition can be excluded and the positive diagnosis of retro-pharyngeal lymphadenitis made, not by inspection, but by palpation. Examination deliberately made by the finger of each and every part of the pharynx and naso-pharynx will afford much more exact information in such cases than mere inspection of the fauces.

Having located the tumor in the posterior wall of the pharynx, the presence or absence of pus may be determined by a puncture or two or three punctures carefully made by a bistoury. The exact position of the tumor varies in different cases; it may be high or low, in the median line or to one side. "McClellan's Regional Anatomy" locates one retro-pharyngeal lymphatic gland opposite the second cervical vertebra, but it is likely that it may deviate from this position, and that others would be located by

close anatomic study. An inflammation commenced by infection of a lymphatic gland would be likely to involve, also, the surrounding connective tissue. When located low down in the laryngo-pharynx a comparatively small swelling may speedily occasion suffocative symptoms.

This paper includes within its scope the treatment only of retro-pharyngeal lymphadenitis, not that of abscess, and apart from general measures the only symptom of the former affection likely to demand interference is dyspnea. Having made preliminary punctures to exclude a possible collection of pus, the question of tracheotomy must be considered. Intubation is out of the question, for the same swelling which stops the glottis would stop the orifice of the tube.

Bokai¹ finds that tracheotomy is rarely necessary, resolution usually taking place in from five to seven days before suffocation becomes imminent. Nevertheless, Bokai² reports a case similar to the one herewith detailed in which he performed tracheotomy. It was a child 8 months old; the posterior wall of the pharynx showed diffuse hard swelling without fluctuation, and a deep incision into the mass had yielded no pus. Resolution occurred without suppuration, the tube was withdrawn at the end of three days and the child recovered.

Unlike diphtheritic croup, early age is no contra-indication to the operation of tracheotomy in retro-pharyngeal lymphadenitis, for herewith are recited two cases under 1 year of age, my own of 4 months and Bokai's of 8 months, in which recovery occurred. Good judgment would therefore indicate that whenever dyspnea has advanced to the verge of suffocation, or even to threatened exhaustion of the patient, tracheotomy should promptly be performed.

VALUE OF ANTROSCOPY (ENDOSCOPY OF THE ANTRUM OF HIGHMORE).

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

BY HENRY LEWIS WAGNER, M.D.

SAN FRANCISCO, CAL.

I am convinced that we all are not always successful in the treatment of empyema of the antrum of Highmore, and consequently we have been obliged to perform a second and more extensive operation. This has taught us the real nature of the disease, and how to thoroughly eliminate the existing trouble. All this may be avoided by a thorough ocular inspection of the maxillary sinus by the antroscope—the endoscope of the antrum.

Two years ago I demonstrated this in a crude state to the San Francisco County Medical Society. I do not need to explain the details of the principles of the endoscope, which are used for illuminating closed cavities, as you are all familiar with them. The endoscope for the antrum is intended to be used after perforating through the alveolar process or through the fossa canina. It can also be used with the proper curvature through an intranasal opening. The latter method I have abandoned during the last years.

The cases in which the antroscope has proven to me to be useful, were:

¹ Jahrbuch für Kinderheilkunde, Band xxxiii, Heft 3, p. 360. American Journal Medical Sciences, p. 120, July, 1892.

² Loc. cit.

1. To determine the presence of a drainage tube in the cavity, which was said to be missing.
2. Where a polypus near the hiatus semilunaris could be located, which had kept up a sero-purulent discharge.
3. Where by a series of bony septa the pus was retained.
4. To ascertain the differential diagnosis of angiodema, where suddenly a severe hemorrhage took place from the antral cavity.
5. To facilitate the thorough scraping of the necrosed bone by means of a bent curette—introducing first the curette and then the antroscope.

NEW INSTRUMENTS.

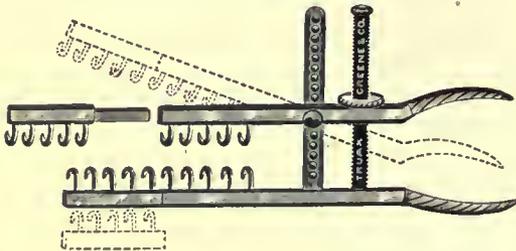

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association held at San Francisco, June 5-8, 1894.

BY SETH SCOTT BISHOP, M.D.

PROFESSOR OF OTOLGY IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, CHICAGO, ILL.

DOUBLE RETRACTORS.

The double retractors take the place of an assistant in keeping the soft tissues out of the way of the operator, and in controlling the hemorrhage during mastoid and other operations of like magnitude. The retractors consist of two shafts, each armed with a series of hooks that can be brought together and interlocked for insertion into the incision, when they can be separated and fixed at any desirable point up to two inches apart. After they have been drawn apart as far as may be required, the thumb screw on the fixation bar next to the hooks should be screwed down firmly into the bar, the handles should be pressed a little together until the tissues are well stretched as the distal ends of the retractors separate, then the thumb nut on the thread bar should be turned down against the movable handle.

If the instrument is properly adjusted the tissues can not slip out of its jaws and their pressure on the stretched lips of the wound reduces the hemorrhage to a minimum. In one operation these hooks proved more effective than five artery forceps.

The following arrangement renders these retractors equally useful in the smallest and the largest mastoid operations: The outer half of the shaft of

hooks can be slipped out of the inner half, leaving the retractors only an inch long. Replacing the adjustable series of hooks makes them two inches long, and by drawing these adjustable hooks outward one-half inch you can lengthen the hooks to two and one-half inches. This has the effect, when the instrument is in position in a large wound, of making an opening two inches to three and one-half

inches wide, by three or more inches long through which to work. However the opening can be made as small as one wishes, and the capacity of the instrument is far beyond what we usually require in operations on the skull, but I have had it made so as to be of service in other and more extensive operations, since its size in no way impairs its efficiency in mastoid cases.

When the adjustable parts of the hooks are removed for small operations the openings in the permanent hook-shafts, into which the adjustable hooks fit, may be securely sealed by a bit of beeswax to prevent the entrance of blood, etc. After being used, this wax will run out on the application of a little heat. A drop of oil should then be put in the same openings to prevent corrosion, or sticking of the adjustable shank.

A PERIOSTEUM SEPARATOR, RETRACTOR AND CURETTE.

This hoe-shaped device overcomes a serious objection to the misnamed periosteotomes we have been using. Indeed these instruments should not be *tomes* at all. They should not cut the membrane, but should lift it from the bone in continuity, so as to carefully preserve its integrity.

The old periosteotomes put the operator at a disadvantage by necessitating an unnatural play of his muscles. With a pushing motion one has not perfect control of the movements of the instrument and it is likely to slip and cut where it is not desirable to wound. In the use of this kind of a lifter the motion is one of drawing or pulling toward one's self so that the muscles brought into play are, together with the instrument, under easy control—on the same principle as the farmer's use of his hoe, after which it is patterned.

As the separator serves the purpose, not only of detaching the periosteum, but of retracting the loosened tissues, or of curetting necrosed bone; it may be said to constitute three instruments in one.

EAR ASPIRATOR.

This instrument is for the purpose of evacuating, or aspirating, the middle ear and adjacent cavities of pus. It consists of an improved air pump and adjustable glass air chamber that fits into the external auditory canal by means of a soft rubber covered tip.

A few gentle tractions of the piston will draw out the discharges from the attic and deeper recesses after the most thorough ordinary methods have proved futile. Not enough force should be employed to cause actual pain or much sanguineous effusion. Yet a slight show of hemorrhage is not disadvantageous, for the parts are stimulated and thoroughly washed of discharge.

The pump is serviceable in chronic cases of caries of the attic, aditus, and antrum in order to obtain complete evacuation and cleansing as the first step in every treatment.

These instruments were made for me by Messrs. Chas. Truax, Greene & Co., of Chicago.

Columbus Memorial Building.

THE CARE OF PREGNANT WOMEN.

Read before the Association of American Obstetricians and Gynecologists, 1894.

BY WILLIAM B. DEWEES, A.M., M.D.

SALINA, KAN.

It is a stirring conviction with many reputable, earnest and progressive obstetricians, that the time has come when we must disclose our power to the world by increasing the usefulness of our labors; and begin to use it for the prevention, as well as for the alleviation, of the sufferings of pregnant women, as has not yet been done, or else get out of the way. In such an event, deliverance will come to this class of suffering women from another source; but woe to those of us who are found at ease with the assumption of this responsibility. The responsibility is tremendous, but the obstetrician can not evade it. He may selfishly shirk it; but it is absolutely out of his province to shift it. That it is our most sacred duty to purpose awakening the profession by arousing one another, until each and every member is fully astir in the line of progression—the indifference of which is the greatest hindrance the medical profession has to contend with to-day—is the writer's hope and belief. The specialist just now is being put to the sharpest test ever known in his history. Whether we as obstetricians will endure it, and turn about to accept it as the greatest opportunity the centuries have brought us, depends upon our readiness to hear and heed the voice of Nature, so very clear and distinct to-day. These are matters of great importance to us, and this is a meet place and time to bring them to notice and to consider them. No one can read, listen, and observe with intelligence now, and not feel that we are living in one of the most marvelous and, for the true-hearted, progressive practitioners, one of the most responsible epochs the world has ever known. That the medical profession is not fully awake to the needs of the hour, as she should be is sadly true. Far be it from me to depreciate in the least degree, the noble work done and the glorious advances made by our profession for human physical betterment. She is unmatched by all other organizations combined in this respect. But, it must be remembered that she should be. It is just this that gives significance to the contrast between what she has done and should have done. She has need to be taught again her first duty: To preserve the human body sound, which begin the first principles of the oracles of God.

Let us recall the three great and noble objects of medical science, namely: 1, to preserve health; 2, to allay suffering; and, 3, to banish disease. The more immediate duties of the obstetrician are to preserve life, to mitigate pain, and to expel disease, amid the natural or accidental difficulties to which pregnant and parturient women are constantly exposed. The study of the diseases and difficulties encountered with a state of pregnancy and parturition, though highly interesting and having at all times attracted the greatest attention of physicians is, however, exceedingly difficult. This circumstance probably atones for the fact that our obstetrical literature still continues to be full of errors. By consulting the best practical writers, missionaries, and travelers, the revelation comes that it is among the higher classes in the more civilized countries—Europe and North America—that women suffer the greater in both pregnancy and parturition; but that the women of the peasantry and the savage are comparatively

exempt. We may therefore very naturally and wisely conclude that it is unnatural for civilized woman to suffer so universally as she does to-day; and that civilization in disobedience to the law of Nature, is the true cause of her present suffering during gestation and childbirth. Thus we may

"Find out the cause of this effect,
Or rather say the cause of this defect,
For this effect defective comes by cause."

It is ignorance, as well as carelessness and viciousness, that has brought about the existing abnormal condition of civilized women. Thus, through unwholesome civilization have come fixed habits of excesses; and if excesses must be indulged, evil consequences will follow and must be endured; for Nature's law would have to be changed before they could be either prevented or banished by any method of treatment. It follows, then, as a natural consequence that to prevent these sufferings will depend, not so much on treatment by application or administration of therapeutic agents, as on the successful education and training of these women, so that they will learn to know how to—and will actually—cultivate the necessary self-discipline requisite to enable them to prevent the continuous irritation from excesses in their modes and habits of life. If the writer's observations have been correct and unprejudiced, it seems that a revival of learning in obstetric science must needs be instituted among us, destined to find the true cause or causes of the unnatural and needless suffering of civilized women. The progress of obstetrics in the immediate future must be made through the knowledge that will be wrought out by the devotees of biology. Thus, we shall find our way, on positive ground back through the morphology of organs, tissues, cells and blood, to a clear comprehension of the origin of vital activity in protoplasm and the pabulum which sustains it. This is the only way open for us into the primitive arcana of Nature, if we would have the wisdom essential to intelligently inculcate that regimen which will successfully prevent the needless sufferings of pregnant and parturient women.

The future distinction of obstetric science can obtain only by an advanced study of human biology. When this truth is propounded, there opens before the thinking mind a vista so transcending all ordinary limitations of obstetrical knowledge, as requires such genius and expansion of the mental eye in order to embrace it in its simplicity as scarce yet obtains. It remains, then, for our guild, to endeavor by rigid scientific investigation through advanced biologic studies, to make patent the causes of the sufferings of pregnant and parturient women, and to determine exact measures for emasculating these causes, or for neutralizing their effects whenever they have eluded detection or escaped emasculation. Thus, by directing our studies chiefly in relation to etiology and diagnosis, and having learned to know the true cause it will become easy to intelligently establish prevention; while, with a correct diagnosis, treatment will become easy.

I verily believe that, the next coming great advance in this, our special branch of medical science, will be in our bringing home to the general practitioner the fact, that the diseases peculiar to women during pregnancy and parturition are very largely preventable. To make him feel his responsibility, both as to their production after the present

generally prevailing methods of practice, and also as to the possibilities of their prevention after improved methods. The family physician must be fully aroused to the conscious realization of the fact that it lies within his power very largely, to prevent many of the diseases among the women of the families intrusted to his care. When this obtains, his moral obligation will impel him to promptly do his full duty, by giving adequate instructions concerning the ill effects of improper posture, dress, food, drink, and erroneous habits of living, including the non-forbearance of indiscriminate, excessive and impure sensual indulgences. Then it will come to pass that the wholesome forbearance of coitus during the entire period of gestation, the puerperium, and three months thereafter, will be insisted upon; together with correct posturing and dressing, proper food and drink, and healthful habits of living. Aseptic accouchments will be faithfully and efficiently practiced; lacerations of the cervix and perineum will be more frequently prevented, and when they do unavoidably occur will be early repaired; rectal and vesical troubles will be corrected in due season; gonorrhœa and syphilis will be also more frequently prevented, and when encountered will be more vigorously treated and kept under surveillance until all discharge and sequelæ are arrested. And, what will be of far greater benefit to mankind, there will be given the requisite attention to the growing girls, with special care about the years of puberty, that more vigorous bodies and more normal reproductive organs be developed. A positive, clear and convincing protest will be made against the present unwholesome state of society which is now urging our girls on to a degree of emasculated physical corruption, by luxurious indolence, deleterious dress and sensual excess, and superbly fits them to live in communities by themselves—in women's hotels—whereby they become ruined for wifely companionship and sturdy maternity. When that day comes—as I verily believe it to be within the province of our intelligence to successfully inculcate—then, and not until then, may we hope to find that the prevalence of diseases among civilized women will cease to be a reproach to preventive medicine. Then will authors and teachers find it necessary to discontinue defining woman as, "an animal with a constipated bowel and a pain in her side."

But as yet, at present we are compelled to meet the situation as we find it. The condition of the suffering of the civilized women of the present generation, however grossly unnatural it has been cultivated, must needs have our most careful attention and require our wisest judgment, lest we fail to institute proper treatment for their relief. In the care of pregnant women much of great importance devolves upon the obstetrician, with regard to safely conducting the mother through the period of gestation, parturition, and the puerperium; the preservation of the life and healthful condition of the child; and his own reputation. The diseases of pregnancy unquestionably is a field only partially and imperfectly explored. When we take into consideration how much of accident might be avoided and how much real good done to this class of suffering women by proper care, it places us at a loss to account for the fact that obstetricians have hitherto neglected their duties, by signally manifesting a want of endeavor to promote the advance of obstetric science,

in a direction quite worthy of the profoundest investigation. It is a noteworthy fact that the conditions which beget the disorders of pregnancy are not thoroughly treated by any of the standard works upon obstetrics. We are so busy thinking, discussing, defending, inquiring, practicing and teaching, about the better modes of alleviating human suffering that we have no time and no leisure of mind for quiet contemplation, to allow the exercise of the intellect to feed upon Nature's truth, without which it is impossible to obtain a clear knowledge of the real causes and how to successfully prevent them. Communion with Nature was never more needful than now. Feverish activity rules all spheres of life. Medical effort is multiplied and systematized beyond all precedent. And all these things make calm fellowship with Nature hard to compass. We can conquer Nature only by obeying her laws, and in order to obey those laws we must first learn what they are.

For the convenience of our consideration, the paramount duties of the obstetrician in the study and care of pregnant women may be classified as follows:

1. To discover if the patient be actually pregnant.
2. To determine positively if the impregnation be uterine or normal, as contra-distinguished from tubal, abdominal, or abnormal pregnancy.
3. To carefully note the pregnant woman's history, including her age, primiparity or multiparity, environments, station in life, general condition of health, period of gestation; as well as her dress, food, drink, and habits of life. To make repeated examinations of the urine and ascertain the temperature, from the time pregnancy is established to the termination of gestation.
4. To make a physical examination for the purpose of accurately determining the diameters of the pelvic straits; the symmetry and size of the bony outlet; the integrity, condition, and position of the vagina, uterus, and other inter-pelvic viscera, and adjacent structures; the state of the abdominal muscles; the presence or absence of hernia, varicose veins, tumors, etc.; the shape, size and condition of the breasts and nipples; the condition of the heart, lungs, mind, stomach, bowels, etc.
5. To observe the state of the fetus, its strength and viability, as well as the implantation of the placenta.

These must all be included in the search for intelligent guidance, as to how the proper management of the pregnant woman should be conducted. With regard to the first, all experienced observers have found that psychologic phenomena often call for an intimate study and wise differentiation of every form of hallucination, delusion, illusion, as well as the delirium of cerebral hyperemia, or the frenzy of the maniac, from toxemia and eccentric irritabilities. And, that such abnormal conditions frequently exist unrecognized, and so continue until they eventually establish their peculiar fixed impress upon the mind and nervous system. Thus when the paranoiac woman simulated pregnancy, and even parturition, she deceived the better judgment of some of the most skilled obstetricians. Pseudocyesis and pseudotocia are recognized abnormal conditions, which so closely resemble the normal condition of pregnancy, and the beginning of parturition, as to demand our highest discriminative faculties in arriving at an intelligently correct diagnosis.

As to the second, it remains a simple self-evident

fact that it should always be positively determined whether the impregnation be uterine or extra-uterine. How to intelligently differentiate normal or uterine from abdominal pregnancy, time forbids to discuss fully in this connection; suffice to say that it may be made by careful palpation of the abdominal parietes, together with vaginal and rectal digital examination and proper posturing. Paracysis and interstitial or cornuate fetation are purposely omitted, as such accidents can scarce be diagnosed at a sufficiently early period of gestation to be of actual benefit. Abnormal implantation of the fetus constitutes a most important class of cases with which the accoucheur has to contend. Extra-uterine or tubal pregnancy is rarely suspected until after certain dangerous and distinct symptoms are manifested, chiefly because no opportunity is had to discover it. These symptoms are such as follow rupture of the cyst containing the embryo with intra-pelvic, or interperitoneal hemorrhage and shock; as sudden seizure of violent agonizing pain in the lower abdomen, fainting, pale, or anemic surface of the body, cold clammy skin, rapid and almost imperceptible pulse, sighing respiration, etc. Whenever extra-uterine fetation is discovered, either before or after rupture of the cyst, the question of treatment is a very grave one. But experience teaches us that this truly marvelous and murderous condition admits of only one line of action to be followed with any degree of ultimate safety to the life of the pregnant woman. Section must be done. No other line of treatment that has been advanced is so rational and certain in the ultimate saving of life as abdominal section. The perfected technique, as we have it to-day, makes it a safe procedure. We must, however, bear well in mind what experience also teaches us, namely: that when the placenta is found still in the tubal sac it is best to enucleate and remove all—the tubal sac and ovary; but that whenever the placenta is found partially or wholly out of the tubal sac and adherent to the peritoneum, bowel, etc., and still alive, the very best that can be done is to let it alone—to keep hands off. In these cases the ultimate safety of the patient lies in removal of the fetus, cleaning out the peritoneum of blood clots and all other *débris*, ligating the bleeding vessels, pack with iodoform gauze, and treat as an open wound; thus allowing the placenta to come away in due course of time by suppuration. We can thus guard against sepsis by drainage and cleanse out the cavity as fast as putrescence develops. My most venerable friend and classmate at the University of Pennsylvania, Dr. Joseph Price, than whose experience in these cases there is none more extended and successful, and consequently he deserves to be accepted as reliable authority, says: "All other lines of treatment that have been advocated fall into insignificance with this manner of managing these cases." He also claims this is a summer disease or accident, being in his experience almost always found only during the summer months; when May comes he looks for extra-uterine pregnancy cases.

The third brings us thoughtfully to consider the influences of those conditions which have been hitherto so grossly neglected, but which demand a decided and determined prophylaxis. The unprecedentedly rapid progress of civilization in disobedience to the law of Nature, as evidenced by the accumulation of wealth on one hand and extreme poverty on the other; the forcing or cramming system of intellectual edu-

cation with lack of requisite physical training; the custom of unwholesome food and drink; deteriorating fashions of dress and habit of society; unbridled sensual indulgences; and the woful endeavor to equalize the duties of women with those of men, have within the last generation very much deteriorated the child-bearing capacity of civilized women. True, the standard of female beauty is increasing, and decided intellectual growth manifested by women in all departments of science and art; but, in the same ratio do we find the remote dangers as well as the immediate accidents of gestation and child-birth have increased. Hence, we find that flaccidity of the abdominal, spinal and pelvic supports; chronicity of the shattered exotic nervous systems; abnormal state of the ovaries; subinvolution of the uterus, etc., have marvelously increased in later years, notwithstanding the much vaunted so-called hygienic advances in improved habits of living and reform in dress. These unnatural conditions are most prevalent among the residents of our cities, and increase from bad to worse as we go from the smaller to the larger and more crowded marts in civilization. They are as prolific sources of chloro-anemias, trophic-nerve paresis, hydremias, hyperemias, and prostrations during pregnancy among the women of wealth, ultra-refinement and excessive culture, as are those women who are subjected to the privations and hardships of extreme poverty. The remarkable fact in history being that there has been a proportionate increase of these conditions among the women of these two extremes of life, whereas the reverse holds good with women who belong to a middle class and are comparatively free from the unnatural behests of modern civilized society, or of irremediable poverty. The pregnant woman whose parentage, as well as herself, has been untrammelled with the deleterious impress of either of these two extremes in life, will terminate her gestation and parturition with much less suffering, and more healthful to herself and her offspring, than will her more unfortunate sister who comes from a stock reared in the excesses of indolence, luxury or poverty. The pregnancies of too early, as well as of too late, marriages are alike to be apprehended as fraught with unnatural conditions. The girl who enters the matrimonial state at the nubile period, from 18 to 20 years of age, will approach the marriage couch with a much better prospect of wholesome fruition, healthy to herself and offspring, than will she who enters the nuptial relationship earlier, under the turbulence of puberty, immature physical development, and illy formulated morale, amid the storm-waves of exalted nerve tensions superinduced by over-taxed educational training, and undue stress of unwholesome fashion and society; or, than she who marries late, say after 28 years of age, who still retains all the productive elements but which have been debilitated by repeated disappointments, now leave her with the elasticity and resiliency of youth—the regulating factors in all growths—defective, and the newly stimulated energies of a life somewhat wasted are revived in a physical organism unfitted for the reproductive process. The ovaries and uterus may properly perform their respective normal functions from puberty to the menopause, but it must be remembered that an opportune impregnation is requisite to preserve woman, if not rosy and plump, at least elastic and buoyant; that her maternity may be exempt from pelvic indolence, so typically manifested

by the flattened chest, the wrinkled face, and some fixed cultivated hobby—to save the rosy-cheeked maiden of 20 from shriveling into the parchment-skinned spinster of 40, by timely desuetude of celibacy. The primiparity or multiparity of the patient also demands its quota of consideration in the etiology of the diseases of pregnancy. The influences of heritage, personal habits, station in life and environments, usually make up the requisite field for the consideration in the primipara; whereas, in the multipara we find it essential to also look well after such conditions as the subinvolution of the uterus, lacerations of the cervix or perineum, tumors, and defective pelvic, abdominal and spinal support, as they often lead to abortion or to direct dangers during parturition.

The thoughtful obstetrician will, with inexorable discipline, advise his patient as to the requisite *regime*. The consciousness of his full duty will impel him to insist upon:

1. Absolute, regular hours and wholesome environment.

2. Plain but nutritious and wholesome food and drink, being principally composed of fresh lean meats, fresh fruits, pure milk, and distilled water.

3. A proper amount of exercise, by walking or light labor on foot and maintaining the correct erect posture. Whenever infirmity forbids such exercise, recourse should be had to massage, and as much time passed in the open air as is advisable under such unfortunate circumstances. Rest in the recumbent posture after meals and fatiguing efforts, with not less than ten hours sleep out of every twenty-four.

4. An open condition of the bowels and skin, which is to be chiefly maintained by proper diet, exercise and bathing, the wearing of flannels, warm low-heeled shoes and loose garments, and, in rare cases, the proper use of laxatives, and hot water enemas.

It, however, not unfrequently falls to our lot to have placed under our care pregnant women who belong to the poorer and less favored class, exposed to too much labor, privation of proper food, dress, and shelter; with whom we find ourselves confronted with the question for bettering their diet, dress and habitation, which assumes such proportions that demand our assistance, not only as medical men, but also, as philanthropists. Fortunately the advantages which the many charities afford enable us to give this class much benefit in every way, save when mental anguish and nostalgia become irremediable factors, in the production of depressing influences which bar the healthful action of the resources at our command. With regard to repeated examinations of the urine and noting the temperature, it suffices to say that as is the urine and temperature so is, very largely, the prognosis and treatment prior to parturition. Urinalysis and thermometry are simple in detail, yet how prolific of averting the culmination of conditions very hazardous to both mother and child. Conditions which otherwise are frequently discovered only by the appearance of anasarca of the inferior extremities, edema of the face or lungs, or a seizure of eclampsia, after which attention is given to these searching steps, but often too late to be of any value in devising a prophylaxis. This very naturally raises the question, Is there a prophylaxis for the albuminuria of parenchymatous nephritis during pregnancy and consequently the avoidance of eclampsia prior to or during parturition?

The experience of an earnest rational endeavor in a limited number of cases warrants the opinion that very much may be done in this direction. So, also, with regard to the prophylaxis of parturial sepsis, which is a problem of equally great magnitude. True, sporadic cases of so-called puerperal fever (parturial sepsis) as well as of eclampsia, etc., ensue in spite of all possible efforts, but it is the writer's firm conviction that these murderous complications can and will be prevented by timely precaution and by banishing every factor in their production. Preparatory hygienic regulations, antiseptis and quarantining will as surely save the mothers from these complications as absolute cleanliness at parturition will save the child from ophthalmia neonatorum.

In proof of this, it is needless to confine reference to personal experience in private practice, for in addition we find the maternities likewise furnish abundant evidence in support of this declaration. Here we may cite, as the most striking example, the indefatigable labors of our eminent Fellow, Dr. Joseph Price, in his connection with the Preston Retreat at Philadelphia, whereby both that institution and himself have become renowned, in establishing this fact beyond all doubt or cavil, that these complications can be prevented.

A word with regard to the term, puerperal fever, which is misleading and fails to express the condition it is intended to imply. It should therefore be expunged from our literature and be replaced by the proper term, *parturial sepsis*. Parturial sepsis is a surgical sepsis, arising from the conditions in which women are found during the extrusion of the uterine contents, similar to those during surgical procedures. The same classes of septic infection and septic poisoning occur in the non-pregnant state, during operations upon the pelvic viscera done without due regard to absolute cleanliness, and in hospitals where patients are crowded together with want of proper sanitation. Facts, as numerous as can be collected in any department of medicine, prove conclusively that the infection and contagion of sepsis, non-specific and variable as they are, can be conveyed by the nurse or attendant as well as by the accoucheur, and thus may likewise poison patient after patient until they also, as well as the accoucheur, either discontinue their labors or subject themselves to the most rigid discipline of absolute cleanliness and sanitary environment. When this prophylaxis obtains, then will parturial blood poisoning cease to be among the cases intrusted to their care, and they will find themselves rewarded with a mortality of *nil* from sepsis. It is very clear to the writer that the more carefully we study and practice obstetrics on sound surgical principles, the better success will we obtain. This, above all else, will secure a thorough preparation of the vagina, that the child may make its exit into the world through a clean channel, which will insure safety to both mother and child. And again, if the forceps or the hand should be required, if laceration of the cervix or perineum should occur, the patient will then have the healthful benefit of the same preparation as is given for surgical procedure. A word also with regard to finding ourselves summoned during the latter period of pregnancy, or at the approach of parturition, to attend one who is suffering from or threatened with eclampsia, and the case being a plethoric subject I should feel it as much my duty to bleed, as I should to clean out the endometrium

whenever parturial sepsis was found to be due to the retention of infected decomposing portions of the secundines. While, if the patient under like condition belonged to the more rare class of anemic cases, I should hope to happily correct the disorder by chloroformation, hot water, the hypodermatic use of morphin and atropin, veratrum viride, etc.

Under the fourth head of the subdivision of this subject, it may be remarked that pelvimetry is an equally essential requisite with urinalysis and thermometry. Deviations from the normal symmetrical pelvis, the diameters of the pelvic straits and the inclination of the bony excavation, exercise marked influences in proportion to the degree that they exist. In an abnormally broad capacious pelvis, with obliquity lessened and supports relaxed, we find that in the earlier period of gestation the tendency is to misplacement of the gravid uterus, either forward or backward and downward, from gravitation in consequence of increased weight. These abnormal uterine positions are usually manifested early by bladder or rectal difficulties with bearing down or pressure in the pelvis, and a dragging sensation from the lumbo-sacral region, etc. The functions of the intra-pelvic nerves, blood vessels and lymphatics being interfered with, we find in a proportionate degree that there is produced a stasis in the venous, vaginal, uterine and rectal plexuses, and consequent dilation of both these vessels and the lymphatics. Thus we have produced a hyperemic state of the entire pelvic circulation resulting in edema primarily, followed by ecchymosa of the peri-vascular, peri-lymphatic, and other cellular tissues, to be succeeded later by varix of the vulval, vaginal, uterine and hemorrhoidal venus plexuses, and consequent trophic nerve changes. It is a noteworthy fact that in these cases there is almost invariably found a want of the correct erect posture. The woman, herself, unconsciously increases the aforesaid difficulties by assuming a more or less stooping posture, in her endeavor to make herself comfortable from the dragging sensation below. Thus we find the abdominal and spinal muscles relaxed, the lumbo-sacral spine receding behind its normal axis-perpendicular with ear, shoulder, hip and ankle—the weight of the superior trunk gravitating back of this normal axis and falling perpendicularly behind the heads of the femurs; whereby the pelvis is swung upon the femur heads from an oblique to a more or less transverse position, while the superincumbent weight of the abdominal and thoracic viscera, instead of being directed forward, by the normally advancing lumbo-sacral spine and supported upon the pubes and lower portion of the abdominal muscles, now falls directly within the basin of the pelvis, exerting its injurious effects upon the contents thereof. The real causes of these conditions being thus clearly revealed, the treatment becomes very simple. This consists in first reëstablishing and maintaining the correct erect posture, thereby securing the normal obliquity of the pelvis by advancing the lumbo-sacral spine in its normal axis of the body. The superincumbent weight of the abdominal and thoracic viscera is then again directed to normally gravitate upon the pubes and lower border of the abdominal muscles, and at the same time there is afforded the normal shelter to the pelvic contents below and behind the promontory of the sacrum. Experience has established the fact that the correct erect posture in these cases is

secured and maintained the more effectually by virtue of proper external support. The external support which fulfills this purpose the better is one fully detailed by the writer in a paper read before the International Congress of Gynecology and Obstetrics, at Brussels, Belgium, September, 1892.¹

The normal equipoise of the superior trunk upon the lumbo-sacral spinal axis having been thus restored, whereby the evil influences from the weight above as a prime causative factor in intra-pelvic disturbances are happily overcome, there remains but attention to be given to the insignificant weight of the misplaced pregnant womb itself. This is usually easily corrected, when free from adhesions, by proper posturing, and afterward maintained by proper internal support with some pessary suitably fitted to the case.

When, on the other hand, the pelvis is abnormally distorted or contracted, the question of how best to conduct the gravidity has been even a more unending source of discussion than the preceding condition. Here pelvimetry furnishes us the chief guidance. But before we progress further, let us first break loose from the traditional shackles of our predecessors and their authority, which have too long retarded freedom of thought to such a degree that he who dared to doubt met but derision. I refer chiefly to the murderous practice of inducing premature delivery and embryulcia in this condition. In the present light of science these procedures have no place in the obstetric art in connection with a viable fetus. They simply deserve to be mentioned that they may be the more effectually relegated to the past. This leaves us to choose principally between but two procedures whenever we find the pelvis so distorted or contracted that it precludes all probability to deliver the living child, namely, symphyseotomy and Cæsarean section. Without specifically considering all the points of this very serious condition—which fortunately for us, is, comparatively speaking, very rarely encountered in the native born American women—I would unhesitatingly advise against the termination of gestation, looking more hopefully to ultimately saving the life of both mother and child by resorting to one of the aforesaid operations. It is to be remembered, however, that it is the duty of every intelligent obstetrician to become thoroughly familiarized with the indications as well as the technique of both these operations, neither of which are to be lightly undertaken by any one who does not possess the requisite skill, both in the obstetric art and abdominal surgery.

With regard to the proper selection of these two operations, I can do no better than quote my friend, Dr. Barton Cooke Hirst, of Philadelphia, who is an acknowledged authority on the obstetric advances, in his address before the Washington Obstetrical and Gynecological Society, Nov. 17, 1893, and published in the *Medical News of Philadelphia*, Dec. 2, 1893: "It is obvious, therefore, that symphyseotomy can be preferred to Cæsarean section on the one ground alone—that it is less dangerous to the mother. A careful study of the results of symphyseotomy and of Cæsarean section will show that the latter is, at the very least, twice as dangerous to the mother as the former. The mortality of the infants is not quite so great in deliveries by Cæsarean section. Moreover, by Cæsarean section the child is sure to be delivered easily,

1. This support is manufactured by the Natural-Body Brace Company, Salina, Kan.

no matter what the size and shape of the pelvic canal may be, and there is no necessity for that nice calculation in pelvimetry that is usually demanded before a contemplated symphyseotomy, a calculation in which even the best of us may err. With my own experience of three perfectly uncomplicated recoveries from symphyseotomy, I feel disposed to regard this operation with more favor than version and extraction in a markedly contracted pelvis. The opposite error of opening the symphysis when the pelvis is too small to permit of delivery by this means is more difficult to escape. It will only occur in a pelvis with a conjugate of sixty-seven millimeters, or under, a degree of contraction not often seen among us; and could we always be sure of the accuracy of our pelvic measurements, the mistake would pretty surely be avoided. I can imagine no more embarrassing predicament in obstetrics than a failure to extract the head after opening the symphysis. I should feel reluctant to operate again at the lowest limit for symphyseotomy unless I had the opportunity first to induce labor and artificially dilate the cervix some two or three weeks before term. In this case I should not hesitate to operate with a conjugate as low as sixty-five millimeters, and I believe delivery might be possible with a conjugate of only sixty millimeters. We may therefore be guided by the rule that at term, symphyseotomy is available only in cases where the conjugate measures over sixty-seven millimeters, while if the conjugate is found to be sixty-seven millimeters or under, the only recourse to be had is Cæsarean section.

The destruction of the embryo is, however, not only warranted, but becomes a requisite under certain circumstances or conditions; such as the presence of large fibroids in the body of the uterus, or large tumors involving both the ovary and uterus, also cancers of the uterus, and in certain cases, of placenta previa. Placenta previa is another abnormal condition deserving attention. It properly belongs to that class of appalling accidents in the lying-in room, as eclampsia, post-partum hemorrhage, rupture of the womb in uterine pregnancy or of the cyst in tubal pregnancy, etc., which allow but time for action. Experience teaches that the proper use of forceps in these cases is to be preferred to the hand. The chief reason being that a narrow-bladed forceps can be introduced much earlier than the hand—requiring a dilation of only about one inch as compared with two and three-quarter inches for the hand—and, by grasping the head and bringing it down, tampon the placenta at once; whence time may be given sufficient to obtain full dilation and delivery with greatest possible safety to both mother and child. In these cases we may very properly follow the one line of action. As soon as the diagnosis of placenta previa is established our action must be prompt in evacuating the uterine contents. Hemorrhage is the danger signal. When this signal is given early, say prior to the sixth month, and the diagnosis established, we should proceed without any regard for the life of the child. When, however, this signal is given later, we should proceed as promptly, but with all possible endeavor to save the life of both mother and child. Whenever hemorrhage takes place in these cases it is Nature's signal to us that there is great danger ahead; that the condition is so serious as to endanger, if not to take the life of the mother at any moment. We can not

accept the situation only as serious, and must act promptly and effectually. The proper antiseptic precautions being observed with special reference to the vagina and the accoucher's hand, the patient being placed under anesthesia, introducing first the index finger into the cervix, dilating gradually until two fingers are successfully introduced, and, when sufficiently dilated to admit of the forceps, pass the fingers through the body of the placenta, rupturing the membranes and place the forceps on the head, bringing it down and tampon the placenta at once. When, as sometimes happens, the dilation is greater and the presentation abnormal or less favorable the accoucher had better resort to the passing of his hand and turning by Braxton-Hicks method and drawing the child into the cervix, and thus arresting the hemorrhage. The hemorrhage once checked, the subsequent delivery will be fully under control.

I have in this paper but sketched some of the salient and mooted points of the prophylaxis of the complications and needless sufferings of pregnancy, with no attempt at thoroughly elucidating or elaborating any one of them. Having no pet theory to promulgate and sustain at all hazards, no long list of cases and statistics with quotation and abstract from an exhaustive roll of writers has been made out. And, while universal conviction may not be with me on premises somewhat narrowly drawn, still I hope the attention of the Association may be drawn to their thorough consideration, that free discussion may evolve all the facts of this interesting subject and, finally, to find with many of you these facts received with favor and not only to maintain an excellent reputation, but also to increase in favor on closer acquaintance.

TRACHOMA OR GRANULAR LIDS.

BY JAMES A. LYDSTON, M.D., Ph.G.

LECTURER ON DISEASES OF THE EYE AND EAR IN THE CHICAGO COLLEGE OF PHYSICIANS AND SURGEONS; MEMBER OF THE CHICAGO ACADEMY OF MEDICINE, THE CHICAGO MEDICAL SOCIETY, ETC.

Trachoma or granular lids (not granulated lids), ophthalmia militaris, ophthalmia Egyptiaca, trachoma verum, trachoma Arlti (Arlt), trachoma folliculare (Horner), trachoma mixtum (Stellwag), as it is variously styled has received much attention at the hands of ophthalmologists, and the literature upon the subject is so copious that it is almost an act of supererogation to attempt to present anything new and interesting upon the topic; but the dreadful ravages of the affection, and the fact that we are still far from a unity of views in regard to the disease, renders an attempt in this direction at least excusable. Not long since an article appeared in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION from the pen of an eminent professor of ophthalmology in which the expression "granulated lids" was used, and while appreciating that by reason of the peculiar anatomic arrangement of the lids, granular and hypertrophic masses are distributed over the conjunctiva tarsi and transitional folds, yet we must insist that such a term should be reserved for the laity as we are not familiar with anything like granulated lids, although such a term can be rightfully applied to sugar.

Before discussing the various forms of trachoma or granular lids, we will note a few historical data with respect to this affection. Relatively speaking, we may assert that it has only been within the last

century that trachoma has demanded much consideration at the hands of specialists, as it was only at the beginning of this century that the disease asserted itself as an epidemic among the European soldiers, hence the term *ophthalmia militaris*. Many concluded, by reason of its first appearance among the soldiery, that it was a product of importation from Egypt, hence *ophthalmia Egyptiaca*, and the disease was laid at the door of Napoleon I. upon his return from Egypt to Europe, it being presupposed that the disease was formerly confined to Egypt. But it subsequently transpired that it had been known in Europe since antiquity, and even to Celsus is accorded the honor of having described the condition, mentioning the characteristic roughness of the lids and the accompanying purulent discharge; and we find to-day a tendency to revert to the old-time methods of treatment by inducing a certain amount of inflammatory reaction which the ancients accomplished by means of friction with fig leaves and by specially devised instruments. So we must conclude from the foregoing that trachoma has existed from the most remote periods, and that the trachoma of to-day is nothing more nor less than modified acute trachoma of olden days, which was characterized by profuse purulency, and that the specific virus upon which its ultimate origin depends has become modified so that it is to-day less virulent in its effects when transferred from one eye to another.

Character.—Trachoma is a chronic, specific, infectious inflammatory affection of the conjunctiva accompanied by distinct purulency, and the name trachoma is derived from the Greek, signifying rough.

Symptoms.—Individuals suffering with trachoma complain of watering of the eyes, agglutination of the lids, sensitiveness to light, pain and disturbance of sight, which are sometimes though not constant sources of annoyance. The eyes are less widely opened as a result of swelling and sensitiveness to light, and upon eversion of the lids we notice that the tarsal conjunctiva as well as that of the transitional fold is reddened and swollen, while at the same time there is a variable degree of roughness caused by hypertrophy which is of two characters in accordance with the different anatomic characters of the affected conjunctiva. The first form of hypertrophy is the appearance of the papillæ so styled, which are elevated patches here and there, newly formed over the conjunctival surface, which accordingly looks velvety, or the papillæ may become so large as to impart a coarse granular, nodular, or even a raspberry-like aspect to the conjunctiva. Thickening of the conjunctiva is absent at this period, consequently the underlying meibomian glands glisten through the conjunctiva. This form of hypertrophy is limited to the conjunctiva tarsi and is styled papillary hypertrophy. This form of hypertrophy is peculiarly prone to attack the upper lids. Trachoma granules are characteristic of the second type of conjunctival hypertrophy. They are seen as grayish or yellowish-gray, roundish translucent gelatiniform bodies, and have been styled from their appearance the sago or frog-spawn excrescences, found chiefly in the transitional folds in such great abundance that when the lower lid is exposed to view the transitional fold projects as a thickened and rigid prominence. The trachomatous granules are sometimes disposed in rows like a string of beads;

while the trachoma granules are likewise shown to exist in the conjunctiva tarsi, they are less prominent and less clearly defined, owing to the close adherence of the conjunctiva to the tarsus in this situation, consequently we discern them, when the hypertrophic papillæ do not obscure them, as minute bright yellowish points, embedded deep down in the deeper structures. The microscope reveals that other parts of the conjunctiva of the eyeball, such as the semilunar fold, conjunctiva bulbi, etc., are not wholly exempt from the trachoma granules. This constitutes the so-called granular type of trachoma, so that we may justly classify trachoma into two classes: 1, papillary trachoma; and 2, granular trachoma; but the distinction can not be so clearly and emphatically made as to enable us to say that this is a case of papillary trachoma, that a case of granular trachoma, inasmuch as frequently in the same case we find the two processes associated, and while such a classification would be quite scientific, yet such is not from a clinical standpoint of any particular importance as the treatment is essentially the same in either case.

Among the results of trachoma are pannus, lid distortion asserting itself under the form of entropion (the turning of the lid inward toward the eyeball), and ectropion the turning outward of the lid from the eyeball), symblepharon posterius and anterior, xerosis conjunctivæ, in which we have dry degenerated patches devoid of secretion here and there, and corneal opacities caused by cicatricial deposit following ulceration, trichiasis (abnormal disposition of the eyelashes). Madarosis and tylosis, baldness and thickening of the lid borders respectively are all disagreeable sequelæ of neglected and maltreated trachoma, and will receive mention under their proper heading during the discussion of the treatment.

Causation.—We are, in the light of modern views relative to trachoma, able to say that the primal origin of the disease is discharge from a chronic blennorrhæa, which being transferred through the medium of the fingers, soiled linen, contaminated wash basins, etc., to the healthy conjunctival sac finds favorable soil for its development; after a variable incubative period a form of granular conjunctivitis or trachoma shows itself which depends for its severity, so far as its inflammatory tendencies are concerned, upon the character of the case from which it took its departure, as well as upon the character of the soil upon which it thus propagates. It is to Piringer that the credit is due of thus irrefutably deciding the origin as well as the subsequent features of the disease. He was able by inoculating eyes already blind, to determine that the disease is essentially dependent, notwithstanding all its variable characteristics, upon one infectious element, which by reason of the different anatomic conditions of the developing soil will assert itself sometimes in one form, sometimes under another; so that it leads us to conclude that possibly we shall finally view the variable types of granular conjunctivitis or trachoma, as well as other simpler types of conjunctival inflammation, as peculiar forms of inflammation or irritation consequent upon the special type of irritant.

With respect to the career of the affection, the hypertrophic elements and the associated discharge increase to a variable degree in different cases and then finally fade away, while cicatricial deposits replace

the hypertrophied areas, and consequently the conjunctival destruction and subsequent cicatricial contraction are directly dependent upon the number and size of the hypertrophic elements and the abundant secretion. So that with respect to the question of treatment two primal indications confront us, namely, reduce the size and number of the hypertrophic papillæ and check the secretion. And fortunately, while we are confronting one indication we are combating the other. Heretofore silver nitrate and copper sulphate have been largely utilized, both to reduce the enlarged papillæ and to diminish the discharge and favor the disappearance of the granulations, and these remedies are still employed and are regarded by many as all sufficient. The rule governing the use of silver nitrate and copper sulphate respectively is to apply silver nitrate when the secretion is profuse and irritative manifestations marked; while copper sulphate finds fitting application in cases of diminished secretion, and little or no irritation. Mercury bichlorid in concentrated solution, 1 to 500, was first applied after the so-called grattage in the clinic of Abadie, and by many is highly esteemed in the management of obstinate cases of trachoma. We must conclude, however, that all treatment should be directed towards assuring abject cleanliness, whether this be accomplished by simple ablution, or by means of antiseptic precautions. While the method of exciting an inflammatory reaction, either by means of medicaments, or by the more active method of jequirity infusion, as advocated by De Wecker (justly superseding the old-time method of inoculation with blennorrhœal pus) the methods of peritomy or syndectomy, or incising the conjunctiva around the cornea, scraping or scarifying the conjunctiva as advised by Grüening, are useful in certain cases. It has been my experience to find that these heroic measures have all been carried to extremes, to such an extent indeed that one of the most important indications in the treatment of trachoma or granular lids has been overlooked, namely, that the inflamed parts should be subjected to a period of rest, and any measure which fails to encompass this end utterly fails of its object. To institute this purpose, and at the same time to meet the other indications of resorption of the hypertrophic papillæ and granular masses combined with a proper degree of antiseptics, I was induced to apply insufflations of papoid (*carica papaya*), the new digestive ferment combined with boric acid, and found that not only did it act efficiently upon the thickened masses, but even in those cases seen in the later stages of trachoma where trachomatous pannus had supervened, I found that the pannus was appreciably thinned, and the inflammatory reaction diminished. I believe the honor of having first instituted this type of treatment belongs to me, and certainly it has proved in my hands a most efficacious method. I agree with Fuchs in his conclusions, after trying all of the methods, both irritative and conservative in their tendencies, that all harsh surgical methods should be eschewed in trachoma during its early and transitional stages, and should be reserved for the correction of the numerous disastrous sequelæ, such as pannus, entropion and ectropion, distichiasis and trichiasis, lachrymal obstruction, madarosis, tylosis, corneal opacities, etc., which have all been heretofore noted as results of the typical siege of trachoma or granular lids.

Suite 804, Champlain Building, Chicago, Ill.

PROFESSOR KOCHER ON MODERN PROJECTILES IN WARFARE.

BY CHARLES G. CANNADAY.

ROANOKE, VA.

"In the time of peace," it has been said, "prepare for war." This necessary evil must sooner or later come to all countries, judging from the past; its evil consequences are sufficient when happy homes are robbed of fathers, husbands and sons, but when the projectiles are of such a nature as to produce great destruction of tissue, owing to shape and velocity, it becomes all true philanthropists to assist the Red Cross, which will figure so conspicuously in future Italian wars, to bring about such a change in projectiles as will cause the least destruction of tissue compatible with "disabling the enemy and causing him to retire from the field." During the riot in this city in 1893, I had the opportunity of seeing the great amount of mutilation and serious wounds produced by the modern firearms in the hands of our military company—those not instantly killed are so mutilated by large projectiles that permanent disability for manual labor is the rule, while the chances for infection from the wounds are very much increased. It becomes all civilized nations, from a humanitarian point of view, to repudiate the idea expressed by Shakespeare in "Henry IV.," that "the arms are fair when the intent for bearing them is just," and so construct all projectiles as to disable with a minimum amount of mutilation—rendering survivors more useful and comfortable. With this end in view I have submitted an abbreviated report of a lecture to which I listened at one of the general meetings of the International Medical Congress in Rome, Italy, in April of this year, delivered by Kocher, of Berne, Switzerland, than whom no one is more competent to speak, as his researches in this line have been very exhaustive, and his investigations respected and indorsed by the civilized world.

This subject may embrace all of us in its scope, and the military and naval officers and authorities should seriously consider this lecture on the subject of "the improvement of projectiles from a humanitarian point of view." Kocher said:

"The reason why ancient Rome, whose hospitality we are now enjoying, acquired the immortal glory which it maintained through the classic ages till our own times, is to be found in the warlike character of its first inhabitants, in the *Virtus Civis Romani*. Notwithstanding the great progress which has taken place in the field of intellectual activity, it is still the case that those nations become arbiters of the world who are always ready to sacrifice their life and all they possess for liberty, truth and justice.

"Military service is a duty which extends to all the citizens and therefore all take an interest in the necessary and inevitable consequences of war. Women and sanitary associations vie with each other to diminish the sufferings of the victims, as also the Red Cross, whose representatives showed us two years ago in this same city the splendid results obtained by them.

"But all this is of no use (I speak simply from a surgical point of view) if modern firearms bring such devastation in the contending armies, while they should only put *hors de combat*—if they mutilate instead of simply wounding. Twenty-five years have

not passed since it was universally recognized that perfected firearms cause enormous damage in the human body. This general opinion is confirmed by the recent communications of Démosthène, Chauvel, Nimier, Bogdanik, Sklissowsky, Morosow and Trauber, by the observation of Kabars and finally by the interesting experiments executed by order of the Prussian Minister of War, by Dr. Schjerming, all of which show the terrible effects of modern bullets. After this must we await further improvements or must we resignedly accept the conclusions of Surgeon-General Dr. Von Coler and of Dr. Schjerming, namely, that with the new rifle life must absolutely be lost?

"The object of war between civilized nations is not, as among savage people, to kill the greatest number of combatants, but to disable the enemy and to oblige him to abandon the field. Nevertheless there are many unexpected deaths caused by injuries to vital organs. But the modern guns surpass greatly this scope, because they tear or destroy the tissues of the body, exposing the victim to the risk of losing his life even through non-vital injuries, and either oppose or prevent entirely the reestablishment of the normal functions. Guns have become real explodent firearms, which are prohibited by international agreement.

"In order to eliminate the damages produced by these arms it is necessary to know the effect of the explosive projectiles, but unfortunately on this matter the opinions of the many authors are too different.

"I will demonstrate, considered by twenty-five years of experience, in what really consists the explosion and by what it is caused; this will be the subject of my lecture. The action of the bullet is different as the object which it strikes varies. We shall therefore distinguish three separate categories in the human body: Elastic tissues, tissues rich in liquid substances, and rigid tissues.

"In elastic tissues the bullet does not explode, at least not immediately, even if fired out of the most modern rifle. Large lacerations of the skin are due to deeper explosions, such as those which take place in the vicinity of the bone, and without these external lacerations are not to be found. In some elastic tissues we can only observe the point of entrance and exit of a bullet whose initial velocity is of 600 to 750 meters; we can not trace any hole at all as the tissues after having been forced aside, resume their former position.

"The effect of an explosion may be observed with far greater facility in tissues which contain an abundance of liquid substances, and is naturally more terrible in those tissues which more abound in them. Brisch was the first who had recourse to hydrostatic pressure in order to demonstrate the effect of an explosion in the cranium; Garfeuil, Heppner and Küster applied the same principle to epilepsy, and I have been able to show by means of numerous experiments the general importance of liquids in the tissues. The action of hydrostatic pressure may be demonstrated on tin boxes containing substances more or less rich in water. The effect of the explosion differs greatly if the box contains fresh horse flesh instead of dry, damp cotton or sawdust instead of dry.

"Here are some elastic laminae that present a very small hole when the velocity of the bullet is small, while enormous rents are made by it when the

velocity is at its maximum. These violent effects are caused both by leaden and by steel bullets; it is therefore impossible that they should be produced by the deformation of the bullet, as it is proved that steel does not undergo any alteration of shape. In any case it is important to observe how the explosion is influenced by the different degrees of deformation if the area which is struck becomes larger.

"Demonstration of the effects of exploding bullets on recent epiphyses, on the glandular and visceral organs and on the muscles. The degree of intensity of the explosion gradually augments with the increase of velocity, while we can only talk of hydraulic pressure in the case of maximum velocity and on parts like the cranium.

"The effect is seen in its full intensity only if the distance is great enough; but also in open tin boxes, where the water is not hermetically closed as in a hydraulic pump a laceration takes place. It is therefore better to abandon the name of hydraulic or hydrostatic pressure and to use that of hydrodynamic laceration.

"The speaker afterwards shows the effect of explosions on flexible substances, such as soap or glass, in which we may with certainty establish, by means of comparative measures of weight and volume, whether we have to deal with a simple shock or with a missile that produces at its maximum velocity the maximum degree of dilatation.

"Also here we find an augmentation in the explosive effect even though there be no rotation or deformation and we must recognize that the intensity of the explosion does not depend from these factors.

"The real nature of an explosion can only be understood if its effects are studied on a solid body. To this end we can fire a bullet at a slab of stone, and we will ascertain that the shock transmits itself with great violence a great distance. The difference between a simple crack and a real laceration may very well be distinguished in a glass slab if the velocity of the missile is not at its maximum, in which case a number of cracks are produced instead of a neat small hole. The best manner of observing the perfect analogy of the effect of the dry explosion with those of hydrodynamic pressure on a tin box is to fill this box with small shot or pieces of stone.

"Numerous illustrations demonstrate the analogy of explosion in dry and fresh bones; which is then the essence of the explosion? Kocher has been able to demonstrate by determining the velocity of the bullet directed to different objects and also on the human body, that for maximum velocities a greater amount of active energy is lost than for the small ones. This augmentation in the loss of active energy is caused by the velocity being too great to pierce the target and by remaining longer imbedded in it produces an unequal shock. By means of measures it is possible to ascertain that the loss of velocity and active energy is greater in bullets of heavy caliber; and consequently the lacerations will be greater.

"Conclusions to improve the projectiles from an humanitarian point of view:

"1. The cause of the laceration can not be avoided because it depends from the augmentation of velocity.

"2. It is necessary then to modify the importance of the laceration which happens.

"3. By diminishing the area struck:

"a, reducing the caliber of the projectile to five to six centimeters;

"b, preventing the deformation by giving it more compactness especially in the point;

"c, by making the anterior extremity sharper so as to increase its strength of penetration;

"d, by augmenting the rotation so as to prevent the oblique penetration.

"Ulterior experiences will demonstrate if to solve the problem from an humanitarian point of view it will be necessary to use again very small copper projectiles or projectiles with steel coating and point. *The results already obtained* by the introduction of the steel coating advise us to follow on the same track: 1, even after the worse results there are no more muscle and lung lacerations; 2, the fracture of bones, is totally limited in extension and intensity, so short the hole of exit is, according to the experience of Coller and Schjerming, reduced for 200 meters distance from 2 to 3 centimeters while before it varied from 7 to 13. One of the greatest improvements from a medical point of view is the reduction of the hole, as the healing of the wound is then materially facilitated and dangerous complications are rendered less frequent. But the extraction of large fragments of bone, and injuries to vital organs such as the heart, the brain and the lungs will always make numerous victims, and also in the next war hundreds of soldiers will end their life on the field of battle.

"But the great mass of our youth who courageously march into the grim jaws of war will be protected by a new Pallas, armed with the shield on which shines the Red Cross."

SOCIETY PROCEEDINGS.

The Canadian Medical Association.

The annual meeting of the Dominion Medical Association was convened in St. John, N. B., August 22 and 23, 1894. The meeting was well attended by medical men from nearly every province, the larger number coming from the Maritime Provinces. The Association had not met in St. John before for twenty years. Fraternal delegates were introduced: Dr. J. M. Jonah, of the Maine Medical Association; Dr. Bulkley, of the AMERICAN MEDICAL ASSOCIATION.

The chair was occupied in an able manner by DR. T. S. HARRISON, of Selkirk.

The subject of

THE TREATMENT OF EPILEPSY

was first taken up, the paper being presented by Dr. Hattie, of Halifax. He gave a description of the various changes that have been said to take place in the cerebral cells during fits of different kinds, and pointed out that the causation might be due to the influence of some irritant acting upon the cerebral cells, which put them in a state of excitability, or which, by being produced in the encephalon, and not eliminated quickly enough, by a nerve explosion was gotten rid of—that the convulsions were due to an abnormal functioning of the cells in some part of the nerve centers, the location determining the character of the seizure. This poison might be generated in the system. If this were the case, the rational treatment would be the eliminative and antiseptic one. This he had tried, by giving in addition to the bromid of potassium, beta naphthol. The results were very gratifying, the number of fits per patient having been materially reduced.

DR. MUIR then gave the history of

A CASE OF TUBERCULOSIS OF THE ARM, BETWEEN THE ELBOW AND THE WRIST,

which had been in existence for some fourteen years, with all the typical symptoms (the tubercle bacillus being present), which, after being scraped, was infected with erysipelas. Subsequently complete cure took place.

DR. SHEPHERD reported a case of cancer cured in this way.

DR. CAMERON said he had tried to inoculate some cases of malignant growths with the germ of erysipelas, but had failed to get it to work, probably because the sarcomatous and carcinomatous germs overcame the invaders.

SIR JAMES GRANT said that he had seen whooping cough very materially relieved in children who had been vaccinated. He had tried vaccination in certain cases of psoriasis he had had, with extremely gratifying results. He believed there was much room for study along this line.

The President of the Association, DR. HARRISON, took as the subject of his address his experience in medical matters during the last half-century. That long ago he settled in the early wilds of Ontario, near Lake Erie. Those were the days of ague, bilious remittent fever, murrain in cattle, and other diseases which now, since the country is cleared up, have become almost extinct. He gave a graphic clinical history of these various diseases and the different forms of treatment employed, both before the doctor arrived in the settlement and after, by those who sought to charm the disease away and those who sought to treat it according to the tenets of Thompson. Whisky, in those days, was considered by the people to be the sovereign remedy. Some doctors bled, blistered and salivated. The President told of difficult experiences he had had alone far removed from medical help in various kinds of operations, major and minor. The latter part of the paper was an advocacy of the establishment of uniform examinations for all who wished to practice in the Dominion, and that the standard should be that of the highest provincial standard. The President was accorded a hearty vote of thanks for his address, and a committee was appointed to consider the matter of reciprocity discussed in his address.

The subject of

APPENDICITIS

was discussed by DR. BELL, of Montreal. He reported forty-eight cases; forty of them operated on with recovery; five not operated on; and only three deaths altogether. He classified his cases into the gangrenous, the perforative, and those bound in with adhesions. These cases should be watched, he maintained, by a surgeon from the first, as little could be done for its relief medicinally. He advocated surgical interference in nearly all cases.

DR. HINGSTON thought the operation was performed unnecessarily. No young man should attempt to enter the abdominal cavity without first consulting one or two others. He had prevented the operation twenty-five or thirty times, and only regretted this step in one case. He was strongly in favor of conservatism.

DA. GRANT, Ottawa, spoke of two cases he had had which appeared to be fit ones for operation, but one was in a gouty subject, the other in a rheumatic. He did not operate and they recovered. It was very difficult to know what to do in these cases. He did not believe appendicitis was due to the presence of foreign bodies in the organ.

DR. SHEPHERD pointed out that the surgeons got the worst cases; so it was difficult to say just what the number of cases was which were operated upon as compared with those that were wholly treated medicinally. His idea was to operate after the acute attack had subsided in the interval. He attributed the tender point of McBurney, not to the appendix, but to the inflamed condition of the mesenteric glands;

for the appendix might be found on the right side in the pelvis, or up under the liver.

DR. STRANGE was in favor of non-interference until there was the presence of a tumor and pus. He had refrained from operating during the acute stage and had not regretted it.

MR. CAMERON, of Toronto, said he followed Mr. Treves in this matter; to wait until the pus formed, open and drain. He considered it unfortunate that the experience of a hospital surgeon of skill, should determine the matter one way or the other. In a possible forty-eight cases he had had in which he had followed out the above treatment, he had had, probably, Dr. Bell's figures reversed. The interval he believed to be the time to operate.

In replying to the discussion on his paper, Dr. Bell made a strong plea in favor of his statement, "one should always operate." It was generally agreed that no one knows when to operate. If the patient were left at any moment, perforation might take place. However, in the forty cases he had operated on, thirty were perforated, and abscess was present at the time of operation. In three the appendix was wholly gangrenous. And in such, he said, one could not wait for the tumor formation or the abscess, because there was none. In two the appendix was bound down; in three the appendix was not perforated, but gave rise to urgent symptoms, yet there was no abscess found. He used to follow the waiting treatment, but found it unsatisfactory. The mortality was much greater than that of his eleven months of the new plan. The greatest mortality statistics for the operation only amounted to from 2 to 3 per cent. The operation, as a rule, was not difficult. He considered the plan of waiting for pus not the best surgery. The very mild cases where the symptoms passed off in say twelve hours, he would not interfere with. They were probably only cases of cecitis.

DR. MORRISON, of St. John, read a paper entitled

EYE-STRAIN HEADACHES.

It had been alleged that 90 per cent. of all headaches was due to eye-strain. This he believed to be true. Many of such were attributed to other causes, as biliousness, "womb trouble," nervousness, masturbation, over-work, etc., when the real cause was overlooked—an over-worked condition of the muscle of accommodation—ciliary muscle. This condition of the delicate muscle was brought about by attempts to correct varying degrees of astigmatism. No cornea hardly had perfect curvature in every direction; and it was these slight degrees of curvature, often overlooked even by the specialist, that lay back of these headaches. The use of cylindrical glasses, with low dioptric power, always relieved the muscle, and consequently the headaches. Constitutional treatment was also advocated, and the avoidance of those conditions of life that tended to increase the trouble.

The subject of

DISEASES OF THE OVARIES AND TUBES

was by DR. SMITH, of Montreal. In gonorrhoeal salpingitis, the clinical history of which he went into, the only safe treatment was extirpation. This was also the course to pursue in the tubercular form, if the general constitution were not too much infected with the poison. He advised medicinal treatment for the functional disorders of the appendages. The paper was illustrated by a number of interesting cases, and the presentation of tubes and ovaries that he had removed.

THE USE AND ABUSE OF THE VARIOUS CAUTERY AGENTS IN THE TREATMENT OF NASAL AFFECTIONS

was treated by DR. E. A. KIRKPATRICK, of Halifax. He referred first to the delicacy and importance of the nasal mucous membrane, and said that too often it was the subject of

too harsh treatment. Caustics were used, perhaps, more in hypertrophic rhinitis than for anything else, and often too severely. Of the caustics he used chromic acid, trichloroacetic acid, and the electro-cautery were the principal. The chromic acid he used in anterior applications, the cautery for the posterior applications. By the injudicious use of caustics he had seen the mucous membrane destroyed. And in some cases he had seen very serious sequela follow in connection with the ear; such as loss of hearing and mastoid disease.

The address in medicine was delivered by DR. BAYARD, of St. John, N. B.; subject,

THE INFLUENCE OF THE MIND ON THE BODY.

This was, he claimed, a subject of growing importance in this rushing age. Most authorities were agreed that surgery and medicine were rapidly advancing. It was also agreed that nervous diseases were on the increase, particularly insanity and neurasthenia. This was largely due to the energy, competition, worry, compulsory education, sensational novels, newspapers, speculation and unrest, which characterized the last part of this century. Another cause was the migration from the country into the town, where the strife for existence was greater and sanitary surroundings bad. Relief from this condition of affairs was largely through the instrumentality of educational reform and the employment of preventive measures generally.

As an outcome of one of the points referred to in the address, at the suggestion of Dr. Hingston, Dr. Bayard moved, seconded by Dr. Hingston, "that the system of education generally pursued in the Dominion of Canada draws too largely upon the brain tissue of children and materially injures the mental and bodily health."

DRS. CAMERON, of Toronto and Powell, of Ottawa thought the terms of the resolution were too sweeping; that there was no specific statement as to what department of the school system was at fault, nor to what portion of the Dominion it more especially applied. Our young people, Dr. Cameron thought, were not suffering, the older people neither, from too much education. The educational system had been the subject of the best thought of our best men, and he considered the motion too condemnatory. A resolution was then passed that the matter be referred to a committee, consisting of Dr. Powell, Dr. Hingston, Dr. Graham and Bayard.

DOMINION REGISTRATION.

The committee appointed to report on the President's address, reported on the matter of inter-provincial registration. It was adopted.

DR. DANIEL moved, seconded by Dr. Powell, "that a committee be appointed in which each of the Provinces shall be represented, to draw up a form of medical act, which, after being adopted by this Association, shall be presented to each Provincial Legislature to be by them passed into law; and that the committee that brought in the report be asked to name such committee."

DR. BULLER moved, seconded by Dr. Laphorn Smith, that a committee be appointed, with power to add to their number, to consider the best means of obtaining a uniform standard of medical education for the Dominion of Canada; and that said committee report at the next meeting of the Association. This carried.

The discussion over the above question was long and animated, and taken part in by several of the men from the different provinces represented at the Association.

DR. J. E. GRAHAM presented a paper on

SOME FORMS OF FUNCTIONAL DERANGEMENTS OF THE LIVER.

The paper dwelt on the great importance of maintaining the integrity of the hepatic cell. It acted as a guard against

the invasion of certain forms of poisons into the general circulation, such as arsenic and phosphorous among the mineral kingdom; the poison of decaying meats and old cheese, in the organic; absorption of poisons generated in a distended stomach; the specific toxins of typhoid and such diseases; and the absorption of poisons from the intestinal tract, say when constipation was present. These various poisons tended to hurt the cell, and passing into the general circulation, had their effect on the nervous and other systems of the body. In the ordinary cases of biliousness the symptoms were caused in this way. The glucogenic and urea producing functions of the liver were also discussed and the results pointed out, of their abeyance, through the damage done to the hepatic cell. As to treatment, Dr. Graham pointed out the absolute necessity of finding out the exact cause of the disturbance before rational treatment could be employed. He recommended restriction and regulation of the diet, suitable exercise to assist the circulation, proper attention to bathing, drinking of mineral water to assist metabolism, where the urea was deficient; the necessity of free purgation, and lastly, the various specific remedies recommended for this condition.

DR. HINGSTON reported

FOUR CASES OF OPERATIONS ON THE BRAIN.

The first two were for epilepsy. The first without the results hoped for. The second was operated on for cephalalgic pain, located in one spot. It had been incessant and severe for a year. The Doctor trephined and found a hydatid pressing on the brain, pediculated, which he removed. The patient made a good recovery. The next case was that of a young man, whom the Doctor presented, who had suffered for twenty years, as the result of a fall and injury to the right side of the brain. He was the subject of paralysis of the left arm, which was drawn up and flexed, the fingers also being flexed in their terminal phalanges and extended in the first. The orbicularis and zygomatic muscles and the others on the left side were spasmodic and overdeveloped, the pupil was contracted, the vision and hearing on that side impaired. On operating, a thickened portion of bone was found impinging on the brain tissue, surrounded by a cartilaginous material which nature had thrown about it. There was no bleeding upon its withdrawal. The expression of the face at once became relaxed, and the patient seemed almost complete in his facial appearance. The arm had improved. Dr. Hingston recommended the use of a large trephine, two inches in diameter, for these operations.

DR. SHEPHERD, of Montreal, gave the history of a case of removal of the entire upper limb for a chondro-sarcoma involving the shoulder-joint; also of the removal of a large enchondroma of the pelvis. The first operation had not been done often, his being the first that been done in Canada. Drs. Hingston, Cameron, and Steeves discussed the paper.

DR. BULLER read a paper on "The Present Status of Asthenopia."

DR. INCHES, of St. John, N. B., read a paper entitled

THE PREVENTION OF TUBERCULOSIS,

in which he advocated the necessity of increased activity on the part of the profession, the public and the government in dealing with this dangerous disease. The patients themselves needed much instruction in regard to the destruction of the sputa, so as to lessen the danger of infecting others in the house. Even in well kept consumptive hospitals there was a little danger. He dealt with the difficulties connected with notification and registration and isolation. He had found it very difficult, even among his wealthy patients, to secure isolation and fresh air; and it was infinitely more difficult to secure such among the poorer classes. Special sanatoria, he maintained, should be provided, and in every instance where the patient was not properly looked after at home, he should be sent to such places. Until such a time, for there are very few as yet, those cases should be reported when preventive measures were not carried out thoroughly at home as recommended by the patient's physician.

DR. L. DUNCAN BULKLEY, of New York, gave a paper on

THE TREATMENT OF SKIN DISEASES.

More success would come to the general practitioner in the treatment of the skin if more attention was paid to each individual case. He advised careful inquiry into every detail of the patient's system and habits. The history of the eruption; careful inquiry as to former eruptions; family tendencies as to presence of asthma, rheumatism, etc., all should be made a note of. If medical men knew eczema,

acne, syphilis well, they would be able to treat the great majority of their cases satisfactorily. As to eczema, too much was often done; it was over-treated often. More and more he had grown to know that much depended on constitutional treatment in all these skin affections. The correction of some fault in diet or habit in life was sufficient to effect relief. The Doctor pointed out some of the principal points in the management of acne, syphilis, psoriasis and urticaria.

THURSDAY EVENING.

The report of the committee appointed at the last Association to consider the matter of the establishment of a pharmacopœia was received and adopted. On motion of Dr. Starr, seconded by Dr. Macdonald, it was moved, "That the same committee be requested to correspond with the different medical and pharmaceutical associations with regard to the advisability of publishing a pharmacopœia, taking the British Pharmacopœia as a standard." Carried.

THE PREVENTION OF CONSUMPTION,

was the subject of a paper by DR. J. F. MACDONALD, Nova Scotia. He advocated the bringing the matter of the contagiousness of the disease before the people by means of the secular press; by the establishment of philanthropic societies for the discussion of the matter, and the adoption of practical measures for the treatment of the cases. He advised the system of registration; a careful system of disinfection; government inspection of infected places; the establishment of sanatoria, and the enactment of laws to prevent the infected from spreading the infection.

DR. H. D. HAMILTON read a paper on "The Adhesions of the Soft Palate and Their Treatment."

DR. J. T. STREEVES, of St. John's Lunatic Hospital, read a paper entitled "A Medico-Legal Romance." It was discussed by Drs. Muir, Macdonald, Morrison, Christie, Hattie and Travers.

DR. FENWICK then presented a paper on "Hysteropexy."

The Association then adjourned to meet next year in Kingston, Ontario.—*Dominion Medical Monthly.*

NECROLOGY.

HERBERT GOUDE, M.D., who for fifteen years had been resident medical officer at the Highgate Smallpox Hospital, has recently died in London, in his forty-eighth year. He was a man of unquestioned fitness for his position as a successor of Dr. Marson at the Highgate institution, and his loss is spoken of with universal regret. He was able to continue the observation and testimony of his predecessors there and, as recently as in May of last year, was enabled to write regarding the unbroken record of fifty-eight years, that no nurse or servant had contracted variola even in a modified form, with the single exception of a gardener who evaded vaccination; and this, too, despite the fact that nurses have actually and accidentally inoculated themselves with variolous matter. This he may well term the crucial test of vaccinal protection, and the unanswerable argument in favor of the operation. Dr. Goude was the author of a full history of his hospital, from the time of its foundation in 1746 at Battle Bridge, King's Cross, up to the present time. As the *Lancet* says: "He sought to enforce the great lesson of the value of vaccination that is still unlearned by thousands, and history will not fail to own its obligations to him and his fellow-laborers."

HANBURY SMITH, M.D., died at Brooklyn, N. Y., on September 12, aged 84 years. He was a native of Staffordshire, England, and a graduate in medicine at a London school, in 1831. He practiced for several years in Stockholm, Sweden. He came to this country in 1847, and resided in Ohio about ten years. In 1859 he took up his residence in New York city, and became a pioneer in the introduction and production of mineral waters for the use of the profession and the public. He is survived by one son, Mr. Bernard Smith at whose home he died as above stated.

HENRY HOFFMAN-DONNER, M.D., the eminent physician, humorous writer, and poet, died at Frankfort-on-the-Main, September 20, aged 83 years. His chief humorous work was "Struwelpeter," which ran through 150 editions and was translated into many languages.—Dr. Rush, of Macon City, Kansas, September 14.—R. P. Watson, M.D., September 24.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, SEPTEMBER 29, 1894.

ON ARTIFICIAL TEETH.

A writer in *Les Nouveaux Remedies* for Sept. 8, 1894, says that "the teeth of the Americans are without doubt the worst in the world." "Also," says this most interesting person, "this eminently practical people have long since renounced the employment of the inferior products furnished by nature, for their substitute, artificial teeth." The writer then produces some statistics to show that some 8,000,000 false teeth have been sold in the last year. He also cites the statistics of M. MAX DE NANSOUTY, who has made a calculation to show the number of pounds of gold used in filling teeth in the United States. This amount, he asserts, is not less than 800 kilograms which represents about 2,500,000 francs. All this precious metal we are told, "is buried with the Yankees when they die," and on this assertion this MARTINUS SCRIBLERUS splutters, "supposing that this continues during some hundreds of years, the un pitying statistician estimates that in three centuries, the cemeteries of the United States will receive a value of 750,000,000 francs in fine gold, equal to the money value of the gold which actually circulates in the country. There is a new California in prospect for the gold seekers of the twentieth century!"

We did not need this sneering ebullition to let us know the great advance America has made in civilization and in the humanities. The French Government sent one of the best native dentists in Paris to attend the International Medical Congress of 1887 and to report on the dental schools and the state of dentistry in the United States. His report was printed in an elaborate volume entitled "*L'Art Dentaire des Etats Unis*." In that official report, which

is complimentary to the United States in the highest degree, the writer regrets that France is so far behind the United States in the dental art. The superiority of American dentists has been acknowledged by the world for more than two decades, and an American dentist (EVANS) in Paris received more decorations of honor than any professional man of his time, whether in his particular field or out of it.

Nor is this superiority the result of the vast number of cases of bad teeth, as our contemporary would have us believe. It is because the Americans have passed beyond the dentistry of the Middle Ages, and realize that sound teeth are conducive to longevity. The filling of teeth is neither new nor peculiar to Americans, and it is doubtless true that the ancients understood the care of the teeth much better than the modern French. The third ÆSCULAPIUS is usually given credit for being the first to extract teeth, but the Egyptians understood their preservation well, and GALEN introduced into the carious tooth a pellet of wax for the toothache, and as a permanent cure he first cleared the cavity with acid and then filled it with powdered pyrethrum with resin or wax as an outer covering. Indeed, the ancient Romans took great care of their teeth, according to PLINY, washing and rubbing them repeatedly, and as we learn from HORACE (Sat. I.) when they lost them they had them replaced with ivory teeth, and when loose they bound them with a thread of gold. Tripoli powder ("red soda") was much used as a dentifrice,¹ and the ancient surgeons, subsequent to CELSUS, punctured alveolar abscesses with the red hot iron. The putative father of French surgery, GUY DE CHAULIAC, (its real father was HENRI DE MONDEVILLE) made a serious plaint that the pulling of teeth had been abandoned to barbers and dentists, and he held that the operation was sufficiently important to be attended to by physicians, but even GUY recommended the filling of cavities with aromatics and resinous substances. SPRENGEL asserts that JOHN ARCVLANUS, the Veronese, (quoted by RHAZES) was the first to use gold leaf for filling teeth, but judging from the remarks of our contemporary, his recommendation fell on stony ground, when it fell in Gaul.

In the matter of the construction of artificial teeth, ivory was alone used, down to the time of ANTOINE NUCK, (he of the Canal) who insisted that the only proper ivory was from the tusk of the hippopotamus. DUBOIS DE CHANANT (1777) was probably one of the earliest to use porcelain teeth. But, like every solid advance in the other branches of medicine, it has been a slow progress, and the present advanced position has been reached by regular steps. The country of our contemporary has done little or nothing in the last century toward the advancement of this branch of surgery.

¹ One can scarcely resist a reference to Catullus' "Upon Egnatius" and "To the frequenters of a certain Tavern" wherein the dentifrice used by the Celtiberians is held up to ridicule.

THE BUDA-PESTH CONGRESS.

As the detailed reports of the Eighth International Congress of Hygiene and Demography are received it becomes apparent that its practical value will be reaped quite as fully by those who staid at home as by those who attended the sessions. It is complained that the division of the Congress into twenty-six Sections made it impracticable to secure a fairly representative attendance at any; from twelve to twenty delegates seems to have been the usual number who could get together on schedule time for any given Section, while some of the Sections were closed entirely, no one putting in an appearance.

Even at the general meeting, on the last day of the session, less than fifty persons, according to the *London Lancet*, assembled to pass upon a long series of resolutions, submitted orally in various languages, and dealing with matters in some cases highly technical, in others involving questions of international importance.

The *Lancet* adds that this "procedure drew forth some vigorous protests from DR. BILLINGS, DR. LOEW, of Vienna, and PROFESSOR CORFIELD, and it is to be expected that such influence and authority as the resolutions may have, will be derived solely from their adoption by the various Sections."

 THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

This Association held its seventh annual meeting at the College of Physicians in Toronto, Canada, September 19, 20, 21, under the presidency of DR. GEORGE H. ROUÉ. This session was well attended by its members and visiting physicians from Canada and the United States, and proved to be the most interesting and enthusiastic convention in the history of the Association.

The papers presented were of an exceptionally advanced grade from a scientific point of view, while the discussions were animated and full in detail. Eighteen names were added to its list of members and DR. CARSTENS, of Detroit, elected the new President. The profession of Toronto left nothing wanting in caring for the welfare of those in attendance.

The yacht ride on the lake followed by luncheon at the Yacht Club was invigorating to the fatigue of long travel and attendance at the sessions. The annual dinner was given at the Athletic Club with His Excellency, the Lieutenant-Governor of Canada as the honored guest.

 THE AMERICAN MEDICAL ASSOCIATION.

A medical gentleman on whom a JOURNAL representative called, said that he did not care to belong to the ASSOCIATION, "because," said he, "the organization is simply a mutual admiration society." Ex-

actly so, and if our fugacious friend wishes to be thoroughly admired, he, too, should join the ASSOCIATION, and assist in the noble work of making it the greatest medical organization the world has yet known. The members of the ASSOCIATION may have their little disagreements on the floor of the convention, but they do sincerely admire each other, for they are all engaged in trying to do their best to advance the interests of the profession. Cranks and pessimists exist in every calling and profession. The AMERICAN MEDICAL ASSOCIATION possibly has its share of them, but the great heart of the organization pulsates with affection toward all Fellows of the ASSOCIATION, and kindness toward all mankind.

Let all true physicians lose no time in coming into the ranks, as effective missionaries in the cause of medical science. Let them reflect what a great power our profession would be were its members only united, and where can they unite with more propriety than under the broad banner of the ASSOCIATION? Let them remember that in the Section work of the ASSOCIATION there is ample field for their highest and best efforts in the cause of scientific truth. The index to the Transactions shows the name of every professional leader American medicine has known, up to the last decade, except those who had passed from the field before its organization. The great work of American medicine in the fifties, in the war period, and the decade immediately following, is set forth in the annual volumes, and medical history would be the loser by their extinguishment. We doubt not that the glories of the past may be surpassed by an even more brilliant future, but valuable work ought not to be frittered away by founding new and exclusive societies. Let us all belong to our local, State and National organizations, as a patriotic principle of devotion to our chosen profession.

 THE JOURNAL.

The Fellows of the ASSOCIATION may congratulate themselves on the new and completely equipped office which they now possess. The new machinery comprises all that is necessary to have the JOURNAL and all reprint work done by its own force. The moving was effected without friction, and the JOURNAL *was issued last week at the usual hour*. Those of our contemporaries who know what it is to move a printing office with all its accessories will, we are sure, appreciate the statement. At an early day we will print an illustration showing the new press and composing room. One of the new presses will print 2,300 impressions an hour, and another 2,000. The rooms assigned the Editorial and Business Departments of the JOURNAL are comfortable and convenient.

Blank Applications for membership in the ASSOCIATION, at the JOURNAL office.

CORRESPONDENCE.

Was It a Case of Subacute Peritonitis?

GRAND ISLAND, NEB., Sept. 20, 1894.

To the Editor:—I wish to report the following peculiar case and to ask the opinions of some of the many members of the Association as to the etiology and origin of the trouble:

Mrs. D., aged 27, widow, almost three years; mother of three children, youngest 6 years and 8 months; aside from constipation of about eight years' standing, and an occasional sick headache, was considered healthy. Was taken with sharp colic pains in the stomach and upper abdomen on the morning of August 2. Saw her about 7 A.M. She located the onset of the pain in a small spot in the median line, just below the ensiform cartilage. She had eaten nothing hurtful. There was no tendency to vomiting, or diarrhea, and the temperature was normal. The pain was quickly subdued by a hypodermic of morphia one-fourth grain. Hot turpentine cloths were applied to abdomen; hot water given to drink, and I directed that as soon as she was easy she should take half an ounce of ol. ricini. Bowels moved freely between 4 and 5 P.M., which provoked some pain, and by 8 P.M. pain was so severe as to necessitate the repetition of the morphia.

August 3. She was fairly comfortable, and having made arrangements to move to another part of the city, just before she was taken sick, and as she seemed able, on the morning of the 4th of August, she was moved that day. I did not see her again for three days, and although she had not felt right she did not think it necessary to report to me. At this visit, 9 A.M., August 8, her temperature was normal and there had been no chill, but she had an uncomfortable feeling in the rectum quite low down.

I should state here that in October and November, 1893, she had had a small abscess, which pointed, and was opened in the right side of the perineum, three-quarters of an inch from the anus. A fistula resulted which opened into the rectum above the external sphincter. I laid it open, curetted and packed with gauze Dec. 25, 1893. There was non-union of the divided muscle, but she had fair control. Thinking her present condition might be due to a recurrence of the rectal trouble I examined the parts, and found a swollen and somewhat tender condition of the anterior rectal wall with a decided tumefaction just inferior to the cervix uteri.

I prescribed syr. ferri iodid in dram doses after each meal, hot rectal and vaginal douches and liquid nourishing diet. This relieved the condition in a few days, and with the exception of a return of pain quite severe on Sunday afternoon, August 12, she continued to improve; was up and around most of the day; her appetite, which had been poor for almost two weeks, became quite good,—to use her own words "she could not get enough to eat;" bowels moving normally sometimes twice a day. She continued to improve, and on Sunday, August 26, had taken a short pleasure ride. I saw her the next day, and as she was feeling so well I dismissed the case.

Everything seemed to be doing well until 6 P.M. of August 29, when, on arising from the supper table she was seized with a sharp cramp, like pain in the same region as her first attack. It was intermittent in character, and some were not as severe as others. Thinking it would cease after a time, she did not call me until 10 P.M. Upon careful inquiry and examination I was fully convinced that the seat of the pain was in the small intestines near the stomach, and that there was total absence of pain in the region of the cecum, umbilicus or hypogastrium. I gave morphia sul. one-fourth

grain, atropia one one-hundred-and-fiftieth grain, and while waiting the effect took the temperature in the mouth, axilla and vagina, and found it normal in each place. Pain ceased without further use of a sedative, and she remained easy until 8:30 of the morning of August 30, when the pain commenced to return, which was as easily relieved as before. For several days she had been eating liberally, of fruits and watermelon, but as she had assured me that her bowels had acted freely on the morning and afternoon of the day of the attack, I gave her no physic at all until Friday the 31st, when I gave IIg. chlorid mite 10 grains, sod. bicarb, 10 grains. There was as yet no rise of temperature, no chill, and no vomiting.

The rest of the clinical history I have copied from my notes taken as the case progressed.

August 31, 9 P.M. Pulse 90; temperature under tongue 101; some pain, but bearable; bowels not having moved. Repeated the dose of the mild chlorid. Gave morphia and atropia; directed that she commence at 6 A.M. and take sal. Rochelle in teaspoonful doses in half a glass of water every half hour until bowels moved, or until I should see her.

September 1, 9 A.M. Pulse 90; temperature 101; no movement of the bowels, rested good all night, and is not in pain now; has vomited twice since 7 o'clock large quantities of what appears to be feces; has some pain in the descending colon above the sigmoid; says it is not severe and is not aggravated by movements of the body. Abdomen distended but symmetrical and not tympanitic. Placed her in the knee-chest posture and gave per enema over two quarts of warm soap water, which is evacuated with difficulty; discharges freely for a few seconds, then stops suddenly. The water returns unstained. She can get out of bed unaided, and without increasing the pain; continued the Rochelle.

September 1, 9 P.M. Pulse and temperature normal; has had no sedative for twenty-four hours, and is not in pain. Bowels have not moved; gave two enemas of the soap water, and the second was followed by the evacuation of about one quart of liquid feces, normal in odor and appearance. Another enema immediately following this brought away a small cluster of grape seeds, skins, and some fecal matter. Stopped the enema for the night, gave morphia and atropia, and left her at 10 P.M. feeling fairly comfortable.

September 2, 9 A.M. Pulse 80; temperature 98 $\frac{1}{4}$. No pain, no action of the bowels, constant nausea but no feces vomited.

September 3, 8 A.M. Pulse 90 and weak; temperature 98 $\frac{1}{4}$. Said she had had a fairly good night; still vomits. Matters vomited are mixed with bile. Discontinued the soap water, and commenced with clear warm water with a view of using a glycerin enema; she can not expel more than one-half of the water injected.

September 3, 9 P.M. Gave an enema of about one quart when she felt an urgent desire to stool, and succeeded in evacuating about three quarts of clear water; gave glycerin 6 ounces, water 12 ounces per rectum; patient in the knee-chest posture. She could retain it but a few minutes, although she tried hard to do so. It was evacuated without result. Gave mild chlorid 10 grains, sod. bicarb. 10 grains and left her with a pulse of 90 and temperature 98 $\frac{1}{4}$.

September 4, 8 A.M. No action of bowels; a little vomiting but not fecal; no pain and the tenderness much lessened. She feels hungry and had taken a part of a glass of milk at 7 o'clock which she retained. Gave calomel in grain doses every hour; was called at 5 P.M. on account of pain in stomach and bowels. Think it due to the calomel. She thinks there had been quite a high fever from 2 to 4, at which time she vomited freely and felt some relief; at time of my visit, 5:45, the temperature was 100 and pulse 120. Morphia one-fourth grain, gave perfect relief in a few min-

utes. Ordered the salts in dram doses well diluted every hour. 9 P.M. She is free from pain and the temperature is normal.

September 5, 2 A.M. Was called on account of the return of pain. The usual dose of morphin soon relieved her. Then gave her per enema ol. petrolia, 16 ounces; had her stand upright to favor the oil rising as high as possible in the intestines; placed her in bed and had her lie upon the right side. She remained quiet about five hours; at the end of which time she had a slight movement of the bowels, but voided nothing but clear water. She took a small quantity of milk and one dose of the salts between 6 and 7, and had retained them. She looks rested and says she feels comfortable. Gave her per enema two quarts of clear warm water which brought away the oil but no feces. Repeated the petroleum and directed the salts to be continued as before.

September 5, 2 P.M. Upon consultation with two other physicians she was given gttss of ol. tiglii in capsule every two hours until she had taken four doses, or six drops in all. Then gave ol. olive in four ounce doses every four hours. She did not retain the first dose but did the next four, taking the last at 4 P.M. of the 6th.

September 6, 7:30 A.M. Pulse 120; temperature $101\frac{1}{4}$. Having decided at the consultation of yesterday to open the abdomen and examine the small gut, provided the indications were favorable, I visited her at 7 on the morning of the 6th, found her as above described, gave an enema of about one quart of warm water, which was immediately evacuated, and with it came about three quarts of water, brownish feces, with oil on the surface, the entire evacuation amounting to about one gallon, in which was a rope of mucus exudate, about one-half inch in diameter, and about fourteen inches long. She immediately exclaimed, "What a relief," and upon returning to bed, took long inspirations, and said she felt good. I immediately telephoned the physicians who came at once, and after they were informed as to the recent facts, and having examined the contents of the evacuation, concurred with me in the opinion that an operation would not benefit the case, as it was evident that the obstruction was due to a diseased condition of the small gut, and involving a considerable portion of it, and not due to mechanical obstruction. By this time, (half an hour after her return to bed), she was much exhausted; hands and feet cold and damp; external heat was applied; digitalis and hot milk punch administered internally, and strychnia hypodermically.

September 6, 1 P.M. Pulse 120 and very weak; temperature $102\frac{1}{4}$. Has muttering delirium; hands and feet getting warmer. At 8 P.M. Pulse 120; temperature $101\frac{1}{4}$; has vomited but little since morning; stomach and bowels full of liquid which emits a splashing sound when she turns or gets up. Voids urine normally and it is normal both in quantity and appearance. At 9:30 P.M. Had a small fecal movement, brownish in color and oil on the surface; although not much pain, I gave the usual dose of morphia and one thirty-third grain of sulphate of strychnia, and she rested good until 2 A.M. of the 7th.

September 7, 8:30 A.M. Pulse 105; temperature, 101; no further action of the bowels; gave a small enema of hot water, which was evacuated without result. She is clear in her mind, can get out of bed and walk without assistance. Gave a sponge bath and changed her clothes.

September 7, 12 M. Pulse 110; temperature 102; gave ol. olive 4 ounces and repeated this dose at 2 P.M. At 7 P.M., pulse 104; temperature $101\frac{3}{4}$; has not vomited since 12 M. At 8 P.M. gave per enema glycerin 6 ounces, water 12 ounces, which resulted in a movement of one quart of liquid feces. Two more movements followed in a short time but less in quantity than the first. She vomited at the same time of the first stool and it was much more feculent than the stool. At 3:35 P.M., pulse 120; temperature 102; delirium more profound.

September 8, 3 A.M. Much worse to all appearances; still recognizes acquaintances, but is much weaker and it is difficult to obtain an accurate count of the pulse. Temperature $102\frac{1}{4}$ in axilla. Bowels more distended; tongue has been clean and moist throughout the entire sickness, is now dry and it is with difficulty she can put it out.

September 8, 12 M. No material change. Temperature $102\frac{1}{4}$; has not vomited since the night previous; has taken and retained ol. ricini 1 ounce and ol. terebinth x gttss. Hot turpentine cloths applied to abdomen reddens the skin; 4 P.M., delirium more profound. At 7:30 P.M. Stupor deepening but will answer when her name is spoken; put out her tongue when asked, and drank a little water. She slowly sank and died from exhaustion at 9:30 P.M., September 8.

Postmortem.—Thirteen hours after death; body much emaciated and muscles shrunken. Abdomen uniformly distended. Upon opening the abdomen a fine, whistling noise was heard and seemed to come from the left side. Intestines much distended and red at the flexures. No fecal staining noticeable anywhere. Omentum adhered to the intestines and almost atrophied. No disturbance of the relations of the viscera. An attempt to push the intestines to one side caused a free pouring out of feces from the descending colon at a point just above the crest of the ilium. A gangrenous spot and a perforation was found in the gut at this point. A ragged gangrenous spot and perforation was found upon the anterior and external aspect of the cecum, a little above the ileo-cecal valve, which had the appearance of having been caused by pressure from without inwards, as the perforation in the mucous coat was not larger than a small pea, while the ulcerated opening through the other two coats was as large as a silver dime, and had a distinct and elevated margin. No other perforations were found. Small intestine distended throughout its entire length, full of feces and reddened at the flexures. Colon also distended and full of feces but not so red. Stomach also full of liquid, one-half of which was fecal matter. The liver enlarged and rather pale in color; the left lobe lying almost wholly to the left of the median line but in other respects it was normal. Spleen and kidneys normal. Uterus small, firm, and occupying a normal position. Bladder not being noticeable was not examined. The feces were of uniform consistency, ash-blue in color and free from foreign bodies or scybala, except a few very small fragments of grape seed, and they were floating free in the feces. No stricture or narrowing of the caliber of either the small or large intestines. Stomach and pylorus normal except they evidenced the signs of the recent inflammation.

And now come the questions: What was the matter? Where the origin and what the cause? Did the beginning of the fatal sickness date from August 2? If so, why that interval of apparent convalescence? If the second attack was a relapse what caused it, and why was there such a sudden and obstinate change in the function of the bowels? For ten days prior to the last seizure the bowels had been moving once or twice daily without the use of physic or laxatives, except she was perhaps eating more fruit than just prior to the first attack. There had been increased ingestion for the last ten days but not what could be called unnatural. Neither was the action of the bowels any approach to a diarrhea. What could have caused such intense pain in the pit of the stomach and so sudden in onset without a rise of temperature for over forty-eight hours? Then it was only 101, and may have been the result of the dose of mild chlorid given eight hours previous. At no time did it require more than a quarter of a grain of morphia combined with a hundred-and-fiftieth of atropia to relieve the pain, and keep her easy six, eight, and twelve hours, and on the fourth day (Saturday September 1) she had no sedative for over twenty-four hours. Several times the hypodermic was used more for its relaxing effect on the bowels than for the relief of pain. At all times she could lie with the limbs extended, could rise suddenly to the sitting or standing posture without increasing the pain, and often when asked to locate the pain would reply: "I have no particular pain," and only once, about the sixth day of the last attack, did she refer to pain in the region of the cecum, yet the postmortem revealed a gangrenous spot, a perforation at this point and a general peritonitis. At no time did the temperature rise above $102\frac{1}{4}$ when it was taken, and three different thermometers were used. Drs. W. B. Hoge and M. J. Gabam were the consulting physicians in the case, and were present at the postmortem—Dr. Hoge being the principal.

I have been somewhat tedious perhaps in going into the details and giving the clinical history daily and sometimes hourly, as the case progressed, but I can substantiate the accuracy and authenticity of the same, as I have given it, and my excuse for the length of this article is the peculiar features of the case, together with the utter inutility of the remedies, and different methods employed for freeing the intestinal tract.

J. LUE SUTHERLAND, M.D.

LETTER FROM COLORADO.

Mountain Fever—Practice of Medicine Act—
Health of Denver.

NEW CASTLE, COLO., Sept. 1, 1894.

To the Editor:—Possibly some of your many readers may be interested in a line from "the heart of the Rockies;" not that we have much disease here, for we have very little where good habits prevail. I have seen an occasional case of "mountain fever," a form of remittent, consequent upon exposure and the hot days and cool nights of July and August, altitude causing a lower type and temperature than is found in the low, damp regions where the disease is most common. Both observation and reason commend the careful use of the still fashionable agents that depress the heat-producing centers.

An enforced idleness consequent upon "labor troubles," "a strike" in a mining camp of 1,200, when the wages were so low they could not live, though they spent annually from seventy-five to an hundred thousand dollars for alcoholics, permitted me to camp out during August in the near by "big game country." Would that many over-worked, under-paid, anxious practitioners could come up here and renew their lives among these grand old mountains, with their pure air and sweet waters, and enjoy elk beef, venison and trout before the game has all gone to join the buffalo in the "happy hunting grounds."

If, however, they come to practice their profession they must remember that at present the State is under the dominion of cranks. Knowing that it had a good medical practice act, such as we have labored for in Kansas for a quarter of a century I took with me my old diploma case containing sundry papers. When in Denver I called upon the Secretary of the State Board of Medical Examiners and presented my diploma. As the law reads: "He shall present his diploma for verification, or furnish evidence of being a graduate of a legally chartered medical school of good standing, and the State Board of Medical Examiners shall issue a certificate to that effect," I was a little surprised at being informed that the diploma was of no account, because issued by a college that did not at that time require a three years graded course. "No," I said, "it did not, nor did any school in America for twenty-five years after that date, but it kept step with progress, and in those days there were 'medical schools of good standing,' and but for the earnest efforts of the old schools and their older graduates progress would never have been achieved."

"We have decided that no school was in good standing when it did not require a three years course." "Then you relegate all the older practitioners to the class of non-graduates?"

"We would refuse a certificate on the diploma of any applicant if the school did not require at the time it was granted a three years course." "Then I understand that qualification is not a question with you, but graduation under recent advances, due to those who must have graduated before the advance was possible." "You must come under the next clause of the law which reads: 'All persons who have made the practice of medicine and surgery their profession for ten years and can furnish satisfactory evidence thereof to the State Board of Medical Examiners shall receive from the Board a license to continue in practice in the State of Colorado.'" "Protesting against your construction of the law, I present this diploma, dated 1848, as evidence of ten years practice." "We do not accept it." "Well, here is evidence of continued and honored membership in the Ohio and Kansas State Medical Societies and in the AMERICAN MEDICAL ASSOCIATION for nearly half a century." "That is not the kind of evidence the Board requires." "Then here is a commis-

sion as Surgeon of the Seventeenth O.V. I., dated Oct. 1, 1861; here are several appointments on the Kansas State Board of Health, the law requiring graduation from a reputable medical college and ten years practice as a pre-requisite to appointment." "I am very sorry to inform you that we can not accept any of these, but want the affidavit of five persons that you have practiced medicine for ten years." "As any ignorant pretender who hawks his nostrums on the streets can get such affidavits, your decision defeats the purpose of the law, the protection of the people, and debases to his level every physician of twenty-five years practice, however honored or honorable."

While in Denver I was impressed with the grand possibilities of that beautiful city, but its health reports show they are not yet attained. If the city was supplied with an abundance of water, brought uncontaminated from the mountains, and a thoroughly flushed sewage system, reaching every cess-pit and carrying all sewage and surface water to a sewage farm, located miles away on the arid plains that surround the city, making it, with far less cost, outrival the famed farms of Berlin, Germany, and leave the city, with its altitude and pure mountain air, the healthiest in the world, practically free from all disease except such as comes from the too ardent worship of Bacchus and Venus, unless the bacteriologist, who makes tuberculosis contagious, should chance to be correct. Then, alas! this home for consumptives, with their transmitted diathesis will long have an unsatisfactory death rate. Very truly,

W. L. SCHENCK, M.D.

Syphilitic Marriages.

ST. PAUL, MINN., Sept. 20, 1894.

To the Editor:—For the purpose of securing reliable statistics on the subject of the marriage of syphilitics, I desire to enlist the assistance of those of your readers who have had experience which will be of value in determining the period when this disease ceases to be communicable and inheritable. I shall, therefore, esteem it a great favor on the part of any physician who will send me answers to the following questions; and due credit will be given in a future publication to those who desire to aid me in this work:

1. What is the latest period from the date of the initial lesion that you have known the disease to be communicated by a patient who has been from the first under your observation?

2. What is the latest period from the date of the initial lesion that you have known: a, a syphilitic man, or b, a syphilitic woman to become the parent of a syphilitic child?

3. Have you ever known syphilis to be either communicated or handed down at a later period than four years from the date of the initial lesion by an individual who has been constantly under your observation during that time?

In answering these questions I should like a brief but complete history of each case and an account of the treatment that has been pursued.

I hope by this means to obtain the experience of a large number of observers and to reach a fairly reliable conclusion as to the time when we may safely permit our syphilitic patients to marry. Yours very truly,

BURNSIDE FOSTER, M.D.

The Societies do Not Send Delegates.

BOSTON, Sept. 18, 1894.

To the Editor:—On page 433 of the JOURNAL for September 15 is a statement that every regular State Society, except those of New York and Massachusetts, sends delegates to the annual meetings. The fact is that both of these States do send delegates. Respectfully,
A MEMBER.

BOOK NOTICES.

Materia Medica, Pharmacy, Pharmacology and Therapeutics. By W. HALE WHITE, M.D., F.R.C.P., Physician to, and Lecturer on Materia Medica and Therapeutics at Guy's Hospital, London, etc., etc. Edited by REYNOLD W. WILCOX, M.A., M.D., LL.D., Professor of Clinical Medicine and Therapeutics at the New York Post-Graduate Medical School, etc., etc. Second American edition, thoroughly revised. Cl., pp. 661. Philadelphia: P. Blakiston, Son & Co. 1894. Chicago: E. H. Colegrove & Co. Price \$3.

The editor says in the preface to this volume that "the radical changes introduced in the last edition of the United States Pharmacopœia has necessitated the rewriting of the entire descriptive part of the materia medica." The National Convention of 1890 instructed its committee on revision to employ the metric system of weights and measures, and the committee say (page 33) that "as directed by the convention the committee has in most cases employed definite weights for solids and measures for liquids in terms of the metric system," but the book continues to use the old British system in giving the doses of medicines. Many of the "definitions," or rather examples, cited in the opening chapter are properly subject to adverse criticism, for example, "Empirical Therapeutics.—Therapeutics based upon clinical experiences only, e.g., the use of mercury for syphilis." This is news to carry to those experimenters who have spent so much time in studying the physiologic effect of this drug. Keyes, Voit, Nega, Mialhe, Buchheim, Grassi, Wilbouchemitz and Brentouneau. How a book of this character can go to a second edition passes our comprehension.

Therapeutics: Its Principles and Practice. By H. C. WOOD, M.D., LL.D., Professor of Materia Medica and Therapeutics, and Clinical Professor of Diseases of the Nervous System, in the University of Pennsylvania. A work on medical agencies, drugs and poisons, with especial reference to the relation between physiology and rational medicine. Ninth edition thoroughly revised. Cl., pp. 1007. Philadelphia: J. B. Lippincott Company. 1894.

The work has passed as current coin for so many years that it were a bold man that would undertake its serious criticism. In its statements of the physiologic effect of drugs it is unrivalled, and as a scientific treatise on therapeutics it has few equals, but while one can not paint the lily or gild refined gold, we may always praise a treatise that has for practitioners the charm of truth. When the author has doubts he frankly says so; and there are so many doubts in real life! The only suggestion we would make to the author would be that the additions made necessary by reason of facts learned by recent experiments, be inserted in the text, instead of the brief reference in a foot note, and that the terms be changed to conform to modern usage. Thus while the author uses the term, "official," correctly in the preface, the old term, "officinal" still remains throughout the book, and the metric system of dosage is not used in the text, although it is mentioned, and tables are inserted in the appendix. However, the book will still remain a favorite, for its merits far outweigh these blemishes.

The Rights and Duties of Citizens of the United States; a Manual of Citizenship. By DR. EDWARD C. MANN, of New York. Advance sheets. Published for the author. 1894.

Every word of the opening paragraph in the preface should be engraved on parchment and hung up in every school room, for it is not less true now, than when Cicero wrote in "De Officiis" that "men inherit their principles and defend them afterward as they do their estates." Our author says:

"The scholars in our public schools and colleges should be instructed as to the elements that go to make up a good and useful citizen of our country, and the obligations, civil, social and political, due to others from them. They should be instructed to yield respect and obedience

to the laws, and to hold on with unflinching firmness to the Constitution of the United States. They should be taught the love of liberty and order, to walk in the path of patriotism, of fidelity to our country, and of duty to God. This is necessary in order that when they become of adult age they may be prepared to exhibit wisdom in the cabinet; the purest patriotism; the highest integrity, public and private; morals without a stain; and religious feelings without intolerance and without extravagance."

The book is dedicated to the National Educational Association, and the doctrines inculcated are such as can be approved by every well wisher of his country, and in these days when so large a proportion of our school children are of foreign born parentage, these are urgent reasons. The purposes and spirit of the Manual should receive support and encouragement.

A System of Legal Medicine. By ALLEN McLANE HAMILTON, Consulting Surgeon to the Insane Asylum of New York city, etc., and LAWRENCE GODKIN, Esq., of the New York Bar, with the collaboration of Prof. James F. Babcock, Lewis Balch, M.D., Judge S. E. Baldwin, Louis Binse, Esq., C. G. Chaddock, M.D., C. F. Bishop, Esq., A. T. Bristow, M.D., B. F. Cardozo, Esq., A. F. Currier, M.D., C. L. Dana, M.D., Geo. Ryerson Fowler, M.D., W. T. Gibbs, M.D., W. S. Haines, M.D., F. A. Harris, M.D., W. B. Hornblower, Esq., Chas. Jewett, M.D., P. C. Knapp, M.D., R. C. McMartini, Esq., C. K. Mills, M.D., J. E. Parsons, Esq., C. E. Pellew, E. M. Judge, C. E. Pratt, W. A. Purrinton, Esq., B. Sachs, M.D., F. R. Sturgis, M.D., Brandreth Symonds, M.D., V. C. Vaughn, M.D. Royal, 8vo, cl., pp. 657. Illustrated. Vol. I. New York: E. B. Treat. 1894.

With the formidable array of talent presented on the title page of this volume an excellent book should be expected and a perusal of the contents of this volume is not disappointing. Unlike a great many of the books with so large a staff the articles are all published under the name of the author, who thus accepts the responsibility for it, and the reader is enabled to know what weight to attach to a particular article when he knows who wrote it. The standard books on medical jurisprudence such as Beck, Taylor, McClellan, Wharton and Stillé, are far behind the recent decisions of the courts, while the knowledge of the organic chemistry has created almost a new science since those revered text-books were the sole authorities. Following as this does, so soon after Witthaus and Becker, it will necessarily come into competition with that work, and it is no disparagement to either that they should be so placed. The work under consideration is devoid of padding, is clear and comprehensive, and the references to cases are so full as to make it encyclopedic in scope. It is, therefore, quite likely to become the favorite text-book on legal medicine for the next decade.

Laboratory Manual of Elementary Chemical Physiology and Urine Analysis. By JOHN H. LONG, M.S., Sc.D., Professor of Chemistry and Director of the Chemical Laboratory in the Schools of Medicine and Pharmacy of Northwestern University. With numerous illustrations. Cl., pp. 366. Chicago: E. H. Colegrove & Co. 1894. Price \$2.50.

This well-written little book consists of eighteen chapters, of which the first nine are given to elementary chemical physiology, and nine to urine analysis. There is an appendix which gives useful tables and formulæ for test solutions. Students will find it of great value in their laboratory work as a practical and simple guide.

A Handbook of Medical Microscopy. For students and general practitioners, including chapters on Bacteriology, Neoplasms and Urinary Examinations. By JAMES E. REEVES, M.D. With a glossary and numerous illustrations (partly in colors). Cl., pp. 237. Philadelphia: P. Blakiston, Son & Co. 1894. Chicago: E. H. Colegrove & Co. Price \$2.50.

The author of this work has long been known as one of the most expert microscopists in the country, and his mounted specimens have been much admired by all who have had the good fortune to see them. In the production of this little volume the author has turned his long prac-

tical experience to good account. He has succeeded in condensing in a minimum space a great deal of material of especial interest to the practitioner. The success of the distinguished author shows that the general practitioner need not despair of becoming a microscopist, if like the author, he will industriously and patiently work out the problem for himself and this book if carefully studied will help to show him how to do it.

Directions for Laboratory Work in Bacteriology. For the use of the medical classes in the University of Michigan. By FREDERICK G. NOVY, Sc.D., M.D., Junior Professor of Hygiene and Physiological Chemistry. Cl. Interleaved, pp. 209. Ann Arbor: George Wahr. (No date). Preface dated April, 1894. Chicago: E. H. Colegrove & Co. Price \$1.50.

This is essentially a laboratory book, which gives the technique of practical bacteriologic study. The life history of the commoner bacteria is taken up and the different steps of their development shown and the directions for their complete demonstration are minute and accurate. It is not a treatise on bacteriology, but as its title indicates, a working guide. The formulæ for staining fluids and culture media are given in extenso. The blank pages will enable the worker to make full notes of his own experiments.

SOCIETY NEWS.

Illinois State Medical Society.—The Treasurer of this Society, Dr. George N. Krieger, Springfield, Ill., requests the JOURNAL to announce to members that the volume of Transactions for 1894 are now ready for issue. Gentlemen who have paid their annual dues have already received them; those who have thus far omitted to send their dues can have their Transactions at once on receipt of the amount.

Medical Society of the Missouri Valley.—The seventh annual session of the Medical Society of the Missouri Valley was held at the city hall, Council Bluffs, Iowa, Sept. 20, 1894, under the presidency of Dr. A. F. Jonas, of Omaha. The meeting was called to order at 10 A.M., and after the various committees had made their reports the regular work of the meeting was inaugurated by Dr. W. Ross Martin, of Omaha, who read a paper on chronic articular osteitis of hip with analysis of 208 cases. The following papers were read:

Chronic Articular Osteitis of Hip; analysis of 208 cases, W. Ross Martin, Omaha, Neb.; Report of an Interesting Case. W. O. Henry, Omaha, Neb.; Erosions and Lacerations of Cervix Uteri, Geo. H. Simmons, Lincoln, Neb.; A Case of Spurious Pregnancy, Adda Bowman, Reynolds, Neb.; Amnionitis, from Abscess of Frontal Sinus, Flavel B. Tiffany, Kansas City, Mo.; Two Interesting Cases which underwent Celiotomy, Donald Macrae, Council Bluffs, Iowa: Absorbable Sutures, J. P. Lord, Omaha, Neb.; Sarcoma of Eye—Traumatic Origin, D. C. Bryant, Omaha, Neb.; The Treatment of Typhoid Fever, W. F. Milroy, Omaha, Neb.; Mental Deficiency in Children, George Mogridge, Glenwood, Iowa; The Proper Management of Cases of Miscarriage, Mary Strong, Omaha, Neb.; Anal Fistula, J. C. Robertson, Council Bluffs, Iowa; Two Cases of Intestinal Surgery in which the "Murphy Button" was used, J. E. Summers, Jr., Omaha, Neb.; The Medico-Legal Aspect of Paranoia, J. Punton, Kansas City, Mo.; Ovariectomy, with Dermoid Cyst, W. S. Ross, Omaha, Neb.; The Morbid and Curative Influence of Mental and Moral Emotions, W. H. Kerr, Fall City, Neb.; Muscular Asthenopia, C. M. Hobby, Iowa City, Iowa; "Anthrax" or Malignant Pustule, W. Jepson, Sioux City, Iowa; The Beginnings of Disease, A. B. Somers, Omaha, Neb.; Hyperemesis Gravidarum, B. F. Crummer, Omaha, Neb.; Operative Treatment for Vascular Naevus, A. F. Jonas, Omaha, Neb.; A Case of Quadrisectional Hemianopia, M. F. Weymann, St. Joseph, Mo.; Total Hysterectomy without Ligation of Uterine Arteries, J. E. Summers, Jr., Omaha, Neb.

Tri-State Medical Society, of Alabama, Georgia and Tennessee.—

The sixth annual meeting to be held in the ballroom of the Kimball House, Atlanta, Ga., October 9, 10 and 11. There

will be three sessions a day—morning, evening and night. Reduced rates on the railroads from all points in the South. Members of the profession are all invited. The following papers are announced:

The Responsibility of a Class of Criminals from a Medico-Legal Point of View. J. C. LeGrand, Anniston, Ala.

Treatment of Stricture of the Urethra by Electrolysis. P. L. Brouillette, Huntsville, Ala.

The Obstructive Urinary Diseases. W. L. Gahagan, Chattanooga.

Urethral Surgery Ten Years ago and To-Day. T. C. V. Barkley, Chattanooga.

Reflex Neurosis in the Male. Andrew Boyd, Scottsboro, Ala.

The Pathologic Import of Albumen in the Urine. E. B. Ward, Selma, Ala.

How to do Abdominal Section without Fuss, Feathers or Foolishness and with Immunity from Sepsis. Joseph Price, Philadelphia.

Puerperal Septicemia with cases illustrating the Several Varieties. J. R. Rathmell, A.M., M.D., Chattanooga.

Reform in the Treatment of the Neurotic and Insane Viewed from the Gynecologic Standpoint. Charles A. L. Reed, Cincinnati.

Essentials of Obstetric Nursing. R. R. Kime, Atlanta.

Pernicious (or Inveterate) Vomiting of Pregnancy. A Plea for the Mother; based on Cases in Actual Practice. E. A. Cobleigh, Chattanooga.

The Induction of Labor to Prevent Blindness. Frank Trester Smith, Chattanooga.

Slaughter of the Innocents. E. van Goidtsnoven, Atlanta.

Prognosis and Treatment of Placenta Previa. Richard Douglas, Nashville.

Uterine Cancer. George R. West, Chattanooga.

Treatment of Uterine Fibroids. W. Gill Wylie, New York.

A Report of some Rare Surgical Lesions connected with the Liver. John A. Wyeth, New York.

The Treatment of Stone in the Kidney. W. E. B. Davis Birmingham, Ala.

Tuberculosis of the Kidney and Bladder. H. Berlin, Chattanooga.

Some Causes Leading to Invalidism in Women. President's Address. J. B. S. Holmes, Atlanta.

Amputation of Mamma for Carcinoma and Treatment of the Axilla. B. W. Bizzell, Atlanta.

Excision of Malignant Tumors of the Breast. Willis F. Westmoreland, Atlanta.

The following notice has been issued:

My Dear Doctor:—You are invited, with your friends, to attend the sixth annual meeting of the Tri-State Medical Society of Alabama, Georgia and Tennessee, to be held in the ballroom of the Kimball House, Atlanta, Ga., Tuesday, Wednesday and Thursday, October 9, 10 and 11, 1894.

FRANK TRESTER SMITH, M.D. Sec'y,
Chattanooga, Tenn.

J. B. S. HOLMES, M.D. Pres't, Atlanta, Ga.

SELECTIONS.

Report on the Etiology and Prevention of Diphtheria—Presented on behalf of the German Committee to the Eighth International Congress of Hygiene and Demography, at Budapesth.

[The following is the summary of the conclusions of this important report:]

1. The productive agent of diphtheria is the diphtheria bacillus. Dispute as to the etiologic definition of this bacillus exists no longer. We can, therefore, henceforth indicate as diphtheria such forms of disease as are infested with the bacillus.

2. Not infrequently cases appear in the early stages to the clinical observer as true diphtheria, which, however, are caused by other organisms, as streptococci, staphylococci, pneumococci, and in light or graver form may be mistaken for diphtheria. But the differential diagnosis can be effected through bacteriologic research. Statistical compilations on the epidemic spread of diphtheria, as well as on the character of diphtheritic epidemics, can not represent an exact definition so long as the bacteriologic investigation of cases suspected of diphtheria fails to mark a division between true diphtheria bacillus and cases merely resembling diphtheria.

3. Diphtheria epidemics show a various character, as do many other epidemics of infectious disease. The course of epidemics is very often light, but also much more severe, indicated by the high figure of the death rate, the rapid infection of the larynx and the nose, and by severe heart and kidney affections, and consecutive paralyses. But also in the same epidemic instances of severe and light forms of disease frequently alternate irregularly.

4. The variation will be determined by several factors: *a* by differences in the number and the virulence of the diphtheria bacilli; the causes of the latter are not yet absolutely known; *b*, by concomitant bacteria, and, indeed, as much by pathogenic as saprophytic; the processes of infection with regard to the diseased mucous membranes in the passages and in the nose appear to influence the course of the disease unfavorably, in part by increasing the virulence of the bacilli, in part by weakening the body through absorption of decomposition products; *c*, by individual tendencies not yet thoroughly recognized.

5. The diphtheria bacillus can appear in the passages, especially of the nose, of separate individuals without causing indications of sickness, which it first induces when it has actually established itself. Lesions of the mucous membranes, small eruptions, catarrhal changes, are favorable to its residence. In brief, meteorologic conditions giving admission by the first approach to catarrh, especially cold damp weather, appear to favor the sickening from this cause. But this influence has to be more closely observed.

6. Diphtheria is most rapidly communicated by direct contact between sick and well through spitting, coughing,

sneezing, kissing and grasping of the hands, whereby the hands come into contact with fresh secretion, but also freely through utensils which the sufferer has fouled, with his excretions by beverages, food, eating and drinking vessels, cast off washing, clothes and other articles, as pocket handkerchiefs, playthings, even long after their actual infection.

7. The sick is infectious so long as he has bacilli upon the mucous membranes. The bacilli usually disappear with or soon after the disappearance of the local signs, but they may be detected still lively and virulent in the passages or nose for weeks and even months.

8. In organic matters condensed and excluded from light the bacilli can maintain themselves for a period of months outside the body; accumulations of dirt, dark and close dwellings favor thus the preservation of bacilli and the extension of disease.

9. As a specially noticeable vehicle for the extension of disease is to be noted the crowding together of susceptible individuals, especially in families of many children. But other gatherings of people, apart from children, where separate persons do not come into such proximity as the members of a family, may offer facility for the extension of infection, as schools, barracks, and the like.

10. The diphtheria bacillus is so far not identified with certainty as the cause or inducer of other diseases similar to diphtheria or of other spontaneous disease of lower animals. The possibility of the conveyance of true diphtheria from sick animals to human beings is thus outside our present knowledge. It is desirable that the governmental investigating committees should combine with research regarding diphtheria coming under their notice the similar diseases of animals, and also the communication from animals to human beings of diseases resembling diphtheria.

11. As prophylactic means are to be considered: *a*, care for cleansing, keeping dry, sufficient ventilation, and lighting of the dwelling; *b*, careful cleansing of the mouth and nose, gargling with weak solutions of common salt and carbonate of soda, thorough brushing of the teeth, extraction of bad teeth, attention to the deeper cavities of the tonsils, and removal of hypertrophied tonsils; *c*, cold douching of the throat in times of diphtheria prevalence.

12. Every case suspected as diphtheria must, when possible, be bacteriologically investigated. The physicians must have easy access to the required materials for carrying on the culture, for example, in the chemists' shops. The investigation has to be carried on by specialists, as in the case or cases of suspected cholera.

13. All cases proved bacteriologically to be true diphtheria, as well as all cases suspected as diphtheria which have not been bacteriologically investigated, must be dealt with as under police regulations.

14. Every diphtheria case must be isolated either in a separate room of the dwelling or in an isolation ward. In order to restrict as much as possible the spread of the bacilli by the sick, a local anti-bacillar treatment must be employed with a view to prophylaxis against the early stages of the disease.

15. One of the most effective means against the spread of diphtheria to be cared for is the protective inoculation of susceptible individuals in the neighborhood of the patient, especially of children. In proportion as the innocuousness of Behring's serum cure through preventive injection is established for curing or prophylaxis, it appears worth while to develop further as far as possible the art of inoculating it in families and in school classes in which diphtheria cases have occurred.

16. In every case of diphtheria disinfection is imperative. This is needed for all utensils for the sick, as well as for the sick themselves and the sick room.

17. Convalescents from diphtheria must not mix freely with others (or children go to school) till bacteriologic investigation has proved the removal of the bacilli, and the sick after a warm bath with soap have been thoroughly cleansed and have put on clean clothing.

18. On the outbreak of diphtherial epidemics, notification should be given in the public press.—F. LOEFFLER, M.D., Professor of Hygiene in University of Griefswald, in the *British Medical Journal*.

PUBLIC HEALTH.

A Healthful Season.—Reports to the JOURNAL from State Boards of Health and health officers of cities in all parts of the country almost uniformly concur in pronouncing the past four months one of the most healthful periods on record. This is especially true in the large cities; New York, for example, is congratulating itself on a reduction of 2,600 deaths in the period from July 1 to September 15, as compared with the corresponding period last year, and estimates that, notwithstanding the increase of population, the total deaths for the year will be less than 42,000 as against 44,500 in 1893; it is noted, also, that the birth rate of the city to the middle of September is nearly 10 per cent. in excess of the usual birth rate for corresponding periods. Even with the smallpox incidence in Chicago, Brooklyn, Detroit and Milwaukee, as well as in New York, the season has been exceptionally healthful. In some of the smaller cities, with defective water supplies, the prolonged dry weather has been unfavorable to the general health in causing an increase of typhoid and other intestinal diseases. But, on the whole, the summer season of 1894, and thus far in the autumn quarter, the general health of the country has been above the average.

Pure Food Exposition.—Under the somewhat ambitious title of the "World's Pure Food Exposition," an exhibit of food products will open in Chicago, October 1, prox., and continue three weeks. It is announced that not only will specimens of all manner of edibles be shown, but that the processes of manufacture of many kinds of food products will be exhibited and explained and "high art cookery" be exploited for the benefit of visitors. If the associations under whose auspices this exposition is held should exert their influence toward legislation for the suppression of adulteration—if even only to the extent of the proper branding of adulterated foods and drugs—they would confer fully as much benefit on the public as by their show. Special Agent Wedderburn, of the Department of Agriculture, asserts that there is 15 per cent. of adulteration in the \$6,760,000,000 worth of food, drinks and drugs which the 65,000,000 people of this country annually consume. That is to say, our purveyors of these articles extort over a billion dollars a year from the hungry, thirsty and sick, under false pretenses. It is true that only about 2 per cent. of the adulteration is injurious to health; but even this amounts to \$135,000,000 annually "paid by the American people for sacrifice of their lives or injury to their health." Mr. Wedderburn, in his recent report, says that foreign competitors of our manufacturers of food products use the fact of this extensive adulteration to their own advantage, and that the United States "occupies the unenviable position of being one of the very few countries that fail to require by law the proper branding of their manufactured food and drugs." The legislation suggested is not less in the interest of the pockets of the people, to the extent of the enormous sum above given, than it is in the interest of the public health.

Typhoid Fever and the Drouth.—Dr. Henry B. Baker, Secretary of the Michigan State Board of Health, has issued a circular note of warning to the health officers of that State on the danger to be apprehended from the pollution of water supplies owing to the recent protracted dry weather. He states that the water in the test well at Lansing in September, 1893, was three inches more than the average of previous years, while it is now four inches less than the average and says: "For the second week in September, typhoid fever is reported from thirteen places more this year than last year. More people should boil their drinking water, and all should be more careful not to breathe or take in on fruit, celery, or other uncooked article, any dust from dried human excreta, that substance being usually the cause of typhoid fever. The danger usually culminates in October."

In an accompanying chart Dr. Baker shows the relation of sickness from typhoid fever to the rise and fall of the water in wells in Michigan for a period of ten years. Although this chart is not recent, its lesson is most striking and appropriate at this time. The curves of depth of soil above the ground-water of wells and of the amount of typhoid are almost identical; in other words, when the ground-water in wells is highest—i. e., the least depth of soil above the surface of the water—there is the least sickness and *vice versa*. Thus, in May, when the ground-water is highest only 5 per cent. of the reports state the presence of typhoid fever; in October, when the ground-water is lowest, 20 per cent. of the reports state the presence of the disease. The graphic curves of the chart add emphasis to Dr. Baker's warning.

Smallpox and Typhoid.—During the last ten days there has been a remarkable subsidence of smallpox, especially in Chicago, where it was feared, from the increase of new cases in August, that an epidemic had begun. Up to the 27th inst. there had been but thirty-six cases in September and during the first four days of the week only three new cases were reported. From Milwaukee. Dr. U. O. B. Wingate, Secretary of the Wisconsin State Board of Health, reports to the JOURNAL, under date September 24: "Since September 10, smallpox has appeared as follows in this State: Dover, Racine County, one case; La Crosse, La Crosse County, one case (that of Dr. Marquardt, member of the State Board of Health, reported in the JOURNAL of the 22d); Milwaukee, Milwaukee County, seventy-nine cases, fourteen fatal; Wauwatosa, Milwaukee County, nine cases, two fatal; Two Rivers, Manitowoc County, two cases. Total number of cases reported in Milwaukee since outbreak of January last, 315, of which there were fatal, 74. Total number of cases now existing (September 24) in Milwaukee, 103. Total number of cases reported in the State since the beginning of the outbreak, 427, of which there were fatal, 107. Total number of places infected in the State since the beginning of the outbreak, thirty-seven; total number of places now infected, seven." The outbreak in Newark, N. J., is reported to be rapidly subsiding. Although there has been some spread of the disease in Leavenworth, Kan., the health authorities do not anticipate serious trouble and believe the outbreak is under control. A case, said to have been contracted in Pittsburg, Pa., during the Grand Army encampment, is reported from one of the neighboring towns in Pennsylvania.—While there is a decided increase in the typhoid fever mortality, largely in excess of the usual autumnal increase, no reports have been received of any epidemic incidence of the disease. Special attention is being paid to water supplies—in many localities as a matter of necessity owing to the cause heretofore noted, namely, the effect of the prolonged drouth on water courses and ground-water. The increase of typhoid fever emphasizes this necessity and a permanent improvement of the quality of water supplies will, no doubt, result in many places.

Iowa Health Bulletin.—The current number of the Bulletin of the Iowa State Board of Health (edited by Dr. J. F. Kennedy, Secretary of the Board,) records a well-authenticated case of the transmission of diphtheria by a pet dog, which was, unfortunately overlooked while taking all other precautions; the reporter, Dr. A. O. Strout, adds: "Wherever any contagious disease exists, especially diphtheria, we should not forget the dogs and cats when disinfecting, and if they are inclined to stay in the house shoot them at once."—Dr. Frederick Becker, President of the Board, renews his warning of the danger of the spread of infectious diseases by itinerating pack-peddlers, and illustrates his subject by cases in point; he is convinced that the pack-peddler is becoming more and more the disseminator of contagion and infection.—The editor dwells upon the frequent fatal accidents from the careless use of kerosene and gasoline and calls attention to the importance of Rule 5 in the Board's circular on "Kerosene Oil . . . Gasoline and Its Dangers," which reads as follows: "If, from leakage from a stove or vessel, there is discovered an odor of gasoline in a room that

has been closed, throw open the doors and windows until the air is changed before a match is struck or a flame of any kind is permitted therein."—Considerable space is given to the correspondence elicited by the attempt to ship the body of Dr. John Sinnett—who died of diphtheria in New York—to his late residence in Muscatine, Iowa; it would appear from this correspondence that the rules for the transportation of the bodies of those dying from contagious diseases are not always carried out, and that in some States they are practically a dead letter; in Iowa, however, they are rigidly enforced, Dr. Kennedy remarking that, while from a sentimental standpoint, the enforcement may be regarded as harsh and unfeeling, from a sanitary point of view it is essential for the protection of the public.—Prefacing an address on the sanitary needs of Dubuque by the physicians of that city and furnished to the Bulletin by Dr. E. A. Guilbert, member of the State Board of Health and President of the Iowa State Board of Medical Examiners, the editor takes occasion to say that "It is an able and earnest appeal and comes from a class of citizens and tax-payers whose financial interests would be best subserved by preventing rather than urging such sanitary measures; the address is not only applicable to Dubuque but will, doubtless, interest many other localities in Iowa."—Dr. Kennedy says there has never been a season in Iowa of such general good health as during the past four months, and finds cause for congratulation in the fact that there has been no case of smallpox in the State for several weeks prior to September 1; but is sorry to admit that there is still a dangerous neglect of vaccination.

MISCELLANY.

Dr. W. M. Scott, of Pittsburg, has been appointed physician to the poor of that city, *vice* Dr. P. D. Perch.

Dr. W. L. Jennings, of Boston, has been appointed Professor of Organic Chemistry at the Wooster Polytechnic Institute, *vice* Dr. George D. Moore resigned.

Dr. Wm. G. Bissell, City Bacteriologist of Buffalo, N. Y., has been appointed Assistant Surgeon of the Seventy-fourth Regiment.

Dr. D. G. Hathaway, of Milwaukee, has been appointed Medical Superintendent of the Oshkosh Hospital for the Insane, *vice* Dr. Wegge, resigned.

Dr. Waldo, a London Health Officer, has found thirteen different kinds of living microbes in a new loaf of bread. It is said that the London underground bakehouses are proverbially dirty.

Biologic Station in Norway.—A biologic station is to be established at Drobatt in the Fjord of Christiania and near the city of the same name. It will be installed on the model of the celebrated station at Naples, and, like the latter, will be open to foreigners.

Physicians and Street Names.—A committee of the Municipal Council of Paris has decided to christen some new streets and rename some old ones after the following physicians and scientists: Jean Baptiste, Dumas, Milne Edwards, Trousseau, Charcot, Ulysse Trélat.

A Japanese Army Ambulance Fired Upon.—The reports from the seat of war near Seoul, Corea, show that the Chinese fired upon an ambulance of the Japanese service, although the attendants wore the Geneva cross. An ambulance surgeon was slain, with others, by the Chinese volley. We trust there is some error in the reports, somewhere.

The Eleventh Census.—The work of the census of 1890 is rapidly being closed up. In less than five months, or about February 1, 1895, the end will have been reached. The work on population and vital statistics is the part that now remains to be completed. Population by occupations has been the last of the population tables to be brought up, but the end is now in sight.

The Ideal Physician.—In an article upon the subject, how to

choose a doctor the author Dr. Kane says: The ideal physician has intelligence, education, courage, patience, sympathy, truth and a high conception of the grand destiny of humanity. When you find such a one, one with a soul as well as mind and body, respect him and do not turn to the first humbug who "knows it all" when your good physician in his honesty sometimes says "I don't know," in reply to a question that science itself has not yet answered.

If he sometimes says that you do not need medicine, and gives you some good advice in regard to your manner of life instead, prize him. He is honest.—*Medical Summary.*

An Anti-Contagium Society in Asia.—At Baku, on the Caspian Sea, the advance wave of sanitary knowledge has been the means of establishing a new society intended to do away with hand-shaking and osculation in the greeting of acquaintances. The ground is taken by the members of this society that these acts tend to propagate and disseminate the bacilli of disease. According to the Paris *Herald* the friends of this movement are males, and the ladies of the city have entered a protest against it to the Governor-General of the province.

Typhoid Fever at Marlboro, Mass.—The prevalence of fever at this place has impelled the State Board of Health to make an investigation as to its causation. Dr. Sedgwick, bacteriologist of that Board, has been detailed to visit the town. From the preliminary studies made, it does not seem possible to incriminate the water supply of the town as the source of sickness. The condition of the sewers, on the other hand, has been the occasion of much complaint, on account of alleged inadequate cleansing and flushing. The investigation is still pending.

Was not Spoiled by Prosperity.—A newspaper paragraph is going the rounds to the effect that a Scotch girl named Lithgow recently graduated from the medical school of Ann Arbor University with a very fair record. Immediately following the event came the news that an uncle had died in Glasgow, Scotland, and left her a fortune variously estimated at \$650,000 to \$800,000. The young doctress exhibited no surprise or emotion on receiving the announcement, but merely said: "That will enable me to relieve the wants of the poor, without any regret for the loss of my time and labor."

Electric Melons.—All organisms and living tissues produce a certain amount of electricity, which may be made manifest by the galvanoscope or other more delicate apparatus. Consequently the following experiment, performed by an English electrician and recounted in the *Revue Scientifique*, is not so singular as it appears at first glance. He took a dozen ripe melons and connected them together so as to form a battery, by running a platinum wire from the top of one melon to the bottom of the next, and obtained a current strong enough to work an electric bell. The experiment only succeeded with ripe melons and when they were insulated by being placed upon glass.

Oikology, or the Science of the Home.—This new science is for the benefit of those, more especially our wives and housekeepers, who are aiming at a truly wholesome condition of the home. The word is said to be Bostonese in origin, and has the same Greek root as economy, namely from *oikos*, a house or domicile. Mrs. Tobey, of Boston, who is President of the Massachusetts Household Economic Association, a branch of that national organization of similar name, has been engaged in lecturing to full audiences on oikologic subjects. The National Association, above referred to, is in its turn a reflex of the sanitary work done at the World's Fair last year, whereby the eyes of many were opened as to the improvements in home life that have been made possible by sanitarians, inventors and food producers. No one can receive any harm from oikology.

A Worthy Saying: Medical Advice Indispensable to the State.—

Dr. E. Long Fox, the new President of the British Medical Association, in his inaugural address spoke upon the benefits conferred on the general public by medical men. Among other notable sayings of his, the following is worthy of lasting remembrance: "Happy is that State that legislates, in all things concerned with the well-being of the people, in dependence upon medical advice."

Here is food for thought. We know here, no less than does the profession of Great Britain, how futile and transitory is much of the legislation on vital questions, simply for the reason that medical opinion is ignored, when the laws are framed. The great feature of medical counsel in law making is that it commonly effects two important purposes, at one and the same moment; it tends to the reduction of pain and human misery (our primal function); secondly it shows the way to a reduced expenditure on the part of the State, especially in the elevation of the deficient classes. These classes are, as the result of medical investigations, to an increasing extent put in a condition of earning, in part at least, their own livelihood. These classes, left to the good offices of the average legislator, would never cease to be a dead weight and a burden on the pauper fund. In fact, the average politician often looks upon it as personal slight to himself to have his imbecile charges trained to work for their own support.

Medical College Notes.

THE WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS was reopened September 18, with a class of thirty-four. The opening address was made by Dr. Mereness.—Toledo Medical College, opened September 19, with a class of one hundred.—The Ohio Medical University at Columbus held its opening exercises September 19, with a larger class than last year. Drs. Brown, Ross and Burner made addresses.—Prof. D.R. Porter, of the Kansas City Medical College has resigned. A reception was given by the Faculty and Alumni Association September 17.

Hospital Notes.

ST. JOSEPH'S HOSPITAL, PATERSON, N. J., is to have a new maternity ward.—The Women's Hospital, Detroit, acknowledges a donation of \$2,500 from the estate of C. H. Buhl.—A contract has been let for a new Catholic hospital in Cincinnati, the cost to be \$15,000.—Anderson, Ind., is to have a new hospital to cost \$100,000; it will be managed by the Sisters of the Holy Cross.—The managers of the Colored Home and Hospital, Brooklyn, N. Y., are disturbed because of a report that the property is in the way of the new East River bridge.—Dr. Simeon B. Bell, of Kansas City, Kan., has given land valued at \$125,000 to found a hospital and medical college. The college is to become the Medical Department of the State University at Lawrence.—St. Mary's Hospital, of Evansville, Ind., was dedicated September 20.—The contract for building the hospital to be erected by the Atchison, Topeka & Santa Fé Railway at Topeka, was awarded September 15. The probable cost of the hospital will be \$80,000. It will be the principal hospital of the system, and in addition to accommodations for railroad men it will be equipped with a ward for others who may be ill or meet with accident.

FOR HOSPITAL AMBULANCES.—The makers of hospital ambulances have learned something from the bicycle makers. They are now using the pneumatic tires, which save the jarring and jolting. The well-known lines of Hood:

"Then rattle his bones over the stones;

For he's a poor pauper whom nobody owns,"

will no longer be applicable to the unfortunates who are conveyed in hospital ambulances.

DR. DAVID GILBERT HATHAWAY, of Milwaukee, was September 19, appointed Medical Superintendent of the Northern Hospital for the Insane, at Oshkosh, Wis.

Washington Notes.

HEALTH OF THE CITY.—There was no death from either diphtheria or scarlet fever reported while there were seven fatal cases denominated as typhoid fever against six during

the same period last year and eight in the year previous to that. The report for the week ending September 15, is as follows: Number of deaths, 90; white, 59; colored, 31. Death rate per 1,000 per annum, white, 13.2; colored, 17.9; total population, 16.4. Twenty-eight were under 5 years of age, 23 were under 1 year old and 12 over 60 years. Twelve of the deaths occurred in hospitals and public institutions. The deaths by classes were as follows: Zymotic, 28; constitutional, 13; local, 42; developmental, 4; violence, 3. The principal causes of death were: Consumption, 6; diarrheal, 12; typhoid fever, 7; malarial, 3; pneumonia, 2; congestion of the lungs, 2; bronchitis, 1; whooping cough, 2; kidney diseases, 1; meningitis, 1; cancers, 3. Births reported: Thirty-two white males, 32 white females, 23 colored males, 23 colored females. Marriages reported: Twenty-eight white, 11 colored. Stillbirths reported: Five white, 7 colored.

MORE BAD PUMPS.—The inspection of pump water continues and more pumps have been found to contain water contaminated with colon bacillus, and have been closed by the Commissioners.

DIPHTHERIA REGULATIONS.—The Health Officer is preparing a compilation of the regulations and rules for the handling of cases of diphtheria and scarlet fever in the District. The present publication is unsatisfactory in being too costly and not complete enough, and he expects to make the cost of the new one so small that physicians of the city may be able to distribute them among the families of their patients and that the instructions will be so full that the danger from infection may be greatly diminished.

GARBAGE DISPOSAL.—Pursuant to act of Congress, the Commissioners have been making investigations into the best and cheapest method of disposing of the garbage of the District, and the Health Officer has been sent to the principal Northern cities to investigate the subject. It is more than probable that the method by incineration will be adopted and Congress will be requested to furnish the plant and have it operated by the District authorities. The authorities of Alexandria, Va., are constantly complaining of the nuisance caused by the presence of the foul smelling scows conveying garbage past their city, and they threaten to sink them.

ARMY SURGEONS DETAILED TO MONTREAL.—By direction of Gen. Schofield, Acting Secretary of War, Maj. Charles Smart, Surgeon, and Capt. Harry O. Perley, Assistant Surgeon, have been detailed to represent the Medical Department of the Army as delegates at the twenty-second meeting of the American Public Health Association to be held at Montreal, Canada, Sept. 25 to 28, 1894.

HOSPITAL FOR LIFE-SAVERS.—The Marine-Hospital Bureau has issued a circular carrying into effect the law extending the benefits of the marine-hospitals to the keepers and crews of life-saving stations. A list of nineteen hospitals where they can be treated is given.

THE HEALTH DEPARTMENT AND NEW CEMETERIES.—The application of the President and Secretary of the congregation of Agoodas Achim for a permit to establish a new cemetery in a suburb of this city, was referred to the attorney for the District for legal opinion. In his decision to the Commissioners, Attorney Thomas says: "That no new cemeteries can be established in the District of Columbia without authority of law, unless by a cemetery association organized under Section 594, and following, of the District Revised Statutes or unless the person or persons desiring to establish the cemetery dedicates land therefor, not exceeding five acres, according to the provisions in Section 604 of said statute. It must be apparent that the Health Officer has nothing to do with the establishment of a cemetery. His functions as to cemeteries relate to interments and disinterments."

HONORS FOR DA. TAYLOR.—Dr. Thomas A. Taylor, Microscopist of the Department of Agriculture, has received from the Society for the Advancement of Hygiene, of Brussels a silver medal, intended as an acknowledgment of the value of his scientific work. Two diplomas have also come to him from the World's Fair, and for his exhibit of 1,000 models of

the mushrooms of America, and the other for his exhibit of instruments of precision invented by himself for microscopic work.

TEMPORARY PRESIDENT ELECTED.—Rev. Samuel H. Green has been elected temporary President of the Columbian University to succeed the late Dr. James C. Welling. Dr. Green has been Vice-President for a number of years.

St. Louis Notes.

ST. LOUIS MEDICAL SOCIETY.—The meetings of the St. Louis Medical Society were resumed on the 15th inst. The program for the meeting on the 22nd inst. consisted of a continuance of a discussion begun at the preceding meeting: "The effect of gases and odors emanating from sewers and various mercantile and manufacturing establishments upon the health of communities;" the presentation of a specimen of tubal pregnancy by Dr. H. C. Dalton, and specimens of strangulated femoral hernia by Dr. A. H. Meisenbach. The discussion of the effects of gases upon health comes *apropos* of much complaint that has been aroused by the city plant for the disposal of garbage, dead animals, etc. A vigorous effort has been made to induce the Board of Health to abate the nuisance, but thus far without success. There seems to be a prospect that the political "pull" will prove to be as strong as the odors; if the community can not weaken the "pull" it can hardly expect to mitigate the emanations from its profitable city establishments.

PROF. W. S. CHAPLIN.—The return of W. S. Chaplin, Chancellor of Washington University, has re-awakened a lively interest, professional and public, in the now famous speech made at the banquet of the Harvard Medical Alumni Association, and in which he reviled and derided the science and culture of the West, and of St. Louis in particular. The Chancellor's thrusts were most pointedly directed toward the medical colleges of St. Louis, which he characterized as institutions founded for the professional advancement and advertisement of medical specialists; but his sweeping imputation to Westerners of profound ignorance of even the significance of the words, science and culture, aroused feelings of enmity in the general public as well as in medical men; and it is rumored that the Chancellor may be invited to find a field of usefulness elsewhere for the exercise of his talents. As if to controvert his statements, the medical schools of St. Louis have entered on a year of striking increase of prosperity; several of the colleges show enrollments of students far in excess of previous years, notwithstanding the fact that all comply with the requirements of the Association of American Medical Colleges. This is especially true of the newer and more progressive schools. This year many students who formerly attended in the East have been attracted to St. Louis by the somewhat low fees that prevail here, so that the hard times have favored our medical schools. With a continuance of the present spirit of worthy emulation in the faculties of our colleges, St. Louis will quickly take the second place as an important center of medical science.

THE CITY BOARD OF HEALTH, it is said, is not a unit in its efforts to control the advertising propensities of the heads of city medical institutions. At least one member of the Board is thought to be in favor of allowing such officers all the scope they desire in the direction of publicity, believing that such posts are accepted largely with a view to future reputation in the community for medical and surgical skill. It would seem that any prestige gained through service as superintendent of a large hospital is legitimate enough, but it is going far beyond limits of even city hospital tradition to use the daily press as it has been used of late. To show the length to which the rules of the Board can be disregarded, a daily paper lately contained the report of an important operation performed at the City Hospital and credited to one of the members of the Board, though it is said that he was not even present at the operation. Such a playful example of medical reporting is a demonstration of the general character of the public statements emanating from the institution. The most serious aspect of this matter, however, is the unlawful and inconsiderate publicity given to cases of an unfortunate character where young women especially are involved; and it is within the bounds of possibility that some patient cognizant of his or her rights in the matter of medical treatment may take occasion to make the

management of the City Hospital suffer for its selfish and inconsiderate indiscretion.

THE BOARD OF HEALTH, during the year notified all former consultants of the City Hospital that their services would be dispensed with. This action, it was alleged, was made necessary by the assumption of this great dignity by unqualified medical men, who made use of this title without authorization, and thus brought discredit to the Hospital and its ethics. The members of the Board have since become the self-appointed consulting staff, and the profession of St. Louis feel secure in the assurance thus given that all will henceforth be as it should be. In justice it should be added that many former consultants were merely so in name, since they could not be depended upon to respond to a call.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Sept. 14, 1894, to Sept. 21, 1894.

Capt. EDWARD C. CARTER, Assistant Surgeon, is relieved from duty at Vancouver Barracks, Washington, and ordered to Fort Buford, South Dakota, for duty, relieving Capt. AARON H. APPEL, Assistant Surgeon. Capt. APPEL, upon being relieved by Capt. CARTER will proceed without delay to Fort Ethan Allen, Ver., and report for duty at that post. Capt. C. N. B. MACAULEY, Assistant Surgeon, is granted an extension to twenty-three days of his seven days' leave of absence. Capt. W. W. GRAY, Assistant Surgeon, is granted leave of absence for twenty days, to take effect upon the arrival at Fort Schuyler of a medical officer to relieve him. Capt. LOUIS BRECHEMIN, Assistant Surgeon, is granted an extension to twenty-three days of his seven days' leave of absence. Major HENRY M. CRONKHITE, Surgeon, is granted leave of absence for one month. Capt. WILLIAM P. KENDALL is granted leave of absence for twenty-one days, to take effect about Sept. 20, 1894.

The Journal of the American Medical Association

Vol. XXIII.

CHICAGO, OCTOBER 6, 1894.

No. 14.

THE MEDICAL COLLEGES OF THE UNITED STATES AND CANADA.

The Editor of the JOURNAL a few weeks ago addressed a circular to the Secretary or Dean of the various Medical Colleges, requesting them to state their plan of education, including the requirements for admission, the facilities they possessed for teaching, the names of the teachers, and the cost of attendance.

The general response to the circular has enabled the very complete summary here presented.

It should be remembered that these statements are those prepared by the schools themselves and in no way changed in this office.

ASSOCIATION OF AMERICAN MEDICAL COLLEGES.

The Association of American Medical Colleges, requires for all members that candidates for matriculation will be allowed admission, subject to the conditions prescribed by Article III of the Constitution of the Association:

ARTICLE III.

SECTION I.—Members of this Association shall require of all matriculants an English composition in the handwriting of the applicant of not less than two hundred words; an examination by a Committee of the Faculty, or other lawfully constituted Board of Examiners, in higher arithmetic, algebra, elementary physics, and Latin prose.

SEC. 2.—Graduates or matriculants of reputable colleges or high schools of the first grade, or normal schools established by State authority, or those who may have successfully passed the entrance examination provided by the statutes of the State of New York, shall be exempt from the requirements of Section 1.

SEC. 3.—Students conditioned in one or more of the branches enumerated as requirements for matriculation shall have time until the beginning of the second year to make up such deficiencies; provided, however, that students who fail in any of the required branches in this second examination shall not be admitted to the second course.

SEC. 4.—Colleges granting final examination on elementary subjects to junior students shall not issue certificates of such final examination, nor shall any member of this Association confer the degree of Doctor of Medicine upon any person who has not been first examined upon all the branches of the curriculum by the Faculty of the College granting the degree.

SEC. 5.—Candidates for the degree of Doctor of Medicine shall have attended three courses of graded instructions of not less than six months each in three separate years.

SEC. 6.—Students who have matriculated in any regular college prior to July 1, 1892, shall be exempted from these requirements.

NOTE:—Colleges belonging to this Association are designated by an asterisk. (*)

THE SOUTHERN MEDICAL COLLEGE ASSOCIATION.

The Southern Medical College Association makes the following requirements, viz.:

Every student applying for matriculation must possess the following qualifications:

He must hold a certificate as the pupil of some known,

reputable physician, showing his moral character and general fitness to enter upon the study of medicine.

He must possess a diploma of graduation from some literary or scientific institution of learning, or certificate from some legally constituted high school. General Superintendent of State Education, or Superintendent of some County Board of Public Education, attesting the fact that he is possessed of at least the educational attainments required of second-grade teachers of public schools. Provided, however, that if a student, so applying, is unable to furnish the above and foregoing evidence of literary qualifications, he may be permitted to matriculate and receive medical instruction as other students, and qualify himself in the required literary departments, and stand his required examination, as above specified, prior to offering himself for a second course of lectures.

The foregoing certificate of educational qualifications, attested by the Dean of the medical college attended, together with a set of tickets showing that the holder has attended one full course of medical lectures shall be essential to attendance upon a second course of lectures in any college belonging to the Southern Medical College Association.

(1), 189—
Dean of Medical Department of University of Tennessee—Nashville Medical College:

DEAR SIR—Mr., of, is a gentleman of good moral character. I recommend that he be allowed to enter upon his medical studies in your college. He has been my pupil months.

Yours,
[Sign here]

(2), 189—
Dean of Medical Department of University of Tennessee—Nashville Medical College:

DEAR SIR—I have examined Mr., of, and find his scholastic attainments equal to those requisite for a second-grade teacher's certificate in our public schools.

Yours,
.
Supt. of Pub. Instruction.

NOTE:—Colleges belonging to this Association are designated by reference mark. (+)

ALBANY MEDICAL COLLEGE.*

MEDICAL DEPARTMENT OF UNION UNIVERSITY, 1894-95.

Three years strictly graded course: Instruction by lectures, recitations, clinics, laboratory work and practical demonstrations and operations.

Fees: Matriculation \$5; lectures, \$100 (perpetual ticket for three or more courses, \$200; dissection, \$10 (material free); laboratory courses in chemistry, histology, and in pathologic anatomy, each, \$10; graduation fee, \$25.

Hospital Advantages—Albany Hospital, St. Peter's Hospital, Child's Hospital, Albany County Hospital, Eye and Ear Infirmary, and their Dispensaries are available for clinical purposes, to students. The regular fall session commenced Tuesday, Sept. 25, 1894, and closes April 17, 1895.

Various prizes are awarded at the close of the term to meritorious students (see catalogue for particulars). Appointments to positions upon the House Staff of the Albany and St. Peter's Hospitals are made by competitive examination, open to the graduating class of the College.

Commencement occurs April 16, 1895. The annual meeting of the Alumni Association held on that day. For catalogue of the College or further information, address Willis G. Tucker, Registrar, 4 Lancaster Street, Albany, N. Y.

Thomas Hun, M.D., LL.D., Dean; Joseph W. Russell, President.

Professors: Albert Vander Veer, Maurice Perkins, John Milton Bigelow, Lewis Balch, Samuel Baldwin Ward, James Peter Boyd, Willis Gaylord Tucker, William Hailes, Cyrus Strong Merrill, Franklin Townsend, Jr., Frederick Colton Curtis, Henry Hun, Samuel Roseburgh Morrow, Joseph Davis Craig, with the assistance of a corps of lecturers, instructors and clinical assistants.

BELLEVUE HOSPITAL MEDICAL COLLEGE.

NEW YORK.

The collegiate year embraces a winter session and a spring session. The winter session for 1894-5 will begin on Monday, Sept. 24, 1894, and continue for twenty-six weeks. During this session there is a vacation from December 24, at noon to January 1, inclusive, and from noon the day before Thanksgiving to the following Monday morning. There are no lectures on February 22 and on Election Day.

The recitations, lectures and clinics for the spring session will begin Monday, March 25, 1894, and continue for twelve weeks. As heretofore, attendance on the winter session only is required for graduation. During the spring session clinical lectures and didactic lectures on special subjects are given by members of the Faculty and others. The lectures and clinics are free to those who are matriculated for the spring and the following winter sessions.

PRELIMINARY EDUCATION.

Medical Student Certificates.—Students beginning the study of medicine or coming to New York to continue their studies should be provided with Medical Student Certificates issued by the Regents of the University, which must be filed with the Secretary of the College before the final examination.

RESOURCES FOR CLINICAL INSTRUCTION.

Bellevue Hospital receives annually between five and six thousand patients. Medical and surgical cases of all kinds are admitted, except cases of contagious diseases.

The City Hospital on Blackwell's Island receives annually between eight and ten thousand patients. A considerable number of the patients admitted into this Hospital are affected with venereal diseases.

The Bureau of Medical and Surgical Relief for Out-Door Poor is in the College building and furnishes most of the cases for the clinics held in the College Lecture Room. The number of new patients treated in this department in 1893 was 42,959.

RECITATIONS.

First- and second-year students are required to attend recitations on materia medica and therapeutics, physiology, anatomy and chemistry.

Third-year students are required to attend recitations on practice of medicine, surgery, obstetrics, etc.

First-year students and second-year students are examined in separate sections. The third-year class is divided into two sections. Each section will be examined once a week on the subjects of the lectures by the professors and their assistants.

REQUIREMENTS FOR GRADUATION.

Students admitted to the College as third-year

students may become candidates for graduation under the following conditions:

1. Candidates must have followed the regular curriculum for the third year and must have reached the age of 21 years, and file satisfactory certificates of good moral character and of three years' study of medicine, which period of study may include the time spent in attending lectures.

2. Candidates matriculated at the College after the regular session of 1893-94 will be required to file a certificate from a regular physician in good standing or from a recognized institution that they have attended at least six cases of labor, as one of the requirements for graduation.

FEES AND REGULATIONS FOR THE THREE YEARS' COURSE.

The matriculation fee, to be paid before any other tickets are issued, is \$5 for each year. The fee for each of the three courses required and for each additional course is \$150. The tickets for dissection, to be taken during the first and second years, are \$10 for each year. The ticket for the regular laboratory course, to be taken during the third year, is \$20. The fee for the examinations at the end of the second year is \$15. The fee for the final examinations is \$15. The fee for final examinations for those who have their first two courses at other colleges is \$30.

Professors and Instructors: William T. Lusk, President; Austin Flint, Secretary; A. Alexander Smith, Frederic S. Dennis, Lewis A. Sayre, Hermann M. Biggs, Joseph D. Bryant, R. Ogden Doremus, Austin Flint, Jr., Charles A. Doremus, Henry D. Noyes, J. Lewis Smith, Francke H. Bosworth, Beverley Robinson, Samuel Alexander, Carlos F. Macdonald, Edward K. Dunham, Edward B. Dench, John A. Fordyce, D. Hunter McAlpin, Jr., William P. Northrup.

Lecturers and Instructors: Leroy Milton Yale, Thomas H. Burchard, John E. Weeks, Joseph N. Henry, Henry M. Silver, J. F. Erdmann, G. D. Stewart, L. M. Silver, R. J. Carlisle, R. Kalish, R. H. Sayre, W. E. Studdiford, G. P. Biggs, W. J. Pulley, J. H. Huddleston, H. A. Hanold, J. H. Titterington, J. A. Mandel, D. W. Hunter, J. C. Lester, H. R. Purdy, E. Harrison Griffin, D. S. Spellman, F. M. Jeffries, Joseph V. Standish, clerk.

BEAUMONT MEDICAL COLLEGE.*

ST. LOUIS, MO.

This College offers to its students a three years' graded course. Each session extends through six months, beginning on September 10. A spring course of two months follows the winter session.

The College has well equipped physical, chemical, physiologic, histologic and pathologic laboratories. The dissecting room contains all modern conveniences and work is done, for the most part, by daylight. A large museum illustrating normal, morbid and comparative anatomy together with numerous charts and preparations furnish illustrations for the lectures. (In all of which the work is compulsory for students.)

Clinical advantages are offered by the Missouri Pacific Railroad Hospital, the Alexian Brothers Hospital, St. Mary's Infirmary and a large out door college clinic, including an out-door obstetric department. All of these Hospitals are under the exclusive control of members of the Faculty. The St. Louis City Hospital, Female Hospital and City Insane Asylum and Poor-House, together with many private hospitals with which members of the Faculty are connected are utilized as occasion offers for clinical instruction.

The Faculty consists of twenty professors, six lecturers and a corps of twenty-one medical assistants.

The fees are: For the Junior year \$50; for the Intermediate year \$60; for the Senior year \$75. The laboratory fee is \$10 and the matriculation fee \$5. No charge is made for hospital tickets, anatomic material, laboratory supplies or diploma.

The requirements for admission are those exacted by the various State Boards of Health.

W. B. Outten, M.D., Dean.

BARNES MEDICAL COLLEGE.*

ST. LOUIS, MO.

A three years' graded course of instruction. Session of 1894-95 commenced Sept. 10, and continues six months. New building, located in heart of the city and five blocks from the new depot; modern in appointments; ample clinical and laboratory facilities; course of study conforms to the requirements of all health boards; tuition moderate. Special terms to sons and brothers of physicians and sons of the clergy; to graduates in pharmacy and dentistry. Largest college west of the Mississippi.

C. H. Hughes, M.D., President. Pinckney French, M.D., Secretary.

BIRMINGHAM MEDICAL COLLEGE.

BIRMINGHAM, ALA.

This College requires an attendance of three terms of six months each before application for graduation; and a general average of 75 per cent. for a degree. The school has good hospital advantages and abundant clinics, and furnishes splendid facilities for the study of medicine. There is an excellent building well arranged for medical instruction, and well equipped laboratories.

Faculty: W. H. Johnston, Dean; H. N. Rosser, J. H. McCarty, J. D. S. Davis, W. E. B. Davis, B. G. Copeland, J. A. B. Lovett, T. M. Allen, Cunningham Wilson, L. G. Woodson, R. M. Cunningham, George S. Brown, J. C. LeGrand, E. D. Bondurant, Demonstrators of Anatomy: W. R. Luckie, G. C. Chapman, E. L. Morris.

Special Lecturers and Clinicians: E. H. Sholl, J. W. Sears, A. B. Burke, G. W. Macon.

Clinical Assistants: D. F. Tally, Ella E. Barnes, F. E. Nabers, W. H. Wilder, R. K. Smith, C. A. Merrill, W. W. Ransom.

BALTIMORE MEDICAL COLLEGE.*

BALTIMORE, MD.

Preliminary fall course begins September 1; regular winter course begins October 1.

Excellent teaching facilities; magnificent new college building; superb lecture halls; large and completely equipped laboratories; capacious hospital and dispensary; lying-in department for teaching clinical obstetrics; large clinics.

David Streett, M.D., Dean.

COLLEGE OF PHYSICIANS AND SURGEONS.*

CHICAGO.

Has recently lengthened its term to seven months and requires attendance upon four annual courses of instruction with a preliminary matriculation examination in English, Latin, physics and mathematics. This examination is open to the public and is held at the College building on the Saturdays preceding the opening of the winter and spring terms. Attendance at the spring term of three months is optional. Special attention is given during the first and second years to thorough laboratory instruction which is conducted in the new Laboratory Building of the College. Three surgical, two medical and a venereal, neurologic and dermatologic public clinics are held each week. Special clinics are also held in the County

Hospital for the exclusive benefit of the students connected with this College. In addition to these general clinics small classes are instructed in fourteen clinic rooms in the West Side Free Dispensary, which occupies the first floor of the College building, where an average of 20,000 patients a year are prescribed for.

The students of this College are admitted to the clinics and autopsies of the County Hospital, and the clinical advantages of the Illinois Charitable Eye and Ear Infirmary; the Woman's Hospital, the Masonic Hospital, the Chicago Hospital, and St. Elizabeth's Hospital are all open to the students of this College.

The fees average about \$100 per year.

Faculty: William E. Quine, Prest.; William Allen Pusey, Sec'y; F. E. Waxham, Daniel A. K. Steele, A. W. Harlan, Albert E. Hoadley, Oscar A. King, Henry Parker Newman, Bayard Holmes, Weller Van Hook, John H. Curtis, G. Frank Lydston, Robert H. Babcock, T. Melville Hardie, Boerne Bettman, J. M. G. Carter, Ludvig Hektoen, W. S. Christopher, John B. Murphy, Henry T. Byford, Moreau R. Brown, W. Augustus Evans, Dudley C. Trott, T. A. Davis, J. A. Wesener, Henry L. Tolman, F. R. Sherwood, Adolph Gehrmann, J. N. Bartholomew, Henry Palmer, John A. Benson, C. M. Burrows, Henry F. Lewis, Ira D. Isham, W. F. Eckley, Edward C. Seufert, G. W. Post, George F. Butler.

CHATTANOOGA MEDICAL COLLEGE.†

MEDICAL DEPARTMENT U. S. ORANT UNIVERSITY, OF ATHENS AND CHATTANOOGA.

Has a Faculty corps of twenty-eight active instructors, covering every specialty of medicine and embracing much in collateral sciences. Course, a *graded* three-year, which is compulsory, and a four-year course strongly urged upon students, but optional as yet.

Annual session of six months, without any preliminary session whatever, commencing about September 15, and closing the following March about same day of month. Sixth annual term opened Sept. 12, 1894.

The usual facilities of medical colleges for practical anatomy, dispensary and bedside clinics and general practical training, including all requisite laboratories of chemistry, physiology and histology, microscopic technique, pathology, bacteriology, surgery, pharmacy, obstetrics, etc. The closest attention is paid to detailed training of each individual pupil in all manipulative matters.

Requirements of admission and graduation those of the Southern Medical College Association, of which this school is an original member.

Fees, total tuition Freshman year, \$85, Junior year, \$80, Senior year, \$75. Examination fees, \$30, prior to graduation.

Faculty and Professors: Bishop I. W. Joyce, Chancellor; E. A. Cobleigh, Dean; R. L. Vaught, G. W. Drake, W. C. Townes, W. T. Hope, H. Berlin, G. A. Baxter, J. R. Rathmell, W. G. Bogart, Frank Trester Smith, N. C. Steele.

Demonstrators: G. M. Ellis, J. B. Lee, A. A. Ellis.

Lecturers: T. C. V. Barkley, C. Holtzclaw, E. M. Eaton, W. C. Heskett, Y. L. Abernathy, G. R. West, W. L. Gabagan, W. L. Nolen, R. P. Johnson, E. L. Jones, Harry Wise, C. H. Smith, H. B. Case, F. B. Stapp, W. M. Bogart, E. M. Murphey, F. L. Case.

CHICAGO POLICLINIC AND HOSPITAL.

CHICAGO, ILL.

A clinical school for practitioners of medicine, 174-176 Chicago Avenue.

The Chicago Policlinic organized in 1886 for the purpose of giving post-graduate medical instruction, now occupies its own six-story, double building, costing over \$100,000, thus providing ample space and

every facility for treating and demonstrating the ample clinical material which is supplied by this city of a million and a half inhabitants.

The building contains, in addition to the large clinical rooms, laboratory, dissecting rooms, etc., a model hospital of a hundred beds provided with every facility for modern surgical and medical work.

The great need and value of post-graduate instruction has long been recognized. The unlimited supply of clinical material in Chicago, with its wealth of hospitals, infirmaries, dispensaries and medical schools, enables the Faculty of this institution to furnish practical instruction on a scale as wide as that found abroad, and to offer unsurpassed advantages to American physicians.

Instruction continues throughout the year in courses of one, two, three, six or twelve months. Fees according to length of course, and physicians can enter at any time.

In constructing and furnishing this institution, the Faculty feels that it has spared neither money nor pains to make a model hospital and school.

Faculty: Truman W. Miller, President; Christian Fenger, Nicholas Senn, John B. Hamilton, Wm. T. Belfield; Fernand Henrotin, Secretary; Moreau R. Brown, Corresponding Secretary; John H. Chew, Treasurer; R. D. MacArthur, A. E. Hoadley, J. Elliot Colburn, George F. Fiske, Malcolm L. Harris, Henry Hooper, James H. Etheridge, Henry Banga, Jos. M. Patton, Archibald Church, G. Fütterer, F. C. Hotz, E. Fletcher Ingals, W. S. Christopher, Henry G. Anthony, E. M. Smith, C. S. Bacon, J. H. McBride, E. L. Holmes, Henry M. Lyman, Otto L. Schmidt, W. H. Wilder, H. B. Favill.

COLLEGE OF PHYSICIANS AND SURGEONS.*

BOSTON, MASS.

Hospitals and Dispensaries are directly connected. Incorporated 1880. Power to confer Degree of Doctor of Medicine by special act of Legislature. Four years recommended, three years required. Graded course. Entrance examination third Tuesday in September. Regular session begins the following day. Beneficiary fund limited to a few worthy persons. Fees \$125 yearly. Material at cost. Graduation fee \$30. Instruction in single branches at reasonable rates. Special evening classes for those unable to attend all of the lectures during the day. Fee for entire three years' course when paid in advance \$275.

MATRICULATION REQUIREMENTS.

In accordance with the recommendation of the Association of American Medical Colleges their requirements have been adopted:

Students conditioned on any branches of the matriculation examination will be allowed to enter on the regular course, but before graduation all conditions must be removed.

Hon. Edward Avery, President; Augustus P. Clarke, Dean; Rev. David Shurtleff, Registrar.

COOPER MEDICAL COLLEGE.

SAN FRANCISCO, CAL.

Thanks to the generosity of its President, L. C. Lane, this school is amply provided with facilities for instruction. Its handsome buildings, its hospital, just completed; and its endowments and funds represent half a million of dollars. An educational qualification or an examination is required before admission. Four courses of lectures are necessary to complete the curriculum, except for such as have through collegiate education or otherwise, accomplished the work required for the first year. The regular or long

term begins June 1, and continues six months. The short term begins February 1, and continues three months. The graduation exercises take place in December. As will be observed the regular course is held in the summer and autumn. The objections to the summer which obtain on the Atlantic border are entirely unknown here. The dryness of the atmosphere prevents decomposition; thus dissecting can be carried on with far more comfort and satisfaction than during the winter or summer months in other climates. Excellent clinical facilities are offered at the City and County Hospital and at the extensive College Dispensary. The Lane Hospital, adjoining the College, now just completed, will accommodate a hundred patients. A fee of \$130 is charged for each of three courses: Matriculation fee \$5; demonstrators' fee, \$10; graduation fee \$40. At the last graduating exercises 42 received the degree; the present graduating class numbers 70; the total matriculates, 226.

Henry Gibbons, Jr., Dean; Wm. Fitch Cheney, Secretary. Faculty: L. C. Lane, President; C. N. Ellinwood, Adolph Barkan, Jos. H. Wythe, Henry Gibbons, Jr., Jos. O. Hirschfelder, Clinton Cushing, W. D. Johnston, R. H. Plummer, Chas. H. Steele, Albert Abrams, H. E. Sanderson, A. M. Gardner, Chas. E. Farnum, G. F. Hanson, Wm. Fitch Cheney, A. W. Hoisholt, Chas. M. Fisher, Stanley Stillman, Emmet Rixford, D. F. Ragan, R. L. Rigdon, W. M. Swett.

COUNCIL BLUFFS MEDICAL COLLEGE.*

COUNCIL BLUFFS, IOWA.

Two commodious and well equipped hospitals within easy reach of the College afford facilities for clinical instruction.

Medical and surgical clinics are held daily.

The County Insane Hospital furnishes clinical instruction in diseases of the mind.

The curriculum is complete and every branch of instruction is under careful and constant supervision.

Work in the histological, pathological and chemical laboratories, which are well supplied with all modern appliances, is made a prominent part of the College instruction.

The standard for admission is in accord with the requirements of the Association of American Medical Colleges.

The qualifications for graduation are four years of study including three courses of lectures of seven months each.

The fees for the first year are: Matriculation (paid but once) \$5; general ticket for all lectures, dissections (including material) and laboratory work, \$60; fees for the second year are: General ticket for all lectures (including material) laboratory work and hospital clinics, \$60; examination (compulsory) \$10. For the third year: General ticket for all lectures (clinical and didactic) and all practical third year work, \$65; final examination (not returnable) \$15; graduation, no charge.

Communications should be addressed to the Dean, Donald Macrae, M.D.

CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS.*

INDIANAPOLIS, IND.

Sixteenth session began Sept. 19, 1894, and continues six months. Three years' graded course. Increased facilities. Excellent clinical advantages. Graduates of colleges having preparatory medical course and students giving evidence of having com-

pleted work equivalent to such course will be admitted to advanced standing. Professors' tickets, \$40.

Samuel E. Earp, M.D., Secretary.

DARTMOUTH MEDICAL COLLEGE.

HANOVER, N. H.
(*Ninety-Ninth Year.*)

Recitations—Winter and Spring. Lectures—Summer and Fall.

Recitation Term begins January 2, ends June 20, 1895; Lectures begin July 16 and end November 21, 1895. Hitchcock Memorial Hospital. Excellent place for study.

For circular address Dr. C. P. Frost, Hanover, N. H.

DENVER MEDICAL COLLEGE.*

MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER.
(*Oldest Medical College in Colorado.*)

The fourteenth regular annual session will begin Sept. 12, 1894, and will continue seven months. Every opportunity is given students of acquiring a scientific and complete medical education. The laboratories of chemistry, histology, and physiology are complete in all details. A large and well equipped clinical department affords students ample clinical instructions. Especial attention is paid to clinical instruction, exercises being held at the School Dispensary and at the several hospitals.

Fees: Matriculation fee (annually) \$5; tuition fee, \$75; graduation fee (not returnable) \$30; demonstrators' ticket, including material \$10; chemical laboratory ticket \$10.

E. R. Axtell, M.D., Assistant Sec'y., Barth Block.

DETROIT COLLEGE OF MEDICINE.*

DETROIT, MICH.

The medical department of the Detroit College of Medicine gives a three years' course of medical study of seven months in each year. A large and commodious new building renders great service in the giving of thorough lecture and laboratory courses. Connected with the College are St. Mary's, Harper, and St. Luke's Hospitals, together with St. Mary's Hospital Free Dispensary, Harper Hospital Polyclinic, the Children's Free Hospital and Harper Hospital Contagious Disease Building. In these institutions students are thoroughly drilled in clinical medicine and surgery. The advanced student is supplied with cases of obstetrics in the House of Providence and in the Woman's Hospital. Many opportunities are also given the student for practical work through the courtesy of the officers connected with the Board of Health, Poor Commission, etc.

The Faculty consists of twenty professors, eleven additional clinical professors, and twenty-six instructors and assistants.

The lecture fees are \$50 per year. The diploma fee is \$30. The total fees for the three years, including all laboratory fees are \$285.

H. O. Walker, M.D., Secretary.

ENSWORTH MEDICAL COLLEGE AND HOSPITAL.*

ST. JOSEPH, MO.

The Ensworth Medical College and Hospital, located at St. Joseph, Mo., is an endowed institution, with a full corps of experienced teachers. Its course of instruction embraces three terms of six months each, and is properly equipped in its several departments. Its requirements precedent to matriculation

are those prescribed by the Association of American Medical Colleges and the State of Missouri. It affords the special advantage of an abundant out-door clinic during the sessions at the Hospital, as well as those afforded by the City Hospital and State Lunatic Asylum. The tuition fee is \$50 for each session. In honor of Mr. Ensworth, the school grants a scholarship to each Congressional District of the State. The Ensworth has under its direct control the largest hospital in the Central West.

H. Christopher, M.D., Dean.

FORT WAYNE COLLEGE OF MEDICINE.*

FORT WAYNE, IND.

The College was organized in 1879, the present term of 1894-5, being its sixteenth session. The length of the term is six months with a three years' graded course. After the present session a four years' graded course will be required. The expense for fees in all the departments will be about \$75 per year.

Clinics are held in the St. Joseph and Hope Hospitals where there is an abundance of clinical material, both surgical and medical. The special advantages are, that in these Hospitals many capital operations are made in the presence of the students, the Seniors being assistants.

The College has fifteen professors, and five lecturers.

C. B. Stemen, M.D., Dean.

GROSS MEDICAL COLLEGE.*

DENVER, COLO.

The Gross Medical College is in its eighth year. Its term extends over a period of seven months, and three regular courses of lectures are necessary for graduation. The requirements for admission are in strict accord with those of the Association of American Medical Colleges.

There is a commodious and well equipped College building, with which is connected a free dispensary.

The special claim is in the advantages gained by practical clinical instruction. Our students are divided into three classes, and the work is systematically graded. Our Senior class, which numbers ordinarily from fifteen to twenty-five, is divided into small classes for section work in the Dispensary, under competent instructors.

Besides clinical instruction drawn from our free Dispensary, where there is received from 1,500 to 2,000 visits per month from patients, there are four excellently conducted hospitals in Denver, upon the staffs of which many of the professors have appointments. These hospitals are utilized to the fullest extent for teaching.

Faculty: Thomas Hayden Hawkins, Pres't; John Boice; Robert Levy, Sec'y; John Elsnor, William Harmon Buchtel, William Henry Davis, William John Rothwell, Robert Fields LeMond, George Fayette Wright, Henry Herbert Bucknum, Charles Franklin Shollenberger, Carey Kennedy Fleming, James William Exline, Mark Hiram Sears, Edward Curtis Hill, Edgar Parker Hershey, Neil Macphatter, Calvin Pickering Butler, William Fairman Bradner, Horace Granville Harvey, John William Higgins, David Hunt Ludlow, Moses Kleiner, Thomas Mitchell Burns, Chas. Jaeger.

GEORGETOWN UNIVERSITY, MEDICAL DEPARTMENT.*

Forty-fifth session opened Oct. 1, 1894, and will continue seven months. Instruction is given by lectures, recitations, clinical teaching, and practical demonstrations. In the subjects of anatomy, chem-

istry, physiology, hygiene, histology, pathology and bacteriology special practical instruction is given in well-equipped laboratories. Excellent and ample clinical facilities are furnished.

G. L. Magruder, M.D., Dean.

HOSPITAL COLLEGE OF MEDICINE,*

MEDICAL DEPARTMENT CENTRAL UNIVERSITY OF KENTUCKY.
LOUISVILLE, KY.

The Hospital College of Medicine, Medical Department of the Central University of Kentucky, is situated in new buildings; the City Hospital, of four hundred beds, is directly opposite. The next regular session of this College will begin Jan. 2, 1895, and end June 18. The course of instruction is conducted by ten professors, and twenty tutors, demonstrators, and assistant instructors.

Freshmen are required to present evidences of good moral character, and satisfactory preliminary education, in documentary form. The course of study is graded and divided into three annual terms of six months each.

Candidates for the degree of Doctor of Medicine must be 21 years old, of good moral character, must have studied medicine four years, including preliminary reading with a preceptor, and have attended three complete courses of lectures, no two of which shall have been taken within a period of twelve months, and the last of which shall have been in this institution. He must have dissected during at least two sessions, and have attended two courses of clinical and hospital instruction.

Regular attendance upon the daily exercises is obligatory upon the members of the class. The course of study at this College, in addition to the usual didactic lectures and quizzes, embraces two clinics every day in the College building; not less than four clinical lectures every week at the City Hospital, besides bedside instruction in the wards of the City Hospital and College Infirmary. The College Hospital or Infirmary has accommodations for thirty patients, and is used chiefly for the accommodation of such cases of surgical injury from the out-door department, as require detention in the Hospital. All the members of the Senior class are required to take part in the clinical service in general medicine, surgery, diseases of the chest, diseases of children, venereal and skin diseases, diseases of the eye, ear and throat, and diseases of women, under the direct supervision of the professors and their adjuncts, in these several departments.

During the regular session, the clinical professors in this College have entire charge of the wards of the Hospital; the class being divided into sections suitable for the purpose, will be taken through the wards daily, during this portion of the term. Separate apartments are provided in the College for the reception and classification of the patients, who are received for treatment in the several departments, each especially equipped for the purpose.

Fees: Professors' fees, \$75. Practical anatomy, including material, \$12. Bacteriology and histology, laboratory fees, first year \$10. Chemical laboratory, second year, \$10. Surgical laboratory, \$10. Fee for final examination, (not returnable) \$30. Hospital fee required by the city, \$5. No fee is charged for intermediate examinations.

Faculty: John A. Larrabee, President; Dudley S. Reynolds, Frank C. Wilson, Samuel G. Dabney, Thomas Hunt Stuckey, John Edwin Hays, H. Horace Grant, Lewis S. McMurtry, P. Richard Taylor, Phil. F. Barbour.

JEFFERSON MEDICAL COLLEGE.

PHILADELPHIA.

The annual session of the Jefferson Medical College begins October 1, and continues over seven months. Preliminary lectures will be held from September 24.

COURSE OF INSTRUCTION.

The regular course is a graded three years' curriculum at college. It is so arranged that the student is trained in both the fundamental and practical branches of medicine. The instruction consists of didactic lectures, laboratory work, clinical lectures, ward classes, and practical demonstrations by the professors and instructors in each branch.

Didactic lectures are given in the Medical Hall on practice of medicine, surgery, obstetrics and gynecology, materia medica and therapeutics, chemistry, physiology, pathology, anatomy, medical jurisprudence and hygiene. In the laboratories special instruction is given in physiology, chemistry, pathology, histology, dissections, and major and minor surgery, with bandaging; while the work in the Hospital consists in clinics on medicine, surgery, obstetrics, gynecology, ophthalmology, laryngology, dermatology, diseases of children, orthopedics, neurology, genitourinary diseases, and otology, and in small ward classes taken to the bedside, or to the various special dispensaries.

The Hospital of the Jefferson Medical College provides a wealth of clinical material unequalled in America and in few places in Europe. It contains beds for 140 patients, which are constantly filled, and in the out-patient departments over three hundred cases are treated daily.

In order to meet the demands for ampler accommodations the Maternity Department has been removed to a separate building at 327 Pine Street. Here bedside instruction in midwifery is given to each member of the graduating class.

FOUR YEARS' COURSE.

All persons beginning their medical studies by matriculation after June 1, 1895, must take four annual courses.

REQUIREMENTS FOR ADMISSION.

To be admitted to the first-year class without examination the applicant must show a teacher's certificate or a diploma from some recognized literary or scientific school, or a certificate of having passed a college entrance examination, or a satisfactory certificate from the master of some academy or high school, or a certificate from the examiners of a county medical society. In the absence of such evidence of having acquired a suitable preliminary education the applicant must stand an examination in English and elementary physics at the College or at a distance, before some examiner appointed by the Faculty.

Entrance examinations, as a test of fitness for entering upon the study of medicine, will be held September 25 and October 3 and 14, at 11 A.M., and at other times by special arrangement.

Any student who has taken one or more courses in an accredited medical college, or two in a dental and pharmaceutical college, desiring to be graded as a second-year student on entrance, must stand an examination in inorganic chemistry, materia medica, physiology of nutrition (see studies of first year), and part of anatomy (osteology, syndesmology, and myology), unless he presents a satisfactory certifi-

cate of having passed in these branches. Doctors of Dentistry are received into this grade without examination.

Any student who has taken two or more courses at another accredited medical college desiring to be graded as a third-course student, must be examined in materia medica, physiology, anatomy, and chemistry on entrance, unless he presents a satisfactory certificate of having passed the final examination in these branches. Graduates of accredited medical colleges may be received into the third grade without examination, and after taking the third course in this institution will receive the degree of M.D., on passing an examination in therapeutics, surgery, practice of medicine, obstetrics, and gynecology. Graduates of veterinary surgery may be admitted into the third-year class in all branches, but will be required to pass an examination in human anatomy on entering, or at the end of the third-year, in addition to the third-year branches. They will also be required to dissect.

No student or graduate is admitted to the fourth year class without showing evidence of attendance on at least three courses of lectures and satisfactory evidence of having passed examinations on the subjects included in these years of study. Students who matriculate after June 1, 1895, will be required to take four annual courses.

EXAMINATION FOR THE DOCTORATE.

The examination for the degree of M.D. is held at the close of the term of lectures. The examination, conducted by the Faculty—each professor in his own branch will be written or oral, or both. Students failing to reach the standard exacted for the degree of Doctor of Medicine may be credited as having passed on those branches in which they have shown proficiency, and will not be required to stand a second examination on these branches should they apply again. The presentation of a thesis will not be required unless in competition for a prize. The candidates are examined in turn upon all subjects of the third year, except those candidates who have been previously examined and passed under regulations then existing.

The candidate for the degree of M.D. must present a certificate of good moral character, and be at least 21 years of age. He must have attended at least three regular sessions of lectures, no two of which shall have been in the same twelvemonth, and of which the last shall have been in this College, and the previous ones either here or in some regular college authorized to confer the degree of M.D., and in which anatomy, chemistry, materia medica and therapeutics, physiology and medical jurisprudence, surgery, practice of medicine, obstetrics, and gynecology are embraced in the curriculum. He must have attended two courses of clinical instruction and practical anatomy. Graduates of pharmacy and dentistry, to become candidates for graduation will be required to show certificates of at least two courses of practical anatomy or dissection, either at the Jefferson Medical College or some other accredited medical or dental college empowered to confer the degree of M. D., and D.D.S.

Students of dental colleges in which five months' winter session is held, and where full courses are given on anatomy, materia medica, physiology and chemistry, may become candidates after attendance

on two courses at such colleges, and the second- and third-year courses at the Jefferson Medical College, provided that in all four annual sessions be attended.

Students of colleges of pharmacy, where full courses are given on materia medica and chemistry, may become candidates after attendance on two such courses at such colleges, and on the second and third-year courses at the Jefferson Medical College including, however, two courses in anatomy and physiology.

Fees: Matriculation, paid once, \$5. First year, full course including laboratory work and dissection, \$140; dissecting material, per part, \$1. Second year, full course of lectures, including dissection and clinics, \$140; dissecting material, per part, \$1. Third year, full course, including laboratory work and clinics, \$140; operative surgery material, \$1. If dissections are taken in this year a fee of \$10 is required. No fee is charged for diploma when the last two years of study are spent in this College. Fourth year voluntary, full course, including special instructions, \$140. Students who do not take the last two years at the Jefferson Medical College pay a diploma fee of \$30 if they take degree in Medicine.

Professors: J. M. DaCosta, Roberts Bartholow, Henry C. Chapman, John H. Brinton, Theophilus Parvin, James W. Holland, William S. Forbes, William W. Keen, Morris Longstreth, H. A. Hare, James C. Wilson, E. E. Montgomery, Wm. Thomson, J. Solis-Cohen, Henry W. Stelwagon, Augustus Wilson, E. E. Graham, F. X. Dercum, Geo. De Schweinitz, Orville Horwitz, W. M. Late Coplin, W. J. Hearn, E. P. Davis, S. MacCuen Smith.

JOHN A. CREIGHTON MEDICAL COLLEGE.

OMAHA, NEB.

The John A. Creighton Medical College, of Omaha, Neb., began its regular session Sept. 25, 1894. The length of term is seven months and the course is four years. The requirements for admission are: 1, a certificate of good moral character from a reputable physician; 2, a diploma or certificate from a recognized college, school of science, academy, normal or high school, a teacher's certificate or other evidence, equivalent to the foregoing, of satisfactory preliminary education; 3, a satisfactory examination equal to the above.

The Creighton Medical College is not dependent upon its faculty or fees from students for its existence and equipment; but upon a fund sufficiently large to place it among the better institutions of the country. Its salaried teachers' list is already equal to that of most schools and exceeds the majority. It is not a stock institution. The chemic, histologic, pathologic and bacteriologic laboratories are supplied with the best apparatus obtainable. The course is thorough and complete. Clinically the school is especially favored. There are about two hundred thousand people in Omaha and vicinity from which number clinical material may be obtained. Creighton College has the exclusive use of St. Joseph's Hospital—an institution of 300 beds and of the most approved architecture. College clinics are held at the Hospital on three days of each week. An out-door clinic is held at the College building every morning at 9 o'clock.

The fees are as follows: Matriculation, \$5; general ticket, \$45; hospital ticket, \$10; dissecting ticket, \$5; laboratory tickets, \$10; graduation fee, \$25.

D. C. Bryant, M.D., Secretary Creighton Medical College.

KENTUCKY SCHOOL OF MEDICINE.†

LOUISVILLE, KY.

This school was organized in 1850 as the direct descendant of the Medical Department of Transylvania University situated at Lexington. The school requires attendance upon three graded courses of lectures of six months each in three separate years and a four years' course of study.

The importance of laboratory and clinical work is emphasized, and the school is prepared to do the most modern work in the laboratories of histology, practical anatomy, chemistry, physiologic chemistry, pharmacy, bacteriology, pathology and surgery.

The Faculty have erected a large hospital adjoining the College which contains a commodious Dispensary department, and every modern convenience for aseptic and antiseptic work. The students of the College are also required to attend the clinical lectures at the City Hospital during the entire term, and for one-half of the term the City Hospital is under the control of the Faculty of the Kentucky School.

REQUIREMENTS FOR ADMISSION.

The applicant must have a diploma from a literary, scientific, or high school; a certificate of having passed a college entrance examination, a teacher's certificate, or a certificate from a county or State Superintendent of Public Instruction, testifying that his literary attainments qualify him for a teacher's certificate.

REQUIREMENTS FOR GRADUATION.

The applicant for the Degree of Doctor of Medicine must be 21 years old and of good moral character. He must have studied medicine four years, and have attended three courses of lectures, of six months each, in three separate years, the last of which must have been in this College. He must have dissected during two sessions, and have attended two courses of clinical instruction. He must have attended one course of practical work in each of the laboratories of chemistry, histology, pathology, bacteriology and surgery. He must furnish to the Dean satisfactory evidence of having complied with the above requirements. He must be regular in attendance upon lectures, and pass a satisfactory written or oral examination upon all the branches taught in the school.

The fees and requirements are as follows: Matriculation \$5; professors' \$75; final examination \$30. The fee for each of the laboratory courses: Anatomy, chemistry, histology, pathology, bacteriology, surgery, etc., is \$10.

KEOKUK MEDICAL COLLEGE.*

KEOKUK, IOWA.

The regular fall and winter session opened Sept. 4, 1894, and will continue for six months.

The Faculty is composed of experienced medical teachers. Clinics regularly at St. Joseph's Hospital.

A ten weeks' reading and recitation course following the regular winter session is provided.

Fees: For regular session: Matriculation, \$5; lecture fees, including hospital ticket, \$28; graduation fee, \$30. Material at cost.

J. A. Scroggs, M.D., Secretary; T. J. Maxwell, M.D., Corresponding Secretary.

LONG ISLAND COLLEGE HOSPITAL.

BROOKLYN, N. Y.

The Long Island College Hospital was organized

for the purpose of practically uniting a Medical School and Hospital.

The success of the system depends mainly on two important facts:

1. The Hospital and Dispensary, in which 17,797 patients were treated in 1893, are under the immediate control of the Regents, and are, therefore, available at all times for practical instruction.

2. The courses of instruction are given in the Hospital buildings, so that the student, without loss of time, is brought in direct contact with patients, not only in the amphitheater, but also in the wards of the Hospital.

Great prominence has always been given to clinical teaching in this institution, which was originally organized for the purpose of fully maturing and carrying out practical bedside instruction. From the commencement of the collegiate year to its close the student is constantly brought in contact with disease and accident. Elementary and didactic instruction are thus daily supplemented by the practical application of the principles taught in the general lecture.

The Hoagland Laboratory, is available to the students of the College. This laboratory fully meets the demand for practical instruction in histology, pathology and bacteriology. Thorough practical instruction is given in these branches. Each student is made familiar with the use of the microscope in the investigation of disease, and with the methods to be employed in the recognition of the known germs of disease, and thus is enabled to make diagnoses which without these means would be impossible.

Under competent instructors, sections of the class are thoroughly drilled in physical diagnosis. The wards of the Hospital and the Dispensary furnish ample material for complete instruction in this branch of medical science.

Patients having wounds, fractures or dislocations, admitted to the Hospital during the session of the College, are brought into the amphitheater, examined, commented on, and treated in the presence of the class, by the Professor of Operative and Clinical Surgery. Subsequently, in the wards of the Hospital, these patients are visited by the Professor, accompanied by students of the Senior class, to whom the changes that have occurred in the cases in the meantime are explained and illustrated.

The Professor of Operative and Clinical Surgery performs the various operations on the cadaver in the presence of the class. Each step of the operation is carefully explained, and then the operation is performed and demonstrated in such a manner as to impress it on the mind of the student.

Senior students in small sections attend all labors in the Lying-in Department of the Hospital. The phenomena and management of labor are demonstrated, and the students participate in the conduct of the cases, making abdominal and vaginal examinations during their progress.

In addition to the course of didactic and clinical lectures in gynecology, the advanced students are present at all the important gynecologic operations performed in the Hospital, including laparotomies and operations upon the cervix and perineum.

Furthermore, all the Senior students attend the clinics of the gynecologists of the Dispensary of the Hospital and are thoroughly drilled in the examina-

tion and treatment of the ordinary diseases of women.

The admission of Senior students to the Hospital, under the supervision of the clinical teachers, gives opportunities for the practical study of the diagnosis of disease, as well as for special bedside instruction in auscultation, percussion, minor surgery, dressing of fractures, speculum examinations, the phenomena of labor, etc.

The reading and recitation term begins at the close of the regular term, and continues into June. It is designed to thoroughly prepare the student for attendance on the lectures of the ensuing regular term. Clinical instruction for advanced students is continued during the reading and recitation term.

In connection with the College building is a Dispensary. The number of patients treated in the Dispensary during the year 1893 was 15,844.

Fees for the first regular term: Matriculation, \$5; lectures and clinics, \$100; practical anatomy ticket, \$5; use of anatomical material (dissection of entire body), \$7; practical normal histology, \$10; total, \$127.

Fees, second regular term: Matriculation, \$5; lectures and clinics, \$100; practical anatomy ticket, \$5; practical urine analysis, \$10; practical pathologic histology, \$10; total, \$130.

Fees, third regular term: Matriculation, \$5; lectures and clinics, \$100; graduation fee, \$25; total, \$130.

Fee for reading and recitation term is \$40.

Alex. J. C. Skene, President of College; Jarvis S. Wight, Dean of Faculty; Joseph H. Raymond, Secretary of Faculty; Frank E. West, Treasurer of Faculty.

LAVAL UNIVERSITY, MEDICAL DEPARTMENT.

QUEBEC.

The college year is divided into four years. The course comprises the following, divided into two sections, Primary and Final.

The Primary section comprises: Anatomy, descriptive and topographic, practical anatomy, histology, physiology, general pathology, hygiene. Students from the School of Arts are exempted from the following, which must otherwise be taken: General chemistry, medical chemistry, biologic chemistry, botany.

The Final section comprises a course in each of the following: *Materia medica*, general therapeutics, practical pharmacy, legal medicine, toxicology, theory of surgery, minor surgery, practice of surgery, gynecology, rhinology and laryngology, internal pathology and special therapeutics, pædiatrics, nervous diseases, mental diseases, diseases of the eye and ear, history of medicine, medical dentistry, a course in the external clinic and a course in the internal clinic, the gynecologic clinic, the clinic of nervous diseases, mental diseases and diseases of children, a course of toxicology and pathology of diseases of infancy.

For graduation as a Bachelor of Medicine the student must have followed the courses conformably to the rules during nine terms of three years and have successfully passed all the examinations of the nine terms. The language of the College is French. Fees, \$180 to \$216, and a diploma fee of \$5, \$8 and \$20 respectively for the Bachelor, Licentiate or Doctor's degree.

Faculty at Quebec: Charles-Eusèbe Lemieux, Doyen; Albert Marois, Secrétaire; Louis Joseph-Alfred Simard, Charles Verge, Laurent Catellier, Arthur Vallée, Michel-Joseph

Abern, Edwin Turcot, Michael-Delphis Brochu, Joseph-Francois-Xavier Lavoie.

Agrégés: Albert Marois, Siméon Grondin, E.-T.-Arthur Simard, P. Coote, E.-René Fortier.

Professors at Montreal: Jean-Philippe Rottot, Adolphe Lamarche, Adolphe Dagenais, Alfred-T. Brosseau, Norbert Fafard, Sévérin Lachapelle, Hugues-E. Desrosiers, Salluste Duval, A.-A. Foucher, W.-H. Hingston, L.-E. Desjardins, L.-P. Mignault, J.-P. Chartrand, L.-A. Demers, J.-J. Guerin, Emmanuel Persillier-Lachapelle.

MARION-SIMS COLLEGE OF MEDICINE.*

ST. LOUIS, MO.

The Marion-Sims College of Medicine which was organized in 1890, has met with much success. This has been due to the untiring energy of the Faculty, and to the disposition of its teachers to equip and maintain a medical institution fitted in line with the most advanced methods of medical instruction. Two years ago a hospital was built by the Faculty immediately adjoining the College, which has been a most valuable aid to the instruction in the institution. This hospital, known as the Rebekah Hospital, has afforded a great supply of clinical material. During the present year, sixty-five laparotomies have been performed in this institution, certainly indicative of its value. The school is well equipped with appliances of all kinds, necessary for instruction in medicine. Its chemic laboratory, its microscopic laboratory, and physiologic laboratory are modern and complete. The college dispensary is a large one, and is continually growing. The dental department has been added during the present year which bids fair to meet with the same success that the medical department has received. The length of the course is six months, and three courses are required as a condition to graduation. The fees are as follows:

Matriculation fee, (paid but once) \$5; entire lecture fee, (each year) \$50; final examination fee, (not returnable) \$25; dissecting ticket, \$10; single professor's ticket, (where the entire course is not taken) \$20; general ticket for sons and brothers of physicians, and sons of the clergy, \$25; lecture fee for three years, including matriculation, dissection and examination ticket, if paid in advance, \$150; hospital tickets free; clinic tickets free.

H. W. Loeb, M.D., Secretary, St. Louis, Mo.

MICHIGAN COLLEGE OF MEDICINE AND SURGERY.*

DETROIT, MICH.

Regular winter session opens Sept. 27, 1894.

The course of study required for the session of 1894-95 extends over three years, with a voluntary fourth year. The work is graded.

All clinics are held at the Detroit Emergency Hospital and Free Dispensary. Practical clinical and laboratory work is required of all.

Women are admitted upon the same terms as men. A separate dissecting room is provided for them.

Fees: Matriculation, annually, \$5; lectures, each term, \$50; anatomy, dissecting, each course, \$10; chemistry, each course, \$10; graduation fee, \$25; practitioners' course, all departments, \$50; single department, \$25; pharmacy department, full course, \$25; graduation, \$5. Optional course: Experimental therapeutics, \$10; physiologic, laboratory, \$10; surgical laboratory, \$10.

Wm. I. Hamlen, Secretary.

Faculty: Hal. C. Wyman, Dayton Parker, L. E. Maire, Edward W. Jenks, Zina Pitcher, Willard Chaney, Samuel Bell, Kenneth Gunsolus, Henry A. Chaney, D. L. Dakin,

W. R. Scurr, James S. Newell, Frank S. Hough, Arthur D. Holmes, A. Ahlborn, R. S. Linn, Geo. J. Dakin, Edward T. Milligan, M. V. Meddaugh, Caryl B. Storrs, R. J. Hamlen, Jas. A. Patton.

MEDICAL COLLEGE OF ALABAMA.*

MOBILE, ALA.

The twenty-ninth annual session of this institution will begin Oct. 12, 1894, and continue six months. The Faculty offer a curriculum that has been carefully and systematically graded, so as to conduct students in a judicious and logical order through the three sessions of study now required for graduation. The chemic, microscopic, surgic and pharmaceutical laboratories are fitted up in accordance with the most modern and advanced ideas, and afford ample and convenient facilities for the practical work exacted of each student in these departments. The dissecting rooms are large and well ventilated, and material for practical anatomy abundant. Medical and surgical clinics are held daily at the City Hospital and College Dispensary. Fees, including laboratory course, \$100 for each session. Diploma fee, \$25.

The genial winter climate of Mobile is peculiarly adapted to earnest uninterrupted mental work. The freedom of the city from epidemics, the refinement, culture and proverbial hospitality of its citizens, combine to make it most attractive as a dwelling place, while its constantly increasing commerce, railroad connections, its machine shops and rapidly multiplying mills and other industrial establishments add annually, a class to its population that increases the number and variety of diseases, and offers superior inducements and advantages to the earnest medical student. The requirements for matriculation and for obtaining the degrees are set forth in the Annual Announcement, which will be sent to any address upon application.

Geo. A. Ketchum, M.D., Dean, Mobile, Ala.

MEDICAL COLLEGE OF INDIANA.*

INDIANAPOLIS, IND.

Twenty-fourth regular term begins Oct. 2, 1894, and ends April 2, 1895. Matriculation, \$5; laboratory ticket, \$5; professors' tickets, \$40; demonstrator's ticket, \$10; graduation fee, \$25; hospital tickets, \$6. Clinics are given at the City Hospital, St. Vincent's Hospital, Bobb's Free Dispensary, City Dispensary and College Dispensary. Daily clinical instruction throughout the course. The clinical, histologic, pathologic and bacteriologic laboratories, dissecting rooms and museum are thoroughly appointed and complete, and no extra charges for same. The munificent gift of Dr. William Lomax, of Marion, Ind., added to the former resources and equipment of the College, enables the Trustees to construct and equip an ideal modern medical college which shall meet the most exacting demands for advanced, thorough medical education.

Franklin W. Hays, Secretary.

MEDICAL COLLEGE OF GEORGIA.*

MEDICAL DEPARTMENT UNIVERSITY OF GEORGIA, AUGUSTA, GA.

Sixty-third annual session. Three separate sessions of six months each.

All the public charities of the city of Augusta and vicinity, representing a population of more than 50,000 people, are under the control of the Faculty of the College. This includes a large out-door poor clinic; the new City Hospital located in the rear of the College building and having accommodation for

100 patients; and the Colored or Freedman's Hospital with room for 50 patients. A large and well lighted operating amphitheater has just been added to the new Hospital, and a morgue or dead-house has been built in the yard between the two buildings. This building has a capacity for 50 advanced students, and autopsies will be held at frequent intervals for the purpose of instructing students in pathology. The new biologic laboratory has been equipped with German microscopes of a superior order; thorough instruction in normal and pathologic histology is given. The City Hospital affords facilities for bedside instruction. This is carried out in all the departments of medicine, surgery, obstetrics and diseases of the eye, ear and throat. The fees are: Matriculation, (once) \$5; tickets, full course, \$75; practical anatomy, \$10; graduation (once), \$30.

Faculty: W. E. Boggs, Chancellor; Thomas R. Wright, Dean; George W. Pains, De Saussure Ford, Theodore Lamb, Wm. H. Doughty, Jr. George A. Wilcox, Eugene Foster, Jas. M. Hull, Thomas D. Coleman, Joseph E. Willet, Joseph Eve Allen, Henry C. Doughty, L. C. Spence, C. J. Montgomery, W. W. Battey, J. B. Morgan, R. C. Eve, F. Wohl, W. B. Crawford.

MEDICAL COLLEGE OF OHIO.*

CINCINNATI, OHIO.

The Medical College of Ohio was founded in 1819 by Dr. Daniel Drake, and annual courses of lectures have been delivered regularly since then. The seventy-sixth regular term opened September 27. The length of each term is six months, and attendance upon three annual courses of lectures is required. Beginning with those entering in the fall of 1895 attendance upon four annual courses will be demanded. This College was the first medical school in this country to establish a bacteriologic laboratory. In addition to this department, its pathologic, histologic and chemic laboratories are thoroughly equipped. The Cincinnati Hospital and the Hospital of the Good Samaritan (the latter under the sole medical control of the College) afford ample clinical material. These Hospitals are supplemented by a large Polyclinic at the College which averages two hundred cases per day; and clinics are held simultaneously in medical, surgical, throat, eye and ear, nervous, gynecologic and orthopedic cases, the classes being so subdivided as to bring the student in close contact with the patients.

MEDICO-CHIRURGICAL COLLEGE.*

PHILADELPHIA, PA.

The course extends over three years of time, a fourth year being added as optional, entitling those who take it to a special diploma *cum laude*. The course is so graded that the fundamental branches of anatomy, chemistry, physiology and kindred sciences are introduced the first year, and continued during the second, when the clinical and practical branches are also begun. In the third year the latter are completed and the various specialties introduced. The special branches are all taught fully, with the opportunity of a certain amount of election during the fourth year. The regular winter course opens the first Monday in October and extends into the third week in April. This is preceded by a preliminary session, extending over the entire month of September, during which time all the clinics are in full operation, and the dissecting rooms and laboratories are open, while lectures on the collateral sciences are delivered by members of the Faculty and the

lecturers connected with the College. Special attention is called to the practical bedside instruction in all the departments by the professors themselves.

The Philadelphia, Pennsylvania, St. Agnes, St. Mary and St. Joseph Hospitals, in addition to the Medico-Chirurgical Hospital, furnish clinical advantages to our students. The completely appointed laboratories in hygiene, chemistry, histology, pathology, bacteriology and operative surgery furnish unlimited instruction in the various branches. A new Maternity Hospital connected with the College offers the students unsurpassed advantages in the practical study of obstetrics.

Four resident physicians are selected by competitive examination from the graduating class to serve one year. A thorough system of quizzing is kept up by the professors themselves and their assistants upon all branches free of charge. The importance of this special feature can not be over-estimated. The fees for each year, including all practical work, \$140.

Fourth year free to those having taken three courses at this College.

All communications regarding the business of the College should be addressed,

Ernest Laplace, M.D., Dean, Philadelphia.

MEMPHIS HOSPITAL MEDICAL COLLEGE.†

MEMPHIS, TENN.

The Memphis Hospital Medical College was organized in 1880. Courses of instruction six months each, and graded. Clinical advantages good, two hospitals and two free dispensaries. Daily quizzes of ten or fifteen minutes, on the previous lecture, by each professor and daily quizzes of one hour each, by the Adjuncts, free of charge.

Requirements: The school is governed by the rules of the Southern Medical College Association.

For graduation: Three full courses of lectures occupying three years, requisite. Candidate must be 21 years old, and of good moral character.

Laboratory work: Building new and ample provision for laboratory departments. Laboratory instruction includes histologic, pathologic, bacteriologic training, chemic and pharmaceutic exercises, physiologic illustrations and operative surgery.

The number of matriculates for 1893-94, was 263.

Fees: First session \$75; second \$75; third \$95.

J. L. Sim, Dean.

MISSOURI MEDICAL COLLEGE.*

ST. LOUIS, MO.

The Missouri Medical College, now entering upon its fifty-fourth annual session, is the oldest medical institution west of the Mississippi. In the way of museum and laboratories it is well equipped. It occupies two spacious buildings, and is now erecting a third. The property is owned and controlled by the Faculty and is so entailed. A large and efficient corps of experienced teachers are responsible for the proper instruction of the pupils. It has a three-year graded course, each annual session being six months in length. The clinical advantages are very great; there were treated last year in the two Dispensaries connected with the College nearly 15,000 cases, and 900 operations were performed. It enjoys the exclusive privileges of St. Johns General Hospital; and with clinics at the City Hospital and other institutions with which the Faculty are connected leaves nothing more to be desired in this particular. Dur.

ing the last session each member of the Senior class was present at and assisted in two confinements at the Maternity. There are held weekly five clinics in general surgery, four in general medicine, two in children's diseases, two in gynecology and one or more in diseases of the eye, ear, chest and throat, and one each in neurology, dermatology and orthopedics. The number of pupils in attendance last session was 184, with 50 graduates. This school is a member of the American Medical College Association, and is in "good standing" with the Health Board of Illinois.

P. G. Robinson, M. D., Dean.

MIAMI MEDICAL COLLEGE.*

CINCINNATI, OHIO.

The Miami Medical College requires attendance upon three full winter courses of lectures, besides dissections, and a course each in laboratory work in inorganic chemistry, organic chemistry, histology, pathologic anatomy, and bacteriology. Daily clinics are given at the College building. There are clinics in medicine, surgery, gynecology, ophthalmology, laryngology, dermatology, diseases of children, etc. In the special clinics students of the advanced class are assigned to practical work for certain portions of the term, the classes rotating from one clinic to another.

The regular session begins about the first of October in each year and ends during the first week in April. A short spring course of six weeks supplementary to the winter's work is given, but attendance thereon is not compulsory.

Students of the College have access to the clinics of the Cincinnati Hospital, in the immediate vicinity, and to the Ophthalmic, Christ's, Children's, Presbyterian and Jewish Hospitals; as also to several private clinics and hospitals, with which members of the College Faculty are identified.

Obstetric cases are attended at their homes by members of the Senior class under the supervision of the director of the obstetric clinic. Public recitations, or oral examinations are conducted by assistants to the professors in the various departments. Private quiz classes can be formed, and will be conducted by junior members of the Faculty for stipulated terms.

Practical courses are given in bandaging, minor surgery, surgical operations on the cadaver, medical jurisprudence, with lectures on mental diseases.

The fees are as follows: First year, \$110; second year, \$100; third year, \$105. These fees are inclusive of laboratory tickets, matriculation, and graduation fees.

Joseph Eichberg, M.D., Secretary.

MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA.

COLLEGE OF MEDICINE, CHARLESTON, S. C.

Three years graded course. Good hospital advantages. Well equipped chemic, pathologic and bacteriologic laboratories. Modern dissecting room. Excellent teaching facilities and ample clinical material.

Every facility afforded for a thorough course of instruction by lectures, demonstrations, quizzes, laboratory work and frequent clinics.

Lectures begin Oct. 16, 1894, and cease March 9, 1895.

COLLEGE OF PHARMACY.

Allard Memminger, John Forrest, Edward S. Burnham.

Two years' course. Moderate fees.

Students coming from other colleges and taking only one or two courses of lectures will be charged \$100 for the general ticket each year.

Students of this class, on presenting certificates of satisfactory examination in the primary branches from other reputable colleges, will not be examined again, unless they desire to be graded and to compete for graduation honors, when they must stand our own examinations.

Graduates, not members of the Alumni Association, may take the course of histology and pathology, including the microscope, for a fee of \$10.

Fees for pharmaceutical students: Matriculation, paid but once, \$5; tuition fee, \$30; practical laboratory work, chemical and pharmaceutical, \$10; graduation fee, \$10, only to be returned in case of rejection.

Medical students wishing to take the practical course in pharmacy are advised to do so, and will pay a fee of \$10.

Fees for medical students: Matriculation, payable once only, \$5; histologic and pathologic laboratory, each year, \$5; general ticket, first year, \$100; general ticket, second year, \$100; general ticket, third year, \$50; diploma fee, payable before graduation, \$30; demonstration and hospital tickets, no charge.

Medical Faculty: Francis L. Parker, Allard Memminger, Manning Simons, P. Gourdin DeSaussure, J. L. Dawson, Jr., J. Somers Buist, John Forrest, Edward F. Parker, Lane Mullally, Robert Wilson, B. E. Baker.

For catalogue and other information address Francis L. Parker, M.D., Dean, Charleston, S. C.

McGILL UNIVERSITY, FACULTY OF MEDICINE.

MONTREAL.

The sixty-second session of this University commenced on Tuesday, Oct. 2, 1894.

The buildings of this Faculty of the University occupy the northeast corner of the University grounds and are directly connected by Carleton Road with the new Royal Victoria Hospital.

Special suites of laboratories are provided for practical training in all of the primary and scientific branches of medicine.

The dissecting room containing twenty-two tables for subjects, with bone room and anatomical room adjoining. Large chemical laboratories and suites of laboratories for physiology, pharmacy, hygiene and pathology are also provided in the new buildings. The course consists of four sessions of nine months each, beginning on September 20 of each year. The fees are \$100 per session, including clinical teaching, laboratory fees, dissecting material and all other laboratory requirements. The primary courses are chiefly practical; the didactic lectures in most departments being reduced to a minimum. The professors of clinical medicine and clinical surgery have charge of the medical and surgical wards of the Royal Victoria Hospital and Montreal General Hospital, each hospital containing about three hundred beds. Two clinics in medicine and two clinics in surgery are given every week in each Hospital. Each student is required to show certificates when presenting himself for a degree, of having acted six months as clinical clerk in medicine and six months as clinical clerk in surgery.

Clinics are also given in both hospitals in gynecology, ophthalmology, laryngology, etc.

The officers are: Robert Craik, Dean; R. F. Ruttan, Reg-

istrar; F. J. Shepherd, Librarian; J. G. Adami, (Cantab) Director of the Museum.

For any further information and calendars applications should be made to the Registrar.

NEW YORK POST-GRADUATE MEDICAL SCHOOL
AND HOSPITAL.

NEW YORK.

The Post-Graduate Medical School and Hospital is now permanently located in its new building, which has been erected to fill all the modern requirements of a medical school and hospital. The new Hospital is so much larger than the old one that the number of all major and minor surgical operations has been very much increased.

Students are brought into closer contact with patients than ever before, by their admission into the dispensary rooms, where they really act as "assistants" to the physicians who examine patients, before they are sent into the large amphitheaters for clinical demonstration.

The Babies' Wards contain sixty beds, and furnish great facilities for the study of infantile diseases. An entirely new course has been arranged in the department of Diseases of Women. Classes are limited to three students. Members of the class are allowed to make all the examinations, and also to perform the treatments. It is proposed during the coming winter to permit competent matriculates to operate in the department of Diseases of Women, under careful supervision. Every branch of medicine and surgery is taught by a system of personal and private instruction, exactly suitable for the general practitioner who wishes to acquire a knowledge of all departments of medicine and surgery. Three or four clinics are given daily in every department. The instruction is entirely clinical; no formal lectures are permitted. The Faculty being connected with most of the great hospitals and dispensaries of the city, also hold clinics at these for the benefit of the Post-Graduate Medical School. Pathologic and histologic laboratories are also a part of the school.

Clarence C. Rice, M.D., Secretary; F. Eugene Farrell, Superintendent.

OMAHA MEDICAL COLLEGE.*

OMAHA, NEB.

Four years graded course of six months after session of 1894-95. Thorough instruction given by means of recitations, lectures, laboratory work in anatomy, chemistry, histology, pathology and bacteriology and clinical work in the Methodist, Douglas County, Immanuel, Presbyterian and Clarkson Hospitals. Obstetrical cases are furnished all Senior students. The College Dispensary also furnishes abundant material for individual instruction in medicine, surgery, gynecology, eye and ear, nose and throat, genito-urinary and skin diseases.

In 1893 a new building was erected at a cost of \$20,000 which is thoroughly modern in its design. The laboratories have been newly equipped.

Fees for each course including all material, \$65; graduation, \$25.

W. O. Bridges, M. D., Secretary.

POST-GRADUATE MEDICAL SCHOOL.

CHICAGO, ILL.

The school is now well located and equipped in its new building. The Faculty is full and the clinical facilities unexcelled.

Faculty: Robt. H. Babcock, John A. Robison, M. H. Lack-

ersteen, Fenton B. Turck, H. W. Gentiles, W. F. Waugh, Weller Van Hook, J. B. Murphy, Dudley C. Trott, D. A. K. Steeie, L. L. McArthur, W. P. Verity, Carl Beck, Alex. Hugh Ferguson, Frederic S. Coolidge, Henry T. Byford, Henry Parker Newman, Fred. Byron Robinson, Albert Goldspohn, Marie J. Mergler, Franklin H. Martin, W. W. Jaggard, W. Franklin Coleman, Casey A. Wood, Boerne Bettman, Francis Dickinson, N. S. Pierce, T. Melville Hardie, F. D. Owsley, George Morgenthau, Daniel R. Brower, Sanger Brown, Sydney Kuh, Richard Dewey, D. J. Hayes, Joseph B. Bacon, Rosa Engelmann, J. C. Cook, H. Newberry Hall, W. E. Coates, Jr., R. W. Bishop, W. L. Baum, Franklin H. Martin, Secretary.

RUSH MEDICAL COLLEGE.*

CHICAGO, ILL.

The fifty-second course of lectures of this institution began Sept. 25, 1894, and continues eight months.

The new laboratory building, in which are located the anatomic departments and all the laboratories, presents an unexcelled series of working rooms for the undergraduate. No more extensive and thoroughly equipped dissecting room is to be found in any medical college. Every student is required to take special courses in laboratory instruction in histology, pathology, bacteriology and materia medica as well as in chemistry. The laboratories for these different special courses are extensively and thoroughly equipped.

A special feature of the instruction in this institution is the large number of men attending exclusively to teaching by recitations in the different classes divided into sections.

The clinics of this College are an especial feature of its instruction. Nearly all of them are held in the afternoon. In some of them the students are required to make their examinations and to defend their diagnoses before the class. The adjoining Presbyterian Hospital affords facilities for clinical instructions unsurpassed anywhere. A vast amount of surgical operations of all kinds is housed in this Hospital and students of this College enjoy the advantage of such operations in the clinics to an extent equalled by no college in this country.

The Central Free Dispensary connected with the College affords about one thousand patients monthly. They are extensively utilized for clinical purposes throughout the year.

Fees: The general ticket costs \$80 and the matriculation fee is \$5. Special courses are \$10 each, of which about ten must be taken during the undergraduate period.

Faculty: Edward L. Holmes, President; James H. Etheridge, Secretary; Henry M. Lyman, Walter S. Haines, James Nevins Hyde, Norman Bridge, Arthur Dean Bevan, Nicholas Senn, John B. Hamilton, E. Fletcher Ingals, Truman W. Brophy, Daniel R. Brower, a large corps of professors of special departments, instructors and demonstrators.

STARLING MEDICAL COLLEGE.*

COLUMBUS, OHIO.

The forty-eighth annual session of Starling Medical College, Columbus, Ohio, opened on August 19, 1894. The College is one of the oldest in the State and has a fine building, with all the modern equipments. Its hospital facilities are of the best, material being supplied from the two largest hospitals in the city, one being in the College building. Students are required to study cases at the bedside, and instructed in physical diagnosis.

Information as to terms, etc., can be had by addressing Thos. C. Hoover, M.D., Registrar, Columbus, Ohio

SOCIETY OF THE LYING-IN HOSPITAL OF THE CITY OF NEW YORK.

The Midwifery Dispensary has been absorbed by this institution. The number of deliveries during 1891, 955; during 1892, 2,070. The administrative building is in the most densely populated tenement-house district in the city. There are accommodations for twenty students, the regular term of instruction being two weeks, with six to fifteen deliveries for each student. Instruction is given during the entire year and is open to practitioners of medicine and students who have attended one course of medical lectures. Students are admitted in the order in which their applications are received, or they may be assigned to special dates when practicable. While waiting they can attend the various hospital clinics, dispensaries, etc., in the city. All deliveries are strictly aseptic, and all cases are attended at their houses as in private practice. Lodgings, instruments and medicines are furnished at the hospital during the two weeks' service, and certificates are issued to those who have performed the service satisfactorily. (Separate apartments for graduates.

Special instruction upon the manikin given by the attending physicians.

Consulting Physicians: Edward W. Lambert, Thomas M. Markoe, Wm. T. Lusk, Wm. M. Polk.

Attending Physicians: J. W. Markoe, S. W. Lambert, J. Clifton Edgar, H. McM. Painter, Austin Flint, Jr.

Chas. Ford, M.D., Superintendent.

TENNESSEE MEDICAL COLLEGE.*

KNOXVILLE, TENN.

Was one of the first in the South to extend the regular course to six months, and to require attendance upon three courses of lectures as an essential for graduation; its great success is a source of special satisfaction to the friends of the school. Knoxville, with its suburbs, has about 50,000 inhabitants.

Plans are being submitted by architects for a hospital on the College grounds, to cost \$30,000; it will be completed by Sept. 1, 1895. Fees for each course \$65, or for the three courses a perpetual ticket is provided at a cost of \$150. This includes everything except graduation fee of \$25.

TUFTS COLLEGE MEDICAL SCHOOL.

BOSTON, MASS.

Organized in 1893. A co-educational institution. Located in the city of Boston, where clinical facilities are of the best, it bids fair to become one of the most successful institutions in the country. The course of study consists of a three-years' graded course of didactic and clinical lectures and recitations upon the different subjects of medical science, illustrated by charts, plates, drawings and dissections. These will be supplemented by individual work in the laboratories and dissecting room, thus requiring the student to become familiar with the various phenomena met with in practice.

Requirements for admission: All students must pass an entrance examination consisting of:

1. A composition written in English, of not less than two hundred words.
2. The translation of easy Latin prose, or showing a satisfactory knowledge of the derivation of medical terms, and medical and pharmaceutic terminology.
3. An examination in higher arithmetic.

4. An examination in elementary physics, including heat, light and electricity.

Students who may fail in any of these examinations may be enrolled as conditioned, and will be required to make up the deficiency during the year before they can be enrolled as students in regular standing.

Exceptions: Such entrance examinations will not be required of students who have matriculated in a regular medical school requiring a similar examination; nor of students who have passed the entrance examination required by the Regents of the State of New York, or similarly constituted authority in other States; nor of students, matriculates or graduates of reputable colleges of literature, science and the arts, or graduates of high schools of the first grade, or of State normal schools.

For graduation: Candidates must be 21 years of age, of good moral character.

They must have attended three full courses of medical lectures of not less than six months' duration each, the last at this College, no two courses to have been taken in the same year.

They must present evidence of having dissected under the direction of a demonstrator of anatomy.

They must satisfactorily pass all the required examinations.

It is understood that attendance upon a course of lectures requires actual presence at a majority of the exercises of each chair each term.

This session commenced on Wednesday, Oct. 3, 1894, and continues until Wednesday, June 5, 1895.

For further information address the Secretary, Prof. Charles P. Thayer, M.D., 74 Boylston Street, Boston, Mass.

Board of Instruction: Elmer H. Capen, President; Albert Nott, Dean.

Charles P. Thayer, Secretary; Henry W. Dudley, William R. Chipman, Walter L. Hall, John W. Johnson, Frank G. Wheatley, Arthur E. Austin, Charles A. Pitkin, John A. Tenney, Samuel G. Webber, Ernest W. Cushing, Thomas M. Durell, J. Cushing Gallison, J. Sterling Kingsley, William R. Woodbury, Harold Williams, Charles D. Knowlton, Richard M. Pearce, Fred. S. Raddin, William A. White, Edward E. Thorpe, Charles L. Cutler, Frank B. Brown, Albert E. Rogers.

THE WOMAN'S MEDICAL COLLEGE, OF THE PRESBYTERIAN CHURCH.

CINCINNATI, OHIO.

This institution began its session September 29, which will continue for seven months and end May 24.

Candidates for admission must present a diploma from a recognized college or high school or a teacher's certificate. Without these they must pass an examination in the English branches.

For graduation a four years' course of study three of which shall be in attendance upon full winter courses of lectures. The course of study is graded and includes practical work in anatomy and in the chemic, physiologic, bacteriologic, histologic, and pathologic laboratories. Ample clinical advantages are afforded by the College clinic, the Presbyterian Hospital and the Cincinnati Hospital.

The College is in no sense sectarian but is under the control of a board of lady managers appointed by the Presbyterian Church, and does not depend upon the fees of students for its maintenance.

It is the purpose of the institution to give to women a complete education in the branches of medicine. John M. Withrow, A.M., M.D., Dean.

TRINITY MEDICAL COLLEGE.

TORONTO, ONT.

Established 1850. In affiliation with the University of Trinity College, the University of Toronto, Queen's University, the University of Manitoba, and specially recognized by the several Royal Colleges of Physicians and Surgeons in Great Britain. The winter session of 1894-5 commenced on Monday, Oct. 1, 1894.

Daily clinical instruction in the spacious wards and theater of the hospital will be given by members of the Hospital Staff on all interesting cases, medical and surgical. Arrangements have also been made for the delivery of daily clinics, out-door, in-door and bedside, in the Hospital, by the respective members of the in-door and out-door Hospital Staff which has been recently largely increased.

Fees for the course: The fee for anatomy, surgery, practice of medicine, obstetrics, materia medica, physiology, general chemistry, clinical medicine and clinical surgery, \$12 each; practical anatomy, practical chemistry, normal histology and pathologic histology, \$8 each; medical jurisprudence, \$6; botany and sanitary science, \$5 each. Registration fee (payable once only), \$5. Students are free in all the regular branches after having paid for two full courses. Surgical appliances is an optional branch, fee, \$5.

Full information respecting lectures, fees, gold and silver medals, scholarships, certificates of honor, graduation, diplomas, fellowship, etc., will be given in the annual announcement.

Faculty, Professors: Walter B. Geikie, Dean; J. Algernon Temple, Thomas Kirkland, C. W. Covernton, Fred. LeM. Grasett, W. T. Stuart, Charles Sheard, G. Sterling Ryerson, Luke Teskey, John L. Davison, G. A. Bingham, Newton Albert Powell, D. Gilbert Gordon, E. B. Shuttleworth, H. B. Anderson.

Lecturers, demonstrators, instructors and assistants: E. A. Spilsbury, Allan Baines, A. Y. Scott, D. J. Gibb Wishart, J. T. Fotheringham, H. B. Anderson, D. Albert Rose, C. A. Temple, Frederick Fenton, A. H. Garratt, Harold C. Parsons, C. Trow, W. H. Pepler.

WOMEN'S MEDICAL COLLEGE.

TORONTO, ONT.

The winter session commenced October 1, and continues six months. The summer sessions will commence April 22, and last ten weeks.

Students are fully instructed in all the subjects demanded by the University of Trinity College and Toronto University for the degrees of Doctor of Medicine and Master of Surgery—and in the full curriculum of the College of Physicians and Surgeons of Ontario.

The primary lecture course includes anatomy, practical anatomy, physiology, embryology, materia medica, inorganic chemistry, organic chemistry, practical chemistry, histology, biology, pharmacy and toxicology.

The first course of lectures includes, medicine, theory of surgery, applied anatomy, practice of surgery, medical jurisprudence, sanitary science, pathology, pathologic microscopy, obstetrics, diseases of women, diseases of children, therapeutics, mental diseases, bacteriology, and diseases of the eye, ear, nose and throat.

The clinical course includes, medicine, surgery, medical and surgical diseases of children, diseases of women, practical midwifery, psychology, ophthalmology, and physical diagnosis.

The hospitals open to the students are: The Toronto General Hospital, (300 beds); Victoria Hospital for Sick Children (200 beds); St. Michael's Hospital (150 beds).

Instruction is given in each of the above at least thrice per week, to classes composed of women only, while all the other clinical classes are available if desired.

SPECIAL ADVANTAGES.

This is the only medical college in Canada which is solely for women. The clinical material is abundant and the facilities which the students enjoy of studying the cases are unusually good. Diseases of women and children receive special attention, over and above the course in these subjects demanded by the examining bodies. The cost of living averages only \$3 per week.

Fees: The course is a four-year graded course. The fee for the full course is \$360, payable in four annual installments of \$90 each. The fees for examination and degree vary with the University selected. University students are admitted at two-thirds of the regular fees. The Hospital fees amount to \$40 for the entire course.

Full particulars may be obtained from the Dean, Dr. R. B. Nevitt, or from the Secretary, Dr. S. J. Gibb Wishart.

WOMAN'S MEDICAL COLLEGE.*

CINCINNATI, OHIO.

The eighth annual session begins Oct. 1, 1894, and ends in April, 1895, extending over a period of twenty-eight weeks. The curriculum is graded and attendance upon three annual sessions is required. Methods of instruction are divided into didactic, recitative, laboratory and clinical. Well equipped laboratories for the study of chemistry, histology, pathology and bacteriology.

Daily clinics at the College building, Ophthalmic Hospital and the Cincinnati Hospital.

Senior students are admitted to several private hospitals and to the Training School for Nurses. They are also afforded the opportunity of attending a number of cases in the thoroughly organized outdoor obstetric department.

Matriculation fee, \$5; general ticket, including fees for all special courses, \$75.

G. A. Fackler, M.D., Dean; Amelia Prior, M.D., Secretary.

WOMEN'S MEDICAL COLLEGE.*

BALTIMORE, MD.

Special stress is given to the laboratory work the first year and in the second and third years the students have to attend the sick and make examination of them, a thorough study of the practical part of medicine, upon which they are examined as well as in theory. The Hospital is large and gives a great number of all kinds of cases for examination and treatment of women, men and children. In addition to the Good Samaritan Hospital clinical lectures, are held at the city alms-house by our teachers, and the number of patients there are 2,500. So we are more than well supplied with material.

Faculty: B. Bernard Browne, Thos. A. Ashby, Eugene F. Cordell, John G. Jay, Hiram Woods, Jr., Joseph T. Smith, John R. Winslow, Pearce Kintzing, Charles E. Simon, Chas. O'Donovan, Henry P. Hynson, B. B. Lanier, Claribel Cone, Ralph Robinson, T. B. Marden, Ida Pollack, Louise Eaton, Profs. Simon and Dr. W. Milton Lewis.

Clinical Assistants: Sue Radcliff, Hugh Forsythe, S.

Griffith Davis, W. Milton Lewis, Edith Eareckson, John Girdwood, Jessie Brevitt.

Our College building, rooms and laboratories are fully supplied with the latest improvements in the way of apparatus to assist in treatment and work.

All communications should be addressed to I. R. Trimble, Dean.

WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.*

PHILADELPHIA.

College opens for registration of students September 26. Lectures begin September 27. Annual commencement for conferring the Degree of Doctor of Medicine, Wednesday, May 8.

REQUIREMENTS FOR ADMISSION.

Applicants for admission to the regular College course must be not less than 18 years of age. They will be required to pass a preliminary examination on the following subjects:

Orthography and English composition by means of a page on an assigned subject written at the time and place of examination; arithmetic, including fractions and percentage; physics, as presented in Avery's Physics or other standard text-book; Latin, including the declension of nouns and adjectives and the conjugation of verbs.

Candidates bringing a diploma or certificate from a recognized college or school, or from a duly organized county medical society which has instituted a preliminary examination (such as that adopted by the Medical Society of the State of Pennsylvania) or a teacher's certificate from a county superintendent of schools or a Regent's certificate of the State of New York or a certificate of having passed the examination preliminary to the study of medicine required by the present Medical Act of Canada will not be required to pass the entrance examination, provided such diploma or certificate shall state proficiency in the subjects of the examination as given above. No examination will be required of applicants desiring to pursue special studies in the College who do not intend to apply for the degree in medicine.

Preparatory education: Women intending to pursue the study of medicine in this College are urgently advised to secure a preparatory education which shall include some knowledge of chemistry, biology and modern languages, especially German, in addition to the branches covered by the entrance examination.

A degree in arts from a college in which the natural sciences have a place in the curriculum, or a college course "preparatory to medicine," similar to that given in the Schools of Biology connected with several American Universities, will admit to the second year: the student thus admitted to advanced standing will, however, be required to make up any deficiencies and pass an examination in all the studies of the first year.

Clinical advantages: The Woman's Hospital, in which over four thousand patients are treated annually, adjoins the College. The amphitheater in connection with the Hospital, has a seating capacity of about three hundred; the building also includes a number of smaller rooms, thus admitting of a systematic classification of patients in attendance upon the daily dispensary service and their treatment by the various attendants in the different departments of medicine and surgery at the same hours. Clinics in the departments of medicine, surgery, obstetrics and gynecology are held by the clinical lecturers. Clini-

cal lectures are also given by specialists in diseases of the skin, the nervous system, the eye, the ear, the throat and in orthopedic surgery.

Clinical instructions in practice of medicine, surgery, gynecology, nervous diseases and orthopedics, ophthalmology, laryngology and rhinology is given to students of the third and fourth years, in sections by the clinical instructors and the clinicians of the Woman's Hospital, under the general supervision of the Physician-in-charge of the Hospital.

Students of this College are admitted to clinical lectures at the Pennsylvania, the German, the Children's and the Philadelphia (Blockley) Hospitals; and by private arrangement classes may obtain instruction in the wards of the last-named Hospital which offers rare opportunities for clinical study. The daily clinics at Wills' Hospital for Diseases of the Eye, and at the Eye and Ear Department of the Philadelphia Dispensary are also accessible. The Philadelphia Lying-in Charity affords advantages to students of this College.

Hospital appointments: Five graduates are appointed annually on the basis of a competitive examination to serve as internes in the Woman's Hospital of Philadelphia. The large out-practice connected with this institution is mainly intrusted to these assistants.

The Maternity Hospital of Philadelphia, the Philadelphia Lying-in Charity, the Sheltering Arms and the Home for the Care and Treatment of Consumptives each make one appointment annually to the position of resident physician. The present residents in these institutions, also in the female department of the Philadelphia County Prison, and in the Insane Department for Women of the Philadelphia Hospital are graduates of this school.

The competitive examinations for the position of Resident Physician in the Philadelphia (Blockley), the German, the Presbyterian, the Methodist Episcopal and the Polyclinic Hospitals of Philadelphia and in the Charity Hospital of Norristown, Pa., and for that of externe in the Polyclinic Hospital are open to women.

The New England Hospital for Women and Children, in Boston, Mass., makes eight; the Nursery and Child's Hospital of Staten Island, N. Y., two; the Maternity Hospital in Detroit, Mich., two; the Northwestern Hospital for Women and Children, Minneapolis, Minn., one, and the West Philadelphia Hospital for Women, two annual appointments of Resident Physician from among the graduates of the various medical schools for women.

Expenses: First year: Matriculation ticket, \$5; general ticket admitting to all the lectures and laboratory courses, including dissection, belonging to the year, \$130; dissecting material, \$6; reading room fee, \$50.

Second year: General ticket admitting to all the lectures and laboratory courses, including dissection, belonging to the year, \$135; dissecting material, \$3; reading room fee, \$50.

Third year: General ticket admitting to all the lectures and practical courses belonging to the year, also to the clinical and ward instruction provided at the Woman's and the German Hospitals, \$135; reading room fee, \$50.

Fourth year: General ticket admitting to all the lectures and practical courses belonging to the year and required for graduation, also the clinical and

ward instruction provided at the Woman's Hospital, including that connected with the out-practice, special instruction at the German Hospital by the clinical professor of medicine, and bedside instruction in the wards of the Philadelphia Hospital by the professor of practice of medicine during his term of service at that institution, \$100; reading room fee, \$50; total, \$516.

WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.

The Woman's Medical College of the New York Infirmary made a four years' course obligatory with the entering of last year's class. Each year is divided into two terms of sixteen weeks each; students are examined at the end of each year on the year's work, and there are frequent recitations on the various subjects throughout the year.

Fees: Matriculation fee, \$5; fees for first year, \$130; fees for second year, \$130; fees for third year, \$130; fees for fourth year, \$80; graduation fee, \$30; dissection material, \$10.

Reading-room fee, 50 cents yearly.

Students taking special courses will pay \$20 for each course of lectures in addition to laboratory fee, should the course include laboratory work.

The aim of the Faculty is to make the course in the highest degree practical, and to this end the work in the laboratories and dissecting room occupies a large part of the time during the first year; later in the course the student, in addition to the usual didactic lectures, spends much time, under supervision, in the clinics of the Dispensary connected with the College, at the bedside of patients in the wards of the Infirmary and in the large and effective out-practice.

WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS.*

MILWAUKEE, WIS.

Milwaukee has a population of 270,000. The Faculty consists of nineteen professors, two lecturers, five assistants and demonstrators, and is now beginning its second year. The curriculum is three years of seven months each, and the course is graded so that the student pursues the various studies in their natural order. The College belongs to the Association of American Medical Colleges, and its diplomas are recognized by the Illinois Board of Health. The requisitions for admission are those prescribed by the Association named above. The annual dues are \$85, (anatomic material not included), and are divided as follows: Matriculation, \$5; lectures, \$60; chemic laboratory, \$10; histologic and physiologic laboratory, \$10; pathologic laboratory, \$10. The fee for final examination is \$30. The clinical advantages are sufficient, and are derived from the following sources: The Free Dispensary and the Presbyterian Hospital adjoining, St. Mary's Hospital.

WESTERN PENNSYLVANIA MEDICAL COLLEGE.*

MEDICAL DEPARTMENT OF THE WESTERN UNIVERSITY OF PENNSYLVANIA.

The regular session began third Tuesday in September, 1894, and continues six months. During this session, in addition to four didactic lectures, two or three hours are daily allotted to clinical instruction. Attendance upon three regular courses of lectures is requisite for graduation. A three years' graded course is provided. Four years required from April,

1895. The spring session embraces recitations, clinical lectures and exercises, and didactic lectures on special subjects; this session begins the second Tuesday in April, 1895, and continues ten weeks.

The laboratories are open during the collegiate year for instruction in chemistry, microscopy, practical demonstrations in medical and surgical pathology, and lessons in normal histology. Special importance attaches to "the superior clinical advantages possessed by this College."

For particulars address the Secretary of Faculty, Prof. T. M. T. McKennan.

UNIVERSITIES.

CLARK UNIVERSITY.

WORCESTER, MASS.

Graduate courses in psychology, physiology, neurology, etc. Special attention given to the study of the brain and central nervous system, with laboratory work and clinics. Exceptional opportunities offered in the sciences underlying the study of medicine.

G. Stanley Hall, M.D., President.

COLUMBIAN UNIVERSITY, MEDICAL DEPARTMENT.*

WASHINGTON, D. C.

The system of instruction includes lectures on anatomy, physiology, chemistry, materia medica and therapeutics, surgery, obstetrics, the theory and practice of medicine, hygiene, bacteriology, otology, laryngology, gynecology, dermatology, ophthalmology, mental diseases, medical jurisprudence, nervous diseases, pediatrics, minor surgery, histology, pathologic histology, orthopedic surgery, and surgical pathology.

These lectures are combined with clinical instruction in the various hospitals and dispensaries of the city.

Laboratory instruction is given in chemistry, histology and pathologic histology, bacteriology and practical pharmacy.

The course extends over four years, of seven months each.

The location of the University at the seat of the National Capital affords several striking advantages to the medical student. He has free access to the Libraries of Congress, of the Army Medical Museum, of the Smithsonian Institution, and of the Patent Office, all of which contain rare and costly works in every department of science and literature. The Army Medical Museum is also open for inspection daily from 9 to 3 o'clock. With its unrivaled collection of anatomic and pathologic specimens, illustrating normal anatomy and the results of disease in every form, and an almost unlimited number of other preparations, showing the effect of gunshot wounds and surgical injuries of every kind, this Museum presents a field for study superior to any other institution of the kind, either in this country or Europe.

[This remark applies to all medical colleges at Washington.—Ed.]

The Garfield, Children's, Columbian and Emergency Hospitals and Lutheran Eye and Ear Infirmary, offer ample clinical facilities.

Fees, regulations, etc.: Matriculation fee, payable only once, \$5; single tickets, \$20; practical anatomy, by the demonstrator, \$10; full course, first

year, \$75; full course, second year, \$75; full course, third year, \$75; full course, fourth year, \$75.

Candidates for graduation must have studied medicine four years. They must be of good moral character and at least 21 years of age.

The candidate must have dissected at least two sessions, during each of which he shall be required to dissect two "parts" of a subject, and it is recommended that he dissect three parts. He must have attended also two courses of clinical instruction.

One month before the close of the session he shall enter his name with the Dean of the Faculty as a candidate for graduation, and at the end of the term present himself for examination. The examination will be both written and oral. The examination for the degree will be held at the end of the session in April.

The diploma is granted only at the annual commencement in May.

Faculty: N. S. Lincoln, J. Ford Thompson, William W. Johnson, A. F. A. King, D. W. Prentiss, D. Kerfoot Shute, William P. Carr, H. C. Yarrow, George Byrd Harrison, H. L. E. Johnson, Thomas E. McArdle, Theobald Smith, William K. Butler, Sterling Ruffin, Charles W. Richardson, A. Clark Patterson, Edmund L. Tompkins, William M. Gray, Veranus A. Moore, A. R. Shands, John Van Rensselaer, O. A. M. McKimmie.

Clinical Professors: J. Ford Thompson, William W. Johnson, George N. Acker, H. L. E. Johnson, Samuel S. Adams, William K. Butler, Charles W. Richardson, Edmund L. Tompkins, George Byrd Harrison, G. Wythe Cooke.

Demonstrators: Sterling Ruffin, E. G. Seibert, Charles R. Clark, Harry W. Rollings, Glendie B. Young, W. F. R. Phillips, John R. Wellington, Henry S. Goodall, Francis Smith Nash, P. C. Hunt, C. M. Ketcham, Frank Leech, E. Y. Davidson, Charles J. Hopkins, Irving W. Rand, Francis T. Morgan, Albert L. Stavely, Edward C. Morse.

Dr. D. K. Shute, Dean.

Dr. E. A. de Schweinitz, Secretary-Treasurer.

HOWARD UNIVERSITY.*

WASHINGTON, D. C.

Medical, Dental, and Pharmaceutical Departments will open the winter session October 1, continuing six months.

Candidates for degrees must have attended four courses of lectures of six months in each year.

Students are expected to attend the laboratory courses in chemistry, bacteriology and histology.

Ample clinical opportunities are offered in surgery, practice of medicine, gynecology, obstetrics, eye and ear in the Freedmen's Hospital. Fees, \$60 per term.

C. B. Purvis, Secretary.

JOHNS HOPKINS UNIVERSITY, MEDICAL DEPARTMENT.

BALTIMORE, MD.

The Medical Department of the Johns Hopkins University was opened for the instruction of students as candidates for the degree of Doctor of Medicine in October, 1893. It has in addition to resources of the Johns Hopkins University and the Johns Hopkins Hospital available for its use a special endowment fund of \$500,000. It forms an integral part of the University and is in close affiliation with the Johns Hopkins Hospital.

The requirements for matriculation are higher than those of any other medical school in this country. Those who are admitted as candidates for the degree of Doctor of Medicine must possess a degree in arts or in science from an approved college or scientific school, and in addition must be able to read French and German and must have had a year's collegiate training with laboratory work in physics, chemistry

and biology; or they must furnish evidence by examination that they possess the general education implied by a degree in arts or in science and the knowledge of French, German, physics, chemistry and biology indicated. Men and women are admitted upon the same terms. No one is admitted to advanced standing without furnishing evidence that the terms of admission as regards preliminary training have been fulfilled and that courses equivalent to those given in this medical school, preceding that year of the course for admission to which application is made, have been satisfactorily completed.

The required course of instruction continues through four years, the academic year beginning the first of October and closing the middle of June, with short recesses at Christmas and Easter. Only the first two years of the course have been organized as yet. The courses for the third year will be started in October, 1895, and those for the fourth year in 1896. The first two years are devoted mainly to anatomy, physiology, physiologic chemistry, pathology, bacteriology and pharmacology, and the last two years to practical medicine and surgery. In the studies of the first two years especial emphasis is laid upon practical laboratory work and in the studies of the clinical subjects upon personal bedside and dispensary instruction and work in clinical microscopy and methods of diagnosis.

Abundant clinical material is afforded by the Johns Hopkins Hospital and Dispensary, this Hospital being unsurpassed by any in the world in the perfection of its arrangements. The clinical amphitheaters and laboratories are in the Hospital buildings. Physiology is taught in the biologic laboratory of the University, which is one of the largest and best equipped in this country. The pathologic laboratory is a four story building on the grounds of the Hospital. This building contains the autopsy theaters, the pathologic museum, the bacteriologic laboratory, the physiologic chemic laboratory and rooms for instruction and special work in all departments of pathology.

A new and commodious anatomic building, three stories in height, has been erected during the past year upon a large plot of ground adjacent to the Hospital and intended for additional buildings of the medical department. The pharmacologic laboratory finds for the present accommodation in the new anatomic building.

The charge for tuition is \$200 per annum. There are no extra charges for instruction in any department or for laboratory courses.

In addition to the regular course of instruction for undergraduates in medicine, special courses of instruction have been given to physicians in pathology and the clinical subjects since the opening of the Johns Hopkins Hospital in 1889. These are to continue. A fee of \$100 covers all of these special courses for physicians. The separate courses can be taken by payment of a fee of \$25 or \$50 according to the subject chosen.

MICHIGAN UNIVERSITY, MEDICAL DEPARTMENT.*

ANN ARBOR, MICH.

The course of instruction covers four years of nine months each. The first two years are devoted to the more strictly scientific work which serves as a basis for the technical and clinical studies which follow. The forenoons are given to lectures and recitations,

three each day; the afternoons to laboratory drill during the first two years, and to the study of methods of diagnosis and means of treatment during the second two years. Four hours constitute a day's work in the laboratory and the hospital.

The University Hospital accommodates a large number of patients and is thoroughly equipped. Clinical material is abundant.

Matriculation fee for Michigan students, \$10; for all others, \$25; annual fee for Michigan students, \$25; for all others, \$35. The total amount of fees paid to the University during the whole four years' course, for matriculation, incidental expenses, materials used, and diploma, is for Michigan students, about \$256; and for others, about \$311, varying a little with the student's actual laboratory expenses.

A combined six-year course leading to the B. S., and M. D. degrees is offered in conjunction with the literary department.

Victor C. Vaughan, M. D., Dean.

NATIONAL UNIVERSITY, MEDICAL DEPARTMENT.* WASHINGTON, D. C.

The eleventh annual course of lectures began Monday, Oct. 1, 1894.

Women are admitted to this school, subject in all respects to the same rules and regulations as apply to other students of the institution. Instruction is given by lectures, recitations, clinical teaching, and practical laboratory work uniformly distributed throughout the year. Oral examinations are held each week by the professors.

Qualifications for the degree of Doctor of Medicine: No student will receive his degree until he has studied medicine at least three years and has passed a satisfactory examination in all subjects of the three years' course, and has presented a certificate from the demonstrator of anatomy to the effect that he has made the necessary dissections of the human body in a satisfactory manner. Candidates for a degree must be of good moral character and at least 21 years of age. No student will receive his degree until he has paid, in full, the required fees.

Fees: Matriculation fee (payable once only) \$5. Tuition fees: First year (four tickets) \$60; second year (seven tickets) \$105; third year (three tickets) \$45; demonstrators' ticket, two years, each \$10; examination fee for graduation, not returnable, \$30.

For further information apply to H. H. Barker, M. D., Dean.

NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, CHICAGO MEDICAL COLLEGE.*

The regular course at this medical school includes four years of eight months each, and is carefully graded. A matriculation fee of \$5 is payable once for the course. An annual fee of \$100 includes all other charges for the regular course except deposits for breakage in laboratory work. If the apparatus used is not broken these deposits are returned.

LABORATORY BUILDINGS AND COURSES.

The laboratory building has a frontage of 110 feet and a depth of 105 feet, is five stories above the basement, and is constructed of cut stone and brick. The arrangement of the building and the equipment are those demanded in modern laboratories of its class.

First-year students work in chemistry six hours a week in general manipulation and general qualitative and toxicologic analysis. Second-year students de-

vote Saturday forenoon of each week to physiologic chemistry, including chemic and microscopic analysis.

Students of the first year work in normal and pathologic histology, two hours a week in cutting, staining and mounting normal histologic sections. Free-hand drawing of a large number of the sections mounted in this course is compulsory. Students of the second year devote two hours each week to the study of mounted sections of pathologic tissue already cut and stained for them. Free-hand drawing of the sections is compulsory. Students of the third year devote two hours each week to the study of specimens of tumors, repair processes and the staining and identification of pathogenic bacteria.

All the work in the microscopic laboratories is done in the presence and under the supervision of the demonstrators. No fee is charged for either of the microscopic courses.

The course in obstetrics is clinical, operative and didactic. The clinical material is ample and is furnished by Mercy, Wesley and Provident Hospitals, and by the College. Each student is required to be present at, but not to conduct, four confinements. Typical obstetrical operations are taught to the fourth-year class, in sections of five, on Pinard's phantom and the cadaver, with actual fetuses, under the direction of the demonstrators.

Physical diagnosis is taught by lectures, by clinics and by demonstrations on the healthy subject. The demonstrators will teach small sections of the second-year class the physical signs in the healthy individual and in patients, and this will be supplemented by the demonstration of abnormal physical conditions in the various departments of the dispensary and in the hospitals.

CLINICS.

Students of the second, third and fourth years only are members of the clinical class. The clinical class consists of two divisions, which are assigned to work in the Dispensary and Hospital on alternate weeks. The dispensary division of the class is again subdivided into classes each of eight or nine individuals. The arrangements are such that during the College session each small dispensary class works two or more weeks in each department of the Dispensary.

The Hospital division of the class is also subdivided. The second-year students attend the clinics at St. Luke's Hospital and the general College clinics. The third-year students attend the clinics at Mercy Hospital and the general College clinics. The fourth-year students attend the College clinics, and may elect either or both Hospital courses.

HOSPITALS.

Hospital facilities are ample.

Mercy Hospital, at the corner of Calumet Avenue and Twenty-sixth Street, is under the exclusive care of the Faculty, and receives a large number of patients annually, both from the city and the country. It has been rebuilt and enlarged during the past year so that its capacity is increased to about four hundred beds. Daily clinics are held in the Hospital amphitheater or at the bedside in the wards, according to the nature of the individual case.

The South Side Dispensary, in the new Davis Hall, contains accommodations as complete as any institution of its kind in this country. Over nineteen thousand patients are treated in this Dispensary an-

nually. It has the following eight departments: Medical, surgical, throat, eye and ear, gynecological, neurological, diseases of children, syphilis and diseases of the skin and orthopedic surgery. Each department occupies a separate room and is in charge of a clinical instructor. The small classes of students are trained by the physicians in charge of the respective departments, in the details of physical diagnosis appropriate to each. Members of the clinical class may serve as assistants to the physicians and surgeons of the several departments of the Dispensary, and to the Pharmacist of the Dispensary, and receive certificates of such service. Members of the Attending Staff and the Dispensary Pharmacist appoint their own assistants, and the term of service is six weeks.

Davis Hall is named in honor of the Dean of the Medical School. It immediately adjoins the laboratory building on the south. The first and second floors are arranged for the clinical and didactic work of the last three years of the course, and contain two amphitheatres, numerous small clinical rooms for the different departments of the Dispensary, the drug store and the College office.

N. S. Davis, M.D., L.L.D., Dean.

NIAGARA UNIVERSITY, MEDICAL DEPARTMENT.*

BUFFALO, N. Y.

The medical department was organized in 1883 with a compulsory three-year course and preliminary requirements for admission to its classes; it contemplates at an early day to advance the course to four years; it possesses fine College buildings and well equipped laboratories; the course of instruction is both clinical and didactic, its sources of clinical material being: The Sisters of Charity Hospital, the Emergency (accident) Hospital, St. Francis Hospital, Buffalo Woman's Hospital, the Sisters' Lying-in Hospital, the State Hospital for the Insane, in which clinics in insanity are given every alternate week, the College Dispensary, the Buffalo Eye and Ear Infirmary and the German Orphan Asylum for Children's Diseases.

The Faculty consists of twenty professors and eight lecturers and assistants.

We have no endowment.

The special advantages of the school consist in its clinical facilities; the advanced preliminary requirements for admission; the thoroughness of instruction; its graded curriculum of study and the rigid examinations required to pass from the lower to the higher classes. We also claim the best clinical course in obstetrics; each Senior being required to attend from five to ten labor cases before he is admitted to the final examination for his degree.

The fees are moderate: Matriculation, \$5; lectures, single course, \$75; perpetual ticket, \$165; practical anatomy, \$10 (annually); physiologic and histologic laboratory, \$10; chemic laboratory, \$10; pathologic laboratory, \$5; examination for graduation, \$25.

John Cronqu, M.D., Ph.D., L.L.D., President; Freeman Lothrop, M.D., Ph.D., Vice-President; A. A. Hubbell, M.D., Ph.D., Secretary.

NEW ORLEANS UNIVERSITY, MEDICAL DEPARTMENT.

NEW ORLEANS, LA.

1. A four years' graded course of study.
2. Is the *only* medical school in the far South which admits women students.

3. Is open to persons of *all races* and religions.
4. Tuition is thirty dollars (\$30) per year.
5. Being located near the center of New Orleans, the metropolis of the South, unexcelled clinical advantages are afforded.
6. Its laboratories are equipped with the object in view of careful training of the students in the various practical courses pursued.

The school is located at 302 Canal Street, New Orleans, La.

C. F. Dight, M. D., Dean.

NORTHWESTERN UNIVERSITY, WOMAN'S MEDICAL SCHOOL.

WOMAN'S MEDICAL COLLEGE, OF CHICAGO.

This school is located at 333 to 339 South Lincoln Street. Thorough and practical instruction given in every department. Hospital advantages unsurpassed. Excellent laboratories. This school was founded in 1870.

Marie J. Mergler, M.D., Secretary.

OHIO UNIVERSITY, MEDICAL DEPARTMENT.*
COLUMBUS, OHIO.

Chartered in 1890. The peculiar feature of this institution is the method of instruction adopted, which consists in the practical abolition of didactic lectures. All instruction, where practicable, is imparted by assigned topics and recitations, and clinics. It has departments of medicine, dentistry, and pharmacy.

Clinics are given in the College building, in the hospital of the Ohio Penitentiary, and at the Protestant Hospital. This school has the exclusive use of the clinical material of the latter hospital.

Fees: Matriculation (once), \$5; course tickets, \$50; dissecting (including material), \$10; laboratory courses (three), each \$5; graduation, \$10.

The College building has been built especially for the needs of the school and is one of the largest and finest in the country. The laboratories are especially well equipped.

J. F. Baldwin, M.D., Chancellor.

QUEENS UNIVERSITY AND ROYAL COLLEGE OF PHYSICIANS AND SURGEONS.

KINGSTON, ONTARIO.

Candidates for degrees of M. D., A. M., and L. R. C. R. S., must have completed a period of four years study, comprising four winter and one summer session and passed a matriculation examination including Latin, English arithmetic, algebra and geometry. Two full courses of six months each, require to be taken in anatomy, practical anatomy, chemistry, physiology, materia medica, practice of medicine, clinical medicine, surgery, clinical surgery, obstetrics and one of six months in jurisprudence, one in sanitary science, one in practical and analytical chemistry one in botany, and two years hospital attendance must be certified. The College presents special advantages as to acquiring a practical knowledge of anatomy and laboratory work.

SYRACUSE UNIVERSITY COLLEGE OF MEDICINE.*
SYRACUSE, N. Y.

Its clinical resources embrace two hospitals, one dispensary and two asylums.

College year extends from first Tuesday in October to first Tuesday in June. By unanimous vote of Faculty a four years course will commence October, 1895.

ENTRANCE EXAMINATIONS.

In addition to the State examination, all students are examined in algebra, geometry and Latin. No student is allowed to enter unless he or she shall have passed *unconditionally* the examinations required by the State and by the College rules.

No student will be advanced from one class to a higher one till he or she shall have passed unconditionally all the examinations made for purpose of such advancement.

Fees and expenses: Fees for an entire year are required in advance. Matriculation, \$5; tuition each year, \$80; dissection, \$12; graduation, \$25. Children of regular physicians or clergymen may have a reduction of one-half the tuition fee.

The Faculty consists of sixteen professors, eight lecturers, four instructors and demonstrators.

TULANE UNIVERSITY OF LOUISIANA, MEDICAL DEPARTMENT.†

NEW ORLEANS, LA.

This institution, founded in 1834 as the "Medical College of Louisiana," became in 1847 the "Medical Department of the University of Louisiana," and in 1884 the "Medical Department of the Tulane University of Louisiana." It is the oldest medical college in the Southwest, and has the greatest number of alumni and of students. To April, 1894, it had registered the names of 10,905 students, and of these it had conferred diplomas on 3,141—namely, on 2,895 graduates in medicine, and 246 graduates in pharmacy.

The next annual course of instruction in this department, now in the sixtieth year of its existence, will begin on Thursday, Oct. 18, 1894.

The Medical Department, as well as all reputable Southern Medical Colleges, have added to the obligatory studies heretofore required for graduation, medical jurisprudence and also one laboratory course in chemistry, one in histology and bacteriology, and one in operative surgery.

The Medical Department now occupies a new site, twice the size of the former one and only two squares from the Charity Hospital, and thereon a four-story building, three stories above a most excellent basement which provides ample accommodation for larger classes and for all the needs now requisite to medical education; larger and better lecture and recitation rooms, and best of all ample and well equipped laboratories for chemistry, for pharmacy, for practical anatomy, for operative surgery, for microscopic anatomy, pathology and bacteriology, and working rooms for practical physiology and for gross pathologic anatomy. These admirable laboratories, now added to the unrivaled practical advantages for clinic, anatomic and pathologic studies given by the Charity Hospital, enable the Medical Department to provide its students with unsurpassed advantages for their medical education. The clinical instruction at the Charity Hospital is unexcelled; this Hospital has 700 beds.

Fees for first course students of 1894-95 taking three full courses: Matriculation fee, first year, \$5; second year, \$5; third year, \$5; professors and lecture, first year, \$120; second year, \$120; third year, \$120; demonstrator of anatomy, first year, \$10; second year, \$10; chemic laboratory, first year, \$15; second year, \$15; microscopic laboratory, second year, \$15; operative surgery, third year, \$10; diplo-

ma or graduation fee, third year, \$30. Totals first year, \$150; second year, \$150; third year, \$165.

All fees are payable in advance, that is on admission.

For any additional information, address Professor Chaillé, Dean, P. O. drawer 261. Letters thus *officially* addressed secure prompt attention even if the Dean be absent.

Stanford E. Chaillé, M.D., Dean of the Medical Department.

Medical Faculty: Stanford E. Chaillé, Joseph Jones, Ernest S. Lewis, Jno. B. Elliott, Edmond Souchon, Albert B. Miles, Louis F. Reynaud.

Lectures, instructors, demonstrators: Henry Bayon, H. S. Lewis, Isadore Dyer, J. D. Bloom, Luther Sexton, Edw. W. Jones, Rudolph Matas, A. McShane, P. E. Archinard, O. L. Pothier, A. L. Metz, T. A. Quayle, Warren S. Bickham.

UNIVERSITY OF BUFFALO, MEDICAL DEPARTMENT.

BUFFALO, N. Y.

The forty-ninth regular session opens Sept. 24, 1894, and continues thirty weeks. The lectures will be held in the large, new, three-story building, containing three amphitheatres and rooms for dispensary patients, chemic, pathologic, histologic, and pharmaceutical laboratories, thoroughly equipped with modern conveniences. Instruction by lectures, recitations, laboratory work, and clinics. Three-year graded course. Clinical advantages unexcelled.

Faculty: Matthew D. Mann, Dean; Edward M. Moore, William H. Mason, E. V. Stoddard, Charles Cary. Roswell Park, Julius Pohlman, Charles G. Stockton, John Parmenter, Herbert M. Hill, Wm. C. Phelps, DeLancey Rochester, P. W. Van Peyma, Eli H. Long, Herbert U. Williams, Fred B. Willard, Loren H. Staples.

Professors of Special Departments: Judson B. Andrews, Lucien Howe, Mahlon B. Folwell, Ansley Wilcox, D. W. Harrington, Henry R. Hopkins, Bernard Bartow, F. Whitehill Hinkel, Ernest Wende, W. E. Ford, James W. Putnam, Wm. H. Heath, Wm. C. Barrett, Willis G. Gregory, Arthur W. Hurd, Francis T. Metcalfe.

Instructors: Fred B. Willard, Allen A. Jones, A. L. Benedict, M. A. Crockett, Edward J. Meyer, Albert T. Lytle, Frank J. Thornbury, Dewitt H. Sherman, Ferdinand G. Moehlau, J. F. Whitwell, Francis T. Metcalfe.

Miss Emma Chappell, Louis Staffeldt.

Clinical Instructors: Drs. Allen A. Jones, Geo. Himmelsbach, Dewitt H. Sherman, Edward J. Meyer, J. Franklin Whitwell, M. A. Crockett, F. B. Willard, James W. Putnam, James A. Gibson, Irving M. Snow, Maud J. Frye, Ernest Wende, Grover Wende, Henry J. Mulford, Geo. F. Cott, Julius Pohlman, Elmer Starr, H. Y. Grant, Loren H. Staples, F. G. Moehlau.

Fees: Matriculation, \$5; Regular term, \$100; perpetual ticket, \$200; laboratory, \$40; dissection, \$20, (\$10 each year); examination fee, \$30, (\$10 each year). For further particulars address,

Dr. John Parmenter, Secretary, University of Buffalo, Buffalo, N. Y.

UNIVERSITY OF COLORADO, MEDICAL DEPARTMENT.

DENVER, COLO.

A three years' graded course of nine months each year. Commencing in 1895 the course will be lengthened to four years. Instruction during the first year is given in Boulder, and during the second and third years in Denver, owing to the superior clinical advantages of the latter city. The District Court has recently decided that the University of Colorado has a right to teach medicine wherever the best clinical advantages are obtainable. Practical laboratory work in chemistry, histology, and pathology. The session commenced the first week in September, 1894.

Tuition is free to residents of Colorado. Non-residents pay a nominal fee of \$20. Two post-graduate courses are held each year.

Faculty: James H. Barker, President; Jeremiah T. Eskridge, Dean; Herbert W. McLauthlin, Secretary; Luman M. Giffin, Treasurer; Charles Skeele Palmer, John Gardiner, A. Stewart Lobingier, Clayton Parkhill, G. Melville Black, John Chase, John W. O'Connor, Herbert B. Whitney, Lewis E. Lemen, George B. Packard, Thomas E. Taylor, Josiah N. Hall, John Vroom, H. C. Crouch, Walter A. Jayne, Samuel D. Hopkins, Francis H. McNaught, Emley B. Queal, Earl H. Fish.

UNIVERSITY OF CALIFORNIA, MEDICAL DEPARTMENT.*

SAN FRANCISCO, CAL.

The next session of the Medical Department of the University of California will begin Jan. 7, 1895, and continue six months. Thereafter, the session will begin September 1 and continue eight calendar months. Attendance is required upon four annual courses of medical lectures, except of those who are graduates of accredited literary or scientific colleges or have spent two years in the study of the natural sciences in a recognized university.

Fees: Matriculation, (paid but once) \$5; practical anatomy, (each of two years) \$10; tuition, (each year) \$100; graduation, \$25.

Students who do not present diplomas of accredited high schools or academies, are required to pass an entrance examination in the subjects usually embraced in a high school course.

The course of studies pursued at this school comprises clinical, didactic, and laboratory teaching. Special prominence is given to the first, although it is endeavored that the three methods shall be so blended as to form one harmonious whole.

The facilities for clinical studies open to the students of the University have been largely increased. Full access is given to the City and County Hospital, a complete and modern structure containing five hundred beds, and presenting for observation perhaps every known form of disease, including those peculiar to tropical and South America. The staff of the Hospital is largely drawn from the Faculty of the University, giving them unusual advantages for developing clinical material. The Professor of Clinical Surgery has charge of three surgical wards (thirty-two beds in each), the Professor of Clinical Medicine two wards, the Professor of Obstetrics and Gynecology and the Professor of Ophthalmology, one ward each. Autopsies are conducted three times a week in the Mortuary by the Pathologist. A large operating theater has been erected, where the major and minor operations of surgery are performed in view of the class.

The Dispensary clinic is located in the heart of a thickly populated district where clinical material of every description is extremely abundant. The clinical rooms are large and airy, and provided with every facility for the successful demonstration and treatment of disease.

A full staff of clinicians and assistants has been appointed and clinics are held daily throughout the year. Cases applying for treatment are classified according to their diseases and assigned to the different clinicians.

During the sessions of the College, every advanced student will have an opportunity to observe and personally attend a large number of cases, under the supervision of the clinical staff.

An obstetrical bureau has been established in conjunction with the clinic, where indigent women may make application for attendance at their homes, during confinement. The clinician in charge of this department will assign cases in rotation to students of the Senior class.

UNIVERSITY OF WOOSTER, MEDICAL DEPARTMENT.*
CLEVELAND, OHIO.

The College course opened September 19 and continues eight months. Students matriculating in 1895 will be required to take four courses of eight months each. New laboratories have been equipped in chemistry, bacteriology, histology, physiology and pathology. A new college and laboratory building will be completed in time for the session of 1895-96. A new hospital, amphitheater and dispensary building has just been completed. The hospital contains seventy-five beds which are under the *exclusive* control of the Faculty, and are used for bedside instruction. The City, St. Alexis and other hospitals in the city are available for chemical instruction. Our aim is to secure students with the best preliminary training and to furnish them with laboratory and clinical instructions equal to that of the best schools in the country.

Fees: Hospital and general tickets, \$100; examination, (\$10 annually) \$30; graduates of medicine, general ticket, \$20; perpetual ticket, (not transferable) \$250; matriculation fee the same to be credited on general ticket, \$5.

A laboratory fee of \$10 is required to be deposited to cover breakage.

Faculty of Medicine: Marcus Rosenwasser, Dean; H. W. Rogers, Secretary; Gustav C. E. Weber, B. B. Brashear, Andrew Squire, C. F. Dutton, Treas., Albert R. Baker, Clyde E. Cotton, G. W. Crile, W. E. Wirt, M. Stamm, H. C. Eyman; N. Stone Scott, Registrar; D. B. Smith, H. W. Kitchen C. B. Parker, Guy B. Case.

UNIVERSITY OF VIRGINIA, MEDICAL
DEPARTMENT.

CHARLOTTESVILLE, VA.

Session begins Sept. 15, 1894, and ends June 15, 1895. The course is graded, and extends over two full sessions of nine months, embracing laboratory and clinical work.

Wm. M. Thornton, Chairman of Faculty.

UNIVERSITY OF IOWA, MEDICAL DEPARTMENT.*
IOWA CITY, IOWA.

Medical Department of the University of Iowa is located at Iowa City, Iowa. The department was established by State authority in 1870. Classes have been graduated annually since that date. The Faculty embraces twelve professors, three instructors and seven demonstrators. The buildings belonging to the department, consist of the medical building proper—containing two lecture rooms, pathologic and histologic laboratories, a dissecting room, museum, and professors' private rooms. Two hospital buildings with accommodations for one hundred patients. As regards requirements for admission and graduation of students, the institution is governed by the rulings of the Association of American Medical Colleges and the Iowa State Board of Medical Examiners. Beginning with the session of 1895-96 the course will consist of a graded course of four years of six or eight months each. At present a graded course of three years of six months each is required.

Instruction is imparted by the usual methods. Clinics in surgery, practice of medicine, gynecology, eye and ear, laryngology and rhinology are held weekly. Special attention is devoted to laboratory work and branches of the Senior year, clinical cases being thoroughly utilized. Being a State institution the department is enabled to offer systematic and thorough instruction at very reasonable tuition, the fees being as follows: Freshman year, \$58; Junior year, \$48; Senior year, \$38.

J. C. Shrader, Dean. J. W. Harriman, Secretary.

UNIVERSITY OF MARYLAND.*

BALTIMORE.

The School of Medicine is one of the oldest institutions of medical education in America, ranking fifth in point of age among the medical colleges of the United States. Beginning with the modest number of five graduates, comprising the first graduating class in 1810, the list of graduates in medicine of the University of Maryland now numbers 4,574 names, among which are to be found some of the most noted names connected with the history of medicine in our country. While the policy of the Faculty of Physic has been one of wise conservatism, it has at the same time never been behindhand in the march of educational progress, and has often been the first and always among the first, in the adoption of measures tending to improvement in methods of medical teaching and to true elevation of the standard of medical education. One of the advantages of the University over other schools of that day was gained in 1823 by the erection of its own hospital, separated from the College by the width of the street and known as the University Hospital. Besides important additions and improvements to the University Hospital, the Faculty has in the last few years expended and is now expending large amounts in the establishment and equipment of its Lying-in Hospital, its laboratories of chemistry, histology, pathology and bacteriology, and is therefore in a position to offer to students of medicine and graduates, a course of combined didactic, clinical and laboratory instruction which will compare favorably with that offered by any medical school in the United States. The course of study embraces three annual graded courses of not less than six months each.

Fees for the three years' graded course: Matriculation (paid each year) \$5; practical anatomy (paid two years) \$10; full course of lectures (first year) \$100; full course of lectures (second year) \$100; full course of lectures (third year) \$100; graduation fee, \$30.

UNIVERSITY OF MINNESOTA, COLLEGES OF
MEDICINE AND SURGERY.*

MINNEAPOLIS, MINN.

The establishment of a College of Medicine and Surgery in connection with the University of Minnesota has met with approbation upon the part of the profession and generous financial support at the hands of the public. The Calendar of 1894 indicates a registration in all the departments of the University of 1,848 students, of which number 199 were matriculates in the College of Medicine and Surgery. The seventh annual course of instruction begins Oct. 9, 1894, and will close the first Thursday in June, 1895. The new buildings of the College of Medicine are located on the general University campus. Apart from the grounds the buildings and equipments have

cost the State approximately \$100,000. At the last meeting of the Board of Regents the four-year curriculum was adopted to become operative next year. Matriculates must furnish a diploma or matriculation certificate from a recognized college or undergo an examination in composition, algebra, Latin and physics. A thorough course of graded instruction is afforded the students of this University in all its departments. The expenses of conducting the College of Medicine is borne by the State. Ample clinical facilities are afforded in both the cities of Minneapolis and St. Paul.

Perry H. Millard, Dean.

UNIVERSITY OF THE STATE OF MISSOURI,
COLLEGE OF MEDICINE.
COLUMBIA, MO.

Organized in 1872. Three years' graded course.

First year: Anatomy (osteology and dissecting), physiology (chemical, nutritive and reproductive), chemistry (laboratory and class-room work), physics, normal histology, laboratory work in mounting and staining normal tissues; general therapeutics.

Second year: Anatomy (general and descriptive, and dissections); physiology (nervous system), chemistry, (laboratory work), microscopy, mounting and staining bacteria; therapeutics, theory and practice of medicine, surgery and obstetrics.

Third year: Theory and practice of medicine, clinical medicine, physical diagnosis, surgery, clinical surgery; anatomy, surgical and topographical; obstetrics, therapeutics, gynecology, diseases of children; diseases of eye, ear, nose and throat; sanitary science; toxicology and medical jurisprudence; work in bacteriologic laboratory.

Students must pass in the work of each class and year, before admission to the next class or year.

Instruction is given by lectures, recitations, clinical teaching and laboratory work.

The length of the session, nine months, renders it practicable to distribute the different branches among the teachers in the most satisfactory manner, and in their natural order and succession. The student is thoroughly drilled each day by examinations upon the lectures of the previous day, and by recitations from text-books.

By this method of teaching it is asserted that the process of cramming—a deleterious practice, too prevalent in the general system of medical education—is avoided. It is believed that the proposed method of teaching will do more to elevate the standard of medical education, and to exalt the dignity of the profession, than any other measure that could be adopted.

The students are taught the use of the microscope, in relation to both pathologic and physiologic studies. The methods of bacteriologic investigation are taught by practical work in the laboratory.

Among the advantages offered by this school is the privilege granted, without further cost, to all students who enter the medical department, of pursuing such studies as they may desire in the academic course. Academic students may take anatomy and physiology in the first year of the medical course, preparatory to entering on the full medical course after graduating in arts or science. Such students are admitted to the second year's medical class.

Conditions of admission: Candidates for admission to the medical department must possess a good

common-school education. This is the minimum requirement, and evidence that the candidate possesses the requisite knowledge must be attested by certificates of former instructors or must be shown by examinations conducted by the Faculty. Students are strongly urged to take degrees in arts or science before entering this department.

Fees: First year matriculation, \$20; second year matriculation, \$50; third year matriculation, \$50.

A preliminary course of nine months will be given after this year in chemistry, biology, physics and Latin.

A. W. McAlester, Dean. Woodson Moss, Secretary.

UNIVERSITY MEDICAL COLLEGE.

KANSAS CITY, MO.

This College is entering upon its fourteenth annual course of lectures. A course of study embraces four years' study of medicine, with three full courses of lectures, of twenty-six weeks each. Its matriculants are required to have a good English education, with a sufficient knowledge of Latin and the elementary sciences to enable them to thoroughly comprehend and assimilate the instruction which is given to them in the different departments of medicine. The fees are small, amounting to about \$60 for each course of lectures. The hospital facilities are ample. Clinical advantages being obtained from over two hundred beds in the different hospitals in the city, beside sixty beds contained in a hospital under the control of the College, immediately adjoining its building.

The University Medical College has made the subject of clinical instruction one of its chief aims and for this purpose has established a dispensary, in which more than 15,000 cases are treated yearly in the different departments. The small number of its students thus gives an unexceptional advantage to each individual student.

Chas. W. Adams, M.D., Dean.

UNIVERSITY OF NASHVILLE AND VANDERBILT
UNIVERSITY, MEDICAL DEPARTMENT.*

NASHVILLE, TENN.

Forty-fifth annual session, eight months' term, three years' course required for graduation. Twelve professors and nine special lecturers and laboratory assistants. One of the oldest and most successful medical schools south of the Ohio River. Ample clinical facilities afforded by the public hospitals. Fees \$75 first and second years; \$100 third year.

Faculty: J. H. Callender, President; Thomas Menees, Dean; Thomas L. Madden, W. L. Nichol, J. M. Safford, C. S. Briggs, G. C. Savage, Richard Douglas, C. R. Atchison, S. S. Crockett, Ambrose Morrison, S. S. Briggs, W. H. Witt, Larkin Smith, E. A. Ruddiman, O. H. Wilson, G. H. Price, M. H. Bonner, J. W. Waters, J. M. Bass. W. G. Ewing, Secretary.

UNIVERSITY OF THE CITY OF NEW YORK, MEDICAL DEPARTMENT.

Fifty-fourth year. The session of 1894-95 will begin Wednesday, Oct. 3, 1894. Attention is called to the fact that the curriculum has recently been entirely remodeled and greatly improved. It now consists of a three years' graded course as follows:

First Year: Lectures and recitations from text-books on anatomy, physiology and chemistry. Dissection and laboratory work in histology, materia medica and chemistry.

Second Year: Lectures on surgical and regional anatomy, experimental physiology, experimental

chemistry, physics and hygiene, and materia medica. Recitations from text-books on pathologic anatomy, practice of medicine, surgery, materia medica, obstetrics and demonstrations on the manikin, laboratory work, in pathology, clinics in Bellevue Hospital and the College building, on medicine, surgery and gynecology, and practical clinical work in sections in medicine and surgery.

Third Year: Lectures on practice of medicine, surgery, obstetrics, gynecology, therapeutics and pathology, with autopsies. Bedside teaching in small classes in the wards of Bellevue Hospital on medicine, surgery and gynecology. Clinics in Bellevue Hospital and the College building on medicine, surgery and gynecology.

Special clinics: Ophthalmology, otology, laryngology, orthopedy, pediatrics, skin diseases, venereal diseases, nervous diseases.

Examinations are held at the close of each year. The marks received for proficiency in practical work in the laboratory, dissecting room, etc., are added to the final examination marks in each corresponding subject.

Faculty of Medicine: Rev. H. M. McCracken, Chancellor; Chas. Inslee Pardee, Dean.

Professors: Alfred L. Loomis, W. H. Thomson, Wm. M. Polk, L. A. Stimson, R. A. Witthaus, Wm. G. Thompson, Geo. Woolsey, H. P. Loomis, Stephen Smith, A. E. Macdonald, J. C. Edgar, E. D. Fisher, C. S. Bull, H. G. Piffard, J. E. Winters.

Clinical Professors: P. A. Morrow, C. G. Coakley, A. M. Phelps, E. LeFevre.

Adjunct Professors: C. E. Quimby, F. W. Gwyer, Ivin Sickles, John B. Knapp, Justin L. Barnes, Irving S. Haynes.

The College possesses a corps of sixty-four professors and instructors in its various departments; and in addition to well-equipped laboratories and a dispensary where 20,000 visits are annually paid, it offers to students exceptional facilities for practical instruction at the bedside in Bellevue Hospital, which is directly opposite the College buildings.

Fees: For course of lectures, \$150; matriculation, \$5; demonstrators' fee, including material for dissection, \$10; final examination fee, \$30.

For further particulars and circulars, address the Dean, Prof. Chas. Inslee Pardee, University Medical College, 410 East Twenty-sixth Street, New York City.

UNIVERSITY OF OREGON, MEDICAL DEPARTMENT.

PORTLAND, ORE.

The Medical Department of the University of Oregon, located at Portland, requires four years' study of medicine including three courses of lectures (delivered in separate years). Commencing with October, 1895, it will enter upon a four course requirement. There is an entrance examination for matriculation.

The school occupies a well-equipped building where didactic and clinical lectures are delivered and laboratory work carried on. Clinics are also held three times a week at Good Samaritan and St. Vincent Hospitals. These hospitals drawing their patronage from Oregon, Washington and Idaho, present more than local phases of disease or injury and represent types of disease prevalent on the Pacific coast.

Fees are for matriculation, \$5; lecture ticket, \$120; demonstrators' ticket, \$10. Students having paid for two full courses are thereafter admitted free except graduation fee of \$30. Special rates are made

to graduates of other regular schools and to students of dental and pharmaceutical schools.

S. E. Josephi, M.D., Dean; Curtis C. Strong, M.D., Secretary.

UNIVERSITY OF PENNSYLVANIA, DEPARTMENT OF MEDICINE.*

The 129th annual session will begin Monday, Oct. 1, 1894, at 12 m., and will end at Commencement, June 4, 1895.

The curriculum is graded and attendance upon four annual sessions is required. College graduates in arts or science, who have pursued certain biologic studies are admitted to advanced standing. Practical instruction, including laboratory work in chemistry, histology, osteology and pathology, with bedside instruction in medicine, surgery, gynecology and obstetrics, are a part of the regular course and without additional expense.

Faculty: William Pepper, William Goodell, James Tyson, Horatio C. Wood, Theodore G. Wormley, John Ashhurst, Jr., Edward T. Reichert, William F. Norris, Barton Cooke Hirst, J. William White, John Guiteras, George A. Piersol, John Marshall, Louis A. Duhring, John S. Billings, Charles B. Penrose.

For catalogue and announcement containing particulars, apply to Dr. John Marshall, Dean, Thirty-sixth and Woodland Avenue, Philadelphia.

UNIVERSITY OF THE SOUTH, SEWANEE MEDICAL COLLEGE.

SEWANEE, TENN.

Closed its third annual course of lectures, Aug. 30, 1894, with a class of about fifty students and seventeen graduates.

The gradual and permanent growth of this College argues that a spring and summer school at this favored locality (2,300 feet above sea level) is an assured fact.

Next session will open March 7, 1895. For information address J. S. Cain, M.D., Dean.

UNIVERSITY OF TENNESSEE.

NASHVILLE MEDICAL COLLEGE, MEDICAL DEPARTMENT.

This institution, founded in 1876 as "Nashville Medical College," became in 1879 the "Medical Department of the University of Tennessee." The expectations set forth by the founders and promoters, among whom were the late Professors Paul F. Eve and William K. Bowling, have been completely fulfilled, and the circle of the College's influence has constantly been growing wider.

The City Hospital is one of the best equipped institutions of the kind in the South. It is perfect in all of its appointments.

St. Margaret's Hospital: This charitable institution is in a prosperous condition, being under the management of the Sisters of Charity.

College Dispensary: Our Free College Clinic and out-door service will enable us to offer at our College amphitheater, an abundance of practical clinical observation to the students, and our College surgical work is probably surpassed by but few schools in the country.

The medical department is located on Broad Street between Vine and High Streets. The instruction at this College consists of didactic lectures, clinical teaching, practical instruction, and examinations or quizzes.

From five to six lectures will be given daily by the Faculty during the session, on the following subjects,

viz: Anatomy; chemistry; physiology; materia medica; practice of medicine; obstetrics; gynecology; surgery; diseases of the eye, ear and throat; medical jurisprudence; diseases of children; State medicine; general pathology; physical diagnosis; dermatology; microscopy; dental and oral surgery; diseases of the genito-urinary organs, and venereal diseases.

Clinical teaching is ample at the New City Hospital, County Asylum, St. Margaret's Hospital and College Dispensary.

Faculty: Chas. W. Dabney, Prest.; Hon. Wm. P. Jones; Paul F. Eve, Dean; J. Ber. Lindsley, J. Bun Stevens, Wm. D. Haggard, J. S. Cain, Wm. E. McCampbell, Jno. A. Witherspoon, Ross Dunn, Hazle Padgett, Wood M. Vertrees, T. Hilliard Wood, Jno. G. Sinclair, Wm. G. Brien, James Y. Crawford, W. Frank Glenn, Haley P. Cartwright, J. Crid. Wharton, Charles Mitchell, James B. Neil, James W. Handley, James S. Ward, Thos. R. Newman, Wm. D. Haggard, Jr.

UNIVERSITY COLLEGE OF MEDICINE.
RICHMOND, VA.

The University College of Medicine was organized in 1893 under the name of the College of Physicians and Surgeons, but for good and sufficient reasons its corporate title was altered.

The location of the College in Richmond, the historic city of the South, is a fortunate one, on account not only of the clinical advantages, it being the largest manufacturing city in the South, but also on account of its superior climatic influences.

The University College of Medicine is a high-grade institution, requiring a three years' graded course. It has three distinct and independent departments, viz.: Medicine, dentistry and pharmacy. The system of instruction is a graded one, and consists of didactic lectures, clinical teaching, quizzes, recitations and laboratory work, so arranged that the work of each year does not conflict with the work of the other two years, the course of study being about equally divided between recitations and lecture work on the one hand and laboratory work and clinics on the other.

Personal work in the anatomic, chemic, histologic, pathologic, physiologic, dental and pharmaceutical laboratories is a prominent and most important feature and without additional expense.

The Virginia Hospital and its Out-Door Departments, and the Richmond Eye, Ear and Throat Infirmary, furnish ample facilities for genuine clinical instruction, and the professors of the different departments are allowed the use of this Hospital as a school of practical instruction.

The regular session began on Oct. 3, 1894, and will continue seven months.

Faculty of Medicine: Hunter McGuire, President; Joseph A. White, Secretary and Treasurer; Hugh M. Taylor, Stuart McGuire, Landon B. Edwards, Thomas J. Moore, Edward McGuire, George Ross, Paulus A. Irving, Lewis Wheat, John Dunn, M. D. Hoge, Jr., W. T. Oppenheimer, Jacob Michaux, William S. Gordon, J. Allison Hodges, Charles H. Chalkley.

Faculty of Dentistry: E. M. Cowardin, Charles L. Steel, Hugh M. Taylor, J. Allison Hodges, M. D. Hoge, Jr., Stuart McGuire, J. Michaux, W. S. Gordon, Charles H. Chalkley.

Faculty of Pharmacy: T. A. Miller, Andrew T. Snellings, T. Wilber Chelf.

UNIVERSITY OF VERMONT, MEDICAL DEPARTMENT.

The thirty-second annual course of lectures will begin Thursday, Jan. 17, 1895, and continue six months, ending July 8.

This extension of the term will increase the scope of the instruction, and prove of great advantage to

the student. The preliminary term has been abolished. No private courses by any of the professors will be tolerated by the Faculty.

Instruction will be given in the following branches: Anatomy, physiology, chemistry, materia medica and therapeutics, practice, obstetrics, surgery, diseases of children, medical jurisprudence, neurology, ophthalmology and otology, gynecology, dermatology, venereal diseases, pathology, and bacteriology, hygiene, sanitary science and examinations for life insurance.

Laboratory courses at this College in urinary analysis, histology, pathology and bacteriology, and practical work in physical diagnosis, surgery and demonstrative obstetrics, are now compulsory.

The instruction is given by scholastic and clinical lectures, by recitations and by practical manipulations by the student.

The clinical advantages are in many respects unsurpassed.

For further information address the Secretary, Dr. B. J. Andrews, Mary Fletcher Hospital, Burlington, Vt.

UNIVERSITY OF TORONTO MEDICAL FACULTY.

TORONTO, ONTARIO.

The eighth session since the reestablishment of the Medical Faculty of the University of Toronto will commence on Oct. 2, 1894. The opening lecture will be delivered by Prof. R. A. Reeve in the biologic department.

Distinct and separate courses of instructions are provided for each of the four years of the medical curriculum.

The course of instruction given by the Faculty prepares students primarily for the degree of M.B. of the University of Toronto, and for the license of the Ontario College of Physicians and Surgeons, but it fulfills the requirements of other Canadian Universities, and it aims at giving the student such a training in the sciences as is now exacted of all students who desire to obtain any British medical qualification in addition to a Canadian one.

Students intending to proceed to the degree of M.B. in the University of Toronto will find the requirements for matriculation to be as follows: Those who are graduates in Arts of any British or Canadian University, or who are undergraduates in the Faculty of Arts or of Law in the University of Toronto or have been registered as medical students in the College of Physicians and Surgeons of Ontario are exempt from this matriculation. A student desirous of obtaining a license to practice medicine in Ontario must pass the *July* matriculation examination of the University of Toronto, including the subjects of physics and chemistry, which entitles him to be registered as a medical student. If, however, he does not wish to obtain the Ontario license and yet intends to proceed to the degree of M.B., he may be registered as a matriculated medical student in the University on passing either the *July* or the *September* matriculation examination. He may delay presenting himself for this examination until any time before the second examination for the degree of M.B., but, if possible, he should matriculate before commencing his medical studies.

The degree of M.B., is given to candidates who have matriculated and who have attended during four winter sessions of at least six months each and one summer session the courses of instruction as required

by the curriculum, and who have passed three examinations taken in the following order: the first at the end of the first session; the second, at the end of the second session; and the final, at the end of the fourth session.

Subjects of the different examinations, first examination: Physics, chemistry (inorganic), biology.

Second examination: Anatomy, physiology, embryology and histology, materia medica and elementary therapeutics, chemistry (organic and physiologic).

Final examination: Medicine and clinical medicine, surgery and clinical surgery, obstetrics, pathology, therapeutics, gynecology, medical jurisprudence and toxicology, hygiene, medical psychology, topographical anatomy.

Fees: Registration (payable once only) \$5; the tuition fees for the first year amount to \$75; for the second year amount to \$75; for the third year amount to \$85; for the fourth year amount to \$85; supply fee for use of microscope and material in first year \$1.50; for second year \$2.75.

Students in the fourth year will be required, in addition, to pay a fee of \$5 for the extra-mural class in medical psychology.

Fees connected with examinations and the granting of degrees: For matriculation or registration of matriculation, \$5; for annual examination (each) \$10; for examination in practical chemistry, 50 cents; for admission *ad eundem statum*, \$6; for the degree of M.B., \$20; for the degree of M.D., \$20; for admission *ad eundem gradum*, \$20.

For all information not covered by this announcement, the intending student should apply to Prof. A. Primrose, Biological Department, University of Toronto.

UNIVERSITY OF BISHOP'S COLLEGE, FACULTY OF MEDICINE.

MONTREAL.

Medical course of study, four years of six months each, and one summer course at end of third year of three months. Fees for four years, including hospitals, etc., about \$400.

Special advantages offered in maternity and gynecological work.

The only University in this Province which admits students of both sexes.

Dental course of study leading to the degree of D.D.S. includes three years. Matriculation examination is identical in details for admission to either.

This Faculty is recognized by the Royal College of Surgeons, England, and the Royal College of Physicians, London. Class tickets for the various courses are accepted by those Colleges as qualifying candidates for examination. The Royal College of Physicians of Edinburgh, the Royal College of Surgeons of Edinburgh, the Faculty of Physicians and Surgeons of Glasgow, and the University of London, also accept the class tickets of Bishop's College, and the diploma of this University exempts its holder from being examined on the subjects of the primary branches and matriculation. Such candidates are therefore only required to pass in the subjects of the final branches, including hygiene. The Scottish colleges acting conjointly grant only one examination, and therefore confer a triple qualification.

The degree of Medicine and Surgery of this University, being accepted by the licensing bodies of Great Britain, its possessor is entitled to the same

exemptions as are allowed all other recognized Colonial degrees. The College of Physicians and Surgeons of Quebec accepts the degree without further examination, provided the holder of such degree has, previous to beginning the study of medicine, passed the preliminary examination exacted by that Board.

The class tickets for the various courses are accepted as qualifying for the examination of the College of Physicians and Surgeons of Ontario, and the matriculation examination of this Faculty is recognized by the General Medical Council of Great Britain.

Geo. T. Ross, M.D. Registrar.

WASHINGTON UNIVERSITY, MEDICAL DEPARTMENT.

ST. LOUIS MEDICAL COLLEGE.

ST. LOUIS, MO.

The fifty-third annual session of St Louis Medical College commenced Sept. 27, 1894, and continues until April 26, 1895.

The building is commodious, capable of accommodating 400 students, and is modern in design and complete in equipment. It has large and thoroughly furnished laboratories for chemistry, histology, pathology, and bacteriology. Unusual facilities are furnished for the pursuit of these branches.

Its clinical opportunities are ample. The city institutions, City Hospital, Poor-House, Insane Asylum and Female Hospitals are open to the students.

The out-clinics of the College are fine and well provided with excellent quarters. The Mullanphy Hospital, the finest hospital in St. Louis, affords exclusive advantages to the students of this institution.

This College has for fifteen years enforced a three years course and has this extended course now thoroughly established and in good working order.

Fees for each year \$100.

Henry H. Mudd, M.D., Dean; E. E. Senseney, M.D., Secretary.

WESTERN RESERVE UNIVERSITY, MEDICAL DEPARTMENT.

CLEVELAND, OHIO.

Presents a three years' graded course, each year a term of eight months. Instruction by recitations, lectures, clinics, quizzes and practical training. Ample laboratory, dispensary and hospital facilities and equipments are provided for all students. Tickets for year, \$100; tickets for whole course, \$250. Special courses as desired, and advanced students given standing according to assured acquirements. Year begins middle of September.

Charles F. Thwing, President; Isaac N. Himes, Dean; G. C. Ashmun, Secretary.

YALE UNIVERSITY, DEPARTMENT OF MEDICINE.

YALE MEDICAL SCHOOL.

In the fall of 1810 a charter was granted to the President and Fellows of Yale College and the President and Fellows of the Connecticut Medical Society authorizing them to unite according to the terms of certain "Articles of Union," before agreed upon, for the establishment of a medical seminary, to be styled the Medical Institution of Yale College. Two years later the school was organized, and in the fall of 1813 instruction was begun. The Faculty consisted of four professors, appointed by the College Corporation from nominations by the Medical Society. Degrees were conferred by the College on the recom-

mendation of the Board of Examiners, consisting of the members of the Faculty and an equal number appointed by the Medical Society. The instruction consisted of didactic and clinical lectures and dissections during the short winter course. Later, instruction was given during the spring months also, and from time to time the number of instructors was increased.

That this dual nature of the school and the method of instruction were wisely planned is shown by the position which the school took at once in the medical instruction of the time. But changes gradually took place in the relations between practitioners and students of medicine, and even greater changes in medicine itself, which demanded a different kind of instruction. This school responded early to this demand, and in 1879 an entrance examination was imposed, and a graded course extending over three years of eight months each, and including considerable laboratory instruction, was adopted. In 1884 by an agreement with the Medical Society, the College authorities assumed the entire control of the school.

In re-organizing the school as an integral part of the University, the inherent defects in the older and still common method of instructing chiefly by didactic lectures, were recognized, and the methods now employed are similar to those in vogue in the other departments. Didactic lectures are still employed as best in some branches, but recitations from assigned readings, with explanatory lectures, laboratory work and personal instruction in the clinics, constitute the main portion of the curriculum. The school has well equipped laboratories for the study of anatomy, histology, chemistry, pharmacy, physiology, pathology, and bacteriology. A new building especially adapted to the requirements of laboratory work, has been added to the equipment recently, and is used for the first time this year.

While the attention of the student is particularly directed to those branches which can be studied to advantage only in a well equipped medical school, the value of clinical instruction is fully appreciated, and amply provided for. The course of instruction is graded to cover three years of thirty-four weeks each. The curriculum consists chiefly of recitations of assigned readings in text-books, systematic laboratory work, and personal instruction in clinics.

Terms of admission: Candidates for admission must be at least 18 years old, and must present satisfactory testimonials of moral character from former instructors or physicians in good standing. Each candidate must present proof that he has passed the matriculation examination of some scientific, literary, or professional college in good standing; or present testimonials from the proper officer that he has pursued the course at some high school, academy or preparatory school, approved by the Faculty; or he must pass an examination in the following subjects:

1. English: An essay of about two hundred and fifty words on some familiar subject to be announced at the time of the examination.

2. Mathematics: The metric system of weights and measures. Algebra, to quadratics. Plane geometry, to the extent included in Wentworth's Plane Geometry, Books I-III.

Physics: Gage's Element of Physics, or some equivalent work.

REQUIREMENTS FOR A DEGREE.

To be eligible for the degree of Doctor of Medicine,

every candidate must fulfill the following conditions:

1. He must be at least 21 years of age, and must sustain a good reputation for moral character.

2. He must have spent three years as a student in this school, or if but one or two years in this school, he must have pursued such studies in some other recognized institution, as are considered by the Faculty to be the equivalent of the remainder of the full term of study. The last year must have been in this school.

3. He must have passed to the satisfaction of the Faculty the prescribed examinations of the course; and he must have presented a satisfactory thesis on some subject relating to medicine. The thesis should be presented to the Dean on the third Wednesday before Commencement.

Fees and expenses first year: Matriculation (paid but once), \$5; tuition, \$140; practical anatomy (including instruction and material), \$10. Second year: Tuition, \$140; practical anatomy (including instruction and material), \$5; practical pharmacy, \$5. Third year: Tuition, \$80; Graduation, \$30.

Herbert E. Smith, M.D., Dean, New Haven, Conn.

Faculty: Rev. Timothy Dwight, President; Moses C. White, Charles A. Lindsley, William H. Carmalt, James Campbell, Thomas H. Russell, Louis S. DeForrest, Oliver T. Osborne, Harry B. Ferris, Graham Lusk.

Other instructors: William H. Brewer, Henry P. Stearns, Samuel B. St. John, Henry Fleischner, Frank H. Wheeler, Charles J. Foote, Henry L. Swain, Joseph H. Townsend, Arthur N. Alling, Louis B. Bishop.

SOCIETY PROCEEDINGS

American Association of Obstetricians and Gynecologists.

Abstract of the Proceedings of the Seventh Annual Meeting, held in Toronto, Sept. 19, 20, and 21, 1894.

FIRST DAY—MORNING SESSION.

The Association met in the Council Chamber of the College of Physicians and Surgeons at 10:15 A.M., and was called to order by the second Vice-President, DR. GEO. F. HULBERT, of St. Louis, Mo.

An Address of Welcome on behalf of the local medical profession was delivered by DR. JAMES THORBURN, which was responded to by DR. HULBERT.

The reading of papers was proceeded with, and the first paper was read by DR. J. HENRY CARSTENS, of Detroit, entitled THE INCISION IN ABDOMINAL SURGERY—METHODS AND RESULTS.

The author summarized as follows:

1. With a small, narrow-bladed, sharp knife make a clean incision through the skin of the necessary length, and with another sweep or two cut through the linea alba, muscle, etc. Lift the peritoneum with your fingers, open it, and enlarge the incision. The use of the forceps to lift the tissues, or the grooved director is unnecessary.

2. In closing the abdominal incision use animal ligature, kangaroo tendon and catgut. First carefully bring together the peritoneum in a running stitch, then the transversalis fascia, and the rectus if the incision is through this muscle. Then carefully bring together, edge to edge, the tendinous insertion of the oblique muscles. The fat and loose cellular tissue above, can be brought together in one or two tiers, according to thickness. Bring the skin together carefully with Marcy's cobbler stitch, thus burying all your sutures.

3. Then seal with collodion, and if everything connected with the operation has been carefully aseptic, absolute primary union will take place, and the different layers of the abdominal wall will have been brought together as near as

possible as they were in the first place, and no hernia will result.

4. In cases of extensive umbilical, ventral, or other hernias, it is best to bring the peritoneum together with an over-and-over stitch of kangaroo tendon or catgut; to make a flap splitting operation of the ring, which is brought together with silkworm gut, or silver wires which are buried, and then the fat and skin are united with the buried animal suture.

PLASTIC SURGERY IN GYNECOLOGY.

DR. JOSEPH PRICE, of Philadelphia, read a paper on this subject in which he said that the practice of surgery in all its branches required a mechanical trend and an ability to devise means to accomplish a given end. In order to mend a perineum intelligently, the mechanism of labor must be understood and the lines of fracture appreciated. In cases of serious pelvic invasion with accompanying lacerated cervix it is often better or imperative, first, to do the pelvic operation, and to follow this at another time with the cervical repair. The author condemns the plan advised by some to perform internal and external operations at one sitting. Perineal tears always occur at certain parts of the perineal structure. These tears are either lateral, under the ramus of the pubes, or central, extending from vagina toward the rectum. The tears toward the rectum tend to run around it rather than through it, owing to the differentiation of structure in these two tubes. The tears of the vagina are always from within outward, from above downward, and therefore the external or skin operations for perineal lacerations are essentially unscientific procedures. All operations for the restoring of the integrity of these parts should be done in the lines of their destruction, and therefore from within outward and from above downward. When the skin of the perineum is involved, mending of this is merely a cosmetic procedure. The cosmetic element too often predominates in many of the so-called perineal devices. The silkworm gut with shot is by far the most preferable material to be used for sutures. As little tissue as possible is to be included within the ligature, and strangulation is to be avoided.

DR. W. B. DEWEES, of Salina, Kansas, read a paper entitled "The Care of Pregnant Women." (See JOURNAL September 29.)

APPENDICITIS WITH REPORT OF CASES.

DR. GEO. S. PECK, of Youngstown, Ohio, read this paper.

Case 1.—Operation during interval of attacks; obstruction July 6; did second operation; recovery. Operation July 27. Appendix buried in mass of strong adhesions between ileum and cecum containing large fecal concretion. Appendix removed in segments. Ileum returned to abdominal cavity. During first six days highest temperature 100. August 4 re-opened incision, found about three feet from ileo-cecal valve complete obstruction by band of dense adhesions. Obstruction liberated, ileum brought out in the incision and abdominal cavity packed with gauze. From the thirteenth day to the present time patient has had from one to three daily passages per rectum; discharged from the hospital on the fifty-fifth day after first operation.

Case 2.—Operation during fourth day; first attack. Large appendix removed, containing two drachms of pus and fecal concretion. Adhesions broken up, incision packed with iodoform gauze. Uninterrupted recovery. Discharged from hospital twenty-eighth day after the operation.

Case 3.—Operation third day of the third attack. Peritoneal cavity opened, adhesions broken up; large appendix removed; uninterrupted recovery.

Case 4.—Operation during tenth day. Death from septic peritonitis in sixty-five hours. Large abscess cavity evacuated; appendix gangrenous and detached; washed out by irrigation. Autopsy revealed general septic peritonitis.

Case 5.—Perforating appendicitis. Operation during third day of attack. Death from septic peritonitis twenty-seven hours, or more, after operation. Case 6, similar to previous one, died from general septic peritonitis.

DR. W. G. McDONALD, of Albany, contributed a paper on APPENDICITIS; OBSERVATIONS BASED ON A CLINICAL STUDY OF EIGHTY-FOUR CASES.

Out of the great amount of literature, controversial and otherwise, three important landmarks are established: 1, that for all practical purposes all inflammatory processes in the right iliac fossa, arise from the appendix; 2, that practically the appendix is always intra-peritoneal, and that any operation undertaken for appendicitis that does not involve the entering of the peritoneum is false in its surgical conception; 3, that idiopathic peritonitis does not occur. That many cases diagnosed as such, are really cases of perforating appendicitis. The author classified the varieties as: 1, acute perforating, fulminating appendicitis with general peritonitis; 2, acute suppurating appendicitis with local plastic peritonitis and abscess; 3, subacute appendicitis, variously termed catarrhal, chronic, relapsing, or obliterating appendicitis, or appendicular colic.

DR. JOSEPH HOFFMAN, of Philadelphia, followed with a paper on "Surgical Appendicitis."

SECOND DAY—MORNING SESSION.

DR. W. B. DORSETT, of St. Louis, read a paper entitled LIGATION OF THE UTERINE ARTERIES FOR THE CURE OF FIBROID TUMORS AND CHECKING HEMORRHAGE.

The object of this paper was to establish the author's priority as well as originality of ligation of the uterine arteries for the cure of fibroids. He made observations during December, 1889, and January and February, 1890, and reported a case of atrophy of the genitalia and described the technique of the operation of ligation of the uterine arteries for the cure of fibromatous growths in a paper read before the St. Louis Medical Society, May 17, 1890, and which was published in the *St. Louis Courier of Medicine*.

DR. HENRY HOWITT, of Guelph, Ont., read a paper entitled REMARKS ON THE SURGICAL TREATMENT OF INTUSSUSCEPTION IN THE INFANT, BASED ON TWO SUCCESSFUL CASES.

In this paper he recommends early abdominal section as being the best method of treatment to reduce the high mortality rate of intussusception in early infancy. Of the two cases cited, one child was at the time of operation under 3, and the other under 6 months of age. In regard to the steps of the operation, among other things he advises a small median incision; evisceration; reduction by pressure on apex of intussusceptum, while the intussusciens is drawn in the opposite direction; and forcing the contents of ileum into colon before returning the intestines to abdomen.

DR. ROBERT T. MORRIS, of New York, demonstrated a method of intussusception in rabbits.

TREATMENT OF DISTENSION OF THE FALLOPIAN TUBES WITHOUT LAPAROTOMY AND REMOVAL.

By DR. FRANK A. GLASGOW, of St. Louis. This paper is intended to bring before the profession a method of curing tubal distension by means of intra-uterine treatment in contra-distinction to laparotomy and removal. By this means the uterine ends of the tubes are made more patulous, and a discharge takes place from the tube through the uterus. He called attention to the fact that the tubes, as far as his observation goes, are always pervious at the outer extremity of the cornu, hence when removing them we must always clamp them before cutting. The obstruction must be within the uterine wall, probably in the endometrium. Gonorrhoeal inflammation is not an adhesive inflammation, and hence it does not follow that the tubes have a true atresia following this inflammation. His opinion is that the closure is due to a swelling of the endometrium and hence a closure at the uterine end takes place. When this inflammation and swelling are overcome by pressure and antiseptic

sis the tubes become patulous again. The intra-abdominal pressure will cause fluid in any pendent portion of the tube to ascend into the uterus. The above procedure can be carried out in three different ways: 1, by gradually packing with gauze, without anesthesia; 2, by rapid dilatation of the cervix and packing with gauze after curetting. This is done under anesthesia; 3, his own method of dilating by means of antiseptic or sterilized elm bark tents. These tents are small strips of elm bark made just long enough to enter the cervix completely and not press on the fundus. They should be kept in an alcoholic solution or bichlorid of mercury, 1 to 4000, and have a strong string attached, by means of which they may be withdrawn. They are partially broken in a number of places for the purpose of making them more pliable. They may be dipped into glycerin or water just before introduction. These tents may be used when it would be impossible to pack with gauze. He had treated twenty or more cases during the past year, and does not recall one in which he did not get some discharge from the tent. All of these cases were either cured or very much benefited.

INFLAMMATORY DISEASE OF THE UTERUS AND APPENDAGES AND OF THE PELVIC PERITONEUM—INTRODUCTORY REMARKS.

By DR. WM. W. POTTER, of Buffalo. Dr. Potter began by recalling the well-known fact that the pathology of pelvic disease has been entirely reconstructed since 1860, and that now we had come to regard inflammation of the pelvic peritoneum as generally symptomatic of disease of the ovaries or Fallopian tubes or both. Mr. Tait within the last ten or twelve years, together with men who have worked abreast of him—some of whom are members of this Association—have driven out the theory of pelvic cellulitis that for so long held sway, and now peri- and parametritis have been dropped from the gynecologic vocabulary. The struggle has been a long one, but abdominal surgeons have demonstrated the truth of this proposition, viz., that pus originating outside of the tubes or ovaries in the non-puerperal state is a very rare condition, and that speaking generally pelvic abscesses are pus tubes. The largest number of women in the consulting rooms of gynecologists are those suffering from pelvic inflammation or its residues, hence the importance of the subject under discussion can not be over-estimated. But he asserted, it is only within the past seven or eight years that anything like uniformity of opinion as to the causes and proper treatment of pelvic inflammation have been adopted. Now, just as we are beginning to agree as to the essentials governing these cases, we are told by a number of agreeable gentlemen who call themselves conservatives that these diseases do not demand operation, but that they can be cured in most instances by tentative measures, such as diet, rest, electricity, and the like. By denouncing the work of abdominal surgeons as unnecessary mutilation, and stigmatizing it as castration or unsexing women, they have created a panic among the medical journals that is reaching far into the ranks of the profession. The effect of this is to turn back the wheels of time and stay the advance of progress with harmful results to suffering women. It must be admitted that these so-called conservative men are clever, which makes their subtle and dangerous doctrine all the more damaging in its results.

DR. C. A. L. REED, of Cincinnati, discussed the clinical history of inflammatory diseases of the uterus and appendages and of the pelvic peritoneum; Dr. L. S. McMurtry, of Louisville, the causation and pathology; Dr. James F. W. Ross, of Toronto, the diagnosis and prognosis; Dr. M. Rosenwasser, of Cleveland, the treatment, along with Drs. A. Vander Veer, J. Henry Carstens and Joseph Price.

DR. JOSEPH HOFFMAN, of Philadelphia, read a paper entitled,

PUS IN THE PELVIS AND ABDOMEN; ITS DIAGNOSIS AND TREATMENT.

He said that pus in the abdominal and pelvic cavities had been treated and considered with far more leniency than pus anywhere else in the human economy. It was the tramp manifestation of all disease. He considered briefly the various organs in which pus makes its appearance, and in the order of frequency he mentioned the kidneys, appendix vermiformis, tubes and ovaries, liver, pancreas and spleen. Each case should be treated according to the demands it makes and according to its complications. There was no rule in doing an ideal operation and have the patient die when it is over. Ideal work was that which gives the best result in the line for which it was done. Surgery of the abdomen was a work of self-denial, of trial, of unexpected complication, and lurking disaster. He best can rise to it who has for his motto "My Patient." Nothing but for the good of her who trusts me. Self-seeking carelessness of lives has its place in the carnage of internecine strife, not in the sorrows of suffering humanity, of dying women.

DR. E. W. CUSHING, of Boston, made some remarks on hysterectomy for cancer of the uterus.

DR. JAMES F. W. ROSS, of Toronto, read a paper entitled, "Personal Experience with Pus Tubes, When to Operate, How to Operate, and the Results of Operation."

DR. H. T. MACHELL, of Toronto, contributed a paper on "Congenital Diaphragmatic Hernia," in which he reported two interesting cases.

A NEW OPERATION FOR THE RADICAL CURE OF INGUINAL AND FEMORAL HERNIA.

This paper was read by DR. C. A. L. REED, of Cincinnati. The operation which the author devised is as follows: The incision in inguinal hernia is made from a point two inches above Poupart's ligament, midway between the anterior superior spinous process of the ileum and the spine of the pubes, obliquely downward and inward as nearly as possible consistent with the access of the inguinal canal to a point at the base of the scrotum. The dissection is then carried into both scrotal and pelvic cavities. The protruding viscera is then reduced and carefully inspected after being brought out above. The sac is then carefully dissected from its scrotal connections and reversed by invagination. It is then opened by two incisions; one toward the pubes, the other toward the ileum, being thus converted into an anterior and a posterior flap. The cord is now dissected loose and placed in the canal, and denuded of its peritoneum at its outer angle. The internal ring is closed by several interrupted sutures, animal or buried silk, these sutures being applied beneath the peritoneal flaps formed by splitting the sac, care being taken that in the closure of the ring undue pressure shall not be brought to bear upon the cord. The posterior peritoneal flap is now excised, the stump being ligated should there be any necessity for doing so. The anterior flap is carried across the now obliterated internal ring and stitched by interrupted sutures to the posterior parietal peritoneum. The external ring is now closed by passing a number of sutures through its pillars externally to the cord, which is now fixed in the internal (pubic) angle of the outlet of the canal. The incision into the abdomen is closed by an interrupted figure of eight suture, the internal loop embracing the peritoneum, the aponeurosis of the transversalis and of both oblique muscles and the external loop embracing the superficial fasciæ, fat and skin. These sutures should not be more than three-quarters of an inch apart. The incision into the scrotum may be closed in the ordinary way. Drainage should not be employed except in the presence of marked oozing or obvious infection.

OVARIOTOMY.

DR. A. VANDER VEER, of Albany, presented a report of

one hundred and forty-five operations done for removal of ovarian tumors and pathologic conditions associated with the ovaries and uterine appendages only. He gave a careful review of the subject of the preparation of patient, embodying all the strong points pertaining to the technique of such work, placing great stress upon the importance of the room in which the operation was to be done being put in a thoroughly aseptic condition, and thorough cleanliness of the patient herself. The operations comprise all the varieties of pathologic conditions met with in connection with the ovaries and tubes. The histories of the cases were somewhat interesting. Thirty-nine gave a history of phthisis, fifteen of cancer, fifty-seven of irregularity of menstruation. The mortality amounts to 11 per cent. While not criticising adversely the methods of other operators in closing the wound by means of different rows of sutures, kangaroo tendon, and other forms of sutures, yet he has no reason to give up his usual method of closing the wound by deep sutures of silkworm gut, placing them three or four to the inch, taking in carefully only a margin of the skin, a portion of the fascia and muscles, and not to exceed one quarter of an inch in width of the peritoneum itself, placing much stress upon the importance of careful, thorough, complete apposition. The causes of death in the seventeen cases were as follows: Obstruction of the bowels due to a coil of small intestines becoming attached to the stump of the pedicle, causing death on the fourth and fifth day, two cases. Septic peritonitis, two cases. Immediate hemorrhage from the pedicle, slipping of the knot, within six hours after the operation, though the wound was re-opened, the vessels secured, abdomen flushed, and hemorrhage controlled, one case. Undoubted hemorrhage from the pedicle, causing general peritonitis although no distension of the bowels was present, death on fourteenth day, one case. Shock within twelve hours after operation, one case. Shock within twenty-four hours after operation, one case. Autopsy in both cases revealed everything in good condition. Pulmonary infarction on sixth day, one case. Aggravated diabetes, one case. Exhaustion on the sixth day, no other apparent cause found, one case. Another case of exhaustion on the third day, symptoms in the last two cases, including an autopsy not revealing any other cause. Multilocular ovarian cyst, tapped twice, operation complicated with four months pregnancy, one case. Puerperal septicemia, one case. Intestinal obstruction one twenty-first day, one case. Advanced age complicated with the recent effect of an attack of la grippe, one case. Delayed operation in a case of extra-uterine pregnancy possibly four months, one case.

(To be concluded.)

American Public Health Association.

Twenty-second Annual Meeting, held at Montreal, Canada, Sept. 25-28, 1894.

The Association met with total membership of 225 present. The sessions were held in the Association Hall of the Y. M. C. A., opposite Dominion Square. The hall was appropriately decorated for the occasion with banners and coats of arms of the three countries which the Association represents, while the stage was decorated with escutcheons of the British Dominion, United States and Mexico.

The members were furnished with an orange and badge of red silk, artistically designed and surmounted with a gilt shield bearing the arms of the Province of Quebec which has the *fleur-de-lis*, and the British lion. The whole was encircled with a wreath of maple leaves surmounted by the imperial crown, while upon each little pennant were written in gilt letters respectively, A. P. H. A., 1894, and Montreal, P. Q. One of the French *confrères* present humorously suggested that the orange or yellow was indicative of quaran-

tine, while the red portion of the badge was indicative of medicine—red corpuscles, etc.

Tuesday or the first day's meeting began at 10:30 A.M., and was called to order by the President, DR. E. P. LA CHAPPELLE, of Montreal, who in a few well chosen words welcomed the visitors. His address was mostly of an informal character, as the formal opening of the Association did not occur until evening. The chairman of the Local Committee of Arrangements, Prof. Robert Craik, was then introduced and in a pleasant manner promulgated a number of important announcements besides expressing the cordial feeling that existed throughout the profession. The report of the Executive Committee through Secretary Watson, stated that about one hundred and fifty applications for membership had been received, and their election to membership was recommended. Dr. A. L. Gihon moved, duly seconded, that the Secretary be authorized to cast the vote of the Association for the list as presented, which was accordingly done.

The next order of business was the following resolution, offered by Dr. A. L. Gihon, of the United States, and seconded by Dr. Frederick Montizambert, of Canada, which was carried unanimously, and the Secretary ordered to telegraph the same to the gentlemen named therein:

Resolved, The American Public Health Association, in session at Montreal, regrets the enforced absence of its first Vice-President, Dr. Carmona Y. Valle, of Mexico, its late Vice-Presidents, Drs. Liceaga and Orvananos, and its other Mexican colleagues,¹ and sends them its fraternal greetings, good wishes, and hopes that we shall see them at the next annual meeting.

The first paper presented was entitled

HYGIENIC NOTES MADE ON A SHORT JOURNEY THROUGH ITALY IN 1894.

By DR. GEORGE H. F. NUTTALL, Associate Professor of Hygiene in Johns Hopkins University, which was in the absence of the author read by Dr. Gihon. The writer dwelt particularly upon the former and modern sanitary conditions of the cities of Naples, Rome, Florence, and Milan, and compared the modern hygienic environments and conditions of those cities even to 300 B. C., as was instanced by Rome's condition at that period, to those of the present day. The sewers, water supply and drainage systems of Naples were described. The aqueducts of ancient and modern Rome, her extensive hygienic laboratories, hospitals, etc., were also described, while Florence was denominated the cleanest city in Italy. Her slaughter houses are large and well kept. Chlorotic girls at the latter city frequently visit those, (at best apparently uninviting) places, and drink the fresh defibrinated blood from the slaughtered animals. There the hair from slaughtered pigs is removed by singeing. This is regarded as the best method but it injures the meat. A description of how the dog pounds are kept and how the unclaimed animals are put to death was minutely dwelt upon.

Cremation in that country has steadily increased. Comparisons were made in this respect with that of the burial of the dead. In 1876 the first crematory was built at Milan, while twenty-one towns in Italy to-day have official crematories. In Milan it costs 40 lire and upwards for each cremation, while in Rome a firstclass cremation costs 180 lire down to 60 lire. The indigent poor in both cities are cremated free.

The President announced that several papers bearing upon similar topics would be read, and suggested that discussion upon Dr. Nuttall's paper be deferred.

DR. FELIX FORMANTO formally moved that discussion upon the above and kindred topics be deferred until the end of the series had been reached. Carried.

¹ There were five members in attendance from Mexico, viz: Drs. Monjarras, Chico, Mendizábel, and the brothers Ramirez de Arellano.

THE CART BEFORE THE HORSE.

This paper was read by DR. BENJAMIN LEE, Secretary of the State Board of Health of Pennsylvania, who said in part: When those who speak the English language desire to characterize a line of thought or of procedure as being in the very highest degree ridiculous and absurd, they make use of the word, preposterous, a word which they have had handed down to them from the days of ancient Rome; for the Roman with his strictly logical mind could conceive of nothing more grotesque and idiotic than placing that which should properly and reasonably be *pro—before*, whether in relative position or in sequence of time, *postero—behind* or *after*. The Saxon, with his love for the concrete and his fondness for epigram, crystallized the thought into the proverbial expression, "the cart before the horse." I know of no more forcible exemplification of this trite but useful adage than the absolute reversal which we so constantly find of the appropriate relative positions in point of time of the introduction of water supplies and the provision of systems of drainage. The first thought of the citizen who proposes to build himself a country residence is beauty of location. The second, architectural adornment. The third, possibly, a copious and pure water supply, and, with this, modern plumbing follows as a necessary accompaniment. Last of all, he or his architect bethinks himself that it will be necessary to find a receptacle for this considerable stream which he is going to divert from its natural course and fill with the accumulated filth of his household. That which should have been most carefully considered first, before a line was drawn or a plan designed is left to be provided last, in some haphazard way, as if it were a trifling detail of no moment whatever. The problem may prove impossible of satisfactory solution to himself. Or if provision can be made in such a way as to relieve himself of annoyance, the chances are ten to one that his neighbor will begin to complain of the flooding of his yard or the pollution of his well; or, what is still worse, and unfortunately of undoubtedly frequent occurrence, sickness may be created in families more remote, the cause of which is unsuspected and therefore unremoved.

The little towns among the hills and mountains of Pennsylvania are peculiarly fortunately situated for the production of an abundance of pure water. The municipal authorities of these towns are besieged by water supply contractors, generally from New England, and therefore having no local interests in the town, with offers to introduce water on very advantageous terms. The temptation is great and is often yielded to before a single rod of sewer pipe is laid in the streets. Then the "practical" and "sanitary" plumbers get in their fine work. Every ambitious citizen must have water all over his house, with all the modern appliances. The kitchen water even though in greatly increased quantity may pass off over the surface and through the street gutters. But what shall be done with that discharged from the water closets? Happy thought! He no longer depends on the old family well for drinking water, so, into that, the soil pipe is incontinently discharged. So far so good. It does not annoy him. But he does not reflect that the same subterranean stream which supplies his well in all probability supplies those of the entire neighborhood. It can be readily understood how that which should have proved to be an inestimable blessing to the community may thus inadvertently be converted into a terrible calamity. Even in gravelly soils, where opportunity for filtration to a considerable degree exists between neighboring wells, this danger is a most serious one. It will easily be seen how much it is aggravated in limestone regions where the water courses along underground for great distances, almost unobstructed. And yet it is just under these circumstances that the temptation to avail one's self of this so called natural drainage is the greatest. The object of this paper may be briefly embodied in the two following propositions:

1. Copious water supplies, with the aid of what is known as modern plumbing, constitute a means of distributing fecal pollution over immense areas through the soil, through subterranean water courses and in surface streams, and can not therefore be regarded with unmodified approbation by the sanitarian.

2. The question of drainage and sewerage whether for individual residences or for communities should always precede that of water supply; and no water-closet should ever be allowed to be constructed until provision has been made for the disposition of its effluent in such a manner that it shall not constitute a nuisance prejudicial to the public health.

OBSERVATIONS UPON SEDIMENTATION IN WATER, WITH ILLUSTRATIONS BY CHARTS.

By DR. WYATT JOHNSON, bacteriologist to the Board of Health of the Province of Quebec. The author stated among other things: "That large natural bodies of water, standing, become purer and less free of bacteria, and water improves as the result of sedimentation. Improvement depends also upon the capacity of water for keeping. The Montreal city supply of water was carefully described. It is received from the St. Lawrence River through an aqueduct six miles long, connected with a reservoir that contains about 35,000,000 gallons, which undergoes a certain amount of change daily. About 23,000,000 gallons is used every twenty-four hours for the city. Relative to the number of bacteria in the reservoir and in the settling basin throughout the year, his observations showed in the Montreal supply the average number of bacteria, throughout the year, was 170 per cubic centimeter in the basin, and but 72 are to be found in each cubic centimeter of water taken from the reservoir. The writer submitted two sets of observations analyzed from water of the Ottawa River as well as that taken from the St. Lawrence.

"The recent theory that sunlight is a great agent to cause the disappearance of bacteria from water was referred to, although his observations and deductions, while not quite clear, do not show that sunlight penetrated into deep layers of water."

The fourth paper of this forenoon session was read by DR. A. N. BELL, of Brooklyn, editor of the *Sanitarian*, on

THE LONG ISLAND WATER BASIN—BROOKLYN'S RESERVOIR.

The author concluded by stating that the waste of streams is enormous; it is nevertheless easy to appreciate, from a knowledge of the conditions of the soil and the examples cited of the wells sunk into it, the inexhaustible adequacy of the Long Island water basin to supply water sufficient to meet the demands of Brooklyn for all time, and the folly of those who would in the face of such knowledge seek it elsewhere.

The fifth paper,

THE WELL WATERS OF OUR FARM HOMESTEADS,

was read by FRANK T. SHUTT, Chief Chemist Federal Experimental Farm, Ottawa. The subjoined is a brief synopsis:

The purest water is undoubtedly to be found in the country, and it is a necessity for farm animals as well as for man to have pure water. That milk from healthy milch cows may be wholesome, and that butter and cheese may be likewise. Clay soils are more or less impervious to the absorption of filth, and in this we should be careful from a hygienic standpoint. Regarding the qualitative tests for diagnosing water, the writer thought no correct inference could be drawn from the sugar, nitrate of silver, or permanganate of potash test. The remainder of the paper consisted in a cursory review of wells and their environments, and directed attention to the fact that much impure water is consumed in the country with serious and often fatal results, and pointed out the principal lines upon which corrections should be made and a reform brought about: "As the agriculturists form a very large proportion of the population, I think it well that we who take an active interest in the health of our people should endeavor to disseminate through the country knowledge regarding the injurious effects of impure water, and the precautions necessary to be taken if pollution of the well is to be avoided. I have no doubt that one of the beneficial results of this convention will be a keener and better and more intelligent understanding of this vital subject, an understanding that will lead to purer water and better health upon our farm homesteads."

The next paper announced, but which was not on the printed program, was entitled

SAND FILTRATION OF WATER WITH SPECIAL REFERENCE TO RECENT RESULTS OBTAINED AT LAWRENCE, MASSACHUSETTS.

By GEORGE W. FULLER, bacteriologist in charge of the Lawrence Experiment Station of the State Board of Health of Massachusetts.

The filter described by the author reduced the bacteria of the Merrimac River from 9,000 to 150 per cubic centimeter, a removal of 98.3 per cent. of the number.

During the five years preceding the use of the filter, the average annual death rate from typhoid fever in Lawrence was 1.27 per thousand inhabitants. The population of Lawrence is 50,000, and this average rate is equivalent to 63

actual deaths per year from the disease. During the past year there have been twenty-six deaths from typhoid fever in that city, a reduction of 60 per cent. Of the twenty-six who died, twelve were operatives in the mills, each of whom was known to have drunk infiltrated and polluted canal water, which is used in the factories at the sinks for washing. Among the operatives of one of the largest corporations where canal water is not used, there has not been a single case of typhoid fever during the past year.

The test of the efficiency of the filter during the past year has been a fair one, because at Lowell the sewage of which enters the Merrimac River nine miles above the intake of the Lawrence filter, there was during the past winter a severe epidemic of typhoid fever.

In conclusion, we may state that it has been found practicable to protect the consumers of infected water supply by means of sand filtration.

The last paper read during the forenoon session of the first day was on

SOME DEDUCTIONS FROM BACTERIOLOGIC WORK ON THE WATER OF LAKE ONTARIO,

By DR. E. B. SHUTTLEWORTH, Professor of Bacteriology Trinity Medical College, Toronto, and bacteriologist to the Toronto Board of Health. The paper dwelt upon the bacteriologic work done in connection with the water supply of Toronto. The city of Toronto is supplied from Lake Ontario through an intake located 2,200 feet from the shore of the Island. The mouth of the intake is eighteen feet from the bottom of the water which is there about seventy-five feet deep. The supply passes through a six-foot steel pipe and thence through a wooden pipe to the south shore of the island where it joins a steel pipe and is carried a distance of 6,000 feet across the land. It there reaches Toronto Bay, which at this point is about 4,500 feet wide, and is conveyed by a three-foot cast-iron pipe and a four-foot steel pipe, both of which terminate in a pumping well on the city side. The entire length of the conduit is nearly two and a half miles. The connections being made by cribs fitted with manholes, through which samples of water can be obtained. These cribs mark the extension of the pipes lakeward, as the intake was at intervals of years carried further out.

The paper contained a review of the normal bacteriologic character of the lake water, the effect of season and the number of bacteria as indicating sewage contamination, and the relation of bacteria to enteric fever. The statistics regarding the latter from December, 1892 to October, 1893, have been alluded to, the abscissæ being monthly periods of time throughout the year. The writer concluded that at the time the accident befell the pipe across the bay on Dec. 25, 1892, by which large quantities of sewage gained access to the supply, increased the number of bacteria per cubic centimeter and increased suddenly the enteric diseases, affording additional and conclusive evidence of the close relation which exists between sewage contamination and this class of maladies.

The succeeding two papers were read by title, as the authors were not present. "Pure Water vs. Purified Water for Public Water Supplies," by MR. DANIEL W. MEAD, of Rockford, Ill. "Water Supply of Towns," by DR. A. P. REID, Secretary of the Provincial Board of Health of Nova Scotia.

The Association convened Tuesday afternoon at 3 o'clock, DR. LA CHAPPELLE, presiding.

The first paper submitted was the

REPORT OF THE COMMITTEE ON THE POLLUTION OF WATER SUPPLIES.

By DR. CHARLES SMART, Major and Surgeon, U. S. Army. This report dealt chiefly with the subject of filtration. In a former formal report the Committee had taken the position that a water contaminated with sewage was unfit for use as a public water supply because neither aeration or sedimentation or filtration could be relied upon to remove the germs of typhoid fever if they chanced to be present in the sewage. Recent experiences had, however, led the Committee to recede from this position. The report of the Royal Commission on the water supply of London, England, published at this time last year was cited as showing the freedom of that city from typhoid fever by reason of its filtered water. The protection of Altona from cholera in 1892 by its filtered water, while Hamburg suffered on account of its unfiltered water, with the freedom of the latter city from the disease in 1893 after the completion of the filter beds for its water supply was also detailed.

The report then referred to filtration in this country, as carried out at Poughkeepsie, Hudson, Ilion and Mount Vernon, N. Y., and at Lawrence, Mass., showing the separation

from the water of 98 per cent. of its bacteria by infiltration through sand filter beds and a reduction of the typhoid fever death rate from 127 annually per 100,000 of the population where unfiltered water was used, to 24, after the filter beds were in successful operation. The Committee would not assert that filtration through sand at the rate of two million gallons daily per acre of superficies would protect from typhoid fever; but it is considered that the evidence so far pointed in this direction and was such as to induce water companies and municipalities to look earnestly into this subject. As to rapid or mechanical filtration processes the Committee allowed them to be capable of producing a clear water, but doubted the bacterial purity of the water. The patent companies have been for a long time before the public and have demonstrated nothing but the clearness of the water. The removal of bacteria from the water could easily be demonstrated, but this had not been done. The Committee then referred to a suggestion which it advocated to endeavor to bring the present chaotic condition of our knowledge of the water bacteria into system by cooperative investigation. The work was conceded to be too much for any one alone, but much good might be accomplished if in cooperative work one group of the bacteria were to be assigned for study and classification to one laboratory, another to another; one laboratory, for instance, dealing with the vibrios, another with the intestinal bacteria; another with the fluorescent forms, and so on. The report closed with a request for the sanction of the Association and such facilities as could be afforded to carry into practice this scheme of cooperative bacteriologic study.

DR. C. O. PROBST, of Ohio, submitted a resolution in accordance with the above suggestion, as follows:

Resolved, That this Association approves the suggestion of a cooperative investigation into the bacteriology of water, and commend the efforts of the Committee in carrying out this work to the officers of State and municipal Boards of Health, to the individual members of this Association, and to all persons interested in the purity of water supplies, for such special assistance as they may be able to render.

This was, under the rules, referred to the Executive Committee, DR. SWARTZ, of Providence, R. I., Chairman.

The report, as given by the Committee, is most thorough and can be read and re-read—each time with interest. The bacilli coli communis is not always present in typhoid fever cases. Mechanical filters have certain advantages over sand filters. Ptomaines may find their way, when filtered, through these. Mechanical filtration is the most expensive, but this may be due to certain conditions, as where sand may or may not be obtainable.

DR. J. H. GARDINER, of London, Ontario, spoke upon some of the subjects under discussion, and closed offering a resolution regarding "The Cart Before the Horse."

Resolved, That in view of the danger to the public health by the contamination of our fresh water lakes, rivers and streams, that this Association memorialize the different Federal governments as well as the State and Provisional governments, to pass laws prohibiting the contamination of these water supplies by sewage from cities, towns and villages, and compel them to provide some means for the treatment and oxidization of this sewage before emptying it into these places.

Also referred to Executive Committee.

(To be continued.)

Doctors' Fees and Lawyers' Fees.—Commenting upon the recent article on this subject in the *North American Review*, the *Pacific Medical Journal* cites some cases in point. "The daily papers," says our California contemporary, "are congratulating ex-President Harrison upon receiving a fee of \$25,000 for four hours work in court; had a medical man of equal or more ability than Mr. Harrison charged a many times millionaire \$5,000 for a month's constant attention, the whole press would be charging him with robbery—a man to be avoided when you are sick, etc. Another case in point. Judge Levy, of this city, (San Francisco) has just allowed a firm of attorneys a fee of \$80,000 for looking after the routine business of an estate for a few months, and yet this very same judge refused to allow a fee of \$30,000 which a medical man had presented for many months' attendance on a millionaire and his family. The actual work was probably a hundred times more than that performed by the attorney who received \$80,000; while the responsibility was probably five hundred times more, yet his Honor, Judge Levy, saw fit to cut the doctor's fee down to \$10,000. And why?" The only answer suggested is that the lawyer is that much more capable of taking care of his own interests.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, OCTOBER 6, 1894.

MEDICAL EDUCATION IN THE UNITED STATES AND CANADA.

The JOURNAL in this number has undertaken to put before its readers a statement from the Medical Colleges showing the existing state of the medical teaching in this country. A few colleges have not responded to the circular sent from this office for information.

It is easily seen that a great advance has taken place in medical education in this western world since the formation of the AMERICAN MEDICAL ASSOCIATION in 1847, one of the great objects for which this ASSOCIATION was founded.

In the first volume of Transactions, 1848, we find that the Committee on Medical Education reported that:

"This ASSOCIATION considers defective and erroneous every system of medical instruction which does not rest on the basis of practical demonstration and clinical teaching, and that it is therefore the duty of medical schools to resort to every honorable means to obtain access for their students to the wards of a well regulated hospital.

"Resolved, That this ASSOCIATION earnestly and respectfully appeals to the trustees of hospitals to open their wards for the purposes of clinical instruction, satisfied that they will thereby more efficiently aid the cause of humanity, and more perfectly accomplish the benevolent intentions of the founders of the charity.

"Resolved, That the practice of appointing physicians and surgeons to the charge of hospitals on political or other grounds than those of professional or moral worth, is inconsistent with the welfare of its inmates, and, of consequence inhumane and unjust, subversive of the objects of its founders, and incompatible with a conscientious appreciation of the high responsibilities devolved on the appointing power.

"Resolved, That we reiterate and strongly recommend to the ASSOCIATION a practical observance of the resolution appended to the report of the Committees on "Preliminary Education," and on the requisites for graduation submitted to the Medical Convention which assembled in Philadelphia in May, 1847."

The three remaining resolutions were recommendations to the Faculties of the Schools to examine the students after the first course, to conduct final examinations publicly, and to require from each student before graduation a written clinical report of not fewer than five cases of disease, and upon which report the student was to be examined.

It will be seen that this ASSOCIATION from its foundation, has been constantly stimulating the schools in efforts for the higher medical education.

The Department of Bacteriology has been the one department of medicine that has created the demand in the present decade for the establishment of laboratories, and it is evident that all our metropolitan schools are now provided with excellent laboratory facilities. These have added very much to the burdens of the teaching faculties, for in very many instances the laboratories have been built by the teachers themselves, our civilization not having yet reached the point of equipment by patrons outside of the profession. There are a few exceptions, but the rule is that the school itself has built and equipped its own buildings.

Proper endowment of the chairs for our medical schools is yet in the future although a start has been made in that direction.

On the whole, it may be said that at no time in our history have the medical colleges been so well prepared to give a thorough medical education as at present, and we shall close this present century with a creditable standing in the eyes of medical men throughout the world. That there are too many colleges is probably true, that many of them are far behind the age is conceded, but they are in the minority, and such of them as deserve to live are annually growing better.

VENTILATION OF ISOLATION HOSPITALS.

From time to time the JOURNAL has taken occasion to chronicle the evidence going to show that the extent of the aerial diffusion of the smallpox contagium, especially from smallpox or isolation hospitals, has heretofore been under-estimated; and has suggested the query whether, in the light of this accumulating evidence, the courts would sustain the establishment of a smallpox hospital, as usually constructed, within at least 2,000 feet of human habitations. Coupled with this suggestion it was added that, "fortunately, it is not necessary—and it has not for many years, been justifiable—to adhere to the usual construction of the contagious-disease hospital," and it was pointed out that "the method of ventilation by aspiration through a furnace or sheet of flame, effectually destroys all possibility of the escape of disease germs into the surrounding atmosphere," so that "the construction of a hospital for

contagious diseases on any other plan should not be countenanced.¹”

In the current issue of the *British Medical Journal* is given an editorial summary of a recent Local Government Board memorandum on this subject. “Whatever may be its explanation,” says our contemporary; “the fact that residence in the immediate vicinity of a smallpox hospital involves some degree of increased exposure to infection is now generally accepted, and recent experience at Bradford and elsewhere has added to the number of those who believe with MR. POWER that the smallpox virus can be carried through the air for considerable distances.” DR. PRIESTLEY’S observations at Leicester, cited in the JOURNAL editorial above referred to, show that there were fifteen cases of smallpox within a circle of 2,000 feet radius around the hospital to every single case that occurred in the rest of the town; this, therefore, may be taken, for the present at least, as the measure of “considerable distances.”

These experiences have caused certain of the English isolation hospitals to be provided with means whereby the out-going air from the wards is cremated, or at least subjected to high temperature, with the object of destroying any disease germs it may contain, and it is with the results of these experiments that the memorandum deals. Gas jets in the outlet flues were found inefficient; the extraction thus caused was not only not sufficient to prevent occasional out-draughts into the open air through gratings intended for inlets only, “but the extracted air, after passing the gas jets, contained microbes capable of cultivation on agar gelatine.” Other devices, depending upon extraction alone, are described in the memorandum; but it is not worth while to enumerate these, since they are characterized as “still more conspicuously unsuccessful” as a means of sterilizing the out-going hospital air.

The only method of ventilation which, according to the *Journal*, “offers distinct advantages for the purpose,” is that adopted at the Victoria Institute at Glasgow, where the air is drawn down a glazed-brick shaft, is screened, washed and warmed *en route*, and is then forced by fans into the wards. It is to be inferred that there are no other sources of air supply, but that the outer air—other than as thus furnished—is excluded by stationary windows, baffledoors, etc., the outgoing air being exposed for the necessary time to a degree of heat sufficient to destroy all contagium and then discharged at a high level, in an upward direction, “thus minimizing whatever risk there may be of diffusing infection in the neighborhood of the hospital.”

The fact that isolation hospitals, with especial reference to smallpox, are being planned or are

already in process of construction, at a number of places in this country, lends timeliness to this reference to the results of the English experiments.

OF PERENNIAL INTEREST.

“Doctors’ fees,” as a topic for discussion, never lose their interest. Our namesake of the British Medical Association evidently believes this to be true, and, in its issue of the 22d ult., indignantly refutes a statement, which it finds in the columns of *Tit-Bits*, a comic paper of London, which, like its congener, our *New York Life*, seems to regard no vilification or misrepresentation of the profession too gross for its pages.

The statement, which the *Journal* mildly characterizes as “extraordinary,” is as follows: “It seems often to be lost sight of, or forgotten, that doctors’ fees are an important factor in sapping the earnings of the poor;” and to this is added that “doctors’ bills keep thousands poor and on the brink of starvation.”

Over here, such statement and assertion would simply strike us as “funny,” but the *Journal* deems it worth while to reply seriously by re-stating the fact that the profession “from time immemorial has been distinguished for the amount of its gratuitous work and for the immensity of its charitable establishments,” while doctors’ bills are notoriously the last to be paid, “and it would not be departing very widely from the truth to say that where there was much difficulty in settling them, in a large majority of cases they are never settled at all, that is, to the satisfaction of the doctor.”

MR. HART also finds time—as he surveys the world from China to Peru—to pay his attention to cis-Atlantic writers and, in his current issue, according to a cable dispatch of the 29th ult., he flatly contradicts DR. GEORGE F. SHRADY’S assertions in the September *Forum*, as to the fees of famous physicians. MR. HART says: “The fees attributed to SIR WILLIAM GULL and SIR ANDREW CLARK for country attendances are multiplied by ten [by DR. SHRADY]. The total fees earned by SIR MORELL MACKENZIE for attendance on the German Emperor, extending over months, are doubled; and no such fee as £50,000 was ever earned by any surgeon in India.”

Thus is it again demonstrated that the doctor, neither saps the earnings of the poor nor extorts from the coffers of the rich.

A GENERAL PRACTITIONER’S ENTERPRISE.

A general practitioner of our acquaintance lives in a country village of less than a thousand inhabitants. The surrounding country is in a state of high cultivation, and the farmers mostly own their farms. To save his time, and for the convenience of his patients, the doctor has at his own expense

¹ “Hospital Spread of Smallpox.” JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, June 16, 1894.

erected a telephone line eight miles in length. The different farm houses along the line have made connections with it, and the doctor's office in the village is the "central office." He thus has all the advantage of a city telephone connection, and at little expense, except for original construction.

He has the advantage of his city *confrères* in being able to converse directly with his clientelage without a wordy struggle with the "hello girl," and does not have to pay a round sum from his hard-earned dollars to a soulless and grinding monopoly.

The plan has worked so well that the Doctor has been urged to construct a new line, in another direction, in order to give his other patients an equal advantage.

From a financial standpoint, although the doctor has made no charge for telephone service, he considers it very successful in an indirect way.

The Doctor's name is A. L. BROBECK, and his village is Wellington, Illinois. He is a member of the ASSOCIATION, as all progressive physicians should be, and we believe that he has invented a plan whereby the life of the country doctor may be made comfortable, and at the same time render himself more useful to the community in which he lives.

TO OUR EXCHANGES.

Our exchanges will please note the change of address of this JOURNAL to 86 Fifth Avenue, and kindly change the mailing wrappers accordingly.

TO VISITORS.

Medical gentlemen visiting the JOURNAL office will please take notice that the passenger elevator is at 96 Fifth Avenue, *Times* Building.

CORRESPONDENCE.

Emasculation for Ovariotomy.

OCTOBER, 1894.

To the Editor:—In your issue of September 22, I find a criticism on the paper entitled "Emasculation and Ovariotomy as a Penalty for Crime and the Reformation of Criminals," by Dr. Mark Millikin, of Hamilton, Ohio. In my opinion the Doctor is in error in some of his statements and has misapprehension of the purport of the paper in others. In the beginning of his article, the Doctor says he is heterodox on the proposed penalty for crime and that a belief in castration is the orthodox doctrine of the medical profession. I am sorry for the Doctor's heresy but glad to hear from him that the medical profession adheres to the true faith. Throughout his entire article he seems to ignore the rights and welfare of society and all of his expressions are in sympathy with the criminal who has forfeited many of those rights. He says: "It is doubtful whether the American eunuch would be the docile, useful thing that his Asiatic prototype is." Why not? Admit that "the Oriental is fat and lazy and has no conception of his rights," do you not think that the same law which we find operative in the Asiatic as well as in the lower animals, in changing their purposes and propensities, would not apply equally well to

the Caucasian? I fail to see upon what ground you base your assertion that the castrated individual would become a "dispenser of dynamite," and that "there seems to be some causal relation between over government and explosives; at least they are found together." Does it not occur to you, that coincidences are often confounded and mistaken for causes and effects?

The question is asked: "If castration and ovariectomy are begun where will be the stopping place?" I reply, there will be no stopping place, until the criminal classes who incur the penalty cease to beget and train succeeding generations of criminals. I do not propose to "unsex the morally weak and undeveloped," or "the physically deranged, the puny, the weak, the tuberculous," but to punish those who are convicted after a fair trial in a court of justice of crimes, the result of heredity, vicious environment and constitutional depravity. In the paper which the Doctor criticises so sharply, I wished to bring out two prominent points:

I. That castration for certain crimes, especially sexual crimes, as well as some other classes of crime, may be neither cruel nor vindictive; that is, may be more effectual in punishing and deterring from crime than any other mode, not excepting the death penalty. The second proposition (the most important of all) was that it limited production and reproduction, and while the process was slow, it would in time accomplish the desired result, the improvement of the race.

Dr. Daniel, editor of the *Texas Medical Journal*, in an admirable paper upon the "Castration of Sexual Perverts," read before the World's Columbian Auxiliary Congress, Section of Medical Jurisprudence, has treated this question in a scientific, logical and humane manner. In this connection I quote from him the following pertinent sentence: "But with the civilized man the procreative function and the right to exercise it *ad libitum* seems to be something sacred; it is respected even in those who have by their misconduct outraged society and forfeited all other rights, civil, religious and political. Is it not a remarkable civilization that will break a criminal's neck, but will respect his testicles?" If you have not read this paper, I recommend its perusal. In a special report made to ("that much maligned man" as you call him) the Governor of this State, by the Superintendent of the Illinois Asylum for the Feeble-Minded, he states that at the close of 1893, in twenty-two State institutions for the care and training of the idiotic and feeble-minded there was a total of 6,044 persons. Taking the country as a whole he remarks that "it is safe to say there are two feeble-minded persons to every 1,000 of the people." In less than two decades, the inmates of the asylum at Lincoln, Ill., have increased from 81 to 544, up to and a little over the full capacity of the institution. I suppose nearly the same increase is found in the other institutions. The census of 1890 gives a total of 95,571. It is certain that does not include the whole number which is probably 100,000 or over. Now this is only one class of the defective population, and if the same ratio of increase obtains in the others, (to quote again from Dr. Daniel): "The wealth of all the Czars would not be adequate to provide asylum and medical treatment for the progeny of these people in fifty years from now." It would require too much of your space to comment at greater length upon the Doctor's article. Let me say, however, this is a practical question—one that is pressing for a solution, and it seems to me to be wiser and better to consider how to humanely and effectually punish the wrong-doer, repress crime and reform the criminal than to descant upon the rights which they have forfeited by their assaults upon the rights and wellbeing of society. When you speak of the ultimate reformation of the criminal without the destruction of a faculty, may I inquire how you propose to do it? Parol

ing, moral instruction and repeated terms of imprisonment have accomplished little in that respect. If you can devise any other mode of punishment and reformation that would be more effectual than the one you criticise, I would be glad to know it, and no one would hail it with greater pleasure than myself. "The congenital criminal is a moral imbecile; no amount of punishment will ever evolve in his brain any idea of morality. This is an established fact and can not be gainsaid. He is dangerous. What shall we do with him?" I have long since passed the allotted limit of human life and have served continuously in the ranks of the profession for over sixty-five years. I have retired from it to seek the rest and quiet which age usually demands. If you desire to pursue this subject I trust you will meet with a younger and better equipped antagonist than myself, as I have neither the time or the inclination to engage in further controversy.

ROBERT BOAL, M.D.

The Relief of Abdominal Pains.

ELKHART, IND., October 1, 1894.

To the Editor:—In answer to J. Lue Sutherland's case reported in the JOURNAL of September 29, the Doctor asks? Was it a case of subacute peritonitis? It may have become so; for, nearly five weeks intervened from time of first attack of pain until death ensued; giving ample time for inflammation to occur, if the first cause of trouble was not promptly removed. Too often the physician's sympathy is enlisted by the entreaties of the patient for relief of pain, so that the proper means to remove the cause is not employed at once. And this is the suggestion I would make in this class of cases: If pain and distress is in gastric region give an emetic; if in lower abdomen, thoroughly empty the rectum and colon by a warm water enema, and then if there is no relief, give a quick active purgative of sulph-mag., castor oil, senna, or seidlitz powder followed within two hours by an enema, and thus remove the cause, or at least satisfy yourself that the contents of the *primæ viæ* is not the cause of the mischief. One may ask, But while removing cause how can you relieve suffering? I answer, If pain is due to acidity of contents, dilution of same by emetic, enema, or physic will often relieve pain. We can also add a few grains of bi. carb. potass. or soda in solution to the agent used to relieve; also we can use well known external applications; such as warmth to feet, cold to head, sinaprisms, warm or hot baths, hot packs or steeps. Employ these until the evacuants act. *In no case give an opiate or astringent anodyne until we are convinced that the alimentary canal is empty:* Then we may not need an anodyne. Follow the foregoing procedure by carefully selected ingesta and we will realize a happy result in nearly all such cases.

Respectfully, J. A. WORK, M.D.

The Blessings of Co-operation.

ST. LIBORV, ILL., Sept. 28, 1894.

To the Editor:—I congratulate you and the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION upon entering your new quarters on Fifth Avenue, where room, conveniences and surroundings will be much more desirable. I would like to see the day when every worthy physician of America shall become a member of the AMERICAN MEDICAL ASSOCIATION, and the JOURNAL making weekly visits to each office. If there is any good reason why any member of the fraternity should withhold his name, himself and his skill, knowledge and influence from the ASSOCIATION I can not imagine what it is.

The one thing above all others, so much needed in the profession is coöperation. If the faculty throughout the country will come into the ASSOCIATION, the long felt need

of coöperation will be established, and the means of communication through the JOURNAL will be perfect. Thus once united, it will be quite within the reach of the ASSOCIATION to classify the membership for the duties of careful and thorough scientific work.

If once united and properly classified, the work that could be accomplished within the six remaining years of this century would eclipse the achievements of the past ages.

Will the day ever dawn when men can and will rise above selfishness and self-interest—above their pocket-books, and like true men labor for the true and best interests of the medical profession, and the people at large?

Is it possible that ignorance and prejudice can not be expunged from our midst? Away with them, and let the sunlight of confidence reign throughout the profession.

Invoking for you and the ASSOCIATION all possible success, and the blessings of Heaven, I am,

Very truly,

JAS. OSBOURNE DE COURCY, M.D.

The Mechanical Appearance of the Journal of the American Medical Association.

AUSTIN, TEXAS, Sept. 25, 1894.

To the Editor:—Our JOURNAL of September 22 tells the good news—of permanent advantages in publication. Allow me to congratulate you, and all the good doctors of the United States. When Dr. Hart came to the United States, some time ago, and gave us much—esoteric and exoteric—valuable information, on the momentous question, "just how to run a journal," he forgot the mechanical part. His small print, on poor thin paper, is a great trial to doctors eyes, and a punishment they do not merit; they pay him for something far better. The (Wakele's) *Lancet*, is just a little better; but it too is abominably bad print; its "export" edition specially bad, with its very thin paper and small print, Our JOURNAL shows them the superior larger print, and better paper, and has the appreciative thanks of American doctors.

Is it not strange, that these two great metropolitan English journals, with their princely incomes, able management, large circulation and long experience, should continue to issue such miserable print? Even the trade journals, and cheapest periodicals, of the United States, are far better printed than the *British Medical Journal*, and the London *Lancet*. Can't you prod them up?

Yours truly,

Q. C. SMITH, M.D.

PUBLIC HEALTH.

Taxes for Disinfection.—*Progres Medical* reports that a tax has been voted in Paris to defray the expenses of cremating infected clothing, etc., and of disinfecting houses during an epidemic or the occurrence of a contagious disease. The tax is progressive and graded according to the furnishings of the house, the minimum value being 800 francs—below that being exempt—and the maximum 20,000 francs. The tax ranges from 5 to 200 francs and defrays the expenses for the whole course of the epidemic or disease, no matter how many cases require disinfection.

Typhoid Fever.—Aside from the increase of diphtheria, elsewhere noted, and the prevalence of typhoid fever in many sections, the public health conditions remain favorable. Thus far smallpox has not increased to the extent that was apprehended on the approach of cold weather. There has been a brisk outbreak of typhoid in the garrison at Fort Sheridan, the disease supposed to have been contracted by the troops while on duty during recent labor disturbances.

The typhoid incidence, attributed to increased density of pollution of water supplies caused by the prolonged dry weather, seems to be more pronounced in the Eastern States; localities in Maine, Massachusetts, Connecticut, Rhode Island, New York and Pennsylvania are the chief sufferers thus far reported. So far as returns have been received the disease seems to be of a very mild type with an unusually low death rate.

Cholera.—There is little of interest, with respect to the cholera epidemic, in the current news of the week. It has continued to extend in Russia and the Austrian territory heretofore invaded; cases are also reported to have appeared at Pressburg in Hungary; and, notwithstanding that the Turkish Government had forbidden communication with Constantinople from Broussa—on account of the recent outbreak at this latter place—a cablegram of the 2d inst., from Consul-General Short to the State Department, announces that the disease has again appeared in the Turkish capital. This occurrence is likely to lead to trouble with the foreign members of the Turkish Sanitary Board, who opposed the desire of the Porte, expressed in the early part of September, to impose a quarantine of ten days on all arrivals from Broussa. A four-line dispatch from Hamburg, October 2, announces that Dr. Oertel of the Hygienic Institute of that city, is dead from Asiatic cholera, resulting from an experiment made with water taken from the river Vistula; no other details are given.

Compulsory Vaccination of School Children.—The Rochester, N. Y., school board, having opposed the enforcement of the rule of the City Board of Health requiring the vaccination of all public school pupils, Dr. Wallace Sibley, Health Officer of Rochester, appealed to the State Board of Health for instructions. Dr. F. O. Donohue, President of the Board, replies that the rule, which is based on a State law, is strictly enforced in other cities and there is no reason why Rochester should be an exception. "While boards of education have, in some instances, arrogated to themselves the right to make their own regulations in health matters pertaining to the public schools and have come into collision with the health authorities of their localities, such conflicts have always been settled by the boards of education receding from their positions." The Attorney-General of the State says it is not discretionary with the school authorities as to whether they will allow unvaccinated children to attend school, but the law is mandatory upon them to refuse admittance to any person or child not properly vaccinated.

Diphtheria.—Reports to the JOURNAL from local health officers and from State Boards of Health indicate an unusual increase of diphtheria throughout the northern States generally; in some localities the incidence is reported as bordering on the epidemic, and in a number of cases the public schools have been closed in consequence. There is a curious contrast exhibited at the present time in the respective attitudes of the profession towards this disease in the United States and in the Old World. Here much attention is paid to the early detection of the true character of throat ailments by biologic examination of the morbid secretions, and the establishment of agencies for the prompt bacteriologic diagnosis of diphtheria, in connection with the usual municipal sanitary machinery, is spreading even to the smaller cities and towns; the curative treatment of the disease, or its prophylaxis, by the antitoxin serum has, as yet, made little headway. The reverse is true of Europe and especially of Great Britain. Our Continental exchanges devote pages to the record of most successful results in the serum therapeutics of the disease, and Prof. Roux, *Chéf de Service* of the Pasteur Institute and President of the French Com-

mittee for the Study of Diphtheria, presented, at the recent Buda-Pesth Congress, the summary of a year's experience with the Behring antitoxin treatment which shows successes never before equalled on similar lines. But the bacteriologic diagnosis of the disease, as well in England as in France, Germany and Austria, seems to have been thus far confined to test experiments, mainly in hospital practice, and undertaken chiefly for the purpose of verifying the claims of the serum treatment. It is fully time that the two methods were used in conjunction, and that the American practice—by which the physician, in an increasing number of communities can obtain a positive diagnosis of any suspicious throat disease in a few hours, without expense—shall be combined with the therapeutic treatment of Behring, which, in the words of the *Lancet*, "has yielded results never hitherto obtained by any other plan." Notwithstanding urgent appeals, notably those of the *British Medical Journal*, the adoption of the American method is still delayed.

Tenement-House Mortality.—Considerable surprise was expressed at the results of Commissioner Carroll D. Wright's census of the "slum" districts of New York, Chicago, Philadelphia and Baltimore, when made public last July. The agents and experts employed in the investigation were nearly unanimous in the opinion they expressed relative to the health of those living in the "slums." Statistics drawn from the schedule replies show no greater sickness prevailing in the districts canvassed than in other parts of the respective cities; and, while the most wretched conditions of life were found here and there, the canvassers uniformly comment upon the small number of sick persons discovered. Dr. Roger S. Tracy, Deputy Register of Vital Statistics of the New York City Health Department, has just submitted to the City Board of Health his report based upon the census taken last year by the sanitary police, in which the results of the "slum"-district census are, for so much, corroborated by the lower rate of mortality among the tenement-house population as compared with the mortality of the total population the former being only 22.75 per 1000 as against 23.52 per 1000 of the total population of the city.

When the conditions of overcrowding—and consequent uncleanness of person, clothing and surroundings; of unfit food—and especially the food of infants and children; and of irregular and intemperate habits of life, which obtain so largely among the tenement-house and "slum" populations are considered, these facts, if they be facts, may well give sanitarians pause. Of what use sanitary effort and sanitary expenditure if they result in, even comparatively, increased sickness and increased death rates?

The only refutation of this implied charge, thus far offered, is that "many persons die in hospitals whose homes are unknown, but were most likely in a tenement district." This should not be a matter of conjecture; it is positively known in certain cities that from 10 to 12 per cent. of the total mortality occurs in hospitals and other public institutions whose inmates are drawn, in vast majority, from the tenement-house and "slum" districts. Were this hospital mortality distributed to its respective sources it would be found that the discrepancy between the tenement-house district and the general death rate would very largely disappear.

Dr. Tracy, however, incidentally furnishes another clue to the resolution of the apparent paradox; he says that the death rate in New York tenement houses is smaller than in any of the European cities. This should be so and in direct proportion to the proportion of adult immigrants in the tenement-house population. This population is largely composed of immigrants over 10 years of age—a life period of the greatest vitality; there is in it a less proportion of infants and children than in the native population and that of the single dwelling and well-to-do residence districts

What this means may be better appreciated by considering the following mortality rates of ages in a group of the large American cities aggregating over 6,500,000 population: Deaths per 1,000 of infants under 1 year of age, 267.5; of all children under 5 years of age, 88.4; of those between 5 and 10 years, 8.9; between 10 and 20 years, 4.6; between 20 and 30 years, 9.4. The newly-arrived immigrants are mainly between the ages of 10 and 40 years, a period when the death rate is about 8 per 1,000. Naturally there will be found less sickness and a lower death rate among these than among the total population. It is not that the tenement-house district is more conducive to health and long life, but that its present population in this country is of the age which has the greatest "expectation of life." When the same proportion of infants and children obtains among the immigrants as among other classes of the population, not even the efforts of so efficient a Health Department as that of the city of New York will suffice to keep the tenement-house mortality proper lower than that of the total population.

It should be added, further, that Dr. Tracy does not use the term "tenement-house population" in its ordinary acceptance; but classes as tenements every building occupied by three or more families living independently of each other and doing their own cooking. This necessarily includes the large number of young married people living in flats or apartment houses in comfortable circumstances and under good if not the best, modern sanitary conditions. This accounts for the enormous figures of the New York "tenement-house population," as returned by Dr. Tracy—1,333,773 persons of all ages, or nearly 70 per cent. of the total population.

On the whole, it will be seen that sanitarians need not yet abandon their vocation, either on account of Mr. Wright's census of the "slum" districts nor of the census of New York "tenement houses," as defined by Dr. Tracy.

BOOK NOTICES.

The Story of Rodman Heath, or Mugwumps by One of Them. Boston Arena Publishing Company, Copley Square. 1894.

This novel has a curious reason for being published, namely, the desire of the author to apologize for mugwump-ery. The story turns upon an alleged injury to the hero, Rodman Heath, who has received a wound on the head while passing the batteries at New Orleans. The blow causes a depression of the skull and loss of memory of what transpired during the action. Years after he is trephined and regains the memory of an order, the garbling of which by an enemy lost him many friends. He finally marries his trained nurse, and everybody is happy. The plot is weak, and the use of English mediocre, but the book has nevertheless a certain interest and the author will doubtless improve his English with practice and with the passing of time.

A Manual of Human Physiology, prepared with special reference to Students of Medicine. By JOSEPH H. RAYMOND, A.M., M.D., Professor of Physiology and Hygiene in the Long Island College Hospital, and Director of Physiology in the Hoagland Laboratory. With one hundred and two illustrations and four full page colored plates. Cl., pp. 382. Philadelphia: W. B. Saunders. 1894. Price, \$1.25.

This book is an epitome of human physiology as taught in the text-books. It is a pretty successful attempt to compress the essence of the subject into the small space it occupies here, and the student who masters this book will be prepared to understand and better estimate the value of the more exhaustive discussions in the larger works.

Essentials of the Diseases of the Ear, arranged in the form of questions and answers, prepared especially for students of medicine and post-graduate schools. By G. B. GLEASON, S.B., M.D., Clinical Professor of Otolaryngology, Medico-Chirurgical College, Philadelphia, Cl., pp. 147. Philadelphia: W. B. Saunders. 1894. Price, \$1.

This is No. 24 of Saunders' question-compends, and like all of its class, contains a limited amount of information on the subject of which it treats. What is in the book is correctly stated, and according to the best methods of the day.

Publications du Progres Medical, Paris, 14 Rue des Carmes. Recherches cliniques et Thérapeutiques sur l'épilepsie, l'hystérie, l'idiotie et l'hydrocéphalie. Compte rendu du service des enfants, idiots, épileptiques et avriérés de Bicêtre pendant l'année 1893. Par BOURNEVILLE, avec la collaboration de M.M. Boncourt, Cornet, Lenoir, T. Noir et P. Sollier. Tome xiv. Un beau volume de lxxiv-384 pages, avec 88 figures et un plan. Price, 7 fr.

"Clinical and Therapeutical Researches on Epilepsy, Hysteria, Idiocy and Hydrocephalus." The report of the service at the Bicêtre during the year 1893, by BOURNEVILLE, etc.

The Bicêtre Alms-house (*hospice*) has long been considered one of the most interesting of its class in the world. It is situated on an elevation about two miles from the Barrière de Fontainebleau, and is said originally to have been a castle built by the Bishop of Winchester in 1204, (Stewart). The Bicêtre during the Revolution was used as a prison, and some fifty years ago was used as a temporary detention prison for convicts. The old well at Bicêtre was said to be more than two hundred feet deep and had a diameter of twenty feet. Fifty years ago its surgeon was Malgaigne and its physicians Voisin, Rochoux, Leuret, Horteloup, Moreau and Archambault.

The Bicêtre of to-day has much enlarged scope. The department for the insane is divided into four sections: The first and second sections are assigned to adult insane, the third to epileptics, and the fourth to children. The children's section is subdivided in three groups. 1, idiot children, paralytic, whether epileptic or not, but invalid; 2, idiot children whether or not paralytic, but healthy; 3, children otherwise healthy, whether or not imbecile, dwarfed, erratic, perverts, epileptics, hysterics.

The first group, says the report, is subdivided in two categories; the first is composed of idiots, paralyzed, neither speaking nor walking, and generally regarded as incurables, but they are nevertheless susceptible of amelioration in a very notable degree. The second group comprises the idiots altogether incurable, (a much smaller number than is generally believed), and the epileptics becoming demented and paralyzed under the influence of the congestions which complicate their cases. They are the subjects of hygienic care and they finally form a special group.

The details of the methods employed by Bourneville and his collaborators are interesting, and the year's work is completely set forth. The bulk of the book is taken up with an exhaustive article on chronic hydrocephalus. The writers consider that surgical interference is useless and sometimes harmful, and the advice is given to rely upon: compression; 2, revulsives; and 3, internal administration of calomel; exercise; massage of extremities; saline baths; douches and tonics. "Time, patience and ingenuity are absolutely necessary."

The work should be read by every physician interested in the care of this class of cases.

Transactions of the American Gynecological Society, for the year 1894. Volume xix. Philadelphia: W. J. Dornan. 1894.

This volume contains the minutes of the proceedings at the nineteenth annual meeting of the Society, and the papers read during the session. Prof. W. T. Lusk of New York presided and there were twenty-five Fellows present on the opening day. This number increased to forty-eight on the second day (p. 35), and the total attendance shows that there were fifty-seven Fellows of this American Society present. The papers are excellent, and have, we believe, been published elsewhere.

The book contains an obituary notice of the late John M. Keating, M.D., LL.D., by Dr. E. P. Davis, of Philadelphia, and of the late Alexander Dunlap, A.M., M.D., by Dr. J. C. Reeve, of Dayton, Ohio. The portraits of Drs. Keating and Dunlap are especially fine.

The book is handsomely printed, and the paper the best quality. The Society will next year meet in Baltimore.

Prescribing and Treatment in Diseases of Infants and Children. By PHILIP E. MUSKETT, Late Surgeon to the Sydney Hospital, etc., etc. Third edition. Edinburgh and London. Young J. Pentland. 1894.

This is a handy book that may be carried in the pocket. Its formulæ are excellent, and the book is a useful one.

Transactions of the Medical Society of the State of New York, for the year 1894. Published by the Society. Pp. 507.

This volume contains the minutes of the eighty-eighth annual session held at Albany, Feb. 6, 1894, under the Presidency of Dr. Herman Bendell, of Albany, and the papers read at the meeting.

The book is handsomely printed and well edited by the Secretary, Frederick C. Curtis, M.D., of Albany.

Dr. George Henry Fox, of New York, was elected President.

Abbott's Bacteriology. The Principles of Bacteriology: A Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania, Philadelphia. New (2d) Edition. In one 12mo. volume of 472 pp., with 94 illustrations, of which 17 are colored. Cloth, \$2.75. Philadelphia: Lea Brothers & Co. 1894.

This book is considerably larger than its predecessor, and much new matter has been added. It is in every way worthy of the success which it has met with, and is destined to become a general favorite.

NECROLOGY.

J. B. HARDING, M.D., of Washington, D. C., September 21. He was a Virginian by birth, and removed from Roanoke County, Va., to this city in 1875, where he resided up to the time of his death. He was 75 years of age.—J. M. McKay, M.D., of Ticonic, Iowa, September 13.—Wilbur F. Crutchley, M.D., of Brooklyn, N. Y., September 18, at Lord's Valley, Pa. He was born in 1842, at Harper's Ferry, W. Va., and was graduated at the Columbian University, Washington, in 1868.—James G. Jewell, M.D., of San Francisco, September 17. He was for many years Superintendent and Resident Physician of the Home for Inebriates in that city. He was born in Allegheny County, Pa., in 1830, and his early education was received in that county. He was graduated at Georgetown Medical College, D. C., in 1854. When the war broke out he helped to raise the First Regiment of the District of Columbia, and retired with the rank of Major. He was U. S. Consul to Singapore during the administration of President Grant. On his return, he practiced medicine in New York for a few years and in 1874 he went to California, where he has since resided.—P. S. Moser, of Boone, Iowa, September 26. He was born in Charleston, S. C., in 1829, and was graduated at the Philadelphia Medical College in 1852. In 1854 he moved to Boone, formerly known as Boonsboro, where he resided up to the time of his death. He was a member of the Iowa State Medical Society, the Central Iowa District Medical Association, of which he was the first president, and the AMERICAN MEDICAL ASSOCIATION.—B. Y. Herndon, M.D., of Sanford, Fla., September 26.—Hiram S. Griswold, of Syracuse, N. Y., September 25, aged 74 years.—Hanbury Smith, M.D., of New York, September 13, aged 84 years. He was born in Staffordshire, England, and studied medicine in a London college. He was graduated in 1831, and then went to Stockholm, Sweden, to continue his studies. During the cholera epidemic there in 1834 he was senior physician of the cholera hospital. He came to this country in 1837 and went to Cincinnati, where he was afterward a health inspector and superintendent of the Ohio State Lunatic Asylum. In 1859 he came to New York, and was among the first to introduce mineral water treatment for chronic diseases.—Theodore Kern, M.D., of Kokomo, Ind., September 21, aged 39 years.—Wm. Barney Mix, M. D., of Milwaukee, September 17, aged 52 years.—C. W. Hall, M.D., of Amherst, N. H., September 18. Dr. Hall was born in Sudbury, Vt., March 29, 1825. He matriculated under the eminent Dr. Horton, whose office he entered at the

age of 17 and graduated from the medical college, then located at Castleton, Vt., in 1846. After graduation he located in Ticonderoga, N. Y. He removed to California for his health, but was compelled to give up practice there owing to the high winds. He removed to New York City. A reverse of circumstances led him to again return to his profession and he located in Amherst in October, 1879.—C. W. Coleman, M.D., of Williamsburg, Va., September 15. He was born in Williamsburg, Va., July 18, 1827, and was educated at the College of William and Mary. He studied medicine at the Medical College of the University of Pennsylvania. After graduation, he began the practice of his profession in Richmond, but shortly removed to his native town, with which place he remained intimately identified professionally and socially. During the war he served as a surgeon in the Confederate Army, and was for some time in charge of a hospital in Richmond.—Charles E. Ives, M.D., of Savannah, Ga., September 19, aged 63 years.—Levi W. Clapp, M. D., of Pawtucket, R. I., was instantly killed September 19, by falling down the bank wall in the rear of his residence, a distance of twenty feet. He was a graduate of Brown University and Harvard Medical School, graduating from the latter institution in 1873. He had been in practice twenty-one years, two years of which was spent in Baltimore and Washington. He leaves a widow and three children.—John R. Thornberry, M.D., of Crawfordsville, Ind., September 19, aged 44 years.—H. A. Bolles, M.D., of Cortland, N. Y., September 16, aged sixty-eight.—J. J. Hofstetter, M.D., of Sabula, Iowa, September 20, aged 74 years. He had practiced medicine in that city for fifty years.

SOCIETY NEWS.

Tri-State Medical Association.—The annual meeting of the Tri-State Medical Association of Iowa, Illinois and Missouri was held in Jacksonville October 2 and 3. The meeting was called to order by the President, Dr. Brockman, of Ottumwa, Iowa, who spoke of the aims of the Association. The Address of Welcome was delivered by Dr. T. J. Pitner, of Jacksonville, and was responded to by Dr. F. B. Dorsey. The following doctors presented papers: F. B. Dorsey, of Keokuk, Iowa; James H. Etheridge, of Chicago; C. E. Black, of Jacksonville, Ill.; Ellet Orrin Sisson, of Keokuk, Iowa; F. Herrotin, of Chicago; Bayard Holmes, of Chicago; F. P. Norbury, of Jacksonville, Ill. In the evening Dr. N. S. Davis, Jr., of Chicago, delivered an address in the State Street Presbyterian Church. Addresses by Dr. John Punton, of Kansas City, and Dr. Bayard Holmes, of Chicago, were also delivered. Several musical numbers were rendered, and at the close of the evening meeting all were invited to the Jacksonville Sanitarium, where they were entertained with a lunch and reception by Dr. C. E. Black. Papers read on the second day were by Drs. Robert H. Babcock, of Chicago; J. H. Kellogg, of Battle Creek, Mich.; James A. Close, of St. Louis; James M. Ball, of St. Louis; Emory Lanphear, of St. Louis; W. M. Catto, of Decatur, Ill.; D. C. Brockman, of Ottumwa, Iowa; and Adolph Myer, of Chicago.

Officers for the ensuing year were chosen as follows: President, Dr. James M. Ball, of St. Louis. Senior Vice-President, Dr. Bayard Holmes, of Chicago. Junior Vice-President, Dr. L. A. Malone, of Jacksonville, Ill. Treasurer, Dr. C. S. Chase, of Waterloo, Iowa. Secretary, Dr. F. P. Norbury, of Jacksonville. St. Louis was chosen as the next place of meeting, in April, 1895.

MISCELLANY.

Change of Address.—Dr. I. S. Stone to 1449 Rhode Island Avenue, Washington, D. C.

Dr. J. S. B. Alleyne, for so many years Professor of Materia Medica in St. Louis Medical College has taken the chair of the History of Medicine in the Barnes Medical College.

Treatment of Equine Rheumatism by Sulphur Baths.—The *British Weekly* states that the town council of Baden, near Vienna, has voted some £2,000 to be expended in the installation of sulphur baths for the use of rheumatic horses. The

proposed establishment will, it is believed, be the first of its kind in existence.

Personal.—Medical Director Albert L. Gihon, the senior officer of the Naval Surgeons' Corps, was ordered as a delegate to represent the Navy Department at the meeting of the American Public Health Association at Montreal, September 24.

First Russian Graduate and Diploma.—In August, 1694, Dr. Peter Vassilevitch Postnikoff, the first Russian to enter the ranks of the healing art, received his diploma from the University of Padua. A century later the Medical Faculty of Moscow granted its first diploma to Dr. Thomas Barsvuk Moisseieff.

International Congress of Chemists Adopt the Metric Measure.—At the recent Antwerp International Congress of Chemists the French liter was adopted as a standard of capacity for graduating chemical apparatus and the Centigrade scale instead of the Reaumur or Fahrenheit for temperature. More than four hundred chemists, representing the countries of the whole civilized world, and representatives of a large number of scientific societies were present. The next congress will be held in Paris in 1896.

The Medical Mirror for September is given up largely to California and its wonders. The illustrations are excellent, and the running commentaries inimitable. Our contemporary has evidently made good use of his time while in California; the readers of the *Mirror* are gainers and our California friends have reason to be glad that the distinguished editor of the *Mirror* was one of the members of the Association who crossed the Rockies to attend the last meeting.

A Certain Determination of Sex.—Dr. X., of Paris, has discovered an infallible method of determining the sex of the child *in utero*. After a conscientious auscultation and palpation of Madame Z., he announces that "It will be a boy," and at the same time notes on his tablets: "Madame Z.—a girl." When the accouchement takes place if the new-comer is a boy, well and good; if it is a girl he exhibits his tablets and assures the mother that she must have misunderstood him. It is not noted what his method is in multiple births.

First Help for the Wounded.—The Minister of War for France has issued regulations for the packet of antiseptic dressings which every officer and enlisted man is obliged to be provided with. The packet is 12 centimeters long by 10½ wide and 1½ thick and weighs 50 grammes. It consists of a pledget of oakum in a gauze compress and a cotton bandage soaked in bichlorid 3-1000, a piece of protective tissue and two safety pins. These are contained in a waterproof sack, wrapped in an outer cover of gray cotton, on which is a label telling how to open the package and apply the dressings.

An English Physician in Morocco, North Africa.—A London publisher announces that an illustrated book by Dr. Robert Kerr, formerly of Rabat, will soon appear, under the title "In the Palace and the Hut." The book will be devoted to this physician's experience as a missionary to the Jews, from one of the English religious bodies, during a period of seven years. Dr. Kerr was for a time the pioneer English physician for that little known and irregularly governed African community. We have read some of Dr. Kerr's writings and know him to be capable of composing an interesting book.

Hearing and Speech Recovered After a Lightning-Stroke.—At Winfield, N. Y., a child aged 13 years, recovered her lost faculties of hearing and speech during one of our September thunder storms. She had been deaf and dumb since her fifth year. The house wherein she was visiting was struck, and she herself was, with others in the house, rendered un-

conscious by the stroke. On her recovery from the stunning effects of the lightning, she raised her hand to her ear, and said: "Mamma, I heard that. Let us go home;" the first words she had uttered in eight years. Her deaf and dumb condition is said to have been the sequel of a severe intermittent fever in her fifth year.

Microbe of Yellow Fever.—It is announced that the indefatigable Dr. Domingos Freire, of Rio Janeiro, has again discovered the yellow fever microbe, has produced a yellow fever antitoxin and is inoculating "with wonderful results." It is to be hoped that the announcement may prove correct; but those of us who recall that Dr. Freire was said to have done the same thing some fifteen years ago; that Sternberg, Woodward, Schmidt and other competent bacteriologists failed to corroborate the discovery, after prolonged and painstaking search; and that, with a much more promising field, the success of Haffkine's anti-cholera inoculation is still *sub judice*—will take the present claims with a little salt.

A Pasteur Institute for Vienna.—An imperial decree announces the opening of a Pasteur Institute in the Rudolphspital in Vienna, under the supervision of Prof. Paltanuf. It is to be available for foreigners as well as Austrian subjects. The treatment by Pasteur's method will last from twelve to fourteen days; inoculations are to be made from 10 to 12 o'clock every morning, and are gratuitous for the present. Admissions, in all cases on physicians' certificates, will be granted only when the wounds are severe enough to require hospital treatment; all other cases must find lodgings outside the Institute.

A Successful Warfare.—In the *JOURNAL* of the 15th ult., it was announced that the Illinois State Board of Health had begun a vigorous warfare on the itinerant nostrum vendors "who annually fleece the people of the State out of a sum estimated at more than \$300,000, by means of brass bands, concert troupes, alleged Indians and other mountebank attractions." At the recent meeting of the Board, October 1-2 inst., the Secretary, Dr. J. W. Scott, reported that there was not a single one of these concerns now doing business in the State; prosecutions had been begun simultaneously in every one of the 102 counties where these itinerants were found, some half dozen convictions were secured, and the rest folded their tents and stole away—not silently, but with loud and picturesque profanity directed against the Illinois law and its enforcement.

Improved Homes in Dublin.—Sir Charles Cameron, M.D., in a recent address, has shown that the sanitary authorities of Dublin have caused 2,700 houses of the poor to be detenanted and closed as unfit for human habitation. One thousand of these houses have not been re-opened, and this has been without compensation to owners. Not a few of these houses had been "fever nests" for typhus, resisting all ordinary measures of disinfection and isolation. The houses that have been allowed to be re-occupied have been put into a good sanitary condition at the charges of their landlords. These radical measures have had the result of "stamping out" typhus fever in localities where it has been entrenched for years. They have also had an appreciable effect in lowering the death rate of the city, although the comparative figures are not given for the improved localities. The vacation of unsanitary buildings in this country is not as a rule readily accomplished, although the occasion for it is constantly coming up in all our cities. The Dublin lesson is a good one for our own sanitarians, teaching the necessity for ampler powers for the management of the chronic greed and resistance to orders on the part of landlords, who claim that they "only get rent enough to pay taxes with." There are far too many landlords who squeeze their dilapidated tenant property for all that it is worth, and evade the expenditure of any part of their receipts for the betterment of the lot of their tenants. The laws of most of our States are wholly inadequate to deal with this scurvy class.

Tippling.—The Catholic School Commissioner for the Province of Quebec, Prof. Brennan, of the Laval University and a prominent practitioner of Montreal, in an address before the American Public Health Association last week, said that from his medical experience he was in a position to say that in women the habit of tippling was far more prevalent and disastrous than is imagined; within the last four months he had seen four women, each the mother of several children and moving in good society, die from the effects of chronic alcoholism. Dr. Brennan's experience can be duplicated by, probably, four out of every five general practitioners in the United States,—not among women alone, but far more frequently among men. And no wonder when, as shown by the figures of the Internal Revenue Commissioner for the year 1893, the sixty-five odd millions, comprising the population of this country, consumed 88,777,187 gallons of alcoholic spirits and 1,054,785, 376 gallons of beer during the year. These gallons would make more than 6,000,000,000 drinks of whisky and nearly 13,000,000,000 glasses of beer, for which there was paid to the barkeeper \$1,226,258,000. The naked figures are sufficiently eloquent of the resultant amounts of misery, disease and premature death.

London Ambulance System for Street Accidents.—There are sixty street ambulance stations for the metropolitan area of London. At each of these, wheeled stretchers with first-aid appliances are maintained. These stations are administered by the Street Ambulance Branch of the Hospitals' Association, inaugurated in the latter part of the year 1889. The number of stations were fifty in 1891; ten others were added in 1892. Their object primarily is to provide prompt service for street accident cases, of which there are about six thousand per annum. Of these cases, about four thousand, five hundred are suitable for removal to hospital, but they do not all require removal by ambulance. Prior to 1880, nearly all removals of these cases were made by cabs. Since that time about one-third of the street cases have been transported by this ambulance system; the cabs being still used for the remainder. The total removals by ambulances in 1892 were 1,267. The report for the year 1893 has not yet been published. As the stations become better known the use of cabs has been superseded, so that the time is not far distant, it is believed, when the conveyance of the wounded will be as adequately provided for as is their treatment at the hospitals and infirmaries of that great city. The funds for the establishment of this system, and for its present annual maintenance, have been given by Mr. H. L. Bischoffsheim, the Treasurer of the Branch. The first cost of the stations was about \$5,000, while the running expenses are about \$1,000 per annum. The Chairman of the Association is Sir Sidney H. Waterlow; office at 428 Strand, London, W. C. Officers of American Ambulance Associations are requested to send copies of their annual reports to their London colleagues.

A Sick Man and an Eccentric Doctor.—Owing to the momentous results which may follow his death, the illness of Alexander, Emperor of Russia, is attracting an amount of attention similar to that given to the cases of Gen. Grant, President Garfield and the German Crown Prince Frederick. Like this latter, also, are the conflicting accounts of the true nature of the malady. He has been, successively, the victim of neurasthenia supervening upon "Russian influenza," of tuberculosis—of the brain, according to one set of physicians; of the kidneys, according to another; of Bright's disease; of cerebral apoplexy; of paresis; of organic disease of the heart; of hereditary insanity, etc. Only one thing is certain—he is a very sick man, and all Europe hangs upon the utterances of the court physician, Prof. Sacharjin, who with Prof. Leyden, of Berlin, is in immediate attendance upon the imperial invalid, and concerning whom many more or less apocryphal stories are being told. Sacharjin, or Zakharin, is undoubtedly an eccentric. A native of Moscow, he adheres to the uncouth costume of the Russian peasant and insists on visiting the Emperor in a dressing-gown and big boots. On arriving at the palace he refused to occupy the

apartments provided for him on the third story, because at home he lived on the ground floor, and required apartments to be provided for him there; he declined to lunch with the Czarina at the imperial table on the ground that he was not in the habit of eating with women; and one day, when the Czarina asked him to visit his patient whose temperature alarmed her, he replied that he was tired but would send his assistant; on the return of the latter with a reassuring report, Sacharjin turned to the anxious wife and said: "You see I was right not to fuss; there is no danger." The sort of doctor thus portrayed would have suited the first Napoleon, who wanted the Empress to be treated in her accouchement as the wife of the veriest bourgeois.

Medical Opinion as to the Use of Opium Among the Chinese.—Dr. Duncan Main, Physician-in-chief of the large Mission Hospital and Opium Refuge at Hang-Chow, gives in his annual report, lately published, his adverse opinion of the evils of Chinese opium smoking in very clear terms. The paragraph here quoted refers chiefly to his observations at the Refuge for opium users who apply for treatment: "During the year ninety-seven who came to us seeking to be relieved of the debasing habit received our kindly help. The number included all grades of society and all classes of men. My opinion about the evil effects of opium smoking is unaltered. No one in his sober senses can say anything in its favor, unless he talks nonsense. We never come across an opium smoker or a non-opium smoker who has anything to say in favor of the habit, and if it were such an innocent affair as some advocates of it try to make us believe, surely we who live among the people from year to year would find it out. I think far too little is made of this most important fact—Surely the voice of the people should be listened to, and the testimony of those who have paid flying visits to opium smoking countries and gathered their information through interpreters should be discounted. Many, I fear, are influenced by pecuniary or personal motives, and some, no doubt, take up the cudgels for it, because missionaries are its chief opponents. To me it seems an utter impossibility for any one who lives among the Chinese, speaks their language, knows their lives, and mixes with them from day to day, to do anything else but condemn the base, cruel and demoralizing habit. It affects the Chinaman's person, principle, and purse, damages his constitution, degrades his conduct and drains his cash, and in many cases leads to ruin and destruction of body and soul.

Spinal Drainage for Tubercular Meningitis.—Stephen Paget reported in the *Lancet*, October, 1893, that he performed a resection of the arches of the fourth and fifth cervical vertebræ, the dura mater bulged, without pulsation, and following a puncture, a jet flowed of about four or five ounces of fluid; incision was then made in the dura mater, and horsehair drainage established. Four days afterward the child died, and the necropsy showed that the veins of the dura mater were distended; in the middle cerebral fossa, there was about a teaspoonful of sero-purulent fluid, and in the posterior cerebral fossa about two teaspoonfuls of clear serum; the convolutions were flattened on the superior portion of both hemispheres, and the brain appeared to the touch more than normally resistant, the third and fourth ventricles were dilated, the lateral ventricles were full of fluid but very little dilated. At the base of the brain the pia mater was infiltrated with sero-purulent lymph and there were found miliary tubercles.

The operation gave relief for a single day, and the drainage had diminished neither the collection of liquid in the cerebral fossæ, nor the inflammatory swelling of the brain. The author is of opinion that perhaps a large opening of the cranium itself might have afforded relief. The *Lancet* of March 10 contains the history of a case diagnosed as tubercular meningitis by Walter Ord and Waterhouse, which recovered after trephining and drainage of the subarachnoid space. Parkin, *Lancet*, November 18, cured a case of hydrocephalus by occipital trephining, and horsehair drainage.

Medical College Notes.

RUSH MEDICAL COLLEGE, CHICAGO, held its opening exercises September 25, with a class of 500 in attendance—The opening exercises of the new College of Physicians and Surgeons of Kansas City, Kan., were held September 18. There were twenty matriculates.

THE TOLEDO MEDICAL COLLEGE has purchased grounds for a new college building, which will cost between \$15,000 and \$20,000. The ground will be broken next spring and it is the intention of the directors to build one of the most complete institutions in Ohio.

UNIVERSITY OF PENNSYLVANIA.—A four-year course in biology has been arranged at the University of Pennsylvania, leading up to the degree of Bachelor of Science. This course will be open to both sexes. A two-year course in this department has been in vogue since 1884, and women students have largely availed themselves of its opportunities; thirty-two out of the class of eighty-six students in 1893-94 were females. The new course will be a full one, suitable for those desiring to become teachers in this specialty, or for those seeking preparation for original research.

Boston Notes.

NEW ENGLAND WOMEN'S HOSPITAL.—The summer season at the New England Women's Hospital, for women and children, has been characterized by the admission and treatment of a smaller percentage of children than usual, although the total number of patients has been as large as in former seasons. The decrease in the number of juvenile patients is due to the prevalence of whooping cough, which has prevented the admission of many applicants. The hard times have resulted in an increased demand for free treatment, but the Hospital has succeeded in meeting all demands made upon it.

WEST END NURSERY AND INFANTS' HOSPITAL.—One of the oldest institutions for the benefit of the children of the poor is the West End Nursery and Infants' Hospital, which was founded by H. C. Haven. It is now in its twelfth year, and is situated on Blossom Street, which is a district abounding in cases which demand the attention of the Hospital.

THE CHILDREN'S ISLAND SANITARIUM is now in its ninth year and supplements the work of the Infants' Hospital quite successfully. It is situated in Salem Harbor. Children between the ages of 4 and 10 are admitted in classes of twenty-five each week. During the season, from July to September, there were 218 children treated; the usual stay of each child extends over two weeks.

DR. JOHN J. MORAN, of Dorchester, died of typhoid fever September 22. He was born in Boston, Sept. 22, 1865, and was a graduate of the grammar and high schools of this city. He also graduated from the Bridgewater State Normal School and from Harvard College. He was head House Physician at the Carney Hospital in 1891 and for a number of years had been the physician of the Free Home for Consumptives and St. Mary's Infant Asylum. He was unmarried.

DEATHS FOR THE WEEK.—The total number of deaths for the week, ending September 22 is 239, as against 197 the corresponding week last year, showing an increase of 42 deaths, and making the rate for the week 24.8. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, fifty-eight cases and fourteen deaths; scarlatina, thirty-six cases and two deaths; typhoid fever, forty-five cases and eight deaths; measles, seven cases. The deaths from consumption were thirty-six; pneumonia, ten; whooping cough, three; heart disease, thirteen; bronchitis, four, and marasmus, thirteen. There were eight deaths from violent causes, including two railroad accidents. The number of children who died under 1 year

was sixty-eight; the number under 5 years ninety-five. The number of persons who died over 60 years of age was thirty-six, the oldest being 92 years. The deaths in public institutions were fifty. There were twenty-five deaths from cholera infantum.

St. Louis Notes.

THE HEALTH of St. Louis during the summer has been really alarming to physicians. It is not too much to say that the majority of St. Louis physicians have had to accommodate themselves to an income reduced one-half; and it is possible that the collection of the income tax in January will show even a greater reduction than this.

BODIES OF CITY PAUPERS.—The question of the disposal of the bodies of city paupers is causing much discussion. Complaints have been many of the crowded condition of the potter's field and the methods of burial in vogue, but there has as yet been no change. A committee has been appointed to investigate and recommend some method of relief, and to examine the feasibility of cremation of the bodies of paupers. Sentiment steps in to oppose this highly sanitary reform, and religious influence will probably prevent its adoption as a general measure; but the cremation of the bodies of those dying of infectious disease should be made invariable. Probably this step in sanitation will be accomplished.

THE CITY GOVERNMENT is accused of indifference to the possible contamination of the water supply of the city through the Chicago drainage canal and the Illinois River. However, Mayor Walbridge has asked the Assembly to appoint a commission of competent experts to examine whether or not the water supply is likely to become contaminated in this way; and there is a prospect that such a commission will be authorized. In case the water supply is found to be in danger, legal measures will be invoked; and in case of failure in this direction it is suggested that the water be taken directly from the Missouri. As is well known, the water at present furnished is not above reproach, though all loyal St. Louisians resent such an imputation and uncomplainingly drink water the color and consistency of which would do credit to a well stirred mud-puddle.

New Orleans Notes.

On Friday September 28, the Faculty of the Medical Department, Tulane University of Louisiana, submitted the following recommendations to the Board of Administration for their approval:

Dr. Rudolph Matas, Demonstrator of Anatomy, for Professor of Surgery, *vice* Dr. Albert B. Miles, deceased. Dr. Henry Bayon, Lecturer on Physical Diagnosis, for Demonstrator of Anatomy, *vice* Dr. Matas; and the following assistants to the Demonstrator of Anatomy were named: Dr. Albert J. Bloch, Chief of Clinic to Dr. Lewis, Chair of Diseases of Women. Dr. Sidney P. Delaup, Resident Physician New Orleans Sanitarium, and Dr. Marion Souchon, son of the Professor of Anatomy. Dr. John B. Elliott, Jr., son of the Professor of Theory and Practice of Medicine, Lecturer on Physical Diagnosis *vice* Dr. Bayon promoted to the Demonstratorship.

Dr. Rudolph Matas, the recent appointee *pro tem* to the Chair of Surgery, Medical Department Tulane University of Louisiana, although born in Louisiana is a full-blooded Spaniard. His early childhood was spent in Paris and Barcelona, Spain, where he familiarized himself with French and Spanish. Later he removed with his parents to Brownsville, Texas, and came to New Orleans to complete his literary education. In 1876 he matriculated in the Medical Department University of Louisiana (now Tulane), graduating with distinction in March, 1880. While he was still a student he was selected as clerk of the commission sent out by the National Board of Health, to study yellow fever in Cuba. His experience in the great epidemic of 1878, rendered his service of great value to that body.

In 1881 he was appointed Medical Inspector by the National Board of Health and stationed at Vicksburg. He was in Brownsville, Texas, during its terrible epidemic of yellow fever, and afterwards in Mier, Mexico. In 1886 he was appointed Demonstrator of Anatomy, Tulane University, and the same year was elected Professor of Clinical and Operative Surgery at the New Orleans Polyclinic. From 1890 to 1893 he was Professor of Anatomy at the New Orleans Training School, and has been Consulting Surgeon of the Eye, Ear, Nose and Throat Hospital since 1890. Although quite a young man, 34 years of age, his literary works have been extensive. For years he was connected with the *New Orleans Medical and Surgical Journal*, and in 1889, was elected associate editor of *Sajous' Annual*. In 1892 he was elected Vice-President of the Louisiana State Medical Association, and its President in 1894.

Washington Notes.

DR. LEON'S CASE.—Judge Cole sets the verdict aside and grants a new (third) trial in the case of Dr. Leon charged with abortion and murder. After a preliminary examination before the coroner, Dr. Leon was committed to jail and an indictment returned Dec. 8, 1893, for murder. The demurrer was argued before Judge Cole December 26 and overruled, and the trial began January 24, lasting till January 30, when a verdict of guilty as indicted was returned.

A motion for a new trial was entered and argued by Dr. Leon's counsel and on March 24 this was granted by Judge Cole on the ground that he had not sufficiently defined the distinction between murder and manslaughter. The conviction was, with possibly one exception, the first ever obtained at common law. The second trial was begun June 19 last, and July 23 the jury returned a verdict of guilty of manslaughter and not of murder.

A motion for a third trial was entered and granted by Judge Cole on the ground that the defendant can not be convicted on the uncorroborated testimony of an accomplice. The harmless prescription did not tend to corroborate by showing that Dr. Leon and Miss B. had acted in concert for the commission of the crime of abortion and that the possession of the prescription had no probative force in establishing the fact that an operation had been performed. "Undoubtedly the character of the crime charged in this indictment is of frequent occurrence, and the efforts of the officers of the law to detect and punish it are commendable. But neither the prevalence of the crime nor the great difficulty in proving it can justify the court in sustaining a conviction upon evidence which long experience has shown to be dangerous and unreliable.

"The conclusion is that the verdict of manslaughter rendered by the jury against the defendant must be set aside and a new trial granted on that charge." The District Attorney says he proposes to bring Dr. Leon to a third trial, either for murder or manslaughter as the court should decide. He said he believed it a blow to public morals to let such an offender escape, and that nothing could be left undone to secure the punishment the law provides.

Large Military Garrisons Hereafter.—A long stride has just been taken by the War Department in carrying out its policy of breaking up small military posts and consolidating the troops into larger garrisons at strategic points. Railroads and the altered condition of the West, consequent upon the rapid growth of settlements have rendered unnecessary the many small posts that were formerly essential for local defense against hostile Indians. A new phase of military service is opening to the view of the United States Army, one which will be highly appreciated by those officers who have spent twenty years of life in one or two company posts many dreary miles by stage to the nearest railway station. Many of the new points of aggregation are in the neighborhood of large cities, but even where this is not the case the mere fact of aggregation gives facilities for amusement, social intercourse and intellectual improvement that are not to be found in the small military garrisons.

The first move recently taken in the redistribution of the troops was the issuance of an order, August 16 last, breaking up the recruiting depots, and thereby vacating the large barracks buildings at Jefferson Barracks, Missouri, Columbus

Barracks, Ohio, and Davids' Island, New York, for use as garrisoned posts. For many years past all recruits enlisted by recruiting officers stationed in various cities were forwarded to one or other of the depots, where they were drilled and disciplined for several months and then drafted off in detachments to fill vacancies in regiments and posts. The order announced that by Oct. 1, 1894, or as soon thereafter as practicable, the depots mentioned would be garrisoned by troops of the line, Jefferson Barracks being absorbed into the Department of the Missouri, and the others into the Department of the East. These posts and also the post of Fort Sheridan, Illinois, although garrisoned by troops of the line would continue to be recruiting rendezvous on account of their proximity to large cities. Recruits received at each would constitute a recruiting detachment to be instructed by officers and non-commissioned officers of the recruiting detail stationed at the post, or, for lack of them, by officers and non-commissioned officers of the garrison detailed by the commanding officer for the duty, the immediate command of the detail being vested in the senior officer on duty with it. The strength of these detachments will be kept by assignments and transfers to regiments so as not to exceed that of a company of infantry. Recruits enlisted at recruiting stations will be assigned directly to military posts to be drilled with their companies. In fact, the object of the order of August 16 was to send recruits to military posts for their military education instead of aggregating them at recruiting depots, and thereby to permit the use of the buildings at these depots as barracks for a regular garrison.

To carry out the provisions of the order mentioned, a second order, of date Sept. 15, 1894, assigns troops to garrison the abandoned depots. It makes many other assignments which when the required movements are effected will lead to the abandonment of no less than nine of the present military posts, to-wit: Fort Marcy, New Mexico; Fort Bowie, Arizona; Fort McKinney, Wyoming; Fort Sully, South Dakota; Fort Supply, Oklahoma Territory; Fort Mackinac, Michigan; Fort Ontario, New York; Newport Barracks, Kentucky, and Mount Vernon Barracks, Alabama. This is the most extensive transfer in the stations of troops that has occurred since war times. Three-fifths of the regiments are concerned in the movements, as follows:

CAVALRY.

I.—First Regiment.—Troop A, from Fort Myer, Virginia, Department of the East, to the Department of the Colorado. The movement to commence upon the arrival of the incoming garrison for Fort Myer.

Second Regiment.—The Junior Major and three troops (to be designated by the department commander) from the Department of the Colorado to Fort Riley, Kansas, Department of the Missouri; and Troop F from Fort Leavenworth, Kansas, to Fort Riley; the movements to take place without unnecessary delay. The Lieutenant Colonel, and Troops B and I from Fort Bowie, Arizona, to Fort Logan, Colorado, the latter to move upon the abandonment of Fort Bowie.

Third Regiment.—The Senior Major, and Troops C, E, F, and G, now temporarily at Fort Sheridan, Illinois, from the Department of the Missouri to Fort Ethan Allen, Vermont, Department of the East.

Headquarters and two troops—one of them Troop D—from Oklahoma Territory by October 1, and the Junior Major, when relieved in Texas, Jefferson Barracks, Missouri. The remaining troops will move to that post so soon as accommodations thereat are in readiness.

Sixth Regiment.—From the Department of the Platte to the Departments of the Missouri and East: Headquarters, Junior Major, and Troops A, E, G, and H, now temporarily at Fort Sheridan, Illinois, to Fort Myer, Virginia; the Lieutenant Colonel, from Jefferson Barracks, and three remaining troops to Fort Leavenworth, Kansas. Indian Troop L will remain at Fort Niobrara. The Senior and Second Majors will, until further orders, continue on duty in the Department of the Platte.

Seventh Regiment.—Senior Major and Troop F from Fort Myer, Virginia, Department of the East, to Fort Stanton, New Mexico, Department of the Colorado. The Lieutenant Colonel to Fort Riley, Kansas.

Eighth Regiment.—Troop H from Fort Myer, Department of the East, and Troop D from Fort Leavenworth, Department of the Missouri, to the Department of Dakota.

Ninth Regiment.—Troop K from Fort Myer, Department of the East, to the Department of the Platte.

Tenth Regiment.—Troop I from Fort Leavenworth, Department of the Missouri, to the Department of Dakota; to move without unnecessary delay.

The troops of the Seventh, Eighth and Ninth Regiments, as in the foregoing, will move upon the arrival of the incoming garrison for Fort Myer.

ARTILLERY.

II.—First Regiment.—The Second Major and Batteries B, H, and M, from Fort Columbus, New York, to Davids Island, New York.

Third Regiment.—From Fort McPherson, Georgia: Headquarters, Lieutenant Colonel, and two batteries to St. Francis Barracks, Florida; the Junior Major and two batteries to Jackson Barracks, Louisiana. The movements to take place under future orders through the Adjutant General's Office.

INFANTRY.

III.—First Regiment.—One company from San Francisco Harbor, California, to San Diego Barracks, California, to relieve Company C, Tenth Infantry, without unnecessary delay.

Fifth Regiment.—To be concentrated at Fort McPherson, Georgia. The companies A, at Forts Leavenworth, Kansas, and F, San Houston, Texas, to move without unnecessary delay; headquarters and remaining companies to move under future orders through the Adjutant General's Office.

Sixth Regiment.—Companies A, from Fort Wood, New York and E, from Newport Barracks, Kentucky, to Fort Thomas, Kentucky; to move with the least practicable delay.

Seventh Regiment.—The companies H, now at Fort Leavenworth, Kansas, and G, at Camp Pilot Butte, Wyoming, to Fort Logan, Colorado; to move without unnecessary delay.

Eighth Regiment.—Headquarters and three companies from Fort McKinney, Wyoming, to Fort D. A. Russell, Wyoming; the movement to take place without unnecessary delay.

Ninth Regiment.—Company G from Fort Ontario, New York, to Madison Barracks, New York; to move at a date to be fixed by the department commander.

Tenth Regiment.—From the Departments of the Colorado, and California, to the Department of the Missouri; headquarters and four companies to Fort Reno; four companies to Fort Sill—the distribution to include the two companies now at Fort Leavenworth. The Lieutenant Colonel and Major will be assigned to posts by the Commanding General Department of Missouri. The movements to take place without unnecessary delay.

Twelfth Regiment.—Headquarters and Companies E and G from Fort Leavenworth, Department of Missouri, and Companies B, C, and D, from Fort Sully, Department of Dakota, to Fort Niobrara, Department of the Platte. The movements: From Fort Leavenworth to take place upon the arrival of the incoming Twentieth Regiment; from Fort Sully upon the abandonment of that post. Colonel E. F. Townsend will be relieved from the command of the Infantry and Cavalry School, and of the post of Fort Leavenworth, by Colonel H. S. Hawkins of the incoming regiment.

Thirteenth Regiment.—From the Department of the Missouri to the Department of the East; headquarters and three companies to Fort Niagara, New York; Major and two companies to Fort Porter, New York; Lieutenant Colonel and three companies to Fort Columbus, New York Harbor. The movements to take place without unnecessary delay.

Fourteenth Regiment.—Company H from Fort Leavenworth, Department of the Missouri, to Vancouver Barracks, Department of the Columbia.

Seventeenth Regiment.—From Fort D. A. Russell, Department of the Platte, to the Department of the East; Headquarters and Companies A, C, D, E, and G, to Columbus Barracks, Ohio; the Lieutenant Colonel, Major, and remaining three companies to the same station, as soon as accommodations thereat are in readiness.

Nineteenth Regiment.—Company C from Fort Mackinac to Fort Brady, Michigan. The movement to take place upon the abandonment of the former post. One officer and ten enlisted men to be continued thereafter at Fort Mackinac, in charge of the military reservation thereat.

Twentieth Regiment.—From the Department of Dakota, to Fort Leavenworth, Department of the Missouri; the movement to commence October 10. Indian Company I will remain at Fort Assiniboine, Montana.

Twenty-first Regiment.—From Forts Niagara and Porter, New York, to Plattsburg Barracks, New York; the movements to take place upon the arrival of the incoming regiment.

PROGRESSIVE HYPOCHONDRIASIS.

(By a rural hypochondriac.)

I'm feelin' kinder peart t'day,
The sky's so clear n' bright
I'd like to go 'n' fly away,
My feelin's air so light.
But then again I I should go
While yet the grass is wet
Perhaps I might repent with woe:
Fer I ain't well just yet.

I've taken ponnds o' quinine pills
'N' thought they did the biz.
They drove away the quakin' chillis
'N' cured my rheumatiz.
I'm sartin that there's somethin' wrong
'N' soon my eyes 'll shet,
If I don't keep on gettin' strong;
Fer I ain't well just yet.

My head is feelin' mighty queer,
At night I get no rest,
My pneumogastric's out o' gear
'N' onions won't digest.
There's a shrinkin' of my eye
'T is atrophy I'll bet.
I fear that I will surely die;
Fer I ain't well just yet.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Sept. 22, 1894, to Sept. 28, 1894.

First Lieut. BENJAMIN BROOKE, Asst. Surgeon, is relieved from duty at Camp Pilot Butte, Wyo., and ordered to Ft. Canby, Wash., for duty.

First Lieut. THOMAS N. RAYMOND, Asst. Surgeon, is relieved from duty at Ft. Canby, Wash., and ordered to Ft. Riley, Kan., for duty.

Capt. JOHN L. PHILLIPS, Asst. Surgeon, ordered to report in person to commanding officer, Ft. Walla Walla, Wash., for duty at that station, the assignment to duty at Ft. McKinney, Wyo., being revoked.

Capt. CHARLES E. WOODRUFF, Asst. Surgeon, is relieved from duty at Ft. Assiniboine, Mont., and ordered to Ft. Sheridan, Ill., for duty, relieving Capt. FRANCIS J. IVES, Asst. Surgeon. Capt. Ives, on being relieved by Capt. WOODRUFF, is ordered to Plattsburg Bks., N. Y., for duty, relieving Capt. HARAY O. PERLEY, Asst. Surgeon. Capt. PERLEY, on being relieved by Capt. Ives, ordered to Baltimore, Md., for duty as attending surgeon and examiner of recruits, relieving Capt. LOUIS W. CRAMPTON, Asst. Surgeon. Capt. CRAMPTON, on being relieved by Capt. PERLEY, is ordered to Ft. Meade, S. Dakota, for duty.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending September 29, 1894.

P. A. Surgeon N. J. BLACKWOOD, detached from Naval Hospital Norfolk, and to the U. S. R. S. "Independence."

Surgeon J. B. PARKER, detached from U. S. R. S. "Independence," home and wait orders.

P. A. Surgeon L. W. ATLEE, detached from the U. S. S. "Pinta," home and one month's leave.

Surgeon HOWARD WELLS, detached from the U. S. S. "Detroit," and to the U. S. S. "Montgomery."

Surgeon HOWARD E. ARES, detached from the U. S. S. "Detroit," and to the U. S. S. "Detroit."

P. A. Surgeon GEORGE B. WILSON, detached from the Naval Hospital, Norfolk, and to the U. S. S. "Castine."

Asst. Surgeon C. D. W. BROWNELL, detached from the U. S. R. S. "Vermont," and to the Naval Proving Ground, Indian Head, Md.

Asst. Surgeon L. H. STONE, detached from Naval Proving Ground, and to the U. S. R. S. "Vermont."

Marine-Hospital Changes.—Official list of changes of stations and duties of medical officers of the U. S. Marine-Hospital Service, for the four weeks ending Sept. 22, 1894.

Surgeon C. S. D. FESSENDEN, granted leave of absence for thirty days Sept. 12, 1894.

Surgeon R. D. MURRAY, to proceed to Beaufort, S. C., on special duty, Sept. 20, 1894.

Surgeon P. H. BAILLACHE, detailed to represent service at meeting of American Public Health Association, Sept. 21, 1894.

Surgeon JOHN VANSANT, granted leave of absence for thirty days, Aug. 30, 1894.

Surgeon W. H. H. HUTTON, relieved from quarantine inspection duty, and ordered to rejoin Station Detroit, Mich., Sept. 12, 1894. Granted leave of absence for thirty days, Sept. 20, 1894.

Surgeon H. W. SAWTELLE, granted leave of absence for five days, Sept. 14, 1894.

Surgeon J. M. GASSAWAY, granted leave of absence for one day, Sept. 17, 1894.

P. A. Surgeon C. E. BANKS, to report at Bureau for temporary duty Sept. 10, 1894. Detailed to represent service at meeting of American Public Health Association, Sept. 21, 1894. Relieved from temporary duty at Bureau, and directed to rejoin station, (Portland, Maine) Sept. 22, 1894.

P. A. Surgeon CARMICHAEL, granted leave of absence for thirty days without pay, Sept. 6, 1894.

P. A. Surgeon J. H. WHITE, detailed as Chairman of Board to locate Quarantine Station, South Port, N. C., Sept. 13, 1894.

P. A. Surgeon W. D. BRATTON, to proceed to Wilmington, N. C., for duty, Aug. 27, 1894.

P. A. Surgeon C. P. WERTENBAKER, to assume command of Delaware Breakwater Quarantine Station, Aug. 27, 1894.

P. A. Surgeon W. G. STIMPSON, to proceed to Port Townsend, Wash., and assume command of Quarantine Station, Sept. 10, 1894. Granted leave of absence for five days, Sept. 15, 1894.

P. A. Surgeon B. W. BROWN, to report at Washington, D. C., for duty Aug. 31, 1894. Detailed as Acting Chief Clerk Marine-Hospital Bureau, Sept. 21, 1894.

P. A. Surgeon E. R. HOUGHTON, granted leave of absence for seven days, Sept. 19, 1894.

Asst. Surgeon J. M. EAGER, to proceed to Mobile, Ala., for temporary duty, Sept. 11, 1894.

Asst. Surgeon EDGAR STRAYER, to proceed to Pittsburg, Pa., for duty Aug. 31, 1894.

Asst. Surgeon EMIL PROCHAZKA, to proceed to Detroit, Mich., for duty, Sept. 10, 1894.

PROMOTION.

M. J. ROSENAU, Assistant Surgeon commissioned as Passed Assistant Surgeon, Sept. 4, 1894.

ORIGINAL ARTICLES.

INTRA-TYMPANIC MASSAGE AND VAPORS IN THE TREATMENT OF CHRONIC AURAL CATARRH.

Read in the Section on Laryngology and Otology, at the Forty-fifth Annual Meeting of the American Medical Association held at San Francisco, June 5-8, 1894.

BY H. V. WÜRDEMANN, M.D.

DIRECTOR WISCONSIN GENERAL HOSPITAL; OCULIST AND AURIST TO THE CHILDREN'S HOSPITAL; AND TO THE MILWAUKEE COUNTY HOSPITAL FOR CHRONIC INSANE; INSTRUCTOR IN EYE, EAR AND THROAT, ELMS HOSPITAL; AND TO THE MILWAUKEE COUNTY TRAINING SCHOOLS, ETC.
MILWAUKEE, WIS.

In the light of our present knowledge it seems that the conservative treatment for chronic catarrh in the middle ear is most generally applicable and that radical surgical procedures should be confined to the cases in which simple measures have been of no avail, where on account of decided sclerosis with distressing tinnitus, vertigo or stenosis of the Eustachian tube it may be necessary to immediately relieve tension or obtain drainage. It must ever be borne in mind that treatment applied directly to the tympanum and tube is but a minor part, and that the chief efforts of the surgeon should be directed to removal of the cause, which usually lies in intra-nasal or pharyngeal disease in these cases. Besides local attention to these cavities, the patient generally needs instruction as to his methods of living, clothing, ventilation of living rooms, etc.; frequently internal medication is of much service.

The routine treatment of the middle ear and Eustachian tube most in vogue is by inflation with the Politzer bag. Some surgeons use medicated vapors and nebulized fluids of various kinds, forced into the middle ear through the catheter by a hand bulb. A few have the compressed air apparatus. Others use passive motion or massage, by the Siegel otoscope, or directly by the cotton tipped probe. The electro-vibrator, the phonograph and the ordinary hearing tube have their advocates. All these act in much the same way by loosening or breaking down adhesions and increasing the nutrition of the membranes.

Among other measures I have found for the majority of cases a combination of massage and the vapor treatment to be best, and for a number of years have been using vibratory massage through the catheter and Eustachian tube in the following simple manner, obtaining thereby the effects claimed by advocates of other forms of treatment: A compressed air apparatus is necessary. (I get great satisfaction from a plant consisting of an air receiver and automatic pump run by city water pressure, which I have used three years, during which period it has required practically no attention.) Either a regulating water valve allowing the pressure to remain at a certain point or a regulating air valve (such as is manufactured

by the Owens Brass & Copper Works of Chicago) must be used, as accurate dosage of the air-pressure is necessary. The compressed air passes through the medicating apparatus (nebulizer or vaporizer) and is conducted to the mouth of the catheter by an ordinary five millimeter diameter pure gum tubing. The air valve is turned on at the required pressure and the tubing at the catheter compressed about every second by the thumb and forefinger, producing an interrupted current, which gently and thoroughly massages or vibrates the lining of the Eustachian tube, the drum head and the ossicles, loosening the joints, breaking up adhesions and increasing the nutrition of the lining membrane, at the same time that the medicated vapor is brought thoroughly in contact with all parts of the tube and tympanum. At first this process is repeated daily for five to ten minutes at each sitting for either ear, and afterwards every other day until no further improvement in the hearing or subjective symptoms results; occasional after sittings being indicated and in many instances the patient being taught the use of the Politzer bag. The course of treatment involves a dozen to a score or more of sittings.

The air pressure at the meter is usually fifteen to twenty-five pounds; it being my experience that such is as much as it is safe to use through the catheter. By the time it reaches the tympanum this pressure can not be more than a couple of pounds. Bishop,¹ of Chicago, and others claim to use an air pressure of sixty to eighty pounds, and that this may be safely borne by a drum head. I shall not forget the fact that I have personally ruptured a tympanic membrane by simple inflation with the Politzer bag, which in my hands does not afford an air pressure of over ten or twelve pounds. In the discussion of Dr. Bishop's paper,¹ read before this esteemed gathering two years ago in Detroit, Dr. Richardson of Washington related two cases in which he had seen the same result from Politzeration. Others, no doubt, have had a similar experience. But Dr. Bishop uses an extremely small quantity of air at a very high pressure and distinctly states that *the higher the pressure the less the dosage* of the amount of air. It stands to reason that a small quantity of air at a high pressure would produce less of a mechanical effect than a large quantity at the same pressure; also that a large quantity of air at a low pressure would produce a similar effect to a smaller quantity at a high pressure. For by the time that the little puff of highly compressed air that Dr. Bishop lets out of his receiver reaches the middle ear, its volume has increased and the consequent pressure diminished to but a few pounds. He expressly states that without a meter to guide the accurate dosage of the air the "high pressure apparatus would not be safely reliable for ear treatment."¹

¹ Bishop, S. S. Compressed Air and Sprays in Diseases of the Nose, Throat and Ear. Trans. Amer. Med. Assn., Sec. Laryngol. and Otol., June, 1892.

A continuous stream of ten to twelve pounds (not more than fifteen pounds) may be safely passed through the catheter into the middle ear, provided that the beak of the catheter be not impacted in the orifice of the Eustachian tube, preventing a free return of the vaporized air. We must remember that shortly after the introduction of the Eustachian catheter, away back in 1838, one Dr. Turnbull of London had an "accident" from a compressed air apparatus resulting in an autopsy and a coroner's investigation upon the body of his patient.² Others have since occurred. Interrupted currents of slightly greater pressure and only minute quantities at a high pressure can be safely given.

A recent article³ by Dr. G. F. Hawley speaks of forcible dilatation. The high pressures claimed to be used in his cases are naturally made much less by the manner of administration and the effects of the "shunt" current and the drum head must certainly be less than ten pounds to the square inch. He gets massage of the Eustachian tube and middle ear and the interrupted current by vibration of the soft palate. This vibration is extremely disagreeable to the patient, and the pressure in such cases as have atrophied palates may be enough to strain them, with natural consequences.

As regards the various vapors⁴ I still adhere to the camphor-iodin mixture for the majority of cases requiring stimulating treatment; have practically given up the nascent muriate of ammonia so highly advocated by Politzer⁵; get good results where there is tinnitus aurium by mentholized air, (in connection with freezing the mastoid by rhigoline spray as advised by Seiss⁶), all used in the Owens vaporizing apparatus or in the Globe inhaler, or in a bottle similar to the ordinary powder blower (ten or twelve pounds pressure) the compressed air being charged by being first passed through the medicament. Camphor-menthol in albolene or benzoinol is used in the modification of Buttle's inhaler (this being useful for mentholizing or iodizing air also) at high pressure, twenty-five to thirty pounds, or in the "Globe nebulizer" at a lower pressure, ten to twenty pounds. Nitrate of silver solution in water may be used in any of the three. (A newly made silver solution in alcohol can be best used although it soon decomposes.) Any soluble medicament may be used in the nebulizer or in the Bishop inhaler. Personally I use but the camphor-iodin, mentholized air, or thymol with eucalyptol and camphor-menthol in benzoinol. Nitrate of silver is used only to the Eustachian tube and is preferably injected through the fenestrated catheter and blown in by the Politzer bag.⁷

⁴ At the request of several hearers of this paper the formulas commonly used in connection with this treatment are here appended.

1. For simple aural catarrh or Eustachian salpingitis:

| | |
|--------------------------------|------|
| R Benzoinol (W. H. S. & Co's.) | 100. |
| or | |
| R Thymol | 50. |
| Eucalyptol (Mereck's limpid) | 1. |
| Benzoinol (W. H. S. & Co's.) | 100. |

2. Where attended by much tinnitis aurium the above, or:

| | |
|-----------------|-------|
| R Camphore res. | 2.50. |
| Menthol cryst. | 2.50. |

M. Triturate until clear oil forms; add benzoinol ad. q. s. 100.

3. In sclerosis:

| | |
|----------------------|------|
| R Met. cryst. iodine | 1. |
| Kalii iod. | 3. |
| Glycerinae | 30. |
| Aq. camph. ad. q. s. | 100. |
| M. Add lump camphor | 4. |

⁵ Politzer, Adam. Ohrenheilkunde, 1889.

⁶ Seiss, R. W. Treatment of Tinnitus in Aural Sclerosis. Annals Ophth. and Otol., Jan., 1894.

In conclusion, I will state that in about one thousand cases of chronic aural catarrh on my books for the last five years I have been able to cure nearly all in those instances where the patient submitted to the required number of sittings, in which the disease had not advanced beyond slight diminution of hearing; to apparently stop the process where sclerosis had set in, and to improve but not entirely restore the hearing; while in advanced cases the subjective sounds have been mitigated and slight permanent improvement in hearing afforded in the majority of instances. There have been some total failures as regards medical treatment and in some of these surgical procedures were tried but with a like result.⁸

805 Grand Avenue.

DISCUSSION.

DR. BISHOP—While the essayist and I do not use the same compressed air apparatus we probably both arrive at nearly the same results. I have tried the hydraulic pump in my office which is on the fifth floor of a six-story building containing water tanks above; but we could not obtain over ten pounds pressure, which is not sufficient for otologic purposes.
