General Fog.—This is probably the commonest of all faults with gelatine negatives. It consists of a veil over the whole plate, showing itself by want of transparency in the shadows. It may be so slight as to be imperceptible, except when the negative is laid face downwards on a sheet of white paper, or may be so dense as to make the time necessary to get a print be measured by days. It is due to one of two causes, which are usually indicated by the names, *chemical fog*, and *light fog*.

The first arises from error in the preparation of the plate. By it is meant that the sensitive film is in such a condition that the silver salt is reduced by the developer without light having acted upon it. In certain cases it may be cured by soaking the plates before exposure in a solution of three grains of bichromate of potash to each ounce of water, afterwards thoroughly washing the plates, and then drying them.

To distinguish chemical fog from light fog, the best way is to develop an un-exposed plate, performing all the operations in total darkness. This is not difficult. If the plate be found to have darkened, the fog will be chemical fog, or, what is practically the same thing to the photographer, light fog, brought about by the action of light on the emulsion whilst in the hands of the manufacturer.

With the well-restrained developer which we gave in the last chapter, chemical fog is less likely to make its appearance than in the case of the feebly-restrained developers usually recommended. The bromide in the developer may even be increased beyond that which we give, but this will necessitate a somewhat longer exposure. We may state that bromide of ammonia in the developer begins to have an appreciable actual slowing effect on the plate when it is used in the proportion of $\frac{2}{3}$ or $\frac{3}{4}$ the quantity of strong ammonia used. When the bromide equals the ammonia, the slowing effect becomes very great.

Light Fog is due to the action of light generally in one of three ways: first, on account of an unsafe light in the dark room; secondly, on account of a defect in the camera or dark slide admitting light; and thirdly, on account of over-exposure.

When the fog is due to light in the camera, this will be recognised by the fact that the portions of the plates covered by the wires or rebates of the dark slides remain free from fog. When this is the case, the camera must be carefully examined by removing the focussing screen, and looking for any the smallest defects which might admit light, the head of the observer being covered with the focussing-cloth. Light finding its way through defects in the slides generally shows itself in the form of streaks or lines. Should no defect be detected, the exposure must be reduced.

If fog from unsafe light in the dark-room be suspected, place a plate in the dark slide, draw out one of the shutters half-way, and then lay the slide for five minutes on the table where the plates are changed and developed; then develop the plate. If one-half darkens, it shows that the light is not safe, and steps must be taken to render it so.

Green Fog.—This defect is always due to error in the manufacture of the plates. It makes its appearance only in the shadows of the negative. If the negative be looked at by reflected light, a black object being laid under it, the shadows will be seen to be bright green. On looking through the negative they will appear somewhat pink, or sometimes a sort of "muddy" colour. Green fog makes its appearance only with alkaline pyrogallic development, and then chiefly when the plate has been under-exposed and development "forced."

A slight amount of green fog is not detrimental to the printing qualities of a negative; but if the defect shows itself in an aggravated form, the best means of preventing it is to resort to ferrous oxalate development. Captain Abney has recently given a means of curing plates afflicted with green fog after development. It consists of bleaching the negative with a solution of ferric bromide, oxalate, or chloride, and afterwards applying the ferrous oxalate developer. Full particulars of the method will be found in the Photographic News for April 28, 1882.

Red Fog seems to be an aggravated form of the last-mentioned disease. In appearance it is a deep red deposit showing itself by transmitted light in the shadows of the negative. It is rarely met with at the present time, although it was common in the early days of gelatine plates. It does not make its appearance in plates developed with ferrous oxalate. Probably Captain Abney's cure for green fog would correct this defect also.

Frilling consists in an expansion of the film to such an amount that it loses its adhesion to the glass, and "frills" off. The phenomenon begins at the edge of the plate, and spreads towards the centre. When it begins at the centre it is termed blistering. It is due to an error in the manufacture of the plate, but is much aggravated by a developer strong in ammonia, by the use of warm solutions, by the use of too strong a fixing bath, or by the use of very soft water for washing. When it makes its appearance only in the fixing bath or during washing, it may be prevented with certainty by placing the plate, immediately after development, in a saturated solution of alum for five minutes. This we advise in all cases; but where there is no fear of frilling, the plate should be thoroughly rinsed before it is placed in the alum solution.

If the frilling be of so aggravated a form as to show itself during development, it is more difficult to prevent its occurrence. Captain Abney states that coating the plates with plain collodion before development is a perfect cure.

Plates which, when newly prepared, frill frequently, after keeping for some weeks or months in a dry place, show no tendency to the defect. In fact, we have found that the keeping of the gelatine plates for some time improves them in every way.

Want of Density or Flatness of Image is usually due to under-development, or to the use of too weak a developer. A consideration of our remarks in the last chapter on development will show how sufficient density may be gained in almost any case; and we may here say that a very common cause of want of vigour is to be found in the fact that the ammonia is not so strong as is supposed. In the case of liquid ammonia of specific gravity ·880 a very short exposure to the air weakens it, by allowing ammonia gas to escape. It will be generally found that the last of the ammonia in a bottle is considerably below the standard strength, simply from the escape of the gas every time the bottle is opened. It is for this reason that we recommended the dilution of the ammonia with an equal bulk of water immediately after purchasing it. Pouring the strongest ammonia from one bottle to another will perceptibily weaken it.

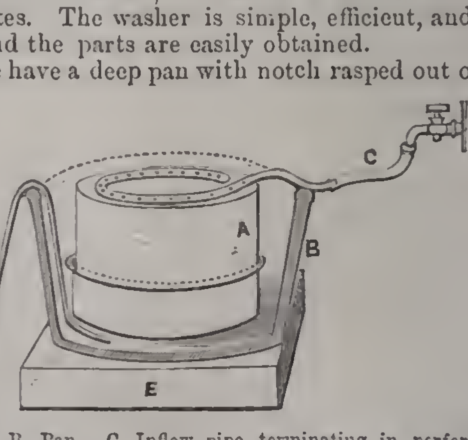
There are some plates which will not give a vigorous negative, however they be developed. This is the case with plates on which the emulsion has been too thinly spread. If such plates are to be used at all, an after-process of intensification must be resorted to. This we propose to treat of in the next chapter. It will occasionally happen, too, with the best of plates, that an error of judgment will be made in development, and the process stopped before density is sufficient. This is another case for intensification.

AN EMULSION WASHER AND A DRYING RACK.

BY HENRY SPINK.

I now give a description of the two following articles which I believe will be found useful to any photographers who may make their own emulsion and plates. The first is an emulsion washer; the second is a rack for drying coated plates. The washer is simple, efficient, and inexpensive, and the parts are easily obtained.

First, we have a deep pan with notch rasped out of edge,



A. Sieve. B. Pan. C. Inflow pipe terminating in perforated ring. D. Exit syphon made out of a piece of bent metal gas pipe. E. Wooden block to raise the apparatus a little above the level of the sink.

and a small syphon of $\frac{3}{8}$ gas pipe, which passes to the bottom and is bent so that the short end shall terminate near the centre of the pan. In the next place there is a sieve having a black varnished copper-wire bottom, to stand in pan so that the edge of the sieve comes just above the top rim of pan, a notch being cut out of bottom rim of sieve to allow the syphon to pass below it in the pan, and over the sieve is a ring of $\frac{3}{8}$ gas pipe, perforated with holes, and connected with the water supply. The emulsion is placed in the sieve, the ring is connected with the tap by a flexible tube, and the dissolved salts are drawn off from underneath by the syphon; the ring lies just within the top of the sieve, and the whole can be covered over with a loose cover, while the flow of water can be regulated so that the in and out flow just balance each other.

The rack consists essentially of two parallel bars of hard wood, these being deeply notched at intervals of two inches apart; but in order to keep the plates steady I provide a third bar, which swings on two arms so that it can be brought down on the plates so as to grip or steady them

The movable arm is triangular in section, and is, of course, notched so as to correspond with the two fixed bars. The wet plates are placed in two's, back to back, in the notches. A rack made 11 in. high by 4½ in. wide will take any size from half-plates up to 10 by 12. They are best made of hard wood, but any one can make them for himself at the cost of a few pence. The arm on which the movable bar swings should be about two inches and a half long, and if the notches are V-shape they do not spoil the edges of the plates, and can be moderately deep. They are best placed not less than two inches apart, or else the plates *sweat* and spoil one another if there is not a good draught. A very few racks hold a good many plates, and the racks can be safely piled one a-top of another in the drying cupboard, and there is free ventilation all through them and between the plates.

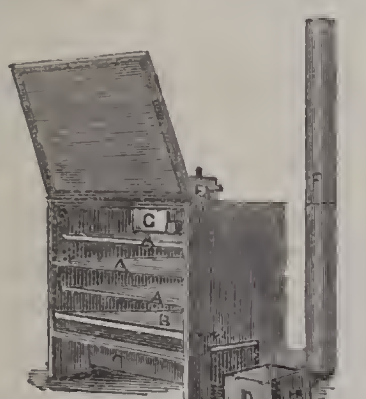
AN AMATEUR'S DRYING CUPBOARD.

BY VERO C. DRIFFIELD.

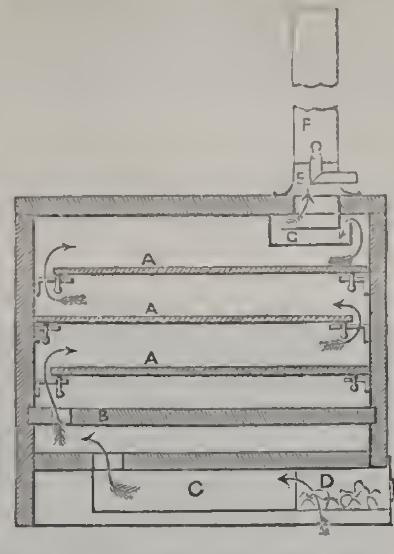
One difficulty I soon found I had to contend with in making my own plates was in drying them; and having just devised and constructed a drying cupboard which has entirely overcome every difficulty I previously experienced, I felt that a description of it might interest many of my brother amateurs.

I originally dried my plates by passing a current of warm air over them, the air being warmed by the same gas flame which created the necessary draught, and though I succeeded in drying the plates without difficulty, they were frequently unevenly dried, marks being produced on them which showed both before and after development. The worst fault, however, was that I could not obtain absolute immunity from frilling. Upon investigation I discovered that the plates which frilled most were invariably those dried nearest the source of heat, and this led me to conclude that the most satisfactory method of drying would be by means of cold dry air.

I then constructed a cupboard, of which I annex a photograph, and to which I will now refer. *a a a* are

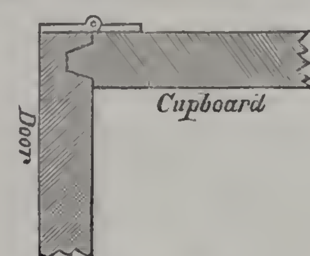


three sheets of plate glass resting upon screws, for the purpose of levelling them. These screws may be omitted, of course, if the emulsion is allowed to set on the plates before placing them in the cupboard. B is a false bottom, which is removed to allow room for the hand when levelling the bottom plate. This false bottom is perforated with holes at one end, and acts as a light-trap, preventing any possible admission of light into the cupboard from the air inlet. C is a tin chamber communicating with the inside of the cupboard. D is a tin drawer, the bottom and one end being of perforated zinc. The bottom of this



Vertical section through centre of cupboard.

drawer is covered with small lumps of calcium chloride. The draw is then inserted into the end of the chamber C, the bottom of which is, of course, cut away for an area corresponding with that of the bottom of the drawer. E is a tin socket, also communicating with the inside of the



Light-tight joint for door.

cupboard, and into which is fixed a gas elbow with a burner perforated with a single fine hole. When the gas is lighted, the chimney, F, is placed on the socket in order to produce the requisite draught. G is a light-trap, to prevent any admission of light into the cupboard from the gas-burner.

My cupboard is capable of drying at one operation twenty-four quarter, twelve half, or six whole plates, and I find them absolutely dry in from twelve to eighteen hours. As soon as the plates are dry, I empty the calcium into a tin dish, and place it in the oven to dry. I use the calcium over and over again, and have been surprised at the small quantity required. I need hardly say that the efficiency of the cupboard depends largely upon the tightness of the door and all connections. No air should be admitted excepting through the calcium drawer. Since I adopted this method of drying, I have seen absolutely nothing whatever of frilling or of marks on the plates.

ON THE EFFECT OF THE SPECTRUM ON THE HALOID SALTS OF SILVER, AND ON MIXTURES OF THE SAME.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

Silver Bromide.

When paper is immersed in a 10 per cent. solution of potassium bromide, then dried and floated on a 10 per cent. solution of silver nitrate, and exposed to the action of the spectrum, the visible effect will be observed as shown in fig. 21. Figs. 22 and 23 show the action of the spectrum after filtration through potassium chromate, the former being what is observed after a preliminary exposure to diffused white light, and the latter when the paper has only seen the yellow light. It is needless to go into all the details

* Continued from page 205.

which were described when silver iodide paper was under examination. The same causes exist for the shape of the curve as they do with the latter paper. It may be interesting to remark that the spectrum observed on paper which has been washed and treated with potassium bromide after sensitising is the same as that shown in fig. 26, whilst when only washed, and not treated with the soluble bromide, it takes the form of fig. 29. The reason of these differences in shape of curve is apparent when it is remembered how the effects on silver iodide paper were traced to their source.

It must be noted that there are several molecular modifications of silver bromide. The first is that form in which it exists in the paper and also in collodio-bromide emulsions when prepared in the ordinary way; also when prepared in collodion by the bath. This form transmits a yellow-orange tint when white light traverses it. Another form is one which I described in the Bakerian Lecture for 1880, viz., a form which transmits a blue-green tint; and a large form which transmits a grey tint, which is found in gelatine emulsions which have been boiled, or treated with ammonia in the manner which is common at the present day. These three varieties were examined both for the visible action of light, and also for development. A plate was coated with the first emulsion named, with the result that the direct action of light gave fig. 25. The blue-green transmitting form gave fig. 24. This form is one which is sensitive to the infra-red rays of the spectrum on development, and it will be seen that the printing action also extended to that region. The printing action on the grey form (which was submitted to the spectrum in a film of gelatine) is shown in fig. 26. On comparing these together, it will be seen that the maximum action commences between G and F (nearer F than G), and that the main difference in their impressed spectra lies in the tails on the least refrangible side. When the colour transmitted by these three forms is taken into account, these differences are to be expected. Whether the silver

34. Ditto ditto	(short exposure).

bromides were exposed with a slight excess of silver nitrate, or with a slight excess of soluble bromide, no difference in the spectra resulted.

We next come to spectra developed on the different preparations of silver bromide. Fig. 27 represents the action of the spectrum on silver bromide paper, prepared as above, which has been washed. Whether development took place by acid developer or by ferrous citro-oxalate, no difference was observable. Fig. 28 shows the same with a short exposure. When the paper was washed and treated with potassium bromide and then exposed, we have as a result figs. 31 and 32. The slight difference in the pairs of figures results from the presence in one case of inorganic matter combined with silver, and in the other case its absence.

When a plate is coated with collodion containing cadmium bromide, zinc bromide, or potassium bromide, and placed in a strong silver nitrate bath, and developed with either acid developer or with ferrous citro-oxalate, we get curves similar to figs. 31 and 32. The same figures also represent the action of the spectrum on collodio-bromide emulsions transmitting orange light by any kind of development. This applies equally whether the plate be exposed wet or dry, or whether exposed in the presence of silver nitrate or other inorganic sensitisers.

Figs. 29 and 30 show the results obtained when using gelatine bromide plates with the silver bromide in the grey molecular state, whether exposed with an inorganic sensitiser, or without, and whether developed with an acid, alkaline, or organic iron developer.

Figs. 33 and 34 represent the action on the blue-green molecular form of silver bromide in collodion, when developed and exposed under similar circumstances to the preceding case.

It will be remarked that the direct visible action of the spectrum and the developed image coincide.

The effect of impurity in the bromide is not so marked as it is in the iodide. The presence of iodide, except in minute quantities, is rare; the haloid most frequently present as an impurity being the chloride. When the spectrum on the chloride is considered, it will be seen that such an impurity is hardly possible to be detected, as the spectra impressed on it are somewhat similar in general character to those on the bromide.

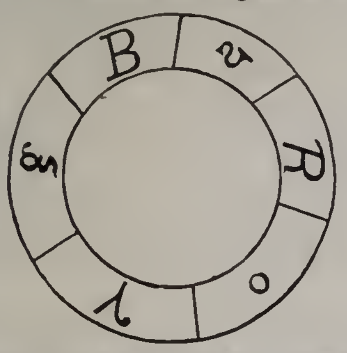
(*To be continued.*)

DARK-ROOM LIGHT.

A consideration of the theory of colours and their relation to actinism, long ago made me question the necessity of any change in the colour of dark-room lights for the better protection of extra sensitive dry-plates; but in the establishment we followed the directions of the plate manufacturers, and, at first, adopted the ruby light. The obscurity of our work-room, however, and still more, the painful effect of the red light on our eyes, induced me to test by actual experiments the value of the new light in comparison with the old. The result showed that our fathers knew what they were about when they settled on the orange tint as the true non-actinic colour. We found, while it admitted three times the working light, it had less effect on the plates, in extreme tests, than the ruby.

As some of your readers may not have thought much about the method of determining complemental or opposite colours, a word on this subject may suggest other applications of theory to our art.

Notwithstanding the old writers, there are but three primary colours—red, yellow, and blue. We know that these, and these only, are primary, because no admixture of any other colours will produce them, which is not the case with the rest; for orange is only a mixture of red and yellow, green is only the shading of yellow into blue, and purple is only blue blending into red. Now, as the last primary colour in the spectrum is seen to join with the first in the production of the intermediate shade of purple, or violet, as it is usually called, we may with propriety curl the spectrum into a circle, in order to represent to the eye the inter-relation of the triad of colour. In the annexed diagram let the capital letters



R, Y, B, represent the primary colours, and the small letters, o, g, v, the compound colours. Now it is natural to infer that if we establish a certain quality as belonging to a certain colour, when we seek for the direct opposite of this quality we should look for it not in any near colour, but in the opposite side of the spectrum, thus returning into itself. It would take too much space to illustrate this at length, but a very pleasing method of testing the complemental colours is to fill the eye for some minutes with some strongly marked coloured light, and then retire into the dark and observe the tint of the image presented to the optic nerves. If we have been looking at a pure red light we shall in the dark see a green image; if at yellow, we shall see violet, &c.; these colours, respectively, being on opposite sides of the spectrum as drawn in our diagram.

Pure blue, or, possibly, blue slightly tending to violet, is known to embrace most of the chemical rays. Hence, to find what rays will operate the least on our plates, we look to the opposite or complemental colour, orange, and are not disappointed. But, whatever may be thought of the theory, the fact is, briefly, we are now developing our dry-plates in front of nine 8 by 10 orange lights, set back about eight feet from a good-size outside window, and admitting light enough for one to read the finest newspaper type on a dark day. It must be understood that the darker shade of photographers' yellow glass is to be selected, not the canary, nor yet the very brown. Strictly speaking, very little of this glass is orange—as it should be—but it is near enough to that colour.

The pleasure of working in an agreeable light, and plenty of it, will, we are sure, be appreciated by all our readers, and we urge them, after they have satisfied themselves, cautiously, that we are right, to save their eyes.—*Philadelphia Photographer.*

Correspondence.

THE "NEW" SODA DEVELOPER.

Sir,—At one of the recent Thursday Evening Meetings, Mr. Reimann is reported to have shown a negative developed with the new formula, viz., washing soda instead of ammonia. This seems to be one of those wonderful and original discoveries which some photographers seem to delight in springing upon the world. I find a formula of this supposed new discovery copied into my note-book, in accordance with which I developed a plate about three years ago.

With regard to the fading of gelatine negatives, I fear there is too much reason to fear that such is the case. It is certainly the case with those developed by means of ferrous oxalate. I have some negatives which are decidedly less dense now than they were two or three years ago.—Yours obediently, A. T.

DEFECTIVE DARK SLIDES.

Dear Sir,—I think some of your readers may find the following dodge useful when their dark slides close so imperfectly as to admit light. Some of my double dark slides let in light where they open in the middle, there being a bead which, when the slide is shut, should fit tight into a groove, and so keep all light out. Mine got warped, and light got round the bead. I cured this most effectively by sticking over the groove a narrow strip of tracing paper, and then shutting the slide up while wet; and when the slide was opened, it was found that the paper had become pressed into the groove, making a most perfect fit. As this is such a simple method, I venture to send it to your valuable paper.—I am yours faithfully, F. K. Barclay.

DETERIORATION OF GELATINE NEGATIVES.

Sir,—Some time ago I had just the same experience as your recent correspondent, "Provincial," as regards the gradual deterioration of gelatine negatives when kept for some time; but my recent experience points to imperfect removal of the hyposulphite as the cause. Some films are so hard that several hours' soaking is required, and treatment with a saturated solution of alum after that. Since I have thoroughly soaked out the hyposulphite and treated with alum, my trouble has quite disappeared.

Bristol, May 10th, 1882. Thomas Thirlow.

ABNEY'S PROCESS FOR REMOVING GREEN FOG.

Sir,—It is, perhaps, but a poor compliment to Captain Abney to say that his process for the elimination of green fog is really what it professes to be, as most of the Captain's inventions have this characteristic. Still, at the risk of confirming what needs no confirmation, I venture to relate my own experience of the ferrous bromide application to this purpose. It happens that when I read Captain Abney's article, I had in my possession two of what I believe were then the finest existing specimens of green fog. The plates were covered in parts with a thick metallic layer, which glistened splendidly in reflected light, while the amount of light transmitted was of the smallest. These excellent specimens had been produced by the abominable practice of developing a lot of plates in the same developer. These, too, were of a costly make of plate, and were evidently of a weaker constitution as regards the application of ammonia, for they would not stand the reckless manner in which I drenched those of my own make which were being developed at the same time. Such, at least, I suppose to have been the reason. But, anyhow, there was the result—the usual dichroic deposit, supplemented by a thick, glossy, golden layer.

These two plates, then, I treated first with the ferrous bromide solution, and afterwards with ferrous oxalate. As the plates re-developed there was on one of them no sign of any deposit whatever, while the other was clear except in one obstinate corner.

One ought not to get green fog, I admit, but still one does, and so I, for one, wish to lift up my voice in gratitude for this new and certain cure.

A Befogged Beginner.

Proceedings of Societies.

Photographic Society of Great Britain.

The ordinary monthly meeting of this Society was held Tuesday evening, the 9th instant, at 5a, Pall Mall East—James Glaisher, Esq., President, in the chair.

The minutes of the previous meeting having been read and confirmed, and three new members elected, the Chairman called upon Captain Abney to read a communication.

Captain Abney opened his remarks by saying that it was hard upon him to have to contribute so many papers, and this evening he only came in as a "stop-gap." He said that during the last four years he had contributed one-third of the papers read, and that those who were interested in the Society ought to bring forward any matters they might have, and not leave all to one individual. He proposed to speak of one or two points first, which, perhaps, he might have spoken about in his Cantor lectures. First, with regard to the comparative sensitiveness of carbon tissue and chloride of silver paper in summer and winter, certain differences were traceable to the position in the spectrum of their respective points of maximum sensitiveness. He had investigated this matter, and had arrived at conclusions different from those of other experimenters, who generally placed the maximum between G and F in the blue, whereas he had found it to be lower down, and the sensitiveness to extend much nearer to the yellow than most people imagine. He did not find that the pigment contained in the tissue had any effect in altering its sensitiveness, and passed round examples of the specimens impressed upon different tissues. Referring to the platinotype process, though the maximum was not so low down in the spectrum as with bichromated gelatine, the sensitiveness extended far lower than with silver chloride, and this would explain the marked advantage which was observed in winter in employing the platinum process. Some albumenized papers were found to print more equably in winter than others, and this he was inclined to think was due to the presence of an organic salt of silver, notably in Mr. Bedford's method of sensitizing, in which citric acid was employed. This brought him to a consideration of the behaviour of different salts of silver when exposed to light. If a film of gelatine containing chloride of silver is exposed to the direct action of light, an image is formed which is practically useless, being almost entirely removed by the fixing solution. By combining an organic salt of silver with the chloride, however, a more vigorous image was obtained, and one which will bear the fixing operation. Specimen prints on glass, fixed and unfixed, were passed round, showing strong, rich images which suffered but little degradation in fixing. These were obtained by mixing with the chloride half the proportion of citrate of silver, and washing the emulsion in the ordinary way; this effect was obtained without the aid of an excess of silver nitrate, and the results were particularly suitable for transparencies, the image being susceptible of toning to any desired extent in the ordinary manner. Alluding to statements that had been made to the effect that gelatine films containing chloride of silver in even the smallest proportion could be detected by their darkening under the direct action of light, Captain Abney passed round a number of plates made from emulsions containing the different haloids separated, and in different combinations, all of which showed more or less colouration, and the deduction he arrived at from his experiments was that iodide and bromide together darkened as readily as a mixture containing chloride.

Mr. W. Bedford asked Captain Abney if all the specimens shown had been exposed for the same length of time. In his own experience he found that chloride mixed with bromide darkened more rapidly than bromide alone.

Capt. Abney replied that similar exposures had been given. With regard to chloride alone, it darkened to a chocolate brown without any of the blue tint which mixtures of bromide and iodide gave.

Mr. T. Sebastian Davis had found that a mixture of bromide and chloride darkened much more rapidly and deeply than a simple iodide plate. He said that *apropos* of Captain Abney's experiments with citrate of silver, he had some time ago produced satisfactory prints by means of phosphate of silver paper.

Mr. Maxwell Lyte said that he had had some experience of a kindred nature, and which confirmed Captain Abney's statement with regard to the darkening of the film. He had employed plates prepared with bromised collodion, sensitised in the usual way, and, after washing, soaked in salt and water, these giving films perfectly free from nitrate, and containing a slight trace of silver chloride. These were then flooded with a mixture of albumen and water in equal parts, to each ounce of which was added one drachm of a saturated solution of chloride of silver in ammonia. The plates, after drying over sulphuric acid and caustic lime, proved highly sensitive; but these experiments were not completed at the time he had been compelled to relinquish his photographic work, though he hoped soon to resume them.

Capt. Abney was not sure whether he had fully understood Mr. Bedford. What he wished to state was that as great a colouration could be obtained with a film containing no chloride, as with a chloride plate—not a pure chloride plate, but one containing a small proportion of chloride. With regard to citrate of silver alone, he had employed it for printing, but found it much slower than chloride. He did not like the so-called collodio-chloride, which should really be called collodio-citro-chloride. He would like to ask Mr. Davis if he had ever tried phosphate of silver in combination with gelatine.

Mr. Davis said he had added phosphate of soda to the emulsion, using the equivalent of silver nitrate.

Captain Abney understood that Mr. Davis employed, instead of the citrate of silver, the phosphate.

Mr. Maxwell Lyte asked if Mr. Davis had not found phosphate of silver very insensitive. Such was his experience. He found it necessary to use sodium carbonate to neutralize half an equivalent of nitric acid liberated by the phosphate of soda, in order to obtain a perfectly neutral paper.

Mr. Davis said, if he remembered rightly, the phosphate paper was much inferior to chloride in sensitiveness.

A vote of thanks was passed to Captain Abney for his communication.

A description was then read of Mr. William England's tent and stand, which were exhibited. The tent, which had originally been constructed for wet-plate work, was now used for developing and changing dry plates, the only alterations made being in the addition of a deeper ruby window, and the replacement of the silver bath by one for hyposulphite. The stand was constructed of bamboo, and was particularly light, and, at the same time, quite rigid.

Captain Abney also exhibited a sleeve-tent, constructed by Major Browne Constable, for wet or dry-plate work.

Mr. Maxwell Lyte said he had had considerable experience with tents, especially in hot climates, and had never sought special portability. The tent he preferred consisted of a tripod about six feet high, with a triangular top. The legs of the tripod were jointed in the centre, and, when folded, the points of the legs passed into an aperture in the triangular top, and were thus kept in position. From the centre of each leg to the next one extended a strip of wood, and these formed a support for a table, which was constructed on the principle of the Tunbridge ware chess-boards, so as to fold into a small space. The covering of the tent, which reached only as far as the table, was made of three thicknesses of calico—one of black, one yellow, and the outer one of white, in order to throw off the heat. The back portion was made with pleats, in order to allow standing-room. A sleeve ventilator was fixed in the top, and this, when in use, was packed lightly with grass or ferns, to keep it open; while, by placing upon the outside of the tent ferns or heather sprinkled with water, he managed to keep it cool in the hottest weather.

Major Brownrigg objected to having his head inside the tent. He had worked 12 by 10 plates in a box tent with sleeves, and found it answered perfectly.

Captain Abney thought Howard's tent admirable for wet plates, but considered it impracticable for dry plates.

Mr. England thought everybody travelling should be provided with a tent, as in the event of wet weather setting in, the time could be occupied in developing.

Mr. W. B. Bolton said Mr. England had mentioned that he had replaced the silver bath by one for fixing. He would like to ask if Mr. England did not find a difficulty in washing the negatives free from hyposulphite when travelling.

Mr. England replied that he had not found the slightest difficulty.

Mr. Bolas asked Mr. England if he had tried the plan of putting the plates into the fixing bath without first washing off the developer.

Mr. England said he had not.

Votes of thanks were then passed to Mr. England and Major Browne Constable for the loan of their tents.

It was announced that the next technical meeting would be held on the 23rd inst.; also that the exhibition would be opened by the usual soirée on the 7th October. The last day for receiving pictures would be the 29th September, and to this rule the committee would adhere most stringently.

The meeting was then adjourned to the 13th June.

South London Photographic Society.

The ordinary monthly meeting of this Society was held at the House of the Society of Arts, John Street, Adelphi, on Thursday evening, the 4th inst., the Rev. F. F. Statham, M.A., President, in the chair.

The minutes of the previous meeting having been read and confirmed,

The Chairman drew attention to the fact that the particulars of the artistic competition had not been sent to the journals last month. The subjects for competition during the next year were "A Country Lane," "Water and Trees," "Playmates," and "The Pet of the Family." He also informed the members that Rule VI. of the competition had been rescinded, and competitors had the privilege of exhibiting their pictures elsewhere. It was announced that the committee had decided that the presentation print of 1881 should consist of Mr. E. Dunmore's prize picture.

Mr. P. Mawdsley then took the chair, and the President proceeded to read a paper on "Realism and Idealism in Photography" (see page 262), in the course of which he handed round some prints illustrative of the manner of introducing appropriate figures and objects into landscape pictures—amongst others, "The Zealot," by Mr. Valentine Blanchard; "The First Night at the Pantomime," by the late Mr. H. Cooper; "The Idle Girl," by the late Mr. O. G. Rejlander; and some examples of successful grappling with costume models, by the same artists and others; also, as an illustration of the effects of lighting, he showed Mr. H. P. Robinson's "Little Sunshine." At the conclusion of the paper,

The Chairman suggested that the best way in which they could treat the very able paper which the President had read before the members would be by having a good discussion, and called upon some of the members to offer remarks upon the paper.

Mr. J. Nesbit said he had been very much interested in listening to Mr. Statham's paper. He had frequently tried to introduce figures into his landscapes, but found they always struck attitudes very different from what were natural. His experience was that it was very difficult to make them assume such a pose as the artist would like to see in his picture. He had frequently tried to reproduce the poses he had seen in Birket Foster's and other pictures, but had found it impossible to make his figures assume the right positions. No doubt others had been more successful, and he would like to hear their views on the subject.

Mr. E. Dunmore agreed with Mr. Nesbit with regard to the difficulty experienced in getting people to pose themselves properly, and remarked that one did not care to risk spoiling a picture by introducing figures which would not pose as they were required to do.

Mr. T. J. Pearsall thought, from his recollection of many pictures he had seen, that if the artist were on the look-out, the right people would present themselves to be made use of as figures, and that the introduction of these elements of life into works of art was a very important matter. He went on to say that students of "still life" found especial difficulty with this deficiency of life in their pictures.

Mr. W. E. Foxlee, referring to an allusion in Mr. Statham's paper to people "getting themselves up" preparatory to sitting for their portrait, said he was of opinion that photographers very often failed in getting good portraits on account of the sitter having just left the hair-dresser's before coming to the studio, and that this was more especially the case with children, who were often brought with their hair arranged as they never had it before or after.

Mr. F. Bridge cited the case of a lady who had her hair curled specially for the purpose of having her portrait taken, and sending it to her husband. He brought the picture home without having recognised it, and showed her that "some woman had been sending him her picture."

Mr. Statham thought they did not sufficiently appreciate the difficulties of photographers. They could do a great deal more if they made the same efforts, and had at the same time received the same remuneration as painters. The public ought to be taught that if they wanted a good artistic photograph they must pay for it, as they would for a good painting. He would like to bring to the notice of the members what he had seen, in visiting one or two galleries, of the remarkable pains celebrated artists have taken over the details of their pictures. Raffaelle, when desirous of introducing a camel into one of his pictures, sketched it in every conceivable position in order to see which was the best; and Birkett Foster was continually making little sketches in his note-book, to be made use of as occasion offered. He thought that when a photographer found a suitable scene he should have no very great difficulty in taking some persons with him and introducing them as figures into his picture. He related an anecdote of an artist in the south of London, some few years ago, who was engaged to paint a family picture. The artist suggested to his patron that he should pose them at the table, and painted them with the governess holding one of the children with her hands clasped, saying grace. The geneteman did not like the picture, and the artist, having it thrown on his hands, exhibited and sold it at the Royal Academy for a high price on account of its artistic merits.

Mr. Foxlee said an artist, some years ago, wishing to represent a man raising a stone with a crowbar, came to him (Mr. Foxlee) himself to be photographed in the desired position. He was taken in several positions with the crowbar, but none of them suited him. A balk of timber was then obtained, and he was set to work to try and force out the side of the studio. In this position he was photographed, and a picture produced just as he required.

Mr. Statham said that an interesting topic for discussion presented itself as to what was the proper method of delineating the body in rapid motion, and referred to the examples of this nature produced by Mr. Muybridge. He instanced that the horse, while trotting, never exhibited its real movements to the eye.

Mr. Pearsall said that Mr. Muybridge had declared that Mrs. Butler was ahead of all painters in portraying animals in motion, and that her pictures were more correct in this respect than even Rosa Bonheur's. He knew that whole regiments of the Guards had been ransacked by her in order to obtain suitable faces for some of her pictures.

Mr. Statham observed that those remarks confirmed what he had said about the pain and trouble taken by some artists.

Mr. W. Brooks said, with regard to taking pains, that some of his pictures had taken him months to get. Painters, he remarked, paint for one person, their patron; photographers work for the middleman or shopkeeper, and as soon as they succeeded in bringing out a good picture the itinerant photographers get up cheap copies of it, selling them for one-half or one-quarter of what the original artist could afford to sell his picture for. He thought the pains and trouble of getting suitable figures and adjuncts for a picture would have to be left for the amateur, as it did not pay professional photographers to do it.

Mr. Statham thought the time would come when thoroughly artistic photographs would command as high prices as good paintings—such productions, for instance, as Rejlander's, who, though dead, still lived in the hearts of many of those present by his works.

The Chairman called for a very hearty vote of thanks to the President for his most able paper, which was heartily responded to.

The President having resumed the chair, and some discussion having taken place relative to a paper for next meeting,

The Chairman thought they required a special committee to arrange papers for the monthly meetings, so as not to be dependent upon chance. He suggested that, failing a paper for the next meeting, some topic for discussion might be acceptable.

The meeting was then adjourned.

Thursday Evenings for Photographers.

At the meeting held on the 4th inst., Mr. A. Cowan occupied the chair.

Mr. A. J. Brown produced some gelatine negatives which, although developed with ferrous-oxalate, showed green fog; and he stated that he found to produce this result it was not necessary to use an alkaline developer. He also exhibited some negatives on gelatine supports; he found it difficult to develop the films sent out by one maker, owing to their curling up in the dish.

The Chairman said if they were squeegeed on the bottom of the dish, when developing or as the development first commenced, they would remain flat throughout the operation.

Mr. W. Cobb said a friend of his had experienced great difficulty in eliminating the hyposulphite from film negatives; negatives that had received what was thought to be a good washing, showing traces of hyposulphite after being kept a few months.

Mr. Reimann suggested that if, when most of the hyposulphite was removed, the negatives were treated with a solution of alum, it would decompose any that was remaining.

Bocas' exposing shutter was then exhibited and tested by setting to various exposures and timing by a watch, the results being apparently correct.

Several photographs by Professor Stebbing of the students at a School of Design in Paris were shown.

The Chairman passed round some negatives on plates coated with an emulsion handed to him by Mr. Henderson. He found them much more sensitive than any to be obtained commercially; but as they were much fogged they could only be considered specimens of rapidity.

Mr. Henderson was of opinion that the emulsion was not foggy, but that it was of such extreme rapidity that it required great care to keep the plates from light. He had produced a distinct impression upon one of these plates by ten seconds' exposure to the light of a lamp covered with deep ruby glass and orange paper.

Photographers' Benevolent Association.

The Board of Management held its usual monthly meeting on Wednesday eveniug, 3rd inst.

The minutes of the previous meeting having been read and confirmed, Messrs. E. Squire and Geo. Higgs were duly elected members of the Association.

The following vote of thanks was carried unanimously:—"The Board of Management tender their most sincere thanks to all those ladies and gentlemen who so kindly gave their services at the soirée on Thursday, the 27th ultimo, to benefit the funds of the Association."

Sheffield Photographic Society.

The ordinary meeting of this Society was held at Freemason's Hall on Tuesday evening, May 2nd. Thos. H. Morton, M.D., presided. The minutes were read and confirmed.

Mr. Taylor (Secretary) reported on the late excursion to Haddon Hall, April 27th, which was numerously attended by members, friends, and ladies, who were also specially invited. The weather was most favourable, and, through the courtesy of the steward, Mr. Nesfield, every facility was afforded the Society to make a photographic survey of this noted baronial mansion.

Mr. Rawson said it was one of the most agreeable excursions he had attended, and proposed a vote of thanks to Mr. Nesfield.

Mr. T. Firth seconded it.

The Chairman remarked that the success was also attributable to able management, and he had pleasure in proposing a vote of thanks to Messrs. T. Firth and G. V. Yates, for making the necessary arrangements.

A large number of negatives and prints from 12 by 10 to 5 by 4 were passed round, Messrs. Taylor, Hadfield, Firth, Rawson, Dickinson, and others contributing.

One able member, however, had a mishap in the field, not to himself, but to his plates, which, when changing, prematurely saw the light, and were hopelessly fogged. The photographic result otherwise was satisfactory.

Mr. Ainley exhibited a holder for negatives, when developing. It consisted of a metallic silvered plate, bent so as to form a V wedge-shaped groove in which the negative was placed, and a handle or arm of the same material soldered to the centre. The instrument would fit almost any plate.

Mr. Rawson suggested that the handle should be curved downwards, so that the end might rest on the table, and not tilt up. This appeared advantageous.

Dr. Morton said he thought that the injurious action of pyrogallic on the skin had been somewhat over-rated; but it was very desirable to have a reliable holder, or some means of raising the negative for inspection and transferring from one dish to another.

Respecting the rapid drying of negatives, suggested by the Rev. J. J. Bird,

Mr. Rawson said he found blotting-paper, to remove free moisture, and careful drying before the fire, a very efficient plan.

Mr. Taylor (Secretary) brought a spring rapid shutter of his construction, the aperture being closed by revolving discs. Portraits shown taken by it were good.

On the proposition of Mr. Leader, F.S.A., seconded by Mr. Dakin, the next excursion of the Society will be to Welbeck, May 25th.

Talk in the Studio.

South London Photographic Society.—We are requested to state that all communications with regard to the Society should be addressed to the Hon. Sec., 9, Norfolk Road, Dalston Lane, London.

The Stannotype Process.—We have received from Mr. Woodbury a little pamphlet describing in clear and succinct language his latest and best simplification of the Woodbury process.

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News*" *Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed* "*Union Bank, Photographic News Co. Account.*"

*** We cannot undertake to return rejected communications.

*** We have received an interesting series of instantaneous pictures of the recent State procession at Windsor, taken under specially unfavourable circumstances by Mr. C. Wyrall, of Messrs. Hills and Saunders.

Major Gordon.—We have received the prints, and quite agree with you as to their clearness, purity, and brilliancy. You have evidently controlled the development to perfection. The interior is particularly good.

W. W. W.—1. Certainly not. 2. Chloride of gold is usually a little acid, and it is to neutralize this acidity that the addition is made.

Christian.—Write to Klic direct.

Eton.—1. In England, pyrogallic development is more in favour; on the Continent, on the contrary, we should think oxalate development is mostly used. 2. Eder's "Modern Dry Plates."

A. d'E.—Thank you very much, but we are quite ready to stand or fall by our own.

G. F.—Very much depends on circumstances, but the matter was fully discussed in the News some months back.

D. A.—He uses a kind of drop shutter, to which are attached numerous powerful india-rubber springs; but it has been doubted whether the exposure is in reality so short as the estimate which he makes.

Samuel Johns.—Not only practicable, but tolerably easy in bright summer weather; still success naturally requires that the worker has sufficient knowledge and experience to take advantage of all circumstances tending to make results more certain. To give you all the information you require would involve writing a comprehensive treatise on the subject.

C. C.—Alcohol, 5 ounces; cadmium iodide, 85 grains; or if for large plates, alcohol, 5 ounces; cadmium iodide, 42½ grains; potassium iodide, 34 grains. It is not desirable that any bromide should be used.

John Cannon.—The colouring matter you mention is one of the most fugitive of reds. Alizarine lake is as permanent a pigment as you will obtain.

H. Spink.—The MS. is to hand. Thanks.

Dark Room.—1. As cold water will only dissolve one-fifth of its weight, such a solution is obviously impossible. 2. Add it drop by drop until the turbidity disappears. 3. The excess is very soon got rid of by washing. 4. Only when freshly prepared.

James Phillips.—French chalk has always answered well in our hands, but care should be taken not to apply it with too heavy a pressure.

A Beginner.—The markings are due to the use of over-iodised collodion; and the remedy is to add more plain collodion, or to increase the strength of the silver bath.

Sunlight.—The proceeding is of but little practical value, unless the bath be made slightly alkaline first. 2. Next month. 3. Write to the Manager of No. 2 department. 4. The gentleman referred to is still managing the concern.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1237.—*May* 19 1882.

CONTENTS.

REVERSED NEGATIVES.

Although several good methods exist for the productiou of reversed negatives, or for the reversal of those already existing, it is a matter of notoriety that most of these processes are subject to drawbacks and disadvantages which prevent their use in many cases; and as the practical outcome, none of those printing methods which require reversed negatives have come into general use.

The use of a reversing prism or of a silvered glass reflector involves considerably increased trouble and care in placing and adjusting the camera; in the former case there is always a considerable loss of light, and generally a notable falling-off as regards definition; while in the latter case the careful polishing of the silver surface after it has been put away for any great length of time involves so considerable a loss of time as to prevent its use by any excepting those who have frequent occasion to produce reversed negatives. It is quite easy, as we have frequently pointed out, to ensure the easy separation of either a collodion or a gelatine negative film from the glass, provided that the plate has been suitably prepared before being coated; but this does not in any way meet the wants of those who may wish to reverse an old or existing negative. As a matter of fact, almost the only available course in such a case was to make a reversed copy of the negative, the risk of attempting to strip it being too considerable in ordinary cases.

Mr. Plener's method of employing hydrofluoric acid to loosen the film will serve to altogether change this condition of affairs—as regards gelatine negatives, at any rate—and it now becomes easy and safe to strip any gelatine negative which we may desire to possess in the form of a film or pellicle.

Mr. Plener's method, as published by us a short time ago, consists in immersing the plate in very dilute hydrofluoric acid, the film having been previously thickened up by a little plain gelatine; but under these circumstances the film possesses a considerable tendency to expand under the influence of the water, and a considerable enlargement of the picture takes place. When, however, the film is treated with dilute sulphuric acid before and after the immersion in the hydrofluoric acid, this does not happen, and it is even possible to somewhat reduce the scale of the stripped negative.

We now propose to give working details for carrying out Mr. Plener's method of stripping, and a considerable improvement has been made by using the solid and easily handled fluoride of sodium instead of the corrosive and somewhat dangerous hydrofluoric acid; the sodium salt being dissolved, diluted, and decomposed by sulphuric acid just as it is required for use.

Should the negative to be operated upon have been varnished, the first step is to dissolve away the resinous film by repeated ablutions with methylated spirit, and if a collodion film exist between the varnish and the gelatine, this must also be removed; a mixture of equal parts of alcohol and ether serving for this purpose. The next step is to prepare a solutiou of a tolerably hard quality of gelatine in about eight times its volume of water, and after the plate has been slightly warmed and levelled, this preparation is poured on until a layer about as thick as an ordinary cabinet mount is obtained, strips of cardboard being placed round the edges of the plate if required. When the gelatinous mixture has set, the plate is either set on edge until it is nearly dry, or it is immersed in strong methylated alcohol for a few minutes. The next step is to allow the plate to remain for five or six minutes in a cold mixture of one part of sulphuric acid with twelve parts of water, and in the mean time one or two parts of sodium fluoride are dissolved in one hundred parts of water, a gutta-percha or ebonite tray being used. A volume of the dilute sulphuric acid equal to about one-fourth of the fluoride solution is next added from the first dish, and the plate is then transferred to the second dish. The film soon become loosened by the action of the liberated hydrofluoric acid; and when complete separation has been effected, it is once more transferred to the sulphuric acid bath. In the meanwhile, a sheet of glass, which should not be smaller than the film, is warmed and slightly waxed on the surface; all excess of wax being well polished off with a piece of flanuel. The film is next immersed in cold water, where it is allowed to remain for about a minute, so that the greater part of the sulphuric acid may be removed. It is next laid on the glass plate and covered by a sheet of wet paper, after which a squeegee is employed to expel the redundant water, and make a close contact between the film and the glass. The paper is next removed, and the edges of the film are clamped to the glass by means of thin strips of wood and American clips. The plate bearing the film negative is now placed iu a warm locality, under which circumstances a few hours will suffice for the complete drying of the film; after which it can be detached from the waxed glass with the greatest ease, it being merely necessary to run the point of a penknife under the edges. During the drying it is necessary that the atmosphere of the apartment should be charged with ammonia, iu order that the trace of sulphuric remaining in the film may become neutralised; or it is better still to place a few drachms of ammonia in a flat dish, and fume the film for a few minutes. Under any circumstances it is well to place a small strip of litmus paper between the film and the glass, so as to indicate when the acid is thoroughly neutralised. The trace of ammonia sulphate formed is not in any sense detrimental; but if a thicker film of gelatine than that recommended be used, it may be necessary to soak the pellicle a little longer in the water, in order to sufficiently remove the sulphuric acid.

ON THE ACTION OF ORGANIC MATTER ON SILVER SALTS.

The action of organic matter upon silver salts is well known, and photographers who suspect organic impurities in their silver baths take the precaution of "sunning" and filtering the solution in order to get rid of them. Dr. Henry Leffmann, the microscopist to the Pennsylvania State Board of Agriculture, has essayed to apply this action of the salts of silver and sunshine to determine organic impurities in ordinary waters, and the following experiments, published in the *Analyst*, were undertaken as a sort of preliminary investigation. The subject of water analysis is so important, not less to the photographer than to others, that every observation of the kind must have some value; and as the reaction is one familiar in the photographic laboratory, our readers are likely to feel particular interest in Dr. Leffmann's investigation.

If we add a salt of silver to ordinary water, says the doctor, the precipitated chloride interferes with the test, and, to prevent this, I used a solution containing marked excess of ammonia. In the following experiments, the proportion used was 2 c.c. of ammonio nitrate of silver to 100 c.c. of the water. The silver solution contained only a few grains to the ounce. When not otherwise mentioned, the water was exposed to the sunlight for two hours.

1. Distilled water... ... ...No colour
2. Schuylkill ,, ... ,,
3. Ditto ,, with 0·1 c. c. urine ...Brown colour.
4. Ditto ,, with 0·5 c. c. urine ...Deep brown.
5. Ditto ,, with 0·02 c. c. urine ...Red brown
6. Ditto ,, with 4 grs. raw sugar.. No colour.
7. Ditto ,, with 2 grs. stale mash...Yellowish.
8. Well water, not perfectly pure, but not unfit to drink ... ...Faint black.
9. Ditto ,, markedly contaminated...Black precipitate almost immediately.
10. Water from a small stream, quite pure...No colour.

Waters containing small amounts of milk, glucose, and albumen gave no distinct effects. Solution of glue produced a faint brown. All the experiments tended to show that the test was very sensitive to the presence of urine. Some experiments were made with highly dilute solutions of the common active principles.

Quinidia, strychnia, and cinchonidia gave no result. Picrotoxin gave light yellow. Caffeine gave light yellow. Quinidine sulphate gave faint brown. Morphia gave immediate precipitate. By calculating the amount of metallic silver reduced, a pretty correct estimate of the organic matter in the water could be formed.

THE PREPARATION OF GELATINO-BROMIDE PLATES IN DAYLIGHT.

Mr. Ernest Edwards, who is well known to our readers in connection with the heliotype process, has made an ingenious application of the de-sensitizing properties of potassium bichromate, the plates being prepared in the full daylight, and sensitized, when required, by mere soaking in water. If Mr. Edwards's process is as successful in actual practice as it appeared to be when he recently demonstrated his method before the Boston Society of Amateur Photographers, it will prove of especial value to the photographic tourist.

Mr. Edwards dissolves twenty-four grains of bromide of potassium and thirty grains of gelatine in one half-ounce of water, raised to and maintained at a temperature of 100° Fahr. Next he dissolves thirty grains of nitrate of silver in two drachms of water, adding liquor ammonia until the black precipitate formed is re-dissolved, the amount of liquor ammonia added being thirty-five drops. This ammonia nitrate solution is then added to the bromized gelatine solution first named, and the two are thoroughly mixed by agitation. To this is added a solution of twenty grains of bichromate of potash in one half-ounce of water, and, finally, two drachms of alcohol, raised to a temperature of 100° Fahr., are added to the mixture.

All these operations may be conducted by daylight.

Next, still working by daylight, the plates are coated by pouring, and laid aside to set and dry. When dry, one of them is taken into a dark closet, soaked in cold water, face downward, for about an hour, the water being changed several times, and then removed from the water and dried in the dark. It is then exposed and developed. The action of the bichromate is to render the bromide of silver insensitive while it is present. The washing removes not only this bichromate, but also takes out the free nitrate and the nitrate of potash, the thin film being the best possible form in which the gelatine can be presented for washing. All necessity for "cooking" the gelatine is done away with by the use of the ammonia-nitrate.

Mr. Edwards recommends that in making plates by this process they be washed as soon as they are "set," without allowing them to dry, as in this way any effect that the light might have on the bichromated gelatine is avoided. The importance of this new departure in the method of preparing dry plates can only be appreciated by those who have made them by the old method, which requires all the operations of mixing, "cooking," washing, coating, and drying to be carried on in a room so dark that it is impossible for the operator to clearly see what he is doing. With properly constructed washing and drying boxes plates may, by Mr. Edwards's method, be made in large quantities much more rapidly and at much less cost than by the method now in vogue. It is hoped that others will experiment upon it, and make public the results of their investigations.

A NEW MERCURO-CYANIDE INTENSIFYING PROCESS FOR GELATINO-BROMIDE PLATES.

BY DR. J. M. EDER.

The negative it is desired to intensify is, after fixing and thorough washing, placed in a solution of bichloride of mercury, just in the same way as in the old process.

The negative is next well rinsed with water and put into a second bath. This is made up by dissolving in 1,000 parts of water—

Cyanide of potassium	5 parts
Iodide of potassium...	2½ ,,
Bichloride of mercury	2½ ,,

The negative will then pass through three stages of change.

1st Stage.—The negative grows more dense and becomes yellowish. This is by reason of the action of the iodine salts upon the mercury. Remaining still in the bath, the negative reaches—

2nd Stage.—The film becomes dark brown; the negative gains enormously in vigour, and the contrasts are heightened. The reason for this is the gradual metamorphosis of the sub-iodide of mercury by the cyanide of potassium. In this condition the image is very vigorous. Flat negatives are by this means rendered quite brilliant, but those of normal character become, as a rule, too vigorous and too hard.

3rd Stage.—If the negative is too dense, it is allowed to remain still longer in the bath. The intensity gradually diminishes, the colour of the negative becomes a lighter brown, and the image is more transparent, *while at the same time none of the detail is eaten away.* The vigour slowly decreases, until at last the negative has no more density than it possessed previous to its treatment.

The changes I have detailed follow slowly. The stages remain for some minutes, and for this reason the process is easily watched and controlled. Owing to the nature of the changes, moreover, this process of intensifying may be adopted for negatives of different kinds.

This mixture of cyanide of potassium, iodide of potassium, and chloride of mercury, may also be employed as a means of reducing density. If very dense negatives (after fixing and washing) are put into it, the image becomes gradually thinner, its harmony being preserved the while. In half an hour or an hour the change will most likely have taken place. Still, although the weakening of the negative proceeds very slowly, it is better to dilute the cyanide solution with an equal volume of water.

The method I have described is a very comprehensive one; that is to say, it may be employed for improving flat negatives and hard negatives. It is more advantageous than the cyanide of silver and cyanide of potassium process, because the brown colour has a more favourable result. Moreover, of this last process it is said that the negative, after much printing, becomes of a rose-red colour, due to the decomposition of the residual cyanide of silver.

Finally, I may say that in the interval between the mercury bath and the cyanide bath, even when the negative is insufficiently washed, there is no chance of any spots forming on the film.

By-the-Bye.

PARIS AND THE SALON.

Paris in May. To the stranger, whether he dwells in town or country, Paris is ever hospitable—ever attractive; but in the sunny days of May, when greenness and freshness prevail in the boulevards and parcs, when the golden rays overhead are scarce screened by the translucent greenery, when it is pleasantly warm and not sultry, when the smart little Victorias begin to crowd the streets, and the Paris *cocher* sports his new hat of shining white or shining black, when the smiling heralds of summer on every side tell us the chill days are gone, then is the French capital indeed delightful. The cafés and restaurants of white and gold are opened up into the street, and long-aproned garçons issue forth with chairs and tables to take possession of half the pavement; flowers and green shrubs are posed under the sun-awnings, and roads and *trottoirs* are sprinkled to allay the dust. Monsieur appears in white waistcoat and straw hat to sip absinthe and read the impaled newspapers at the little marble tables, and *bonnes* put on their summer finery and long ribbons to parade youngsters yet more fine and be-ribboned. Roundabouts and *cafés chantants* in the Champs Elysées and in the Bois are in full swing, gaily-flagged boats are to be seen on the sun-lit lake, and so intent are Monsieur, Madame, et Bébé on amusement, that the crowded cabs and omnibuses leave the stranger without means of locomotion.

It is the Salon, of course, opening, like our Royal Academy, early in May, that increases the number of visitors just now in Paris. There is this marked difference between the annual art collections of England and France: with us, the pictures are to be seen at the Academy, and at the Academy alone; while in Paris, so widespread is the influence of the Salon, that one sees the reproductions of the principal pictures of the year in the windows of print-sellers and photographers. It is true our painters at home are gradually becoming more alive to their interests. It is not so long ago that they would consent on no account to the reproduction of their paintings by the camera, so we shall not be surprised if the time does not shortly come when, as in Paris, reproductions are to be met with on every hand at the same time that the originals are on exhibition at the yearly gathering. These reproductions not only bring profit to the painter, but increase also the prestige of his original work, for this becomes familiar before it has actually been seen. It strikes the eye at once, if the latter has seen anything like it before, and thus all those paintings that have been copied, become at once famous to the public.

In regard to reproductions, we may mention a new class of picture that seems to be causing some attraction in the streets. We allude to tiny paintings in oil, many of them very well executed indeed, and presenting a *fac simile* in miniature to the original painting. They are some of them no bigger than a cabinet card, and rarely measure more than ten inches. Although apparently on canvas, they are executed upon wood, and are really paintings, the outline and detail being in the first place produced by means of photography. The price is from ten to thirty francs, some of them being exquisitely finished, and entailing much work. No doubt a large number are painted at the same time, and in this way they are produced at a reasonable figure.

Coming to the Salon itself, we may at once say, for the information of the uninitiated, that the wall space covered by paintings is probably four or five times that available at the Royal Academy. From the circumstance that France has a much greater population than Great Britain, it is not surprising that she should have more capable painters. After the number of paintings, the next thing that strikes an English visitor is a difference in style. The French paint stronger and more vigorously than with us at home, and also, we think, there is more attempt at classic work. The French speak of our Academy this year in depreciating tones, admitting, however, that there are some nice little works. We would in reply say that, while their pictures undoubtedly display much force, there are many very nasty ones in the collection. Imagine a large picture in the main Salon which has for its subject the dragging of a drowned corpse to the surface of a weed-grown pond! A boat-full of men have grappled the livid body of a drowned man, and this they are pulling out of the water, entangled with weed and slime. The picture is most graphic, and exceedingly well painted: but the subject is horrible to a degree. In the same way, we are treated to an allegorical picture of "Remorse"—a brown-clad monk, with terrible visage, tearing a wound in his breast, from which the dark-red blood flows, causing a clotted pool beside him. "A Reverie on Death"—a man sitting down contemplating a dead body, from the head of which issues a stream of dark blood—is another unpleasant picture, to use a mild phrase; and so is the "Last Visit at the Hospital," where friends gather round an open coffin in which the rigid features of death are visible.

Another phase of the Salon to which we take exception is the battle and military scenes, of which, fortunately, there are but few. These are of the old conventional type. Charpentier's "En Avant" is a very good example, a score of horsemen, fighting and rushing forward to the attack. There is the same cavalier sabreing some unfortunate on the ground, the same horseman raising his sword on high to encourage his fellows, the same riderless horse always shown in a battle on canvas. An attack on Sfax suffices to introduce the naval element, and we have steam launches conveying soldiers and sailors on shore to take part in the contest that we see raging in the smoke and fire.

As usual, the Salon is very strong in pictures from the nude, studies which, if too frequent here, are decidedly too rare with us. The portrait poses are certainly in advance of those we show, and there is a greater number of character sketches. A "Columbine," a delightful creature with laughing mouth and merry eyes, holding a champagne glass aloft, which she has just emptied, is the embodiment of brightness and go. M. Moreau's husbandman, standing leisurely with his scythe beside him, one leg across the other, while he lights his pipe, is most easy and graceful. A touching little scene—without a dead body—is "The Gardener's Daughter," in which we see a coffin covered with pall in a garden amid fresh blooms and growing flowers.

We have a good many pictures of funerals and religious ceremonies in which mourning women are shown us in sackcloth and ashes; but the sackcloth is always cut to the latest fashion, fitting most exquisitely the slender waists, and, if anything, a trifle décolleté. Somehow, one never feels much sympathy for lovely woman, however bowed down with grief, when we see a lace-trimmed corsage and finely clocked stockings; we see she is in mourning, and only think how nicely it becomes her. Several of the French artists have missed the pathos of their subject by paying too much attention to costume.

Van Beers shows us the Syren once more, the little puss that captivates every one at the Academy. Here the Syren is steering a skiff, and facing a manly form, whose features are cleverly covered by a soft felt hat. She sits in the little boat enveloped in furs, her bright eyes and ruby lips as ravishing as ever. She has the same bewitching costume, and draws admirers round her the whole day long.

M. Michelet shows us a "Public Letter-writer," which is not to be compared with Mr. Burgess' painting of the same subject in our Academy. Nor are the landscape pictures more successful than those to be seen at Burlington House, with the exception, perhaps, of some coast scenes, which our French neighbours manage very well. One of the finest paintings in the Salon is a fisher scene; the boat has just touched shore, and the little one of the family is handed in to the father, who holds the urchin fondly aloft prior to embracing it. Mother stands on a jutting rock just in front of the boat, looking fondly at the chubby limbs of her darling. "The Kiss of the Syren," by Wertheimer, is another fine picture, the syren in her embrace drawing a sailor from his boat down with her into the deep waves.

A quaint subject for a *genre* picture is a dentist's room, the patient ready in the arm-chair with her head thrown back, and the dentist taking up the forceps from the table in front. It is by Rasel, and called "Un moment difficile," a disagreeable picture at best, and in our experience scarcely true to nature, for dentists, as a rule, do not have their implements in front of the patient. "Every Age has its Pleasures" is more pleasant. It is an artist's studio, and a fly has settled upon a statue—the Venus of Milo. An urchin has mounted upon a damask settee, and, oblivious of the costly furniture and more costly statue, is in the act of catching the insect. The picture is all the more attractive, since there is a singular absence of humour and brightness among the Salon pictures this year. The impression they convey is for the most part lugubrious, and in some cases, as we have shown, the sentiment verges upon the horrible.

The "At Home" next week will be "Mr. W. J. A. Grant on board the Arctic yacht *Kara*"; the following "By-the-Bye" will be "A Unit of Light."

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Photographs on Moving Sensitized Plates—The Discussions at the Photographic Society—Freckled Sitters—Photography as a Profession.

Photographs on Moving Sensitized Plates.—The researches of Mr. Muybridge have revolutionised one's ideas as to "instantaneous" photography. It should not, however, be forgotten that as far back as 1874 M. Janssen's "photographic revolver" employed in connection with the Transit of Venus was successfully used to produce successive photographs of the moving planet, photographs which even in these days of gelatine plates would be considered as nothing short of marvellous. The extreme sensitiveness of modern plates has turned the attention of photographers to the question of exposure; but it can scarcely be said, in spite of the multitude of instantaneous shutters, that perfection in mechanical means has yet been arrived at. As there is no reason to believe we have got to the *Ultima Thule* of sensitivenes, this question becomes day after day of more importance, and it is interesting, therefore, to learn what has been the experience of M. Janssen on the subject. In the "photographic revolver," the method of exposure adopted was the rotatory movement of the plate, which was stopped mechanically each time an image was taken. This plan succeeded well up to about a dozen images in a second, but failed when a greater rapidity was sought, by reason of the practical difficulty which the stopping and moving of the plate presented. This difficulty is indeed self-evident, and it occurred to M. Janssen to consider whether the stoppages could not be done away with, and successive pictures taken on a moving sensitive plate. His supposition has turned out to be correct, and he has exhibited to the French Academy photographs on which identical portions of the solar surface were represented, and these photographs have demonstrated the perfect success of his theory. One of these portions was taken on the plate while the latter was at rest, and the other while the plate was moving about six inches in a second, and a close comparison showed that no difference between the two could be detected. The possibility once admitted, it became simply a matter of calculation as to how many successive photographs could be obtained in a given time—the calculation being based on the known sensitiveness of the plate, its velocity, and also the nature of the object to be photographed. M. Janssen has satisfied himself that images following one another at intervals of $\frac{1}{100}$ of a second may be readily obtained by this means, and that even this number may be exceeded. The relations between astronomical and every-day photography are not so close as to make it plain what influence M. Janssen's discovery may have upon the general work of photography; but the fact that an image can be impressed upon a moving plate is an interesting one, and may lead to further important results.

The Discussions at the Photographic Society.—It sounds rather oddly to hear of a dearth of papers at the Photographic Society, when, at the same time, intermediate or "technical" meetings, as they are called, have been established presumably for the purpose of allowing the members to get rid of their superfluous knowledge, which there is neither time nor opportunity to make public at the regular monthly meetings. The fact that these intermediate meetings bear the name of "technical," would seem to indicate that the council have come to regard the meeting on the second Thursday of every month as a "theoretical" one. If this be the case, we would ask whether the distinction is a wise one. It is, of course, desirable that theories affecting photographic phenomena should be made public; but it is also desirable that the discussions should be such as the "average member" may occasionally join in. When a subject is introduced which touches upon a vital point in practice, the increase in the liveliness and interest is very marked. The meetings of the Photographic Society—whether rightly or wrongly—have acquired a reputation for solemnity and importance which is not calculated to encourage timidity, and hence, it may be, arises the deficiency of papers. If it be found that the "technical meetings" are pleasanter, because less formal, than the regular monthly meetings, the latter will assuredly suffer, and "stop-gaps" become more than ever necessary. Why is it that there has been such a tendency during the past two years to form other photographic societies, clubs, or whatever name they may be called by? This, at all events, should not indicate a lack of subjects to discuss, but rather the reverse. Yet the Photographic Society, which should be at the very head of all other societies, finds it difficult to get papers.

Freckled Sitters.—A sitter with a freckled face is undoubtedly a source of great worry and annoyance to the photographer. In spite of the most liberal application of the powder puff, the abominable freckles insist upon showing, and the negative requires no end of retouching before it can be made to yield prints sufficiently gratifying to the sitter. Some of the Daguerreotypists of old had a novel dodge by which they tried to get rid of the spots. Here is the method as recommended by one of the very earliest authorities in the art. "To obviate a freckly face, let the person rub it until it is quite red, and the effect will be to lessen the contrast; the photogenic intensity of the red and yellow being nearly the same, an impression can be produced nearly free and clear." Probably; but we fancy a lady of to-day, if she were told by the photographer to scrub her face violently, would doubt whether he had not taken leave of his senses.

Photography as a Profession.—The personal experience of men who have succeeded in photography would be of immense service to those about to begin. It is often said that the artistic faculty is rarely to be found in the same person combined with a business capability, and we believe that this is true to a certain extent. But it would be a mistake to suppose that because a man is artistic in feeling, and conscientious in his treatment of sitters, he cannot, if he chooses, acquire enough of business habits to make his practice a success pecuniarily as well as artistically. The one thing upon which all photographers agree is that the secret of building up a good business is to send out the very best of work. At the same time, if there is habitual delay in forwarding proofs, or further delay in completing orders, and unpunctuality in the keeping of appointments, the best of work cannot save a man from bankruptcy. A photographic business in the present day is based upon the recommendations of sitters; it is surprising how soon a man's reputation, either for good or bad work, for punctuality or carelessness, gets known. If they have confidence in him, customers will run after a photographer and put themselves to inconvenience to seek him out. Hence no one who commences photography as a profession need despair. as good work and business habits are bound to tell, if—and there is much virtue in an if—he waits long enough.

Review.

General Hand-book of Photography (Ausführliches Hand-buch der Photographie), by Dr. Josef Maria Eder. With 600 woodcuts, and six tables. Part I.: The Chemical Action of Light and Photography. (*Halle, Germany: Wilhelm Knapp.* 1882).

We have received from Dr. Eder's publisher, Herr Wilhelm Knapp, of Halle, the first part of the Handbook of Photography, of which ten will make up the volume. When this is complete, it will be, far and away, the best authority on photography and photographic processes that has ever been attempted. The name of Dr. Eder stands quite as high in this country as it does in his own, for no more hard-working investigator or thorough chemist has devoted himself to photographic science.

The first part of Dr. Eder's book consists of no less than 96 pages (the entire volume will number about 800 pages) of closely-printed matter, and deals with the history and development of photography, as also with the chemical action of light. The early experiments of English investigators are referred to in detail, and due justice is rendered to Fox-Talbot, Herschell, Ponton, Robert Hunt, and other pioneers in this country. Although at first sight the numerous notes and authorities give his pages rather a concrete look, Dr. Eder's language is of the simplest, and his style terse and interesting; while the numerous illustrations interspersed help further to make the book eminently clear and intelligibie. We have, indeed, been struck, in perusing his chapters, by the interest with which he has been able to invest even the barest facts he desires to bring before his readers.

Part I. at once shows how fully and exhaustively the author proposes to deal with his subject; but, in an introductory page, he sketches the purport of the subsequent chapters. There is not an important phase and branch of photography with which Dr. Eder does not propose to deal, and, as we have said, the finished volume must needs be in years to come the recognized authority on matters photographic, both in the old world and in the new.

To those who are wholly ignorant of the German language, Dr. Eder's volume will be of little avail; but to those who have but a casual acquaintance with the language of the Fatherland, we heartily recommend this invaluable work. The printing is in Roman characters, therefore easily legible, and we will vouch for it that any indifferent German scholar who is a good photographer will be able to study the pages with advantage. The price is 2 marks 40 pfennigs each part, and, as International Post-office orders are now obtainable, we make no doubt that Herr Knapp will be ready to send the parts as they appear, in return for a P.O.O. for two shillings and sixpence forwarded to Halle.

We ought to have mentioned that a capital heliogravure, by Klic, of Vienna, of Major Russell, forms the frontispiece to Part I.

ON SUBMARINE PHOTOGRAPHY.

BY W. D. VALENTINE.

A few weeks ago I noticed in the News the name of my firm mentioned in connection with an attempt we made at submarine photography, and a fortnight since there was given the result of experiments made by M. Forel to determine how far down the action of light penetrated in the clear water of the Lake of Geneva; perhaps it may interest the readers of this journal to have a short account of my experiences—I regret I cannot write successes—in submarine photography. At the time of the Tay Bridge catastrophe it was suggested to me that it would be of the utmost value could a photograph be obtained of the large girder in which the engine lay in the bed of the river; and as the late Sir Thomas Bouch kindly gave me the use of a steam lighter and experienced diver, of course I fancied it a very good opportunity to try such a novelty in landscape, or rather seascape, work. I first had constructed a very strong box of 1½-inch pine of sufficient size to hold an 8 by 10 camera and lens focussed. In front of it was inserted a piece of patent plate to serve as a window for the lens, said window being provided with a sliding shutter for the diver to slip open when he wished to expose the plate.

After the camera was put in with the dark slide opened, this being done in a dark room, the back of the box was put on and made fast with very powerful screws, thick india-rubber having been placed between; heavy iron legs were screwed on the box like an ordinary camera tripod, and a large hook was bolted underneath to hang the weights necessary to sink this somewhat ponderous machine to the bed of the river. I chose a very bright day in the beginning of March to try my first experiment. It required about 10 cwt. to sink the submarine camera, the whole affair being lowered by a powerful crane from the steam lighter. The diver went down at the same time, with full instructions as to placing and exposure. I gave one of Swan's gelatino-bromide plates, twenty-five times as sensitive as wet plates, twenty minutes' exposure, with the full opening of a Dallmeyer 10 by 8 rapid rectilinear, and on subsequent development there was not even a trace of fog. The depth of water my experiments were made at would be a little over 30 feet, and was strongly tinged with yellow. The plate in this case might as well have been exposed with the dark slide shut, showing unmistakably that at the depth of 30 feet of Tay water, little or none of the actinic rays penetrated. However, the experiments were not without a certain value should I ever have the opportunity to try submarine work again.

First, I believe it is impossible to construct a submarine camera of wood so as to be water-tight under the enormous pressure to which it is subjected; should I again try it, I should have it made of metal with the back to screw on. Secondly, I found in some of the preliminary dips given to the camera that the lenses and glass window "steamed" so much as to render work impossible. This difficulty was eventually overcome by unscrewing the lenses and rubbing them with glycerine, the window receiving the same treatment. In conclusion, I must add that I very much doubt whether submarine photography will be of any practical value. The electric light has been suggested, but where it will give aid I fail to see. The light would require to be placed about the same distance from the object as the camera, which in most cases would not be less than from ten to fifteen feet, and as in my experiment a powerful sun failed to penetrate thirty feet, I cannot think that the most powerful electric light, even with a very prolonged exposure, would give any practical results. At the time this attempt of mine was made the diver assured me that he could distinctly see objects at a distance of over thirty feet.

ODD JOBS.

BY THE AUTHOR OF "LOOKING BACK."

No. 8.—A Photographic Nuisance.

There are numerous subjects who may be distinguished by the above title. Imprimis, I may mention the starving employer who advertises for a "first-class operator," whose sole intention is the securing of a goodly supply of specimens for his shabby show-cases. Then there is the gentleman of the press, "who will give you a good line" in return for an unlimited supply of his own pictures. There is the seedy, bombastic, third-rate actor, who struts all over the place humming a tune, under the impression, no doubt, that it is gentlemanlike, and who desires his pictures at a "redooced" price, because he is a "pro." There is the inquisitive amateur who whistles, "To Know, don't you Know?" and, when told, gravely assures you that he thinks his own *modus operandi* the best, after all.

But of all nuisances that haunt the photographic studio, the artist—the Vandyke, the Rembrandt, the Sir Joshua of silver and carbon enlargements—is the acme; the *ne plus ultra*. Remember, I do not allude to R.A's; I allude to the class who "tear to tatters, to very rags," the works of art that line our galleries. I allude to those great little men who go sneering through our photographic exhibitions, and laugh loud at the bare idea of photography and art being anything but diametrically opposed to each other. "They are as wide apart as the poles, sir!" one of them exclaimed to me the other day, with a contemptuous wave of his hand.

The other day the Yahoo of the establishment came up to me with so peculiarly pleased a grin on his face that I knew something unpleasant was in store for me. I was not deceived, for he burst out with—"Yer in for it to-day, Mr. B———; the 'hartiss' is going to give you a sittin'. He has been took by the seventeen operators before you, an' is not pleased with any of them. Ha! ha!" And he chuckled like a laughing hyæna. Quite indifferent to the "hartiss," or his being pleased, I went on with my retouching until his arrival, which took place about half-past seven. He was a hairy little monster, with a large mouth, a flat nose with the nostrils showing absurdly, and great, light, staring eyes. He barely noticed me on entering the studio, but strode along the glass-house, pulling his slouched hat very much on one side, while he cast a wild and critical eye upon the blinds and shutters. "Hum! very good; still, this one would be better drawn a little more," quoth he, suiting the action to the word; "and the shadow side is too dark."

"I beg your pardon," I put in, as he was proceeding to throw a cross light upon the spot where the sitter would be; "but if you do that you will have a flat picture with neither high lights or shadows?"

"Ah! ah!" he answered, as he turned to me; "true, that may be so with photography—I forgot—I was arranging the lighting from an artistic point of view."

Inwardly I ejaculated "cad," and could not help smiling as I turned to arrange the camera. He saw the smile, and a settled sneer took possession of his hirsute phiz: he sneered at the furniture—he sneered awfully at the apparatus—he sneered at the Yahoo, when he appeared with the dark slides, much to that amiable young gentleman's delight—I am not sure but he sneered at himself in the looking glass—if he did not he should, for he was the only thing worth sneering at in the studio, unless it was a toy monkey that we have for amusing children.

With the self-possession that comes with years of practice, I went to work—placed a chair—and invited the "hartiss" to take a seat. Down flopped the ill-bred fellow with the air of a surly coal-heaver.

"Ah! thank you—that's nice—quite natural, but not so easy as I should like," I drily remarked, while I moved the top lights; I could feel, although I did not see him, that he gave me a look, while he brought his figure into a little better form. I spoke very little after this; but posed him—lighted him—focussed him—and was all ready for exposing, when up he jumps, shakes his shaggy head, and marches up and down the studio exclaiming, "Never do, sir, never! No mortal that was not double-jointed could ever stand such twisting! God forgive them! And they talk about photography in connection with art!" and he laughed in the most insolent manner as he looked at me.

"When you are ready, sir, I shall be happy to commence again," was my calm ejaculation, while I felt the blood boiling in my veins. Had I been the "guv'nor" I would have had less command over myself. However, as a quiet word turneth away wrath, so my manner subdued this son of the palette and brush. He condescended to inform me that his talent was hereditary; in short, that he was come of a family of artists, and descended in a straight line from the famed Sir Joshua Reynolds; asked if I had seen his last fancy picture, "Little Dewdrop," and what I thought of Sir Brown Smith's great picture of the member, and did I not think that the pose was photographic?

"Do you mean to insinuate that photographers are inferior to you artists in posing?" I asked.

"Certainly, certainly!" he replied with the greatest coolness; "there is always a—a stiffness—a—a want of nature—of life—of soul, that the artist alone can supply upon the canvas."

"My dear sir!" I could not help saying, "you speak like a book; all that I am amazed at is that such an all-souled genius as yourself should be so much indebted to us mechanical photographers as to cover over our work with your paint, and prig our ideas in posing. Were I in your place I would scorn to work longer upon vile enlargements, or finish up unartistically posed carbons; I would do nothing but canvas work, and show an enlightened public the difference—the real difference—between art and photography."

He evidently did not know how to take this, as I spoke it with an earnestness that robbed the words of any appearance of satire. He only gave me a long stare with his great eyes, and muttered something about "genius stooping his lofty head for bread." I could have told him that if genius had to stoop, he had no right to scorn the means that put that bread in his mouth. He asked to be allowed to pose himself, which I granted; and of all the spread-out-to-dry, lunatic-looking pictures ever I saw, that beat them hollow. The Yahoo nearly went into fits over it. He advised me, when in want of the next situation, to send one as a specimen of artistic posing. Having secured something of this admirable genius, I felt my spirits rising at the prospect of getting rid of him; but fancy my disgust when he started a long discussion upon the gelatine process, of which he knew nothing himself, but his brother made some wonderful studies with them: he was of opinion that when really instantaneous pictures can be taken, then, and not till then, could photographers claim any kin with art.

"By art, of course you mean, holding the mirror up to nature—something natural—eh?" I asked. "Certainly, that is it; something natural," he answered.

"Well," quoth I, "I'm hungry! That's something natural—eh? And according to your logic it is art: so excuse art and photography for going to get some lunch!"

It is needless to say that albeit the pictures were very good of him, I was classed as the eighteenth operator who had tried and failed to please the "hartiss."

DARK-ROOM ILLUMINATION.

BY EDWIN DODDS.*

From the time gelatino-bromide dry plates were introduced, to the present day, it has been a moot point how much light can safely be used in the dark-room. Before the advent of dry plates, collodion workers insisted on the necessity of perfect dark-slides, cameras free from cracks, and a developing-room from which white light was rigidly excluded. It was claimed for the earlier-made gelatine plates that they were from six to ten times as sensitive as collodion, and it was, therefore, consistent enough that it should be stipulated that they were to be changed and developed in a very much weaker and less-actinic light than photographers had been accustomed to use. Dark-room windows were reduced in size, and the flashed orange glass was replaced with "double thicknesses of the deepest ruby glass, specially tested by the spectroscope," some zealous disciples taking so much care to ensure safety in this respect that proper development was rendered impossible; the operator was reduced to the mechanical work of pouring on his developer, leaving it on for a certain time, and then washing and fixing. He over-developed, he under-developed, he upset his bottles, broke his measures, left air-bells on his plates, scratched his films, and often he damaged himself and lost his temper; but he persisted in working in a room where he literally could not see his hand before him.

After a time photographers were startled by being told that canary-coloured paper afforded a perfectly safe light by which to work, an assertion which called forth scornful opposition and much correspondence. The outcome of this was, that though most photographers did not feel inclined to trust it, those who tried it were surprised to find how little fog it gave. Canary medium, however, would probably now be considered by some a useless obstruction, for we hear reflected candle-light, naked gas-light, and even diffused day-light recommended as being perfectly safe to develop by, and particularly calculated to add brilliancy to the negative. I cannot think that this belief is wide-spread, but it seems to me so very harmful that I have written these notes in order to protest against it.

Most photographers, I believe, use what may be called a sensible light, that is, they have a window proportionate to the size of their dark-rooms, and which, by means of ruby glass or red paper, or some combination of the two, admits an amount of red light by which print or manuscript can be easily read, and by which the bottles on the shelves can be readily distinguished. If a dry plate of ordinary rapidity were exposed a few feet from the window in such a room, it would probably not show fog during the time needed for ordinary development.

Operators who use less light than this work at a disadvantage, chiefly because they are more likely to make mistakes. They cannot see to measure either so quickly or so accurately; they cannot see how the plate comes up in the all-important first half-minute; and if there has been any error in exposure, they are more apt to do what I suppose we have all done at some time, to pick up the wrong bottle. Their peace of mind, however, caused by knowing that their light is safe, places them, in one respect, at an advantage over the men who use too much light. This class may be separated into two divisions (though the whole body is not a large one): first, men who are too lazy to exclude the white light properly, who leave cracks round their windows, and crevices round their doors, or who, if they use a red lamp, always have the chimney cracked or the cap lost; the other division consists of men who, though they would scorn the slovenliness of the first party, wilfully use a light as strong as or stronger than they used for collodion, and not only use it themselves, but try to induce others to do so.

The workers in both these divisions place themselves under one obvious disadvantage. If anything in the shape of fog appears, the man who has a dark dark-room looks to his plates or his developers, but he knows it is not his illumination; the man with the light dark-room, whether he belongs to the lazy or the scientific section, must entirely re-arrange his lighting before he can turn to the other possible causes of error. And this is perhaps the most important objection to a strong light, for it must be admitted that very fine work indeed is produced in over-lighted dark-rooms; their occupants get into a way of dodging the rays of light, and they acquire a deft way of looking at the plate which enables them in part to evade the danger by which they are surrounded. Another thing to be considered is that though fog is an undoubted evil, and a very great one, yet there are some hard negatives which a very slight veil of fog would soften and improve. Operators who use too much light may sometimes make a hit in that way, but it is an undeniable fact that the general character of their work would be much improved if they would use a sensible light.

I have at various times made experiments in the lighting of the dark room, and I have lately repeated some of them carefully, for if one would safely use, say, reduced gas-light, it would certainly be very pleasant. In attempting to change the plate from the dark slide to the developing dish in candle-light or reduced gas-light, even when a card cover was employed, and all possible celerity was used, I have never been able to avoid deep fog. When the plate is changed in a safe light, the developer poured on, and development allowed to commence, and white light from gas or candle is then used, if the dish is kept covered, and the plate only looked at once or twice very quickly, the fogging is not so perceptible; in fact, in a negative which covers the plate it is sometimes difficult to detect it; but if a part of the plate is kept unexposed, the action of the light is very obvious. If ferrous oxalate developer is used, it affords better protection, apparently, than ruby glass, for while the plate is covered with a reasonable depth of it, bright gas-light in the room does not appear to affect it; but this only holds while the plate is covered with developer, and the light must be reduced when the plate is to be examined. It is generally considered that the plate is most sensitive while yet dry—that is, before development is commenced—and that it becomes less sensitive to light as development proceeds. There is a misconception here. The sensitiveness of the plate probably remains unaltered, but the developing solution, if used in any of the older forms of alkaline pyrogallic, soon turns a non-actinic yellow-brown colour, and protects the plate from the action of light to a considerable extent, even if the film is merely wet with it. Hyposulphite, too, after it has been used a short time, acquires a similar and equally protective tint. But it should be remembered that the plate is not really less sensitive at the end of development. If it is taken out of a discoloured developing solution, and exposed to light, it will fog. If any of the developer has been left on the film it will discolour rapidly—exposure and development going on at the same time. If the film has been thoroughly washed under the tap, and the developer entirely removed before it is exposed to the light, there will be no discolouration; and if the plate be then fixed it ought not to show any more fog than if it had not been exposed between development and fixing. Practically, however, there is so often a trace of developer left in the film, that a negative which, say when partly fixed, has been exposed to strong light, and then replaced in the hyposulphite bath, too often shows by an irregular stain that this is not a good way of working. It may be news to some photographers that if a gelatine plate is exposed to light, and then placed in the hyposulphite bath without being developed, it will fix quite clear. Operators often look at a plate by gas-light or even day-light after they have developed it and given it a rinse at the tap, but before it is fixed. This is a bad habit, for, as we have seen, if there is any of the developer left in the film, the purity of the plate will be marred. In short, the only reasonable plan is to change, develop, wash, and fix the plate in a red light. If reasonable precautions are taken to keep the plate from the direct action of this light, it may be used freely, and it will be found that not only the most reasonable and the safest, but also the most comfortable way to work is to have the dark room well illuminated with ruby-coloured light till every label in it is

* Read before the Newcastle-on-Tyne and Northern Counties' Photographic Association.

readable and each bottle may be recognised by its form, but not to let this light fall unnecessarily on the plate. Have light enough to see when the image first appears, and to be able to judge when sufficient density has been obtained; but during the greater part of the time of development, when there is no advantage in keeping the plate exposed to light, let it remain in shadow or covered up, and do not let any white light whatever reach it until it is completely fixed.

Notes.

Sir H. Wolff intends to move the rejection of the Copyright Bill which is now before Parliament.

Our readers will peruse with interest Mr. Valentine's account of submarine photography in practice.

Those interested in M. Léon Vidal's sensitive little photometer, to which we referred last week, will be glad to hear that there is a possibility of buying it shortly. The cost, including selenium plate, battery, and galvanometer, will be about a hundred francs, or four pounds.

Makart, the well-known Austrian painter, has given his name to a photographic portrait, the slender promenade being termed "Carte-Makart" in South Germany; now we are to have the Tadema-format, a name our American cousins invite us to accept for a monster carte they have recently sent over.

For some time past, the Paris police authorities have taken the portraits of all children found in the streets of the French capital, the majority of whom are suspected of being designedly lost by parents and guardians. It has now been decided that copies of such photographs shall be sent round to all newspapers having an office to which the public are admitted. *Le Figaro* announces the receipt of the first pair of such pictures, representing a little lad of five, discovered in front of the Louvre stores. In one of the photographs the boy is laughing, in the other he is crying.

The Arctic yacht *Kara*, which sails at the end of this month for the Polar Seas in search of Mr. Leigh Smith and the *Eira*—which never returned from her last voyage—carries with her the intrepid amateur photographer, Mr. W. J. A. Grant. This is Mr. Grant's sixth vogage to the "Frozen Deep."

The diffusion of solids into solids was regarded as impossible by the chemists of even ten years ago; yet M. Colson has demonstrated that many solid bodies penetrate each other at temperatures far below their melting points.

Solid carbon and iron placed in contact will diffuse into each other, even at 250° C., or at temperatures nearly a hundred degrees below the melting point of lead; while a similar mutual diffusion occurs between silver chloride and sodium chloride.

Just in the same kind of way are the old notions as to the way in which the halogens replace each other being ruthlessly set aside by modern research, as chlorine turns bromine out from bromide of silver, or bromine replaces chlorine, according to the conditions which obtain. M. Potilitzin, whose results will be found detailed in the proceedings of the Russian Chemical Society, has previously made similar studies with regard to iodine and iodides.

We are glad to find the Photographers' Benevolent Association is making satisfactory progress. The balance-sheet this year puts the receipts at £50 16s. as compared to £42 12s. 6d. last year; and as the subscriptions from honorary members "show a lamentable decrease," we may take it that this year's income is altogether of a more *bonâ fide* character. It will be quite time enough to call upon honorary members to subscribe more liberally when the working members testify by their adherence to the scheme that they are in earnest about helping one another. We think they are beginning to show this, for the Association now bids fair to be a firmly-established, self-supporting institution.

We have already referred to the wonderful micro-photographs of Bacteria of Dr. Koch, of Berlin, who has proved such a powerful supporter of the antiseptic treatment of our eminent surgeon, Mr. Lister. From the position of an obscure medical practicioner in Germany, Dr. Koch's microscopic researches have raised him to one of the formost scientific positions in the world. Dr. Koch has himself in these columns detailed the manner in which he succeeded in taking photographs of the minute animalculæ to be found in animal tissue, and which presage the various diseases that flesh is heir to; and last week the first public exhibition was given by Professor Lister, at King's College, of a collection of Dr. Koch's interesting results.

Those who still complain of the brown tint of negatives developed with pyrogallic acid will do well to adopt Mr. Herbert Berkeley's oft-repeated advice to employ sulphite of soda in the developer; or, better still, to make trial of the sulpho-pyrogallol, a developer made up according to that gentleman's formula. Besides sulphite of soda, the sulpho-pyrogallol contains, we believe, a citrate salt, both of which help to keep the negative clear and transparent. A negative developed with pyrogallol in this way has for the first time the appearance of a wet plate.

A glass which soon becomes partially decomposed on the surface is well known to be quite unfit for photographic use, whether for making lenses or for supporting photographic films.

Wagener's recent researches would lead one to regard glasses as consisting essentially of definite silicates; but these silicates, when melted, dissolve certain proportions of various refractory bodies, and it is only by first studying to obtain a highly stable silicate as a basis, and taking care that the dissolved body shall not be present in too large a proportion, unless this is itself but little subject to change, that a good glass can be produced.

If an emulsion is over-cooked or brought close upon the verge of chemical fog, a red brown tint results on adding a moderate preparation of tannic acid; and our esteemed correspondent, Mr. Otto Pfenninger, who gives us this information, tells us that this reaction may form a useful test for over-boiling.

A great deal of confusion is likely to arise if we go on naming photo-mechanical printing processes in the hap-hazard way hitherto observed, and we are glad to see that Dr. Vogel has called attention to the fact. It is not bad enough that we should have the word "heliograph" to signify a photographic print and a "signal by sunshine," with the heliostat at the same time, but we must perforce give half-a-dozen names to one and the same kind of print. Take the collotype process as an example—that is to say, the process that admits of half-tone impressions in fatty ink being printed from a gelatine surface. This process is known by the names of Lichtdruck, Heliotype, Phototype &c., beyond the generic term of Collotype. The last is, perhaps, the best name, since it implies that in printing we have to do with a colloid substance, such as gelatine, albumen, &c.

Dr. Vogel thinks that the Goupil process deserves more than any other to be designated photo-engraving, since it is a mechanical copper plate process with half-tones; but then what shall we call Woodburytype or photo-relief printing, of which Goupil's process is a modification? For photo-engravings on copper, in which lines are employed to give detail, the name of helio-engraving is proposed; while all photo-mechanical blocks for the printing press—etchings on zinc, for instance—it is suggested might be termed photo-types—a very good idea, we think.

In the meantime, we might at any rate divide all photo-mechanical prints showing half-tone or detail into two classes, viz., those secured by surface printing, and those printed from hollowed surfaces. The first might be called either Lichtdrucks or Collotypes, and all the last photo-engravings.

The photographic establishment of Messrs. Valentine and Sons, at Dundee, has been placed under the Factory Act, the first instance, we believe, of photographers being made amenable to this law. The reason is, that not only do Messrs. Valentine employ a large number of hands—there were fifty employés on the premises when we visited them two months ago—but steam power has lately been introduced for the burnishing of pictures after mounting, and machinery of this kind must be under Government inspection.

Messrs. Maple and Company have brought an action against the Junior Army and Navy Stores to restrain the latter publishing an illustrated catalogue, which is stated to contain engravings copied by photography from the Maple hand-book. The existence in London of several phototype establishments makes the copying of woodcuts a very quick and easy matter; but it should require no great skill to discover whether an engraving is original or a photographic copy. We wonder preparers of illustrated catalogues have recourse to drawing and engraving at all. Why do they not have the objects themselves photographed—whether fenders, hats, tables, chairs, crockery—and then get prints struck off by the collotype process?

In Vienna, Munich, Berlin, and, indeed, throughout Germany, where the collotype or Lichtdruck process is generally practised, more than half the work upon which the presses are engaged is connected with pictorial catalogues. This plan of illustrating is also more satisfactory both to buyer and seller; there is no disappointment on the part of the former when he comes to see the object he purchases, for, with the best will in the world, a draughtsman who depicts a fender, or hat-stand, or drawing-room table, is sure to make it better looking than it really is.

We rejoice to learn that our esteemed correspondent, Dr. H. Fol, of the University of Geneva, has been nominated "Officer de l'Instruction Publique" by the French Minister of Instruction, in recognition of his researches in connection with animal life in the Mediterranean. Dr. Fol has employed photography to good purpose in securing pictures of the animal kingdom, and we are glad to say that next week we shall publish an interesting paper of the professor's, touching certain improvements in emulsion making.

Mr. W. Cobb tells us that our suggestion as to the use of the Swan lamp for lighting an outside show frame is quite successful from a business point of view; the public taking evident interest in the new light. Mr. Cobb uses a five-candle lamp, and four quart cells of Bunsen battery.

They seem to have been remarkably successful on the 17th, in photographing the eclipse, several good negatives of the corona having been obtained, the spectrum of the corona being for the first time satisfactorily delineated on a photographic plate; and our readers will find further information in Captain Abney's letter which we print in another column.

The bitumen backing which we suggested as a remedy for halation was adopted, as offering the most certain safeguard against this troublesome source of failure.

In this country the eclipse was very partial, only one-fifth of the sun's diameter being covered, and we were fortunate enough to wake just in time to see several crescent-shaped images of the partially eclipsed sun on the wall of our room, these being formed by small and irregularly shaped openings in the Venetian blinds. A camera was quickly placed in position, and a plate exposed.

The Pope on photography. Even the master-hand of Apelles, says Leo XIII., could not paint a more beautiful picture than does the art of photography; for the Pope, it seems, has recently been photographed in the Vatican under the rapid auspices of gelatino-bromide, and was fairly enchanted with the result. We reprint the rhapsody in its original Latin in another column for classic photographers to study.

Half a hundredweight of well-toned and deeply-printed landscapes were treated by Mr. W. Bedford when he made his recent experiments, and the metallic value of the prints proved to be as nearly as possible 8d. per pound. The ingot of gold weighed 175 grains, and the silver 435 grains.

If M. Fritz Luckardt has made a fortune by not photographing babies, Mr. Joshua Smith, of Chicago, has prospered on their pictures exceedingly. "We come all the way from Chicago," will still be remembered by visitors to the last Paris International Exhibition, the legend being written beneath a bevy of baby faces that laughed at every spectator who presented himself. Mr. Smith's profits arising out of these baby pictures are estimated at many thousand pounds.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. X.—Defects and Remedies.

At the end of the last chapter we described the conditions which give rise to the occasional necessity for intensifying a negative. The term almost explains itself. It means the increasing of the density of a negative. A good intensifier will increase the density of every part of a negative proportionately; that is, when there is, after fixing, clear glass as in the shadows, no darkening will take place there, but every grade of density, from the finest detail to the densest high light, will be increased in a proportionate degree. The process ought to be thoroughly at the command of the operator, who should be able to produce any desired increase of density.

We may say at once that there is no thoroughly satisfactory intensifier for gelatine negatives, and that such a thing is a great desideratum. It is not within our province to enter into the discussion as to which is the best of the various more or less imperfect methods which have from time to time been published, but we shall give a formula which has at any rate the advantage of simplicity, and which will be found to give fairly good results. It is one of the "mercury" intensifiers. It has two drawbacks. First, the results are not always permanent. Second, there is great difficulty in regulating the amount of intensification given by it.

The first objection is much lessened, however, from the fact—not, we believe, generally known—that when a mercury intensified negative fades, it can generally be brought back to its original condition by performing again the process of intensification. We shall suppose that a negative on printing is found to give a poor-looking print, lacking contrast. Let the following solution be prepared:—

Bichloride of mercury	1 ounce
Water	10 ounces

The whole of the bichloride of mercury will not dissolve, but the residue may be left in the bottle, and as the solution gets low through necessary waste, water may be added.

Let the negative be very thoroughly washed. Let it be placed in a dish, and let the mercury solution be poured over it. It will gradually become whitened or bleached. When the film is bleached throughout—as indicated by its being white at the back—let the solution be poured back into the bottle, and let the negative be most thoroughly washed. On the thoroughness of this washing seems to depend to a great degree the permanency of the results.

The negative has now to be treated with ammonia solution, which will blacken it, but the strength of the ammonia solution must be varied according to the amount of density required. Thus, if the print got from the negative previous to treating with mercury was very nearly up to the mark, a very weak solution of ammonia must be used; one or two drops to the ounce of water will be enough. This solution is poured over the negative, and it will be seen gradually to darken. When all action ceases, the process is complete. The negative will now be of a curious orange tinge by transmitted light. If, on the other hand, the negative was one giving a very shadowy print, a solution of ammonia of one to twenty may be used. On this being poured over the plate, darkening will take place almost instantly, and the result will be a fine black-coloured negative.

Too great density of image is a fault sometimes met with. It is always due to error of judgment in development. It may be corrected by performing the first part of the process for intensification. This method is objectionable, however, as the results may not be permanent. A better plan is to immerse the negative, after fixing and washing, in a solution of one part of eau de javelle to three or four of water. After the desired amount of reduction has taken place, the plate should be again fixed and washed.

Spots of various kinds are liable to be found in the finished negative. They are of various forms, and are produced in various ways. Minute transparent spots or pinholes are caused by dust on the plate during exposure. The plate should be brushed with a broad camel's hair brush before it is placed in the slide.

Small transparent spots with irregular outlines are due to defect in the manufacture of the plate, and cannot be corrected by after manipulation.

Small transparent perfectly circular spots, with well-defined outlines, are due to air-bubbles in the developer, and are only produced when too small a quantity of developer is used. Air-bubbles do not, as is commonly supposed, form on the surface of the plate under the surface of the developer; they form on the surface of the developer, and, if there is too little solution, come in contact with the surface of the plate, and there adhere.

Opaque spots are always due to defects in the plates, and cannot be corrected by after manipulation.

A yellow stain, or rather a yellow veil, in the shadows of a negative is often found after pyrogallic development, especially if the process has been very prolonged, or if much ammonia have been used. Such stains should never occur if our instructions be carefully followed, but if it do, it may be removed by placing the negative, after fixing and washing, in the following solution:—

Saturated solution of alum ...	10 ounces
Hydrochloric acid	$\frac{1}{4}$ ounce

Mr. Herbert Berkeley has recently introduced a new developer, which totally prevents any yellow stains from occurring, and which deserves strong recommendation. The pyrogallic stock solution is mixed with four grains of neutral sulphite of soda to each grain of pyrogallic. The whole is rendered slightly acid with citric acid, for it must be understood that so-called "neutral" sulphite of soda is really alkaline. Care must be taken to use the *sulphite*, not the *sulphate*.

Unequal thickness of film is sometimes found in commercial plates. It arises from careless coating of the plates, and is, of course, incurable by after treatment. The negative resulting from a plate more thinly coated at one place than at another *may* be lacking in density at the thin place; but it should be borne in mind that it need not certainly be so. Plates are generally coated with films considerably thicker than is absolutely necessary, and, in the case of a plate unequally coated, the thinnest part may contain enough of the silver salt to give the necessary density. Plates should, therefore, be tried before being condemned for unequal coating.

Various *streaks, scratches*, &c., occur in gelatine plates, and are evidently due to defect in manufacture. They call for no particular remark.

A white powdery deposit is sometimes found on the surface of the negative after drying, especially after ferrous-oxalate development. It is, in such a case, caused by lime in the washing water. It may be removed by dipping the negative in a 1 per cent. solution of hydrochloric acid. If the solution of alum used before fixing be acid, and the negative be not sufficiently washed between the alum and the fixing-bath, a deposit of sulphur will form in a fine powder. This may be removed by gently rubbing the face of the negative with a plug of cotton-wool, while water is running on it from the tap.

Irregular action of the developer, causing zig-zag lines across the plate, may occur if the developer has not been made to flow over the plate in one wave at first.

Halation is caused chiefly by reflection from the back of the plate. It makes itself evident only when the subject includes very strong contrasts; for example, when an interior with windows open to the sky is photographed. It shows itself in the form of a halo round the highest lights, and produces a very unpleasant effect, sometimes known as blurring. It occurs only to a small extent with plates that are very thickly coated. In the case of an attempt being made to photograph a very trying subject, such as the interior mentioned, it is well to "back" the plate; that is, to paint or otherwise cover it at the back with some substance which will absorb light. The following is a good method to adopt. Procure a piece of black carbon tissue, cut out a piece slightly smaller than the size of the plate to be used (there should be about ⅛ of an inch margin all round) moisten the black surface of the carbon tissue with glycerine, allow all that will to drain off, and press the tissue against the back of the glass. It will adhere, and may be removed just before development.

A METHOD FOR DETERMINING THE EXPOSURE OF INSTANTANEOUS SHUTTERS.

BY ARNOLD SPILLER.

It seems a curious fact, in connection with methods for determining the exposure of the so-called instantaneous shutters, that the same idea has of late often suggested itself to independent individuals.

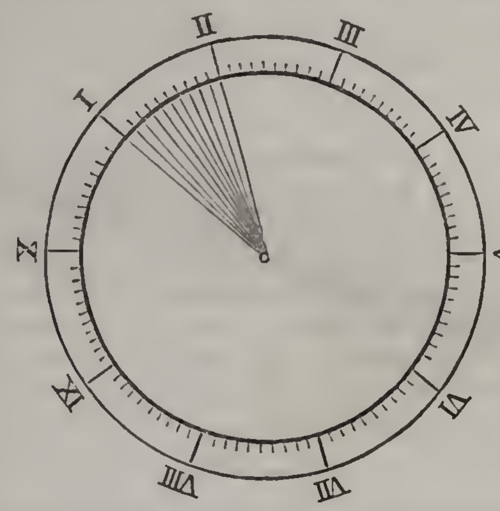
About a year ago Mr. Hadau suggested that a pencil connected with a vibrating rod, if allowed to strike against the "drop" of the shutter, would give a graphic determination of the exposure, by calculating from the number of vibrations drawn on the "drop." A short time afterwards Captain Abney exhibited a model constructed on the same principle, and stated that he had worked out the method independently of Mr. Hadan.

The mode I am about to describe was suggested by M. Léon Vidal about a month ago; but in justice to myself, I may state that I constructed the apparatus, and tried it with Mr. Brougham Young, in December last.

The principle, which most of my readers may know, depends on photographing a needle rotated by clockwork, the exposure being made by the shutter under consideration. My first idea was to use a chronometer fitted—as some are—with a hand rotating once in a second; but not having one at command, and accidentally coming upon a clock which, after removing the pendulum, gave the required rate of speed, it was soon adapted to my requirements. The hand was replaced by a large bright pin, the dial coated with black paper, and graduated—in white figures—into hundredths of a revolution; thus each division is equivalent to $\frac{1}{100}$ part of a second.

The following is the mode of working:—Place the clock on any convenient stand directly facing the sun, and about the same height as the camera, and at such a distance that the image on the ground glass is about two inches in diameter; all being ready, wind up the clock, let the hand have time to complete two or three revolutions, so as to ensure the normal speed, and expose.

On developing the plate, a negative will be produced somewhat similar to the subjoined wood-cut, which is



copied from the first of the following experimental determinations:—

Description of Exposer	Number of Divisions Registered.		Duration of Exposure Indicated.
Shutter with six-inch aperture of drop	10	...	$\frac{1}{10}$th of a second.
Same shutter using only half the *latter portion* of aperture	4·5	...	$\frac{1}{22}$ of a second.
Rotating disc, as fitted to Lancaster's instantograph ...	1	...	$\frac{1}{100}$ of a second.

Gelatine plates of about twenty times the rapidity of wet collodion were used for the above determinations, the sun shining brightly all the time.

ON THE EFFECT OF THE SPECTRUM ON THE HALOID SALTS OF SILVER, AND ON MIXTURES OF THE SAME.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

Silver Chloride.

Paper was impregnated with a 10 per cent. solution of sodium chloride, and sensitised on 10 per cent. solution of silver nitrate.

Paper thus prepared was exposed to the spectrum in a damp state, and also in a dry state, and the visible impression recorded. Fig. 35 shows the action. When the paper was exposed for twenty seconds to diffused light a different curve, as shown in fig. 36, was found; an approach to the same curve being also shown with very prolonged exposure without the preliminary action of light. This is probably due to the action of the diffused light in the prism.†

Similar paper was washed, some was used in this state and other was afterwards treated with a solution of sodium chloride and again washed, leaving thus only a trace of an organic salt of silver in the fibre. The action of the spectrum on the simply washed paper is shown in fig. 37. With a short preliminary ex-

* Continued from page 269.

† I have not taken into consideration the spectrum impressed on silver chloride visibly darkened by the light. This, as is well known, is impressed throughout the spectrum, and takes the approximate colour of the spectrum. This is true whatever vehicle is used to hold the silver chloride, and also whether exposed in the presence of an excess of silver nitrate or other sensitiser, and also when organic compounds of silver are mixed with it.

posure, traces of an impression between F and C were obtained, tending to show that the preliminary action in fig. 36 was effective on the chloride besides on the organic compound of silver. Fig. 38 gives the action of the spectrum in the chloride which had all traces of silver nitrate removed by the wash of sodium chloride.

To obtain an emulsion of silver chloride in collodion, 20 grains of calcium chloride were dissolved in 1 oz. of collodion, and 1 gr. more, or 1 gr. less, according as excess or defect of silver nitrate was required, than the equivalent of silver nitrate dissolved in another ounce of collodion; the former solution was poured in the latter, shaking at intervals, till a perfect emulsion was obtained. In some cases the emulsion was washed in the ordinary way known to photographers, and in others used when made as above, and the films washed or exposed in their natural state. In no case did any difference in the resulting impression of the spectrum appear. I may also state that other chlorides were tried, and there is no apparent difference from those obtained where sodium chloride was employed. Fig. 38 also gives the action of the

spectrum on such emulsion, there being no apparent difference between the washed emulsion or the emulsion exposed with an excess of silver nitrate, or with an excess of the soluble chloride, unless it be one of general sensitiveness. In other words, the spectrum seemed to act on the silver chloride in one and the same manner. Fig. 39 shows the printing action on the chloride when enveloped in gelatine. The emulsion was formed in the usual manner habitual amongst photographers, each ounce of emulsion containing about 25 grs. of converted silver nitrate. Fig. 39 has reference to this emulsion after it was heated to its boiling point for half an hour, and when treated with ammonia; when used unboiled it took an impression similar to fig. 38.

When these same preparations of the chloride in gelatine are exposed for a short time to the spectrum and developed with ferrous citro-oxalate developer, or with gallic acid and silver, we get figs. 42, 43, 44, and 45, the first two expressing the result of the unboiled emulsion which transmits yellow-orange light, and the two latter numbers that on the boiled emulsion which transmits a blue-grey light. The first numbers of these pairs of figures show the result of exposures ten times longer than the exposures shown by the second numbers of the pairs.

Silver chloride in collodion, by whatever means prepared, and whether exposed with an excess of silver nitrate, or an excess of soluble chloride, gave figs. 40 and 41, the former being the result of exposure ten times longer than that shown by the latter. The mode of development had no effect on the spectrum developed.

The washed paper gave on development the same result as that shown for the direct action of light, viz., fig. 37. The mode of development had no effect on the result.

The washed paper subsequently treated with a solution of sodium chloride and again washed, when exposed to the spectrum, gave on development with either gallic acid and nitrate silver, or with ferrous citro-oxalate, the same figure as that obtained by the direct action of light, viz., fig. 38.

When a brief preliminary exposure to white light was given to either the paper or the different emulsions, fig. 46 was obtained on development. On looking at figs. 35 to 46 it will be seen that invariably the maximum intensity is reached between H and *h*. According to many authors the maximum is near G, whilst according to others it is in the ultra-violet. I have carried out about 200 experiments on the chloride with sunlight and with the electric light, and in no case have I found it possible to alter the maximum. Of course if candle or gas light be used as a source, the maximum will be about G, since the ultra-violet rays are almost absent with these. The idea suggests itself that the prismatic arrangements employed may be at fault; in some cases, where the most definite results have been registered, a direct vision spectroscope has been utilised. I need hardly say that such an arrangement, from the very nature of the apparatus, is unsuited for photo-spectroscopy. Such a spectroscope transmits very few rays beyond H, and at H their intensity is much diminished. In order to settle the matter to my own satisfaction, I used a diffraction grating with the same results as those shown in the figures under consideration. In the paper read before the British Association in August last, I pointed out the great need of caution in measuring daylight intensity by the chloride, and my subsequent examination of the subject has more than ever confirmed me in my opinion therein given.

Methods of obtaining Mixtures of Silver Iodide and Bromide, Silver Iodide and Chloride, etc.

To test mixtures of the iodide and bromide, paper was prepared by immersing it in a solution of potassium iodide and potassium bromide, the proportion of each being so arranged that there should be definite proportions between each, supposing that each salt was entirely decomposed by the silver nitrate. Unfortunately this is never absolutely the case, and hence the results obtained with the paper must be received with some caution. Chemists know that silver bromide or silver chloride cannot exist in the presence of a soluble iodide, nor can silver chloride in presence of a soluble bromide. Hence when we have an iodide and bromide impregnating paper, the silver iodide will first be formed, and then the bromide; or, again, with iodide and chloride, the silver iodide will first be formed, and then the chloride; and, finally, with bromide and chloride, the bromide will first be formed, and then the chloride.

It was necessary to make these remarks, as a right conception of the results might not be taken on casually looking at them.

The same remarks apply with equal force when a sensitive film of the double salts is prepared by the ordinary silver bath when very short immersion is given to the plate. The only true way of obtaining definite results seems to be by means of separate emulsions, in which a definite amount of soluble chloride, bromide, or iodide is fully converted into silver chloride, bromide, or iodide, and then to mix these emulsions, after proper washing, in the required proportions. It was in this manner that the emulsions which will be discussed presently were prepared.

I would here call attention to a somewhat remarkable behaviour of silver iodide. It is well known that if silver iodide be prepared with an excess of soluble iodide, it is totally insensitive to light. Thus if we prepare (say) an emulsion in collodion with an excess of iodide, and wash it thoroughly in the usual manner, and after redissolving the pellicle resulting from the washing operations, expose it in the camera, no amount of development will bring out an image. If, however, to such an emulsion but a drop of a bromide or chloride emulsion be added, sensitiveness will appear. This seems to be due to the last trace of soluble iodide being converted into silver iodide.

(*To be continued.*)

On Photographs of the Spectra of the Nebula in Orion.

BY HENRY DRAPER, M.D.*

For about eighteen months I have been giving attention to the nebula in Orion with two objects in view: first, to ascertain whether any changes are taking place in that body, by making a series of photographs to be compared in the future with a similar series; and second, to photograph the spectrum of the nebula in various parts, so as to see whether any new lines could be found, and also whether the composition is uniform throughout.

As to the first of these objects, I have recently succeeded in taking a very fine extensive photograph of the nebula containing most of the delicate outlying parts which were not in my earlier photographs. This is in the hands of the photo-lithographer now, and will shortly be published. The experiments have been very difficult, because an exposure of more than two hours in the telescope has been necessary, and an exceedingly minute motion of the stars relative to the sensitive plate will become apparent on account of the high magnifying power (180) employed.

In carrying out the second object, two contrivances have been used: first, a direct-vision prism in the cone of rays from the objective before they had reached a focus; and second, the two-prism spectroscope with which I have taken photographs of stellar spectra for some years past.

During the month of March I have made two good photographs with each of these arrangements. Those with the direct-vision prism, without a slit, have of course demanded that the image should be kept stationary on the sensitive plate throughout the exposure, viz., two hours, and they are as difficult to get as good photographs of the nebula itself. On the contrary, those obtained with the slit spectroscope do not require the same steadfast attention.

The results derived from these photographs are interesting, partly from what they show, and partly from what they promise in the future. A number of photographs, under various conditions, will be needed for the full elucidation of the subject.

The most striking feature is perhaps the discovery of two condensed portions of the nebula just preceding the trapezium, which give a continuous spectrum. At those places there is either gas under great pressure, or liquid or solid. I have not been able to detect any stars of sufficient magnitude in these portions to produce this effect, either in my photographs of the nebula, or in any of the well-known drawings of the object. It seems to me also that the photographs show evidence of continuous spectrum in other parts of the nebula. In these respects the conclusions arrived at by Lord Rosse in his memoir (Phil. Trans. Royal Society, June 20, 1867, p. 70) are to a certain extent borne out.

The hydrogen line near G, wave-length 4340, is strong and sharply defined; that at *h*, wave-length 4101, is more delicate, and there are faint traces of other lines in the violet. Among these lines there is one point of difference, especially well shown in a photograph where the slit was placed in a north and south direction across the trapezium; the Hγ line, λ 4340, is of the same length as the slit, and where it intersects the spectrum of the trapezium stars, a duplication of effect is visible. If this is not due to flickering motion in the atmosphere, it would indicate that hydrogen gas was present even between the eye and the trapezium. I think the same is true of the Hδ line, λ 4101. But in the case of two other faint lines in this vicinity, I think the lines are not of the length of the slit, one being quite short, and the other discontinuous. If this observation should be confirmed by future photographs of greater strength, it might point to a non-homogeneous constitution of the nebula, though differences of intrinsic brightness would require to be eliminated.

The April number of the American Journal of Science contains an account of a photograph of the spectrum of this nebula taken by Dr. Huggins. I have not found the line at λ 3730, of which he speaks, though I have other lines which he does not appear to have photographed. This may be due to the fact that he had

* Read before the National Academy of Sciences, April, 1882, at Washington, U.S.

placed his slit on a different region of the nebula, or to his employment of a reflector and Iceland spar prism, or to the use of a different sensitive preparation. Nevertheless, my reference spectrum extends beyond the region in question.

As illustrating the delicacy of working required in this research, it may be mentioned that in one of these photographs the spectrum of a star of the tenth magnitude is easily discerned. It is only a short time since it was considered a feat to get the image of a ninth magnitude star, and now the light of a star of one magnitude less may be photographed, even when dispersed into a spectrum.

Correspondence.

THE ECLIPSE EXPEDITION.

Sir,—I have received a brief telegram from Egypt regarding the Eclipse Expedition, and as it is in cypher I give the gist of the news. "Very successful all round. The blue end of the spectrum with lines has been photographed on a continuous background. Prominences photographed with the prismatic camera (showing, of course, ring spectrum). Three photographs taken of the corona. A comet close to sun photographed with the prismatic and also ordinary cameras."

The success here indicated is undoubted, and Dr. Schuster, who has superintended this part of the Expedition, is to be congratulated, not, too, forgetting Mr. C. R. Woods, who has done all the manipulations.

It is satisfactory to find that gelatine has behaved so well in a climate in which we now know the shade temperature during the day was 108°. No doubt Mr. Woods used the nitrate of ammonia to cool his developing solutions and wash water, since he was able to develop the same day, not waiting till night.—Yours faithfully,

W. de W. Abney.

FADING OF GELATINE NEGATIVES.

Sir,—I see by your last issue that my experience with regard to the fading of gelatine negatives has not been exceptional, although I was inclined to think that it was from the fact that no attention had been called to the subject. Now I see that several others have been troubled in the same way, and the evil is attributed to the imperfect removal of the hyposulphite. We are all aware of the instructions to well wash gelatine films; but I, for one, shall be glad to learn what amount of washing will give immunity from this evil. I have quite thought that my plates have been well washed, as I have left them soaking for several hours—always through the night—and have at intervals changed the water for at least a dozen times preparatory to giving them a good rinse under the tap, and I fear that many like myself will find that their otherwise valuable negatives have become almost worthless from a want of knowledge upon this point.—Yours truly,

Provincial.

DEATH OF MR. ROBERT BIGGS.

Dear Sir,—I much regret to have to communicate to you the news of the death of Mr. Robert Biggs, a valued member of this Society, and well known to your readers under the signature of "Photo-Chemicus." He possessed a most genial nature, and was in every respect generous in heart, while his research in photographic chemistry has been often and often productive of most instructive communications to the journals.

Amongst the members of our Association he will be most seriously missed, his bright and cheery manner making his presence at the meetings, when circumstances permitted, most welcome. But with a large practice as a surgeon at Bath, and also holding the appointment of public vaccinator for that place, and that of deputy-coroner for East Somerset, he had but little time for his favourite hobby. In fact, I fear he is another victim of over-work, which, followed by a severe chill, resulting in congestion of the lungs, robbed his large circle of friends of a good and true friend.

Large numbers, including many of the poorest, followed him to his last resting place, and with unmistakeable evidences demonstrated their sincere sorrow at his loss. Much sympathy is felt for his widow and family of twelve children.—Yours faithfully, H. A. H. Daniel.

Hon. Sec. Bristol and West of England Amateur Photographic Association.

Proceedings of Societies.

Newcastle-on-Tyne and Northern Counties' Photographic Association.

The ordinary monthly meeting was held in the College of Physical Science, Newcastle-on-Tyne, on Tuesday, May 9, at 7·30 p.m., Mr. H. S. Mendelssohn in the chair.

The minutes of last meeting were read and confirmed.

Three new members were nominated, and Messrs. J. Davidson, J. E. Stead, R. A. Collins, and W. P. Stainsby were unanimously elected members of the Association.

On the proposal of the Chairman, seconded by Mr. Doudney, Mr. Allison, of the Old Rectory, Monkwearmouth, was elected a honorary member of the Association.

It was resolved, after some discussion, that the Secretary be requested to write to the Photographers' Association of America and say that this Association will endeavour to send an exhibit, and to ask the date for sending in.

It was agreed that there be two out-door meetings this summer; the first to be held on the second Wednesday in June at Castle Eden, and the other to be held on Bank Holiday in August at Walkworth.

Mr. Louis Davidson was requested to take charge of the portfolio and photographs belonging to the Association. The Hon. Secretary read a letter from Mr. Stead, and showed some negatives and transparencies sent by that gentleman.

Mr. Dodds then read a paper on "Dark-room Illumination" (see page 279).

A short discussion followed.

The Chairman (Mr. Mendelssohn) said that he quite agreed with Mr. Dodds in thinking that it was necessary to use a ruby light, and to use it through all the operations till the plate was fixed. He considered that the best results could not be obtained unless the illumination of the dark-room was properly attended to.

Mr. J. P. Gibson said that he thought Mr. Dodds had insisted too strongly on the necessity of fixing in the dark. He had for a long time been in the habit of washing his plates and fixing in daylight, and had not observed that they were at all injured by his doing so. He now, however, fixed in the dark-room, though he did not think there was any gain in the change, save that it was more convenient. He quite agreed as to the advisability of having only red light in the dark-room, and stated that he had recently excluded daylight entirely, and now only used artificial light to develop by; and he always kept his developing-dish covered with a pane of ruby glass.

Mr. Mendelssohn said that he could quite endorse every word that Mr. Dodd had said.

Mr. Gibson remarked that he thought Mr. Dodds rather exaggerated the case in the matter of fixing, but, generally speaking, quite agreed with that gentleman.

The Hon. Secretary exhibited a number of carbon prints which were printed by Mr. Swan about 1866-7, and which passed through the severe fire at Mawson and Swan's, and had been much acted upon both by fire and water, yet preserved the details and purity of colour in a very marked manner. Even though the paper had rotted away, the tissue was perfect.

Thursday Evenings for Photographers.

At the meeting held on the 11th inst., Mr. E. T. F. Goodwin occupied the chair.

In the course of a few remarks upon film negatives, Mr. Brown said he did not find it necessary to grease the edges of the film; he found that if the film was laid in the developing tray and flooded with water and then drained, it would lay flat on the bottom of the dish through all the operations of developing, &c.

Mr. W. E. Debenham showed a negative upon a plate that had been unevenly coated. When developed, the film appeared to be perfectly clean and free from spots or markings; but upon his treating it with mercury for the purpose of intensification, a number of brownish spots appeared in all thick parts of the film. He then again placed it in the hyposulphite bath, and so dissolved the mercury out, when the colour disappeared from the spots, leaving small whitish superficial spots visible only by daylight. He attributed the markings to some compound of silver left in the film, after fixing, which had combined with the mercury.

Mr. Brown thought that perhaps a trace of bromide might have been present.

Mr. Henderson asked if anyone had tried a mixture of cyanide and hyposulphite for fixing gelatine plates? He stated that he used the following formula for reducing gelatine negatives successfully, the plates having much the appearance of wet collodion plates; viz., first apply equal portions of a saturated solution of mercuric chloride and ozone bleach, wash, and treat with a solution of cyanide of potassium, and again wash.

The Chairman exhibited a roller for mounting prints; it consisted of a piece of red rubber tubing placed over a piece of wood and revolving in a handle.

Mr. Henderson showed a plate that had been wrapped in brown paper, a circular hole being left in the paper at the back of the plate; over this was placed several thicknesses of white tissue paper similar to that used for cigarettes; it was then placed in a dark box and left for the three months; when developed, the circular opening in the paper was marked by a strong insensitive mark. This he attributed to the phosphoresence of the white paper, as it had been kept where no light could possibly have reached it, and as the paper had not been in contact with the film, it could not be due to any chemical compound in the paper.

The Photographic Society of Ireland.

The last meeting of the session of this Society was held in the Royal College of Science, Dublin, on Friday, 12th inst., Mr. J. V. Robinson in the chair.

Messrs. Robert Mitchell and Marcus Moses were duly elected members.

Mr. Herbert Bewley explained, with experiments, various methods of printing in uranium, iron, carbon, and platinum. The specimens in uranium and iron were very interesting, as they showed the different steps that photographic printing took before it reached its present form. There seemed to be a general consensus of opinion that the Platinotype process is, for permanency, decidedly the best. An ordinary silver print was laid side by side with the carbon and platinum pictures for contrast; the platinum, however, which was printed by the Chairman specially for the occasion, still held its own.

Mr. Bewley found he could get better results with this process from *hard* negatives than from those most suited for silver prints.

In the discussion which followed, the Chairman informed the meeting that he had subjected the platinotype paper to several severe tests with a view to finding whether it would keep its tone or not. He placed a print in an almost saturated solution of cyanide of potassium without perceiving any change.

A very strong solution of muriatic acid was next tried, and with the same result; and lastly, into a solution of nitro-muriatic acid as strong as not to destroy paper, and could not get any change. The results were considered highly satisfactory, and established the theory as to the permanency of the prints more than ever. As to the developing, he had found that for an under-exposed print it was better to use the solution of oxalate of potash at a much higher temperature than 190°, and for an over-exposed picture the temperature can be lowered below 190° with advantage; also that the best results were obtained by evaporating the solution until re-crystallization was about to take place, then to plunge the paper in (flooding, in his opinion, not being at all necessary), and to treat it in the usual manner.

Mr. Thos. A. Bewley drew attention to the utility.

The Chairman exhibited Captain Edwards' electric instantaneous shutter, which was the subject of much discussion as to its merits, &c. A drawing of this instrument lately appeared in the journals.

Mr. Woodworth drew attention to some gelatine film negatives which he had used in portraiture; his experience led him to believe that films were altogether unfit for this class of work, as the contraction of the gelatine caused a very unpleasant amount of distortion as shown by the proofs produced. The subject of the excursion having been brought forward, a committee was appointed to make the necessary arrangements.

A cordial vote of thanks was passed to Mr. Herbert Bewley for his communication. The meeting was then adjourned until Friday, the 13th October.

Talk in the Studio.

Photographic Society of Great Britain.—The next Technical Meeting of this Society will be held on Tuesday next, May 23rd, at the Gallery, 5a, Pall Mall East. The chair will be taken at 8 p.m.

The late Royal Wedding.—Messrs. G. Tuohy and Co., of Richmond, have had the good fortune to receive an expression of Her Majesty's approval of the group picture they succeeded in obtaining at Chertsey of the Duke and Duchess of Albany.

The Micro-Camera and Medicine.—On Monday, Professor Lister and Mr. W. W. Cheyne held a microscopical demonstration of some of Professor Koch's finest specimens in the physiological laboratory of King's College, and a large number of eminent physicians and surgeons attended. These specimens showed the baccilli of anthrax, erysipelas, tubercle, &c., which are exciting so much interest in the scientific world. The large rod-like baccilli of anthrax were plainly visible, even to an unpractised eye; but those of tubercle, &c., were only to be made out by a good microscopist. All the specimens were under first-class microscopes magnifying from 800 to 1,600 diameters, and the light was very carefully arranged. The preparations were stained with various aniline dyes; the dyes enable the specimens to be photographed, and then the baccilli are much more plainly visible. Dr. Koch's method of photographing these tiny creatures has been described in the News.

Processes in use for Book Illustration.—Last Monday Mr. J. Comyns Carr delivered the second lecture of a course of three Cantor Lectures, on "Book Illustration, Old and New." The lecturer, after having drawn a distinction between books in which the printed text is the main feature, and those which depend principally on the illustrations for their value, proceeded to discuss the gradual development of the art of wood engraving, and, as he regards this method as being by far the most important illustrative method, the greater portion of both lectures was devoted to its consideration. Many who practise the art lose sight of the circumstance that the white line should be the integral factor of the wood engraving, just as the black line forms the characteristic feature of the plate or intaglio engraving. Those wood engravers who unduly crowd their work with complex cross hatchings of black lines handicap themselves, and often miss the artistic ideal. Examples of wood engraving which were handed round served to illustrate the perfection with which the most delicate gradations of light and shade, as involved in representing the delicate variations in facial expression, could be rendered by varying the width of the closely-packed white lines, and if those who draw designs for wood engravers were to frequently execute them in white on a black ground, it is not unlikely that excellent results might follow. Many subjects well adapted for reproduction by engraving on wood cannot be satisfactorily engraved by the plate method, as, for example, the bold, clear, and broad lines and touches of Dürer and Holbein, every fraction of which has a deep artistic significance. In the hands of a master engraver like Bewick, the "white line" often takes the form of irregularly dug-out patches, which may produce an effect comparable to a stipple or coarse grain. Next Monday Mr. Carr will treat of modern processes of illustration, and those based on photography will be explained and considered.

Motes, the Photographer, secures the Gold Medal at the Exposition.—As a *Constitution* reporter was passing up Whitehall Street yesterday he spied a large crowd in front of the entrance to Motes' photograph gallery, and thinking there was a sensation brewing, approached. Just as the reporter entered the crowd, some one said: "Yes, that is fine work. It can't be surpassed, and I am told that it secured the gold medal at the Exposition." This remark gave it all away, and the reporter knew that the crowd was examining and discussing the beautiful photographs in the glass case. He had passed by it a hundred times, but never before had he noticed how beautiful and attractive it was, and the more he studied it the more beautiful and attractive it became. In the room above, where the display is made, there are hundreds of photographs equally pretty. In fact, the walls are covered with them, and a lover of the beautiful could pass a day looking at the collection. After examining the work the reporter was not at all surprised to learn that Motes had been awarded the gold medal, even though the best photographers of the north made a big effort to secure it. The photographs which took the prize hung upon the wall. One is of a child, and the other of one of Atlanta's leading society ladies. They were picked by Mr. Motes at random from his stock, and were made long before the Exposition was thought of, and were not made with a view to securing the prize. Any one who examines the work in Motes' gallery will not be surprised to learn that the International Cotton Exposition awarded him the gold medal for the finest work in photography.—*Atlanta Constitution.*

Luminous Cartes-de-Visite.—We have received a very effective luminous picture bearing the imprint of Mr. Malby, of Chichester; the picture having evidently been rendered transparent by means of some kind of varnish, and then mounted over a phosphorescent surface. It is probable that there would be a considerable demand for luminous portraits if they could be offered to the public on about the same terms as the ordinary picture; and we understand that Mr. Malby intends introducing them as a special feature of his business. It may be worth mentioning that a carbon print, a Woodbury print, or a collotype would be more suitable for this use than is a silver print, as the silver image might easily become transformed into sulphide.

Photography and Sculpture.— Since the photographer has to study modelling and lighting after the manner of a sculptor, art-training in a sculptor's studio would doubtless form the best education for a photographer. M. Adam-Solomon's success as a photographer was due simply and solely to his art training and experience as a sculptor. So says a Chicago journal, the *Picture*, and so said one of our "Notes" some weeks back. Singular instance of agreement of opinion!

The Pope on Photography.—According to our contemporary, the *Archiv*, Pope Leo XIII. recently expressed himself in the following lines upon the art of photography :—

Expressa solis speculo
Nitens imago, quam bene
Frontis decus, vim luminum
Refert et oris gratiam!

O mira virtus ingeni!
Novumque monstrum! imaginem
Naturae Appelles aemulus
Non pulchriorem pingeret.

Origin of Names of Fabrics.—The origin of some old names are given by Sir George Birdwood as follows: Damask is from the city of Damascus; satin from Zaytown, in China; calico from Calcutta; and muslin from Mosul. Buckram derived its name from Bochara; fustian comes from Fostat, a city of the Middle Ages from which the modern Cairo is descended. Taffeta and tabby from a street in Bagdad. Cambric is from Cambrai. Gauze has its name from Gaza; baize from Bajae; dimity from Damietta, and jeans from Jaen. Drugget is derived from a city in Ireland, Drogheda. Duck, from which Tucker Street in Bristol is named, comes from Torque, in Normandy. Diaper is not from D'Ypres, but from the Greek *diaspron*, figured. Velvet is from the Italian *vellute*, wolly (Latin, *vellus*—a hide or pelt). Shawl is the Sanscrit *sala*, floor, for shawls were first used as carpets and tapestry. Bandanna is from an Indian word, meaning to bind or tie, because they are tied in knots before dyeing. Chintz comes from the Hindoo word chett. Delaine is the French "of wool."

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News*" *Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed "Union Bank, Photographic News Co. Account."*

*** We cannot undertake to return rejected communications.

R. Morton Day.—The Silvertown India-rubber Company (100, Cannon Street, London) will doubtless make it for you.

Unbeliever.—If you had carefully read the rest of the article, you would have perceived that the printing of "second" instead of "minute" was the result of a slip of the pen on the part of the writer.

T. L. C. M.—In general a simple drop shutter would be most suitable; but most of the commercial shutters will give excellent results if intelligently used.

Achromatic.—1. It is a combination consisting of a double convex lens of crown glass, cemented to a double concave lens of flint glass. It occasionally happens that the flint glass is flat on the uncemented side, but even in this case most persons would consider the term "actinic meniscus" as being sufficiently exact for ordinary conversation. An achromatic lens is corrected especially for colour, while an actinised lens is corrected so as to ensure the coincidence of the chemical focus with the point of greatest visual sharpness; but an actinised lens is frequently referred to as achromatic. 2. We have not used the apparatus, but were much pleased with its design and appearance.

Red Sea.—In such cases we would advise you to immerse in a five-grain solution of chrome alum before commencing to develop, and should this not prove effectual, you might try Captain Abney's plan of coating with plain collodion. It is of importance that the plates should be kept prefectly dry, or the gelatine may undergo a kind of deterioration calculated to occasion the difficulty you complain of.

George Terry.—You cannot do better than obtain Captain Abney's "Instructions in Photography," which is published at our Office. A new edition is in the press.

T. Tame.—1. A very light buff tint is suitable in most cases. 2. A really good press is generally to be preferred.

G. B. (Cork).—It is rather a matter for our advertising columns.

J. Loder.—Write to the gentleman you name. A letter addressed to St. George's Hospital, London, W., will reach him.

J. M. Monto.—1. A rectilinear or symmetrical lens will prove the most suitable in a fairly good light, but under more unfavourable conditions you may have to make use of a portrait combination. 2. There are several in the market, and we believe that excellent results may be obtained with either.

T. C. H.—1. The process you describe is not very satisfactory, as the block usually suffers by the thorough wetting which it receives, and you will find it more satisfactory to prepare a fatty transfer on paper, and to transfer the image to the wood block by means of a lithographic press. 2. Sometimes it is prepared by being flooded with a weak gelatinous solution. 3. No. 4. Probably not.

Retoucher.—You can hardly complain with reason because your employer keeps you to that work for which he engaged you, as he perhaps finds this to be the only way of utilising your services to advantage.

J. R. -It is difficult to explain the affair except by assuming that the gentleman in question has but little regard for the truth.

B. Lands.—1. Add about 3 per cent of caustic soda. 2. Bichromate of potassium 2 ounces, sulphuric acid 2 ounces (fluid), and water one pint. 3. It is very likely that the carbon thread has become fractured.

C. R. Deed.—1. Generally in parallel circuit. 2. See our last number. 3. About five-eighths of an inch in diameter. 4. Not unless it has been previously softened. 5. Try the effect of five or six successive applications.

O. Gebrader.—Gutta-percha was used as a moulding material, and the surface was rendered conductive by means of fine copper bronze powder.

A Beginner.—Treatment with methylated spirit will be sufficient in ordinary cases.

Cambrian.—So much depends on local circumstances that it is impossible for us to express a decided opinion; but unless the street is unusually narrow at the part in question, the latter expedient should be resorted to.

Commerce.—Such matters can never be satisfactorily regulated by any system of combination, as such wide variation exists with respect to the quality of the work.

Thomas M——.—1.—Only through our advertising columns. 2. Three parts of the former and two of the latter. 3. No. 3 is more to our taste than either of the others. 4. A small proportion always remains in solution, but in most cases this may be disregarded. 5 Nitric acid 2 parts, and water 5 parts. 6. Not at present.

Kennington.—The immediate effect would be to make the plate considerably less sensitive; but it might, as you appear to think, prevent any decomposition of the organic matter setting in.

Enlarger.—1. The usual method is to first make a carbon transparency; but excellent results have been produced by the method you refer to. 2. Not unless it is new and in very good order.

Carlo.—The reaction sets in immediately air is admitted, but you will find it much better to revert to your old method of working.

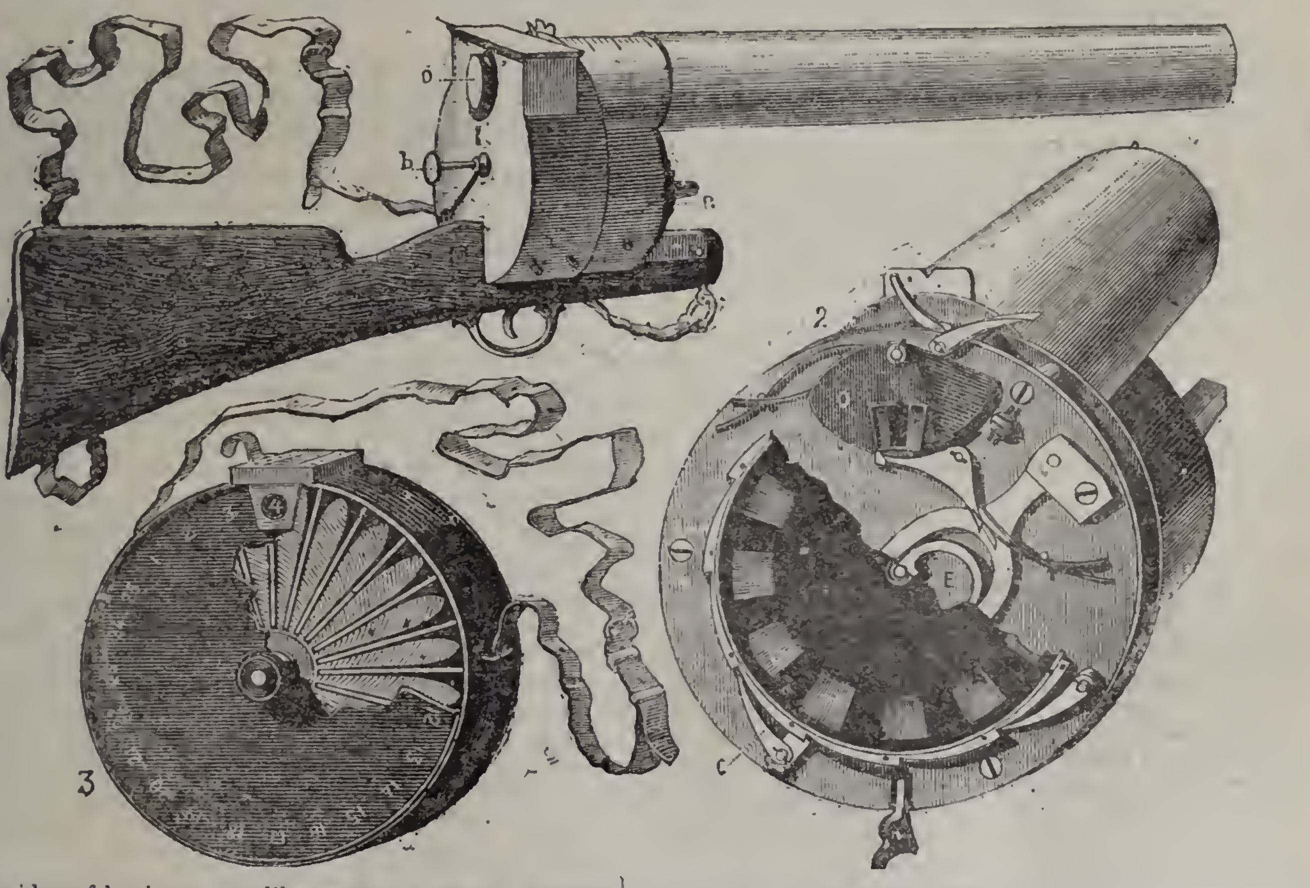
THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 123.—*May* 26, 1882.

CONTENTS.

MAREY'S GUN CAMERA.

We are able to place before our readers a sketch of M. Marey's recently constructed camera for securing rapid exposures in series. It is obviously an instrument of somewhat limited application, but the designer of the apparatus has been successful in obtaining with it many valuable pictures, that teach us something more than we knew before about the flight of birds. Mr. Muybridge's wonderful pictures of animals in motion led M. Marey to the construction of his instrument, and the latter seems to have been as successful as the former in his results. By securing a number of photographs one after another of a bird on the wing, M. Marey has been able to analyze the action of the wings, which constitutes the act of flying, in a manner that has never been attempted before.



The idea of having a gun-like camera which can be held in the hand and aimed is not new, neither is the notion of making a rapid succession of exposures, for the French astronomer Janssen does this in his photographic revolver; but the combination is new, and so exquisitely ingenious is M. Marey's apparatus, which has been submitted to the Academy of Sciences, that we make no apology for bringing it before our readers.

The sketch of the apparatus which we take from our contemporary, the *Bulletin de la Societe Française*, speaks for itself. Fig. 1 is a general view of the apparatus, fig. 2 shows the disc which acts as a cap and means of making the exposure, and fig. 3 is the box containing twenty-five sensitive plates. The photographer raises the gun to his shoulder as if in the act of shooting a bird; he aims as truly as he can and pulls the trigger, when the lens is uncovered for the short space of $\frac{1}{720}$ of a second. If the photographer can cover the bird for the space of one second, as many as ten exposures may be given one after the other within that time.

The tube of the gun contains the lens. At the breech of the gun is a cylinder which revolves by the action of clock-work. When the trigger is pulled, it puts into action all the necessary movements of the gun. A centre axle, which makes twelve turns in a second, has under control all parts of the instrument. It is, in the first place, an opaque disc, which serves to cap the lens, the narrow slit it contains permitting the exposure as it revolves. Thus there would be twelve exposures in the second, since this revolves as many times in this period.

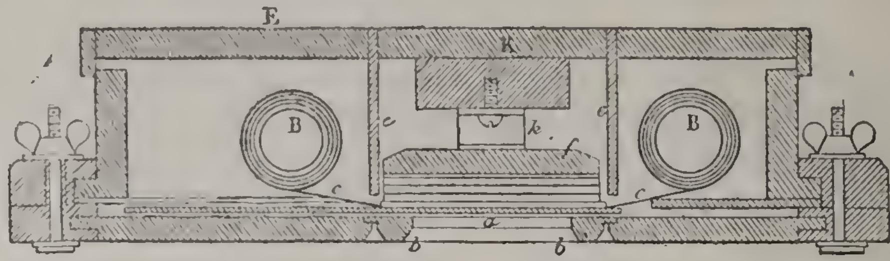
Behind this disc, and turning freely on the same shaft, is another disc, having twelve windows or apertures behind, and behind that again is the sensitive plate, either of circular or octagonal form. The disc with windows must revolve with an intermittent action, so as to stop twelve times per second in front of the pencil of rays that shines through the lens, just as the slit that makes the exposure passes. An eccentric placed upon the shaft produces the rotation required, by imparting a to-and-fro movement to a little projecting rod or tooth, which seizes at each oscillation one of the teeth, of which a series run round the disc that carries the windows.

The focussing of the instrument is brought about by lengthening or shortening the gun tube, the action of which is to advance or draw back the lens. The focus may always be verified by observing the little ground glass screen seen through an opening in the breech of the gun. A dry-plate box of circular form, similar to those obtained in commerce, serves to keep a stock of twenty-five plates, which may be lodged one after another in the gun, and subsequently withdrawn without exposure to light.

TROMEL'S REPEATING FRAME FOR PHOTOGRAPHIC PRINTING.

THE subjoined cut illustrates the latest developments of the roller printing-frame, and it is easy to believe that it may prove of considerable value to carbon printers, or to those who wish to make numerous impressions on gelatino-bromide paper.

The negative is laid over an opening, *a*, which can be



adapted to the required size by means of movable frames, one of which, *bb*, is shown in position. The band of sensitive paper is coiled on one of the two wooden rollers, BB, the free end being attached to the other roller, and contact between the negative and the paper is established by closing the door, *k*, so as to bring the platen *f*, into position. After the required exposure has been given, the door, *k*, is unfastened in order to release the paper, and a fresh portion of the paper is brought into position by sufficiently turning the uncharged roller.

It is, of course, possible to place several small negatives in a line across the frame, so as to print several pictures at once. Any which are less dense than the remainder require to be sufficiently shaded with tissue or mineral paper; and the band of impressed paper may be cut up into convenient lengths for development or other subsequent operations.

THE UTILISATION OF EXTREMELY THIN GELATINO-BROMIDE NEGATIVES.

FEW regular workers with the gelatino-bromide process have not occasionally produced negatives so exceedingly thin and ghost-like as to discourage all hope of intensification being possible. A negative of the kind we now refer to is seldom fogged, but the film is often slightly discoloured, and although scarcely any trace of an image is visible unless the negative is placed in an oblique position with regard to the light, it often happens that a careful examination will show that a highly-detailed picture, possessing full gradations of tone even in the lighter tints, is, in reality, present. Should this be the case, it is always practicable to so reproduce the negative that all gradations shall be proportionately intensified, and a vigorous replica of the original be obtained. The first step is to prepare a collodion positive by means of the copying camera, care being taken to make use of a moderately new collodion, to give a full exposure and to develop with an extremely weak iron developer, four or five grains of sulphate of iron to the ounce being sufficient in most cases; but intensification with pyrogallic acid and silver is better avoided, as often leading to granulation and roughness of the deposit. If reasonable care has been exercised in the production of this transparency, it often happens that it is sufficiently vigorous to serve by itself for making the reproduced negative; but should this not be the case, one or more additional transparencies must be made without in the least altering the adjustment of the apparatus as originally used, and it is well to employ a glass of extra good quality, and as thin as practicable. The transparencies thus obtained are placed over each other in exact register, and securely fastened by means of strips of gummed paper, after which the compound transparency is reproduced in negative form by means of the ordinary copying camera; but a lens of long focus, and well-stoppered down, should be employed, in order to reduce to a minimum any defects which may tend to result from the circumstance of the several constituent parts of the complex transparency resting in different planes. If it be preferred, a contact negative may be made from the complex transparency by the carbon process or on a gelatino-bromide plate; but in such a case it becomes necessary to print by approximately parallel light, the frame being placed either at the bottom of a deep box, or inside a room at a considerable distance from a small window. When, however, an old-fashioned, straight chimney of large internal measure is available, it can be advantageously used for printing by parallel light.

Success in the kind of reproduction now referred to cannot well be attained if old collodion be used and a short exposure be given, as under these circumstances vigour and contrast are obtained by the sacrifice of detail and modelling as regards the more delicate gradations of tone. It is scarcely necessary to remark that every circumstance which tends to produce even the slightest trace of fog must be most carefully avoided, and in order to prevent too large a proportion of silver intermingling with the iron developer, it is well to dip the plate for a few seconds in a weak silver bath—say about ten grains to the ounce—either before or after exposure. These remarks apply more particularly to the production of the transparencies, as if the multiple transparency be fairly vigorous there is generally no objection to using a tolerably strong developer, and moderately intensifying with pyrogallic acid and silver, when the reproduced negative is made.

The texture of a negative carefully reproduced by the collodion process will often compare favourably with that of a reproduction obtained through the medium of a carbon or collodio-albumen transparency.

STRAY NOTES ON DRY PLATES.

BY J. PLENER.

M. JANSSEN'S experiments, which you recently related, have enabled him to formulate two laws for the gelatino-bromide plates, viz., 1st, that a deposit on a plate of this kind is proportionate to the time of exposure and to the intensity of light, if the latter is not very great; and, 2nd, that when the intensity is very considerable, then the deposit increases in smaller ratio than the intensity of light.

In order to test the correctness of these laws, let us suppose for a moment that the second law does not exist, and that the first alone governs the formation of the deposit for all the intensities of light, and let us see what bearing this law will have on a developed plate which has been exposed for the time t under a *cliché* having continuous gradations of shades from white to black.

If we consider any two contiguous elements in the scale thus obtained on the plate, and designate the difference in the quantity of the deposit in them by dy, and by di the difference in the intensity of light which caused the decomposition of silver salts, then we are able to construct the following equation: $dy=\mu t di$ where μ represents the deposit corresponding to the unity of light's intensity and the unity of time; and the constant t the time of exposure. On the other hand, if we designate by a the least deposit perceptible to the eye, and by s the sensitiveness of the plate, then we have $\mu=as$. Substituting this in the equation above, we receive—

$$dy=astdi\ldots\ldots\ldots\ldots(1)$$

Let us apply this equation to the case of a sensitometer graduated in such a way that the difference in the transmitted light by two contiguous divisions will be Di. If we designate by P the maximum of the deposit the plate will give, and the corresponding intensity of light to it by i, then $i=nDi$ where n is the number of gradations obtained on the plate from P to the end of the scale. The equation (1) will give us—

$$\int_0^P dy=ast\int_0^{nDi} di, \text{ or } P=astnDi\text{; hence } n=\frac{1}{s}\cdot\frac{P}{atDi}$$

We observe here that n stands in inverse ratio to the sensitiveness—viz., the smaller sensitiveness—the greater is the number of gradations and the longer the scale. But in practice the reverse happens: a slow plate always has a shorter scale than a quick one. It is evident from this that the equation (1) does not hold good for all the scale of gradations, just as M. Janssen's first law sets forth. So far, all is right. But the reason of slow plates having a shorter scale must be sought for, and M. Janssen's second law, if it were true, might have accounted for the fact had it besides included the supposition that with the quick plates in high lights the deposit decreases much more rapidly than with the slow ones. If this were admitted, the curves for the plates, quick and slow, would be respectively like OBK and PCK. Nevertheless, we have direct evidence proving that in the slow plates the deposit does not decrease, but increases in greater ratio than the intensity of light.

Let us examine a slow plate which has been exposed under a sensitometer, and which gave for sensitiveness No. 10. As a rule, No. 1 will be as dense as, if not more dense than, the same number in a quick plate. We must try to calculate here the relation between the light i_{11} for No. 10, and i_1 for No. 1, and the respective deposits a and P. Mr. Warnerke's sensitometer gives us for the relation

$$\frac{s_{11}}{s_1}=12$$

It ought to be the relation of—

$$\frac{i_1}{i_{11}}$$

and for such we take it; consequently we may write—

$$\frac{s_{11}}{s_1}=\frac{i_1}{i_{11}}=12$$

Hence

$$\frac{P}{a}=\frac{i_1}{i_{11}}=12, \text{ or } P=12a.$$

If this were true, we could not make between a and P more than four gradations; therefore, we must admit that

$$P>12a,$$

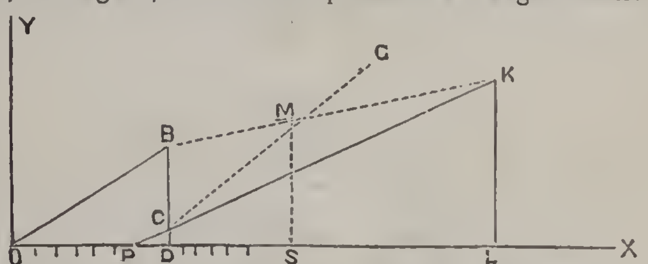
and that

$$\frac{P}{a}>\frac{i_1}{i_{11}}$$

Hence it follows that the deposit increases in greater ratio than the intensity of light.

To sum up the above, we say it is only in the quick plates that the deposit from a certain point begins to increase in smaller ratio than the light's intensity, while in slow plates the reverse happens, viz., the deposit increases in greater ratio. It seems beyond doubt that M. Janssen experimented only upon quick plates, for which his laws were formulated. It is clear now why slow plates have a shorter scale of shades. The deposit increasing more quickly than the light, the graphic power of the plate becomes sooner exhausted. This disproportion between the light and the deposit makes it possible that photography sometimes, by exaggerating the contrasts, renders distinct the shades which, in nature, are imperceptible to the eye. This is, too, one of the causes of the production of hard negatives.

Now we return to the diagram. The divisions upon O X represent different intensities of light, D C and D B represent the deposit in two plates of different sensitiveness, O D the light's intensity up to which the equation (1) holds good, P C G will represent the changes in a slow



plate, and O B K those in a quick one. The parts P C and O B are straight lines, but C G and B K are curves, and we do not know the law they follow. At the point M, common to both, they have for the same intensity of light, O S, the same deposit, M S. From this point the ordinates for M G will be greater than for M K. If, for the determination of sensitiveness, instead of the faintest tint, we were comparing the deposits represented by ordinates of M G and M K, we should find what is generally considered as a slow plate to be the quickest, and it may happen that in photographing a drawing in black lines a slow plate would require shorter exposure than a quick one.

Should we venture to explain the phenomena attending the formation of the deposit, we might suppose that, besides the known factors i, t, and s, there are two others more, opposite in their effects, one predominating in the quick plates, and another in the slow. As for the latter, it may be the electrolytic action that so much increases the deposit in them. On the other hand, in the quick plates, the relative decrease of the deposit may be the effect of solarisation, or some other unknown causes.

We said above that we do not know the laws the curves C G and B K follow, consequently we must write their equation thus—

$$\frac{dy}{di}=at\phi'(s,i,\beta)$$

where β may be a composite function of solarisation, electrolytic action, and some other unknown causes. From experience we know that, up to a certain value of i, the $\phi'(s,i,\beta)$ remains equal to s, and the above equation represents a straight line. But from this point the $\phi'(s,i,\beta)$ is

$>s$ for slow plates, and $<s$ for the quick. We may put it thus—

$$\phi'(s,i,\beta)-s=q \text{ for slow plates.}$$
$$\phi'(s,i,\beta)-s=-q_1 \text{ for quick plates.}$$

Here q changes with sensitiveness from a positive value for the slow plates to the negative q_1 for the quick. There must be some plates for which q approaches 0, the $\phi'(s_1 i_1 \beta)$ $-s$ and the curve P C G—straight line. Now arises the paramount question, how to know such plates?

M. Janssen gives us a good method to do this. He obtains on the plate two continuous gradations of shades, and superposes them in opposite directions. If the deposits were proportionate to the light and the time of exposure, we should obtain a tint of equal transparency throughout all the length of the scale.

Here is another means. If a plate really possesses the property of giving deposits proportionate, within the practical limits, to the intensity of light and the time of exposure, then it is capable of rendering truly all the shades we perceive in nature. Suppose we got a scale of shades ranging between the deepest black and the purest white, constructed in such a way that each shade differs, as regards the intensity of the reflected light, from two other contiguous shades, just as much as to make the difference perceptible to the average eye; if we photograph this scale, and manage to give right exposure, then a good plate will reproduce faithfully all the gradations of shades, while a bad one will render perceptible only some of the differences in shades, because here the graphic power, though it be the same as in a good plate, will be mismanaged in such a way that some gradations will be exaggerated, while others will disappear. It remains to count all the perceptible differences in shading to have the number which may be taken as expressive of the quality of the plate.

At Home.

MR. W. J. A. GRANT ON BOARD THE ARCTIC YACHT, "KARA."

By the time these lines are before our readers, a gallant little yacht, built expressly stout for Arctic voyaging, and manned by a crew equally gallant and stout-hearted, will be running down the Thames on a brave errand of mercy. The yacht is the good ship *Kara*, of 40 tons register, Sir Henry Booth master, bound for Franz-Josef-Land, and the desolate ice-bound sea that lies between Novaia Zemlia and the North Pole. Its object is to search the inhospitable bays and inlets in that far-off solitude of snow and ice for Mr. Leigh Smith's craft, the *Eira*, which for several years past has made surveying voyages to the far north, with a view to completing our geographical knowledge of that region. From his last voyage Mr. Leigh Smith failed to return; he was provided with provisions for a twelvemonth only, so that, whether safe on land or in a dangerous position on the ice, he must now be in sore straits. The *Hope*—a larger vessel, under Sir Allen Young—is likely to start also to his assistance shortly; but, meanwhile, the *Kara*, unhampered by a dozen difficulties which beset joint-stock expeditions, has cleared the dock, and stands ready for the voyage.

"That little craft lying by the jetty yonder, with a crow's nest aloft," says the dock constable at St. Katherine's, to whom we have turned for information. His information is good. There are masts without number before us; but only one carries an upright cask at the mast-head, designating her an Arctic voyager; for in Arctic sailing, we may mention to those who may be as ignorant as ourselves, the captain does not take his post on the bridge, but aloft, when he is once among the ice floes, for he can in this way best guide the vessel along any channel of clear water there may happen to be.

We have said the *Kara* only measures forty tons; but, if she is small, she is very strongly built. Her prow, or cut-water, is protected with iron, to prevent damage from ice, and presently, when we go below, into the hold, the cross-beams of oak and thick iron brackets at once attract attention, the destruction of the vessel by being nipped in the ice being one of the greatest dangers of Arctic voyaging. In the hold are the tanks of fresh water (for the frozen sea, although drinkable, since the salt crystallizes out, is not palatable, Mr. Grant tells us), and every nook and recess is filled with tinned meat, provisions, and stores. But we are progressing too fast; let us first descend into the cabin, and introduce our readers to Mr. Grant.

The main cabin measures about twelve feet by six, an elegant little apartment, with just room for a narrow table, a pair of benches, and a stove. At one end is a small library; on brass hooks, neatly arranged overhead, are some formidable-looking rifles; and swinging from the centre, under the skylight, is a circular little shelf, filled at this moment with a bevy of golden-tipped champagne bottles. A tiny "state-room" on either side, containing little else beside a berth, affords sleeping accommodation to Sir H. Booth and Mr. Grant; while a steward's pantry and a photographic dark-room complete the list of apartments aft.

Our readers are already familiar with the name of Mr. Grant. Still a young man, the better side of thirty, he is the hero already of half a dozen voyages due north. Under Sir Allen Young, as also in the recent voyages of the *Willem Barents*, Mr. Grant has served again and again as a scientific volunteer, and his observations in connection with deep sea soundings and meteorology, let alone his services as one of the most ardent of our amateur photographers, as well as his repeated experiences of Arctic life, have made him one of the best authorities on the subject of voyaging in the Polar seas. It is, therefore, with no surprise that we find our friend the heart and soul of this new expedition to the Frozen Deep, quietly and quickly arranging details of the internal economy of the ship, and speaking with equal promptness on the subject of magnetic observations, and of fish-hooks for the acquisition of food when the *Kara* gets north.

We doubt if ever a photographer required to equip himself with so much foresight as Mr. Grant. Now-a-days, we are apt to think that with gelatine, the whole forest of difficulties connected with photography is swept away at a stroke. An inspection of Mr. Grant's preparations soon dispels the illusion. Here in a corner is the stock of plates that Mr. Grant takes out with him; they are in their packages as they come from the maker, but every one of the packages is in a tin case carefully *soldered down*. The heavy sea fogs are so searching that nothing short of soldering can be relied upon to keep the plates dry and sensitive. These cases are never opened until the plates are required, and then the utmost care must be used to protect the films as much as possible from the damp salt air; as many people know, you can frequently taste the salt in a sea-breeze, and a deposit of salt—one of the most deliquescent of substances—upon gelatine plates simply means ruin to them. So that when Mr. Grant has rapidly unpacked his plates, and put them into their dark slides, these latter are immediately slipped into a well-fitting tin case, made as air-tight as possible by leather fittings. This tin case is then put into an outer case of stiff waterproof, to be a second time enveloped and strapped in a waterproof sheet.

Double dark slides are used, with slides that pull right out, these being employed not only for the sake of convenience, but as more likely to keep out the damp sea air. The tin case takes three of these slides, or half-a-dozen plates.

In this way the plates are carried across the ice for exposure in the camera, and yet, with all these thoughtful precautions, the plates are not always free from insensitive patches, &c. Once out of their soldered case, indeed, Mr. Grant seems to distrust the films, and he is never happy until the plates are developed and the films once more dry. "I always develop the same evening," says Mr. Grant, introducing us to his little dark-room, which is here in the warmest part of the vessel, leading out of the main cabin. A curtain pulls across the entrance, but as no rays can fall direct upon the door-way, the dark-room is well protected from daylight.

There is probably no more convenient photographic laboratory afloat than this well-fitted little recess on board the *Kara*. A spacious table and sink is before the photographer, and under these, convenient to hand, is a shelf carrying the ebonite developing trays. On one side are the developers, on the other side the drying shelves—perhaps the most important feature of Arctic photography. For it stands to reason, that no sooner is the picture developed and fixed, than, to secure it from harm, the film must on no account be permitted to freeze. Therefore, says Mr. Grant, rapid drying under your eye is of very great importance.

A well-built whole-plate camera Mr. Grant prefers for his work, and as the most steady stand, relies upon one of those tripods in which each leg consists of three supports, one drawing out from between the other two. The whole of his apparatus is packed in leather-lined metal boxes similar to uniform boxes, for the double reason of reducing the risk of breakage to a minimum, and preventing the action of that arch-enemy damp.

Many of our readers have seen examples of Mr. Grant's capital work—indeed, it is not so long ago that he secured a medal at the Pall Mall Exhibition—but few will guess how valuable some of his pictures are likely to become. The little bays and headlands on the dreary coasts, at many of which food depôts have been established or important documents deposited, have many of them been depicted in the camera by Mr. Grant, and these pictures will afford to other vessels far more valuable information as to the whereabouts of such stations than any written evidence. That the pictures, again, give us stay-at-homes a more perfect picture of the Polar regions than we are able to realise from a mere written description, is another interesting feature, for it may truly be said that until photographs of these desolate wastes of interminable ice, and these stretches of cold inhospitable shore, were put before us, a very vague idea existed of Arctic voyaging.

An ingenious pair of snow-goggles our amateur wears on his expeditions, which consist simply of caps of ebonite, one over each eye; at the end of the ebonite cap is a slit to look through, which slit can be widened or narrowed according to the glare, and another slit under the cap permits the eye to glance downwards. These two slits, when the goggles are in position, are, curiously enough, quite sufficient for the eye to look in any direction. Here also is Mr. Grant's belt for carrying his watch, whether for judging exposures or other purposes; the watch is in a fob at the end of a bit of leather, and to consult it, you unfold, much in the same way as you let down the steps of a carriage. The belt also carries two cartridge cases, so that cartridges may always be at hand, for a white bear, it seems, may turn up round the corner at any moment; "we shot eleven of them on our trip last summer," says Mr. Grant.

Here, by the way, on the cabin table, is a chart, which shows at a glance the proposed voyage of the *Kara*. After sailing due north and leaving Great Britain behind, on her left, the *Kara* coasts Norway and rounds the North Cape, as the most northern point is termed; keeping still well to the right—or rather we ought to say east—on her voyage north, the *Kara* will come to Novaia Zemlia, which she will also coast in case Mr. Leigh Smith's ill-fated crew may be here. "In fact, it was here, half way up Novaia Zemlia," says Mr. Graut, "that we last had tidings of the *Eira* in the summer from a walrus hunter. He told us Mr. Smith had collected what provisions he could and gone north." To the north of Novaia Zemlia you come upon the first serious ice difficulties; it is yet a hundred and twenty miles due north to Franz-Josef-Land—the point reached by the Austrian expedition some years ago—and it is only when open channels exist through the ice barrier that this land can be made. The Austrian expedition abandoned their ship in Franz-Josef's-Land, for the ice closed up the channel after they had gone north, and prevented any return, so that they had to make the best of their way back to Novaia Zemlia with sledges and boats. Mr. Grant thinks it not unlikely that Mr. Leigh Smith has been compelled to do the same, and for this reason it is that the coast of Novaia Zemlia will be thoroughly searched.

Novaia Zemlia has inhabitants, it seems, for the Russians have recently established an observatory there. "There is going to be a chain of observatories round the Polar Seas," Mr. Grant tells us, all the principal European nations taking charge of one; Great Britain has not, however, yet made up its mind where hers is to be placed, albeit Russia, Denmark, and Holland are already represented.

It is because she may have to afford relief to the *Eira* that the little *Kara* goes out stuffed full of provisions. She herself will not require much; all told, the crew numbers but eleven souls. She is to be navigated by Captain Bannerman, an experienced whaler captain from Dundee, and he is assisted by a mate and six able seamen. These, with Sir H. Booth, Mr. Grant, and the steward, make up the crew, all of whom will be required to lend active assistance. Besides acting generally as scientific authority and doctor, Mr. Grant's intimate knowledge of the Novaia Zemlia coast (he has photographed many of the headlands) renders him invaluable as a guide, ice-pilot, and general adviser, for if the crew of the *Eira* is located in Novaia Zemlia, he is, perhaps, more likely than any other man to find them.

The stout little craft has by this time started on her venturesome voyage, and in a few days she will be battling with the stubborn waves of the Arctic Ocean. It says something for the pluck and endurance of British blood to find gentlemen of position and independence, such as Mr. Grant and the gallant owner of the yacht, ready to sacrifice not only the comforts and luxuries of civilised life, but their health, and, may-be, their lives, in an endeavour to save brethren in danger. That they may enjoy a prosperous voyage and have a speedy and successful issue to their perilous voyage is, we are sure, the earnest hope of all of us.

The next "By-the-Bye" will be "A Unit of Light"; the following "At Home" will be "Monsieur J. Ganz in the Rue de l'Ecuyer, Brussels."

FRENCH CORRESPONDENCE.

Improvement in Photo-Engraving—Gelatine in Astronomical Work—Action of Light on Undried Bichromatized Gelatine—Luminous Photographs—Photographic Formulæ—The Rouen Prize Medals—Edinburgh International Competition.

Improvement in the Process of Photo-Engraving with Bichromatized Albumen.—A noteworthy improvement in the process of photo-engraving by means of bichromatized albumen has recently been published. The metal plate, whether of copper or of zinc, is, in the first place, coated with a very thin layer of bitumen of Judæa, and when this coat has become perfectly dry, a film of bichromatized albumen is flowed over the plate. It is then exposed to the light, and afterwards washed with water in order to dissolve all the albumen which has not been rendered insoluble by the luminous action; it is next treated with spirit of turpentine, which dissolves all those parts of the layer of bitumen that have become exposed. The plate can then be attacked directly by water acidulated with from four to six per cent. of nitric acid. The great advantage of this method consists in the high sensitiveness of the bichromatized albumen, at the same time preserving the solid reserve produced by the bitumen of Judæa on a metallic surface. The albumen flows completely over the bitumen layer, and there is nothing in the process different from its original form, except it be the use of the spirit of turpentine in order to clear the metal in those parts which have been previously stripped of the albumen. I believe that this modification will be proved to be a most interesting one, and I am glad to be able to recommend it to the notice of my colleagues.

Gelatine Plates in Astronomical Work.—Great preparations are being made by the different expeditions for observing the transit of Venus. Photography will be called in, in aid of all the observations, for it alone can give accurate information on all the phases of the phenomenon; these it will be able to reproduce in great variety during the five hours that the transit lasts. I have been asked whether gelatino-bromide plates can be used with advantage, and without having any reason to fear that the image will be distorted, the question is, will it be possible to carry out strictly accurate measurements on these images, for the least bit of distortion will lead to considerable errors? My own opinion is, that there will be no distortion if the plates are coated with a very thin film of gelatine, which has been made to adhere to the glass by some kind of substratum—as, for example, silicate of soda. Competent persons maintain that it will be impossible to rely upon gelatine in this respect. I do not, myself, share this opinion, though it is possible that I may be mistaken. I would therefore ask any of my readers who have been able to obtain information on this subject to be good enough to communicate it to the Photographic News. It is a question of to be or of not to be, so far as regards the use of gelatine plates in astronomy. If, however, there are any who are in possession of facts opposed to this view, I think that they also would do well to indicate them. Anyone who is of my opinion will also do well to mention it, in order that the observers of astronomical phenomena may know how best to avail themselves of the aid of photography.

The Action of Light on Bichromatized Gelatine which has not been Dried.—There appears to be a prejudice as to the action of light on bichromatized gelatine which has not been dried; it is supposed that in this state it has no sensitiveness. Now this is a mistake, as may be readily proved by coating either a negative or a positive on glass with bichromatised gelatine, and then exposing it to the action of light on the other side of the glass. It will be found that the bichromatized gelatine is completely protected against all luminous action except that which passes through the plate. If, after this exposure, it is treated with hot water, it will be seen that the gelatine is not entirely dissolved; the parts that have been acted on by light have become insoluble, and a relief is obtained of considerable depth. Besides, if I am not mistaken, it is on this principle that is founded the process for taking photo-reliefs which came to us from America, and of which we saw some remarkable specimens at the last international electrical exhibition in the *Palais de l'Industrie.* By means of this process we may coat a plate—either negative or positive—with a thick layer of gelatine, and then, having exposed it to the light through the glass, at the end of a certain time the layer of bichromatized gelatine will have become insoluble to a depth of perhaps 4 or 5 centimetres; then, on developing with hot water, we have a print either in depression or in relief of considerable depth. We may use either natural or electric light, as so long as the gelatine is fixed, it is not necessary that it should be dried, as this would reduce the height of the relief. When the exposure has been carried on for a sufficient length of time, the plate is treated with hot water, and this will remove the whole of the gelatine which has been rendered insoluble by light.

Luminous Photographs by the Dusting-on Process.—The following is a method for producing luminous photographic prints in which, instead of the images being on a luminous ground, the image itself is made to appear luminous on a dark ground. For this purpose is used the process of taking photographs in coloured powders published by Poitevin. A film is made of perchloride of iron and tartaric acid on a surface of softened glass; when it has been exposed, sulphide of calcium, rubbed to a very fine powder through a sieve, is dusted over it. The image is formed in the same way as if it had been dusted with any other powder, and it can then be transferred to paper. There can be no doubt that pictures of this sort will be much sought after, more so than those which can be obtained by transferring a carbon print or a Woodburytype to a surface of paper previously coated with sulphide of calcium.

Photographic Formulæ stated in Parts, and not by Weight.—I have been reading in the *Bulletin de l'Association Belge de Photographie* a very interesting article recommending that formulæ should be drawn up in parts, rather than in weights. Of course weights vary in value according to the country, whereas the proportion given in parts remains invariable. If, therefore, an arrangement of this sort could be universally agreed upon, the difficulty of reducing weights from one denomination to another would be avoided. It would only be necessary, for instance, to speak of so many parts of nitrate of silver instead of so many grammes or grains, as the case might be; or, again, so many parts of water, instead of so many ounces or so many cubic centimetres. This would enable the operator to apply the proposed formula immediately, without it being necessary for him to enter into intricate calculations. The idea seems to me to be an excellent one, and I cannot too strongly recommend its adoption.

Prize Medals Offered by the Industrial Society of Rouen.—The Industrial Society of Rouen offers competition prizes in the following subjects:—A gold medal for the application of photo-engraving to copper cylinders used in printing woven fabrics; a silver medal for the application of any photographic method to printing on stuffs.

The International Competition proposed by the Photographic Society of Edinburgh.—While I am on the subject of photographic competitions, I may say a word on that which has been established by the Photographic Society of Edinburgh. It is laid down (1) that the negatives must be able to give at least five hundred prints by a permanent process, and at a cheap rate, and that they must be lent to the Society for this object: (2) the competitors must, if required, send in their negatives to be examined before the prizes are awarded. Now, I must confess I do not understand these two regulations. What is meant by a negative capable of giving five hundred prints by a permanent process, and at a cheap rate? Should not *a plate* be written rather than *a negative*? As for the second article, it seems to be only a recapitulation of the first. If I had any desire to be a competitor it would be very difficult for me to decide accurately what the Edinburgh Society wants; greater clearness seems certainly to be much wanted.

Leon Vidal.

ON THE EFFECT OF THE SPECTRUM ON THE HALOID SALTS OF SILVER, AND ON MIXTURES OF THE SAME.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

Mixtures of Silver Iodide and Bromide.

Equal Equivalent Proportions of Iodide and Bromide.—Paper was soaked in a solution of equivalent proportions of soluble iodides and bromides, and, after drying, was sensitised on a 10 per cent. solution of silver nitrate for such a time that the back of the paper

* Continued from page 285.

became thoroughly damp. The silver nitrate solution was acidified in order to prevent the formation of any sub-salts.

A strip of such paper was exposed to the spectrum whilst moist, and the printing action noted. The result is given in fig. 47. Similar paper was washed and treated with potassium nitrite, and exposed whilst moist; the effect of the action of the spectrum is seen in the same figure.

Paper was next washed, and portions were treated with a solution of potassium bromide, and again washed. Strips of these two specimens were dried and exposed to the spectrum, and in both cases the printing action is seen in fig. 48. Similar papers, in a moist state, were also exposed without any deviation of the result. Again, paper which had been prepared as above was allowed to dry with the excess of silver nitrate on it, and exposed, and fig. 48 again approximately resulted; as also it did when the washed paper treated with potassium nitrate was dried.

The difference between curves 47 and 48 is very remarkable, and at first sight might not seem to admit of explanation. A study of the experiments described, however, affords a clue to the apparent incongruity of the results. According to text-books on chemistry, bromine will displace iodine in combination, whilst iodine displaces bromide. Later researches seem to modify the first statement to a certain extent. Bromine will only displace a definite proportion of iodine when it is in excess; but for our purpose we may take the text-book statement as practically correct. When the paper was exposed wet with either silver nitrate or potassium nitrite (I may remark that other halogen absorbents gave the same result) the iodine and bromine liberated by the action of light would be at once absorbed by them; in the one case silver iodide (or bromide) and silver iodate (or bromate) being formed, and in the other potassium iodide (or bromide); so that each of the two kinds of sensitive salt would have its full action. When the paper was washed and exposed in a dry state the result would be different, and the question would arise, what would become of the iodine and bromine liberated by light.

If silver iodide be exposed to light and treated with a trace of bromine, the sub-iodide combines with the bromine, and all trace of the action of light is destroyed. Thus when the mixture of iodide and bromide is exposed to light, both iodine and bromine being liberated, the bromine will at once combine with the sub-iodide and destroy it. Thus,

$$Ag_2I + Br = Ag_2IBr,$$

the only factor remaining being the sub-bromide, which is developable. Now it may be said that the iodine liberated should also destroy the sub-salts; but it is a matter of fact that, in the presence of light, it has no power of destroying the sub-iodide, since it is immediately again shaken off from the molecule.* Iodine can destroy the sub-bromide molecule, and form a new saturated molecule; thus,

$$Ag_2Br + I = Ag_2BrI.$$

Whether the two molecules Ag_2BrI and Ag_2IBr have the same value is a moot point, but the evidence tends to show that such is the case. If the equivalents of bromide and iodide were equal—that is, if the bromide and iodide of silver were equally distributed—supposing both the above actions took place, the locality of the spectrum in which the iodide and bromide are equally sensitive should show an almost entire destruction of a developable image, and also of a printed image.

This locality is doubtless about G, and when we come to analyse the curve in fig. 48 we see that there is very small effect about G, whilst there is an increased effect between G and F. Now, to test the matter further, paper prepared with washed silver bromide was exposed to light till it darkened thoroughly, and such paper was treated with a very dilute solution of iodine, and then exposed in the spectrum, with the result given in fig. 74, in which it will be seen that the new molecule is more sensitive to the green between G and F than above G; in fact, we have very little action comparatively at G and above it. In this case we have then a paper prepared in which there is an absolute imitation of the action that takes place in the mixed iodide and bromide. It cannot be said that by this treatment we have $Ag_2I_2 + Ag_2Ba_2$, since the molecule formed by light is Ag_2Br, and the addition of the iodine is simply to form Ag_2BrI, which is very different from a simple mixture. This experiment, then, seems to show that this new molecule is more sensitive to the blue-green than it is to the violet. The point then comes as to how, when the original paper is exposed to the spectrum, we have not only a fall of sensitiveness at G and beyond it, but also a greater sensitiveness in the green. Now, silver iodide, as has already been shown, is not in the least sensitive to beyond a very small region below G; therefore, in the green the only component of the mixture of bromide and iodide that can be acted upon is the bromide. As we see when bromide is acted upon, one atom of bromine is liberated from the molecule; thus,

$$Ag_2Br_2 = Ag_2Br + Br.$$

The liberated atom of bromine immediately attacks the molecule of iodide in its immediate neighbourhood, and forms a new bromo-iodide molecule liberating iodine. Thus

$$Br + Ag_2I_2 = Ag_2IBr + I,$$

and the iodine either escapes, or else forms the molecule Ag_2BrI; thus

$$Ag_2Br + I = Ag_2BrI.$$

Here, then, it is probable that we have a new saturated molecule formed by the action of light, which on formation is susceptible of being acted on by light in its turn. Whether iodine or bromine is liberated from this new molecule I am not at present prepared to state, but it is my belief that it is the iodine, since density in development by the alkaline method is readily obtained when experimenting with it.

To sum up, the difference in shape between curves 47 and 48 seems to depend on the destruction of the sub-iodide when formed, and its conversion into a new molecule, which is sensitive to the blue-green, the same new molecule being formed by the liberation of the bromine from the molecule of silver bromide when the sub-bromide is formed. In the case of the paper which is dried in the presence of silver nitrate and potassium nitrate the same result occurs. Bromine and iodine attack these salts when in a crystalline state with difficulty, and hence will in preference form the new molecules as before.

Fig. 49 shows the curve of washed paper when developed with ferrous citro-oxalate, and nearly the same result is seen when the development proceeds by acid development, the difference being that the dip in the curve between h and G is less pronounced. To illustrate this further, in fig. 50 we have the case of a collodion film containing equal parts of silver iodide and silver bromide and an excess of silver nitrate, the latter salt absorbing both the iodine and bromine liberated. In fig. 52 we have the results obtained from the same film, but thoroughly washed from all excess of silver nitrate. Whether the plates be developed by acid, alkaline, or an organic ferrous salt, the curves remain in all essential particulars the same. In fig. 51 we have the curve resulting from the same mixture (equal equivalent proportions) held in gelatine when developed by ferrous oxalate or alkaline developer. At first sight it might be said that this action is really due to the "reversing action" of light, of which I have treated in the "Proceedings of the Royal Society," in 1878, and the "Philosophical Magazine," in 1880. That this is not the case is shown by fig. 53, in which the exposure was exceedingly short; in fact, when very quick exposure was given the curve started at h and reached a maximum as shown in fig. 53. These results are exceedingly interesting and important. There is a figure showing something somewhat similar in Vogel's "Lehrbuch der Photographie," Berlin, 1878, but there is no explanation of the cause, nor has it been noticed by any other observer, as far as I am aware.

(To be continued.)

* At the same time it must be noted that the iodide is much less sensitive to light when no absorbent of iodine is present. This is fully accounted for by the immediate recombination of, at all events, a portion of the iodine liberated with the sub-iodide molecule.—Dec. 19.

Notes.

The Geneva Photographic Society proposes to publish an annual journal.

We are glad to hear that Mr. Russell Manners Gordon has returned from Madeira in improved health.

The German photographers have this year chosen a very central spot for their annual gathering, which is to be held at Eisenach in August next. Eisenach is not far distant from the castles of Rheinhardtsbrunn and Rosenau, where the late Prince Consort passed his "Early Days," about which Her Majesty has told us in one of her books

The Owen's College, at Manchester, is now provided with a spacious and well-fitted photographic laboratory, and we are informed that arrangements are likely to be made before long for organising a course of instruction in photography. Several well-arranged groups from the camera of Professor Roscoe may be seen hanging in some of those rooms of the College which are occupied by the teaching staff.

Sir H. Wolff is evidently no photographer, although we should not be surprised if he or his friends had something to do with publishing photographs. The key-note of his speech last week against the Copyright Bill was utter astonishment that there should be anything copyright in a photograph at all. His amazement at the impudence of photographers who thought that the posing nd lighting of their sitters involved a knowledge of art principles was, in fact, expressed so naively that one almost lost sight of the crass stupidity of his remarks, and for the moment forgot the sheer nonsense he was talking. Either Sir H. Wolff must have been speaking from interested motives, or he was profoundly ignorant of the subject he undertook to discuss.

Many people, unfortunately, besides Sir H. Wolff, maintain that no art knowledge is necessary to secure a good portrait. Yet, when they require pictures of themselves, they do not go to the first best photographer who can make a clean plate, but select a firm whose portraits, for some reason or other, are unusually attractive and elegant. What is it that renders pictures agreeable and attractive, and inclines the customer to pay highly for them? Or, why is it, when the model himself takes the posing into his own hands, the result is usually a stiff constrained position that breathes of self-conceit and coxcombery?

Posing and acting have much in common. There is scarcely a representative of the crutch and tooth-pick school who does not imagine himself a born actor, and capable of playing the part of *jeune premier* in any play. Only, when he attitudinizes in a free and easy style before an audience, instead of displaying gentlemanly complacency, to the looker-on he is merely vulgar. So in posing, when the model flatters himself he has assumed the freest and most degagé of positions, a portrait is the result which, painful enough to the photographer, invariably makes the victim begin to wish he had never been born.

A great deal of fuss has been made in the newspapers during the week about Big Paul, the new bell of seventeen tons weight which is to be slung in the belfry of St. Paul's. Its movements have been chronicled day by day, as if the carrying of heavy masses of metal was unheard-of in these days of eighty-ton and hundred-ton guns. Indeed, the first "Woolwich Infant" represented no less than thirty-five tons, and it is a dozen years or more since this was a novelty! Fortunately, it has been the custom, when devising new tackle and machinery for the lifting of our modern ordnance, to have the whole arrangement of ropes and pulleys photographed, and the pictures thus secured furnish valuable information to those who have the task of lifting the big bell into its place.

The *Medical News*, of Philadelphia, suggests that all hospitals should have a camera and stock of dry plates on the premises to enable the doctors themselves to take photographs of interesting cases in the wards, to record the progression of a disease, and to secure pictures of specimens likely to be valuable in the science of medicine. In this country, Dr. Diamond was one of the first to make use of photography for the study of disease, and he possesses at this moment a valuable collection of medical records secured by the camera. Certainly, the suggestion of our American contemporary would be exceedingly advantageous for instructional purposes.

Photographic printing upon fabrics has made but little way at present, and we are glad to see that the *Société Industrielle*, of Rouen, has determined to encourage the art. The Society offers a gold medal for a photo-engraving process applicable to copper cylinders, such as are usually employed for fabric printing, and another similar award of silver-gilt for any other practical plan of printing upon stuffs. The medals will be awarded next December.

It has been known for some time that charcoal, or other similar forms of carbon, possess the property of separating gold from an aqueous solution of the chloride, but this has been supposed to arise from the reducing action of occluded gases, or some extraneous influence. The recent experiments of Koenig prove that carbon is actually oxidised to carbon dioxide by the joint action of auric chloride and water.

Moist bromide of silver loses about 2·3 per cent. of bromine by a prolonged exposure to the rays of the sun, and Dr. Tommasi, who has made this determination, regards the brown product as containing both basic bromide and metallic silver.

Dr. Eder has been trying the addition to emulsion of various promising bodies; dextrine, according to his experiments, seems to induce fog, but an addition of sugar appears advantageous.

As everybody knows, gelatine is of itself such an untrustworthy body, that even the best formula and most skilful manipulation sometimes fail to result in clear and sensitive plates. For this reason, the Berlin Photographic Society have determined to offer a gold medal for a process which, under all circumstances, will give a *uniform* material suitable for emulsion making; whether the product is got from raw material or from commercial gelatine is of no moment.

A gift in money by some of the members of the Society will, in all probability, accompany the gold medal, which will be awarded to the best essay sent in before the 1st of October next, to Dr. Franz Stolze, 23, Schwerinstrasse, Berlin. The essays may be written in the German, French, or English language.

Mr. Swan has found the production of carbon lamps more profitable than carbon prints. Although the first to make carbon printing a practical process, we believe Mr. Swan never profited by his improvements one penny. On the other hand, the preparation of carbon thread for the incandescent lamp has turned out a very profitable affair. The Company purchased the lamp for £25,000 in money, and £25,000 in shares, and as this company has now sold its property to another, at a premium of something like fifty per cent., Mr. Swan may be classed among that small body of inventors who reap a handsome reward for their labours.

A German insurance journal comments upon the value photography might be in effecting insurance policies. By far the larger number of policies, it is well known, are effected through agents, who send up to the head office the certificate of some local medical man who has examined the applicant for an insurance. This medical certificate is carefully overhauled by the more experienced medical adviser of the Insurance Company at head-quarters, and he has to read a good deal between the lines. If he could get but a glance at the applicant's face, that, with the certificate he possesses, would enable him to form a very good opinion of the value of the life. The medical adviser often has his suspicions on reading the certificate, and these would be set at rest, one way or the other, by viewing the applicant's features; he has seen so many faces that he can guess a person's constitution by glancing at them. A photographic portrait, therefore, untouched, sent up with the medical certificate, would aid greatly in forming a correct opinion.

A mixture of 40 parts of clear linseed oil, 10 parts of strong vinegar, 5 parts of oil of turpentine, and 1 part of hydrochloric acid is recommended for polishing photographic cabinet work.

The Institute of Chemistry seems to be somewhat at a discount among the Lancashire chemists just now. Several of the leading men have already withdrawn their names, and a general secession is not unlikely.

When a Manchester man subscribes two guineas a year, he likes to know that good use is made of the money, and the advertising of his name in the public journals twice a year he evidently thinks no adequate return. A rival body, the Institute of Chemical Industry, issues a really valuable monthly journal—almost an English equivalent of "Dingler"—and, in consequence, will no doubt prove more attractive to those chemists who feel that the Chemical Society is not all sufficient for their wants.

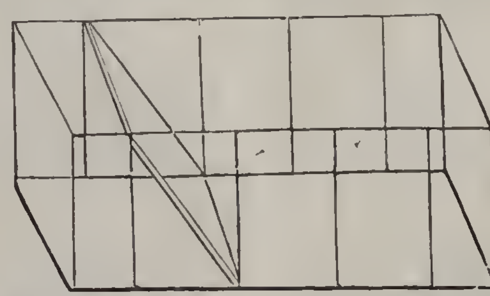
BI-CHROMATE OF POTASSIUM IN EMULSIONS.

BY A. J. BROWN.

WITH regard to Mr. Ernest Edwards's process which you published in your last number, I may say I have experimented almost on the same lines. Perhaps it may interest some of your readers to know what I have done and purpose doing.

For many months I have not made an emulsion without using potassium bi-chromate. When the emulsion is cooked, should it be acid, I make it slightly alkaline, and drop in (for what will be 10 ounces of emulsion when finished) 30 grains of bichromate, dry, shake till dissolved, and pour out to set. The bichromate is of course removed along with the other salts during washing. I can strongly recommend this; it is a much easier and better way than squeezing into the bichromate solution; it gives scarcely any additional trouble; it in no way interferes with or alters the sensitiveness, but destroys thoroughly light, and so-called chemical fog, which latter I believe does not differ in kind from the former in any way. If it occur, the emulsion or plates are simply sensitive, perhaps, far into the red, or it may be beyond (to our eyes) the visible rays, and so even be fogged, in the cooking, by those rays which make themselves more manifest to us as heat.

It was only an easy step from this practice to what will be known as Mr. E. Edwards's formula. Without going quite so far as to prepare plates in white light (which is unnecessary, and may be harmful),* I have made them after the plan he advocates, but do not like the state the film is left in after the salts are dissolved out. It is far better to wash the emulsion first, then add the bichromate—which need not be in anything like the quantity he uses—coat, and, while still wet, wash again. They require a good deal of washing, and for very rapid plates well repay the extra trouble, giving "bare glass" where not exposed, which is a very different thing from "bare glass for shadows" which we hear so much about. The plan I would advocate is this (I am, indeed, at work upon the rack and trough, and had not your article appeared, I myself should have brought it forward in probably two or three weeks): wash the emulsion, then add to each ounce two grains bichromate, filter, coat, and allow to set, then place them in a frame of tinned iron wire as per sketch; place in



Only a small number of wires are drawn, with one plate in position—film side down—for sake of clearness.

running water in a trough; after well washing, take from this to the drying cupboard—still in the rack—where it will rest upon laths, and dry at low temperature. But little water I expect will cling to the wire. From the stacking in the frame all operations may be performed in absolute darkness, and away from harmful heat rays. By the way the plates lean they may also be packed in darkness quickly and carefully, if Mr. Cowan's wrapping apparatus be used, by hand, with a little extra care. All I have written of course refers principally to really rapid plates. Should anyone care to follow Mr. Edwards's method, I would suggest the use of good yellow light—by no means white.

* I had one batch of emulsion which was left with the bichromate in for a few days—I forget how long, as it was some time ago—which became almost insoluble; it melted only just below boiling temperature, and was then like thick gum, and, of course, was quite useless. I mention this as a caution. It had only seen pure red light.

THE LAST NEW DEVELOPER.

BY W. T. WILKINSON.

Experimentalists, amateurs, and manufacturers, are chiefly interested in the various discussions upon the improvement of gelatine emulsions and drying-cupboards, &c.; but the majority of professional photographers are chiefly interested in the best method of development. Up to about two years ago the pyrogallic acid was used dry, and either weighed out in small quantities, or guessed at, until Mr. B. J. Edwards introduced his formula containing glycerine, amongst the many advantages of which was, that for the first time it was possible to dispense with the waste of time and pyrogallic involved in weighing, and the uncertainty in guessing; and, at the same time, to depend upon the solution of pyrogallic keeping in good condition for any length of time (in reason).

Advantageous as Mr. Edwards' glycerine formula was in many respects, the danger and risk of air-bubbles so easily formed when a colloid body, such as glycerine is present, was introduced. The publication of Mr. Cowan's formula, wherein citric acid was used as a preservative, was a great improvement, and Mr. Cowell's process of clearing the pyrogallic-stained shadows by immersion in a mixture of citric acid and alum seemed to promise the acme of perfection, as, with the expenditure of a little extra care and trouble, negatives could be obtained of the best quality, and free from the objectionable yellow stain in the shadows almost inseparable from alkaline pyrogallic development.

No sooner, however, were photographers settling down to this tedious but necessary method of getting good negatives, than Mr. Berkeley re-introduces a process advocated by him eighteen months ago, offering the many advantages of absolute certainty in the keeping quality of the pyrogallic solution, the greatly-improved brilliancy of the negative image, and the entire freedom from yellow or other pyrogallic stains, as well as—especially when a large quantity of negatives are developed in a batch—great economy in the quantity of pyrogallic used; and I venture to predict that, at no distant date, this formula will be the universal one.

The formulæ that I find best for portrait and general commercial work are as follows:—

No. 1.

Sulphite of soda	4 ounces
Water	40 ounces

Dissolve; then add sufficient of a saturated solution of citric acid to produce a slight acid reaction upon litmus paper; now add one ounce of pyrogallic, and make up bulk to 54 ounces with water. This gives a solution each ounce of which will contain about eight grains of pyrogallic.

No. 2.

Ammonia ·880	1 ounce
*Bromide	180 grains
Water	40 ounces

Equal parts of this will give a four-grain pyrogallic solution, a strength which is a good average. This developer will be found all that its author claims for it—viz., simple and perfect. In my hands I can get a good negative out of a plate, no matter what is the exposure (in reason). If, upon applying the developer, it is found that the exposure has been too short, wash the plates thoroughly, flood with ammonia-bromide solution, and allow it to act for three or four minutes, when the details will gradually develop, without, however, gathering density, which is easily obtained by returning the plate to the ordinary pyrogallic and ammonia-bromide mixture. When all the details are out by the method, there is immense latitude, and no danger of getting the hard negatives so characteristic of under-exposed gelatine plates. On the other hand, in case of over-exposure, stop the development, wash thoroughly, and immerse in a mixture of pyrogallic solution 4 parts, ammonia-bromide ½ or 1 part, and, instead of the ordinary flat and thin negative, useless for anything (except smashing), a good negative is obtained, only very thick and slow in printing, but yielding good vigorous prints.

If a batch of plates are to be developed, the same solution will do for them all, merely adding a little more now and again of No. 2 to replenish the ammonia that has evaporated.

Negatives possessing the colour and characteristics of wet collodion negatives are obtained by first of all soaking the plate in No. 2 solution for one or two minutes; then pour off, and apply the half-and-half mixture of Nos. 1 and 2. This plan also is strongly recommended when the exposure is either known or guessed to be short.

* Of course the bromide must be altered to suit the particular make of plate used, as recommended by the maker.

STRAY THOUGHTS TOUCHING OUR RECENT EXHIBITION.

BY J. POLLITT.*

When our energetic Secretary (Mr. W. J. Chadwick) asked me, a few days ago, to contribute a short paper for this evening, I felt that—although I had no special subject to bring forward of sufficient importance to rank as the fitting sequel of a session of unusual activity—if I could string together in an intelligible form a few of the vague generalities already floating in my mind, the effort might at least be not altogether unprofitable.

The exhibition of photographic art-treasures held in this room in November last will, doubtless, be long remembered as a red-letter day in the history of this Society, not only from the fact that no previous collection of the kind outside the metropolis had ever equalled it, either in extent or merit, but also because it was the first considerable exhibition that had been planned and successfully carried out by the Manchester Photographic Society; and, occurring as it did at what may be called just the transition period, when the old style was being gradually thrown overboard to make room for the new, the educational advantages of such an exhibition, at such a juncture, were so vastly important that, notwithstanding the heavy pecuniary loss sustained by the Society thereby (and, may I also add, notwithstanding the severe castigation which the Secretary, as well as we lesser luminaries of the committee, have received at the hands of some disaffected exhibitors?), we may rest assured, even in the depths of our poverty and humiliation, that the effort was neither short of popularity, nor will its influence be wanting as a means of future good.

It is only by means of such exhibitions that the general public (already too much familiarized to pressing invitations of the street-door tout, and his offers to produce a considerable number of "k'rect" likenesses for an inconsiderable number of bronze pieces) are made aware of the almost boundless capabilities of our art-science, and how, by an intelligent mastery of its principles, its productions are often made to rank with the ideal.

I have said we were passing through a transition period. We may be said to have already passed through it; but, like great political and international events, the importance of the transition can only be rightly estimated by the light of after history, and opinions and conclusions so frequently become modified by lengthened experience and collateral circumstances.

As regards the gelatine process: I am not here to say one word other than in its praise. Its advantages over all its forerunners are in many ways numerous and unquestionable; but we live too near the birth of the process to grasp the limitations or extent of its powers. We are, in fact, as yet surrounded by an atmosphere of enthusiasm which hardly leaves our judgment free. It is so great a departure from our previous lines of working, with the cumbrous *impedimenta* of chemicals, tents, and the like, that photographers have become in a sense intoxicated with its charms, and many have pinned their faith to it exclusively and absolutely. Not a few are boasting, as if it were a praiseworthy matter, of their rapid forgetfulness of all former methods of working; and, as in the case of fashions, some individuals must needs rush into extremes, so there are a few (presumably with advanced ideas) who have sold off collodion, baths, and all the belongings of former processes in the full and certain expectation that gelatine will henceforth reign supreme.

* A communication to the Manchester Photographic Society.

But the grand object of an exhibition of photographs such as the one recently held here is not to exalt any particular method of working over all or any others, nor to recognise motives of a personal nature, if any such should exist in the minds of exhibitors. It is an effort to bring under one general view all the capabilities of photography—not as a mere mechanical or chemical pursuit, but showing what can be accomplished in the higher walks of art when an intelligent mind controls manipulative skill. It is not so much a race of various processes, although many processes and methods, and still greater number of ideas as to their management, are represented—widely different, it may be, in many respects, but all vieing with each other in a friendly competition for excellence. But, over and above these mere methods and means to an end, it is the judicious domination of mind that alone marks the pathway to the beautiful.

The advent of the gelatine process has, undoubtedly, given a vast impetus to photography. It has immensely increased the amateur ranks, and has also considerably influenced the professional practice of the art; nor can there be a doubt of its permanent effect in the future. At the same time, it is not so much the inherent value of the process—although that is considerable—as the great charm of its simplicity, that has brought about its so extensive adoption; but no process, however simple and satisfactory as to its mechanical details, can be successfully worked without both skill and judgment, and hence we see a marked variation in the productions of different men—as widely different and more characteristic than their own hand-writing. Some take up photography, and, without any apparent trouble or tedious initiation, seem to go on producing really good work without any noticeable drawbacks; whilst others, again, after years of study and almost continuous practice, never appear to produce anything that attains to mediocrity.

Many of us remember that, so long since as twenty years, the works of Rejlander and Robinson were each in their way vastly in advance of the general character of the work produced at that period, and this not so much from any superior knowledge of chemistry or highly-trained mechanical skill, especially in the case of Rejlander, who was known to have been a slovenly operator; but from a clear conception of the intrinsically-beautiful and an unhesitating readiness to use any means, orthodox or otherwise, for its accomplishment.

To come to our own Society: we are all of us (at least the older members) familiar with Mr. Coote's charming pictures by the collodio-albumen process, and I merely mention his name for the sake of pointing out that in his able hands the gelatine process—which, I believe, he has worked almost exclusively for the past two years—has produced work not a whit inferior to the very best of his collodio-albumen productions; whilst the rapidity of the process has given him a new power in dealing with subjects which previously were beyond his reach. Much beautiful work has also been done in dealing with incidents of life and motion by Messrs. Wade, Blakeley, Chadwick, and other of our members, including Mr. Percy Collis, around whose beautiful productions recently shown in this room there seemed to be all the aroma of poetry.

If a photographer would excel, he must have no vague notions about his work, but a quick and ready appreciation of what is wanted to produce a pleasing and an artistic result, and, above all, the ability to deal successfully with every difficulty he may meet with.

I must ask the indulgence of my hearers for these rambling remarks. My time and attention have been too much taken up to do the justice that the subject demanded, and which it might have received in abler hands; but my chief object has been to point out the immense influence for good of these periodical exhibitions in an educational sense. And, although we cannot hope—at least, for some time to come—to get up another which shall equal either in merit or magnitude the grand exhibition recently held in this room, I think the Society has acted wisely in deciding that there shall be something of the nature of an exhibition next autumn, in the shape of a collection of members' own work, and which possibly may be augmented by outside contributions. Such an exhibition—taking into consideration the great number of able workers which this Society now contains—cannot fail to be both of great interest and advantage.

The season has opened auspiciously, and there is every promise of a glorious summer. Let each "put his shoulder to the wheel" with a determination and a will to produce a rich autumn harvest.

KNAPSACK TENTS.

At the last meeting of the Photographic Society, both Mr. William England and Mr. Maxwell Lyte described their arrangements for out-door photography. Mr. England said:—"At the request of Captain Abney, I have brought to-night a tent. It was made originally for working wet plates some fourteen or fifteen years ago, and has been in use since that time. At present I use it for developing and changing gelatine plates. No alteration has been made for this purpose, except to place a piece of ruby-coloured calico over the window. In place of the nitrate of silver bath, I substitute a hyposulphite bath for fixing, and with these slight alterations it is admirably adapted to its present purpose.

During the last two years I have developed in it five or six hundred plates.

But little description is needed. The support for the covering is made of frame-work, which folds up for portability, and covering is then wrapped round, which forms a protection when packed up for travelling. The whole is very portable, and weighs under fourteen pounds, with stand, so that it can be carried as a knapsack on the back.

I may also remark that, as I always prefer to sit whilst developing, it is made low for that purpose; those who prefer to use it standing can, of course, have the stand made higher.

The bamboo stand exhibited this evening is made by Mr. Collins, and is similar to one for which I gave him the design about sixteen years ago, and the one I have in use at the present time was made about that period; so that, in point of durability, I think the bamboo makes the most durable and, at the same time, the most rigid of all supports for the camera.

Mr. Maxwell Lyte said: I have had a large experience in out-door photography, particularly in hot climates—as the south of France and Spain. I never aimed at getting extreme portability, but was satisfied with a tent which a man could easily carry. The tent I used was shaped triangularly at the top, similar to Mr. England's, and was covered with a cloth not coming down to the ground like Mr. England's. It stood, however, much higher. The skeleton of the tent was, in fact, a tripod-stand, only much higher than the ordinary ones—taller, indeed, by about six or eight inches than I am tall. The three legs of the tripod were split at the upper ends in the usual manner, fitting on to the three sides of a wooden triangle, and kept open by the usual cross-pieces of wood. The triangle had a hole in the middle. The split portion of each leg extended about $2\frac{1}{2}$ feet down from the triangle, and was then prevented from going further by an iron ring or ferrule driven on. Down as far as this ring the upper parts of the legs were round; but below the ring they were left square, and in this square part was a hinged joint on each leg, so that they could be folded up inwards, and the ends of each leg made to pass through the holes in the triangle, so that they thus folded into a fairly short, not inconvenient, bundle, even when not dismounted from the triangle. When set up, the whole formed a tall tripod-stand, about six or eight inches taller than myself. I may be permitted, for the sake of better explanation, to now assume any one of the legs of this tripod to be called the front of the tent. This being so, of course the back would be the space subtended between the other two legs. Now, on the front leg, at the square part, just below the hinge, and consequently at a point just below the level of my waistband, I had two small iron eyelets screwed at each side of this front leg, and there were two others screwed into the wood at the same height on each side of the two other legs. On to these were hooked two subtending light bars of wood, and, a third bar being hooked on between the ends of these at the back of the tent, the three legs of the tripod were thus firmly linked together. On the triangle thus formed I placed a table. This was made to roll up, composed of strips of light wood fixed on canvas, covered with india-rubber, rolling up just like those rolling-up chess-boards they make at Tunbridge Wells, with strips of wood glued on to canvas, the only difference being that the glue I used was india-rubber glue.

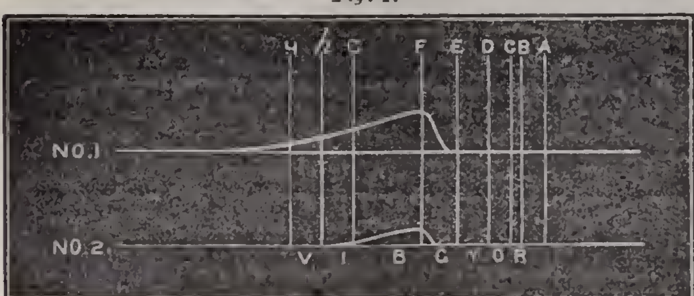
It hardly requires any further explanation to show how this table being unfolded formed a good strong platform resting on the triangle which bound the legs of the tripod together. In this table was a long hole cut in one of the strips, into which my vertical nitrate bath was sunk, the top of the bath projecting about two inches above the table, and when in place but not in use, it was kept covered with a cap of patent leather, to prevent any drops of developer or other liquid from entering it. On the table, in front of the bath, there was plenty of room for a levelling-stand and bottles of collodion, developers, nitrate of silver for darkening, fixing liquid, or what not. The tent was only covered down to the table. The cover was of cloth at the back and sides, but had a window composed of several layers of yellow calico in front. On the top of the apex of the cover was my ventilator, like a sleeve of a coat, about one foot or eighteen inches long. When at work, I kept this stuffed loosely with ferns, twigs with leaves on, or grass ; and as it was allowed to fall over like the peak of Phrygian cap, no light could enter by it, though air could circulate through it. I believe it to be impossible to work a wet process in a tent in a hot climate without such an appliance as this. At the back of my tent the cover was much gathered at the apex, so that it hung in thick loose folds, and when I was inside, these gathers left room for my head, which was not thus inconveniently pushed forward. The fulness of this back part of the tent-covering was such as just to allow room for my body standing in front of the table, and of being hooked to two hooks underneath the table, so that, when I was inside, no light could enter except through the window in front. I thus had a tent strong, fairly portable if made of light wood, light-tight but well ventilated, and not composed of too many complicated parts ; in fact, there were only practically six pieces—the tripod, which I never took to pieces—the table, and the three pieces for supporting it, and the covering. I may add that, as to this latter, it was covered with white linen over all, so as to heat to the least possible degree in the sun ; and that often in very hot weather I tied round it ferns or small branches with their leaves on, and sprinkled these with water to promote cooling by evaporation. With this tent I succeeded in making a large number of good photographs. No doubt with bamboo it could bo made much lighter and portable.

RELATIVE SPECTRUM SENSITIVENESS OF PRINTING PROCESSES, AND ON A NEW FORM OF SILVER PRINTING PROCESS.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

I propose to-night to speak on the relative spectrum sensitiveness of different printing processes, and then to introduce to your notice a modified silver-printing process. First, I propose to take carbon-printing, and to give the results of my spectrum analysis of it. In a book that I published on photography, I mentioned that when using the original "Autotype" actinometer, in which silver-chloride paper was used to discolour to a certain depth by exposure to light when placed alongside the carbon print, that in summer two standard tints were required, whilst in winter some five tints were necessary for the latter to be fully printed with a negative of ordinary density. I am aware that the effect of the spectrum on bichromate and gelatine has been studied; but, as far as I know, it has not been studied when the film was coloured. I have therefore thought it advisable to examine the question, as to the reason of this requisite shorter exposure in summer than in winter. Through the kindness of the Autotype Company, at the beginning of this year, I was supplied with various samples of tissue which I had intended to utilize for my Cantor lectures. Unfortunately, however, my lectures closed without my having the opportunity of discussing the question of carbon-printing; so I now venture to bring the subject before the Society. Becquerel and others gave the spectrum impressed on bichromate and gelatine as extending

Fig. 1.



Nos. 1, 2. Spectrum on Bichromate of Potash.

from beyond F to the ultra-violet ; but I must say I was not prepared for the fact that the maximum of sensitiveness lay beyond F, more towards the yellow. Such, however, is the case. You will see by No. 2 that, with a short exposure, the maximum lies beyond F. No. 1 is the curve for different-coloured carbon tissues, such as is supplied commercially by the Autotype Company ; and you will see that the spectrum impressed is a long one, and quite different to that impressed on the chloride of silver (No. 5). The maximum of intensity of the spectrum is in this last case between H and *h*, or at the borders of the violet and ultra-violet. It may be objected that the pigment used may have some effect on the sensitiveness ; but the example before you shows that it is not the case,—that it is the same exactly as in Nos. 1 and 2. The blue print on glass is ordinary gelatine which was impregnated with bichromate and then printed in the spectrum. The blue is merely dye with which the film was impregnated *after development*. From this we learn that no solid pigment, at all events, alters the position of the maximum of effect of the spectrum. I doubt also whether a dye as a dye will do it. We thus have a very good explanation of the reason of the greater sensitiveness of the bichromated film over the chloride film, since the proportion of green rays to violet and ultra-violet rays in daylight is much larger in winter than in summer. Carbon printing, however, is more rapid than silver printing in summer, and much more so, therefore, in winter ; it is therefore a gain at any time.

I next come to the newer mode of printing—viz., platinotype printing. It will be in the recollection of the Society that platinotype is based on the reduction of ferric oxalate to the state of ferrous oxalate. I have here a rough example of a gelatine plate impregnated with ferric oxalate ; it was submitted to the spectrum, and developed with potassium ferri-cyanide. It is somewhat difficult to fix the place of maximum sensitiveness when using the electric light, since near G we have carbon bands of intense brightness ; but I believe I shall not be wrong in taking the maximum one-third way from G towards F.

Fig. 2.

Nos. 3, 4. Spectrum on Ferric Oxalate.

It was a matter of curiosity to find out if the platinum salt used had any effect. The print I produce shows three separate spectra taken by sunlight with varying exposures. It is evident that the platinum salt has no bad effect. The maximum is situated about the place I indicated, and extends as far as where ferric oxalate alone is used. This is a matter of some interest, since the same reasons apply for the rapidity of its printing in winter, over silver chloride. Carbon printing, however, ought to have an advantage in winter over the platinotype, though not much.

I have now to bring to your notice a process which may not be new, but which, at any rate, has the form of novelty to most. It consists of printing on a film of gelatine emulsion containing silver chloride and an organic salt of silver. You may take gelatine chloride and print on it, and the image will at once appear, full of vigour and of great beauty ; but, when once an attempt is made to fix it, the image vanishes almost entirely, and, for printing purposes, unless the exposure is very prolonged indeed, is useless. In the old collodio-chloride process, introduced by the late Mr. Simpson, it will be in your recollection that citric acid is introduced in the presence of an excess of silver, and he expressly stated that its introduction was to give vigour. In fact, what is wanted is an organic compound of silver, be it albumenate or citrate, in order to give what is the foundation of vigour in all printing processes—an oxide of silver when exposed to light. Looking at it in this point of view, the old collodio-chloride process should in reality be called collodio-citrate or citro-collodio-chloride, but preferably Simpson-type.

With this object in view, I have made an emulsion of citrate of silver together with silver chloride. The method of preparation is as follows :—

1.—	Sodium chloride	40 grains
	Potassium citrate	40 ,,
	Water	1 ounce

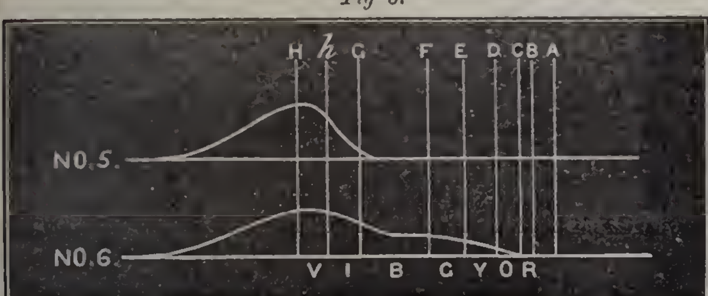
* Read before the Photographic Society of Great Britain.

2.—Silver nitrate	... ...	150 grains
Water	... ...	1 ounce
3.—Autotype gelatine	... ...	160 grains
Water	... ...	3½ ounces

Nos. 3 and 2 are mixed together, and then an emulsion formed by adding No. 1 in the usual way when forming a gelatine emulsion. When set, I squeeze the emulsion through canvas into cold water, and, after allowing it to remain in the water for ten minutes or a quarter of an hour, dissolve it up, with the addition of about 3 drachms of alcohol and 2 grains of chrome alum dissolved in 2 drachms of water. Plates or paper are then coated with the emulsion, and printing takes place in the usual manner. The rapidity of printing is very great; I think I may say that it is more than twice as rapid as ordinary albumenized paper. The image prints of a violet tint by reflected light, and of a rich chocolate colour by transmitted light. If fixed without toning, the colour of transmitted and reflected light is burnt sienna colour, and of great vigour and beauty. Prints can be toned by any of the ordinary toning baths. Borax and chloride of gold give a pleasing tone; the sulphocyanide toning bath gives a black rather approaching an inky tone. Platinum can be used to tone the fixed print, but it has a great reducing action, and there is a tendency for the whites to become yellowed to a slight extent. For lantern slides or transparencies the untoned picture would not be at all disagreeable. No doubt endless variations in the organic salts used might be made, but the citrate has answered well with me.

I hope the members of this Society will try the process, and improve on it; I think it has a future before it if properly taken up. I need scarcely say that the prints should be well washed. I doubt, however, if they would fade in the same way that albumen prints are so prone to do, as the organic salt used is a definite compound, and not one which is so complex and uncertain as the albuminate of silver is. I have in my possession prints made by Simpson-type more than thirteen years ago, and they are as fresh as the first day on which they were printed: not one has faded. The liability to fade is less with the above formula than with one which has an excess of silver present. The potassium citrate is in large excess; hence no silver will attack the gelatine. I ought to have mentioned that at first the emulsion may appear grainy; if, however, it be boiled for ten minutes, the grain disappears, for the silver citrate is soluble in warm water. The rapidity of printing by the boiling is certainly increased. The plates, when coated, are rather transparent, and *primâ facie*, a vigorous print might not be expected from them. As regards the light to which it is sensitive, I must refer to the spectrum No. 6, by which it will be seen that it is more sensitive to the blue and green rays than the chloride (No. 5).

Fig 3.



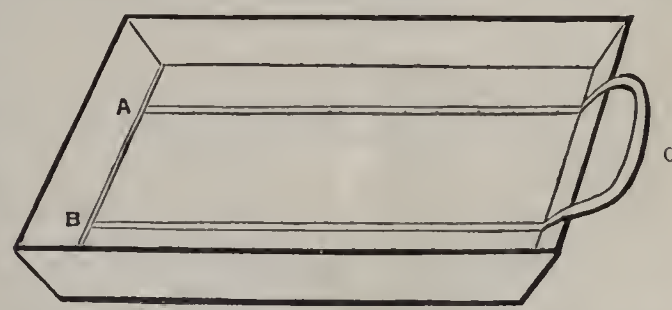
No. 5. Spectrum printed on Silver Chloride.
No. 6. Spectrum printed on a mixture of Silver Chloride and Silver Citrate

My last subject connected with printing is that of the discolouration of different sensitive salts by light. It has been assumed, I think, that a plate will not discolour so rapidly if chloride be absent as it would do if it were present. I hand for inspection plates containing a variety of mixtures, by which it will be seen that a plate containing nothing but bromide and iodide has, with me, discoloured as much as a plate containing iodide, chloride, and bromide; even equal parts of iodide and bromide discolour deeply to a fairly-deep green-black colour. Pure bromide, boiled and unboiled, takes but a slight colour; whilst both boiled and unboiled chloride take the same dirty-brown tone, which, however, as before stated, almost entirely disappears on fixing. Plate No. 1 is a mixture of bromide and chloride; No. 2, iodide and bromide; No. 3, chloride emulsion boiled; No. 4, chloride emulsion unboiled; No. 5, iodide, bromide, and chloride. I am not quite certain about the proportions. No. 6—one part of iodide to eight of bromide—is coloured quite as strongly as any chloride plate can be. No. 7 is one part of iodide to one part of bromide; No 8, bromide by itself; No. 9, one part iodide, one chloride, and eighteen bromide; No. 10, unboiled iodide with no bromide; No. 11, boiled bromide. I simply wish to bring these experiments under the notice of the members of the Society, so that they may not conclude hastily that, because they have got chloride in a plate, it blackens rapidly. It does, in fact, nothing of the kind, as iodide or bromide blackens quite as rapidly.

Correspondence.

A DEVELOPING DISH FOR PYROGALLIC SOLUTIONS.

SIR,—Seeing in the PHOTOGRAPHIC NEWS a great many complaints against the action of pyrogallic on the body, I enclose sketch of a developing dish by the use of which



the plate can be raised from the solution without contact with the fingers. A B C is a piece of wire hinged to the dish at A B, and rising from the dish in the form of a handle at C. By lifting the wire at C, the plate is of course raised from the solution, and can be examined at ease without touching it with the fingers. The dish should be of zinc or tin, and the wire of copper or galvanized iron. —Yours very truly, W. J. WILLIAMS.

DEVELOPING WITH SODA.

DEAR SIR,—A correspondent who signs himself "A. T." writes in your issue of the 12th inst. to draw attention to the fact that I have discovered a "new old" process of developing with soda instead of ammonia, and that I showed at a recent Thursday evening meeting a negative treated with this "new formula."

Before I saw this letter I was not aware that the words "new formula" were so much as uttered at the meeting. However, in looking back at the report given in your journal of the proceedings at the meeting in question, I find these words:—"Mr. Reimann showed a negative developed with the new formula, *i.e.*, using common soda instead of ammonia." This statement escaped my notice, as I seldom read the reports of our meeting, or I would have corrected it at once; as it is, the report is quite erroneous. The facts of the case are simply these. Seeing some time back that Captain Abney had suggested hyposulphite of soda in the developer in lieu of ammonia as a preventive of green fog, I tried it, and for some reason or other did not succeed as well as I should have done. I happened to mention the matter to Mr. A. L. Henderson, who advised me to try common soda, and developed a plate in my presence from a batch that gave green fog with ammonia, and under the influence of the soda no green fog made its appearance; he then suggested that I should repeat the experiment at home with different plates in order to confirm his results or otherwise. The negative I showed at the meeting was the result of that experiment, and showed that even with great under-exposure green fog was altogether avoided with the soda, whereas plates (commercial) from the same batch, developed with ammonia, gave a considerable quantity of it. All this was laid before the meeting, and a conversation took place on the subject; but never was it hinted on my part, nor was it understood by anyone present, that I had discovered and brought forward a "new formula" for developing.—Yours very truly, A. Reimann.

Proceedings of Societies.

Photographic Society of Great Britain.

The tenth technical meeting was held on Tuesday, April 25th, T. Sebastian Davis, F.C.S., Vice-President, in the chair.

Mr. G. L. Addenbrooke exhibited some paper negatives, taken by Dr. Ranking on Mongan's specially prepared paper, and stated that they were placed between two sheets of glass, and, he believed, were developed with ferrous oxalate. The sensitiveness was about one quarter that of commercial gelatine plates. They really seemed as sharp as negatives on glass; nor did the prints show grain. *Note.*—I have since ascertained that the alkaline process was used for development with the addition of sulphite of soda.

Captain Abney stated that, when in India, he had used the Callotype process, which was a most charming one, but he found that it was slow in developing. He was astonished to find that the prints from the paper negatives now exhibited were so free from texture.

The Chairman remarked that they approximated more to an ordinary wet collodion plate, and stated that in the old Callotype process he had used a frame which contained the damp paper, fastened upon pin-points. This, when dry, became tight, and, after exposure, was easily removed and developed.

Mr. Addenbrooke said that the paper used was thicker than that used for the Callotype process. He had, however, heard that Messrs. Morgan intended introducing a thinner and even more transparent paper, and that in these negatives there was an absence of blurring as compared with ordinary negatives taken on glass, though this would certainly have been even less had not a glass plate been used in front of the paper to keep it flat.

Mr. W. Bedford said that gelatine paper negatives would be liable to become spotted with the silver in printing unless they were coated with a suitable varnish.

The Chairman observed, in reference to the paper being placed at the back of a glass, that the rays of light were refracted, the angular rays became curved, and therefore any plan which did away with the glass in front would be better.

Mr. England said that the results shown tempted one to experiment in that direction, and that there was a great practical advantage in the use of paper negatives for sizes larger than 10 by 8. He suggested that ebonite would be better than the glass, to place at the back.

Mr. Cowan thought that this paper would be very good on Warnerke's roller slide.

The Chairman suggested whether blocks could not be made with this paper.

The Chairman then introduced the question, "What is the Ratio of the Light emitted by Warnerke's Phosphorescent Tables compared with the Standard Candle?" and said that in using Warnerke's sensitometer it was easy to test $4\frac{1}{4}$ and $3\frac{1}{4}$ plates; but for testing larger ones, or for giving several exposures on one plate, a modified form of holder and shutter should be constructed, the quarter-sized tablet still being used. In order to equalize the action of the light upon a silver-bromide gelatine film, emitted from a standard candle and a phosphorescent tablet, as usually used, an exposure in either case of thirty seconds' duration, he had varied the relative distances between candle and plate. Placing the light four inches in front of a white screen, he found the requisite distance approximately to be about nineteen and a-half inches, and considered the sensibility of differently prepared plates more correctly tested against ordinary daylight in this manner than by the illumination proceeding from a phosphorescent surface.

Captain Abney said that great precaution must be taken in shutting off reflected light.

Mr. Mawdsley said a good plan would be to make four exposures on one plate, and cut the plate with a diamond before development.

The Chairman said he had found, without reference to the light being compared with the tablet, that a film placed one yard from a candle, and one metre from the white screen placed behind it, and at right angles thereto, to be a convenient standard of sensibility for practical purposes.

Captain Abney said that his gas flame was of seven-candle power, and this gave the same number on the sensitometer, when placed six feet off the plate, as did a phosphorescent plate when used as in Warnerke's sensitometer.

Mr. W. Bedford said there would then be the direct rays of the candle in addition to the reflector. This might make 100 per cent. difference. Then, again, the reflector must always be the same size, if it is to serve as a standard.

The conversation then drifted into the use of the sensitometer, and testing before and after fixing, during which Mr. Mawdsley stated that it was most dangerous to take a gelatine plate into daylight before fixing, but, after being put into the alum bath, it might then be taken into a feeble white light.

The Chairman said that, in testing for sensitiveness, if twelve was the number arrived at after fixing, it would about correspond probably to fourteen before. Some of his own plates, though by no means so sensitive as some commercial plates he had recently tried, showed the figures more clearly defined, and the backgrounds in greater regularity of intensity, owing, he considered, to the introduction of silver chloride and free hydrochloric acid into the emulsion.

Captain Abney remarked that there were two ways of testing plates—by the numbers impressed, and by the range. Perhaps by the numbers was the most important. Some plates would show twenty-five numbers on the sensitometer, and many would be of the same density. Such plates were not so useful as when the ratio of density varied more.

Mr. England said he did not care to go beyond 12 or 10 for landscapes.

Captain Abney said that plates ought to be slow, if only fifteen or sixteen were arrived at; and that in his experiments good density would be the result when the plates went up to twenty-three.

Mr. Cadett observed that after twenty-three there was loss of density.

A conversation then arose about the subject of emulsion preparation, more especially respecting some made by Captain Abney, whose process had been seen and then tried by a member, but who did not arrive at such good results.

Captain Abney said that he introduced a minim of hydrochloric acid into an emulsion in the following way:—He mixed ten minims of acid with one hundred minims of water, and ten drops of this solution were introduced into seven ounces of emulsion according to his formula.

Mr. Cadett had observed that ammonio-nitrate plates were more transparent than those made by the boiling process, and stated that all plates, the more sensitive they were, the more transparent they were.

Manchester Photographic Society.

The usual monthly meeting of this Society was held at the Mechanics' Institution, on Thursday, May 11, Mr. Alfred Brothers, F.R.A.S., Vice-President, in the chair.

The minutes of the previous meeting were read and confirmed.

The Hon. Secretary exhibited a quarter-plate camera, styled the Instantograph, the camera being a most ingenious and well-contrived instrument, swing-back for horizontal and upright pictures, with a lens which the Hon. Secretary had tried and found to give excellent definition. Respecting the instantaneous shutter, which was admired by all for its simplicity, the Hon. Secretary said he had not had a fair opportunity to test it. He thought it might be improved by enlarging the aperture in the revolving disc, so as to give a longer exposure whilst actuated by the elastic spring. The lens could, of course, be worked without the instantaneous shutter. The dark slide was a good one, and the legs very light and portable. The Hon. Secretary then exhibited one of Mr. Alfred Pumphrey's filmograph and changing bag, also some film negatives sent by Mr. Pumphrey. He then exhibited the method of working the same, and many of the members were struck with the lightness and simplicity of the apparatus notwithstanding the excellent quality of the results produced.

Mr. Alfred Brothers then read a short paper entitled "Hyposulphite, or Thiosulphate of Soda."

Mr. Pollitt then contributed a paper entitled "Stray Thoughts touching our Recent Exhibitions" (see page 298).

Mr. Greatorex showed several negatives on commercial dry plates exhibiting small opaque spots, and in reply to enquiries as to the cause, various opinions were offered.

Mr. Charles Pearson exhibited negatives on plates possessing insensitive marks.

Mr. Blakeley brought a swing-front and shutter, which he had ingeniously contrived to fit his camera.

Mr. Alfred Knott exhibited several prints from negatives takenby Messrs. Marion's Academy cameras, viz., a small camera for one and a-quarter square plates. They were very fair results. Several of the members expressed their views of the camera from experience.

Photographs were shown by Messrs McKellen, Coote, Brier, Blakeley, Wade, and W. J. Chadwick, many or most being the results of the first out-door meeting of the season, which took place on Saturday, May 6th, when fourteen members enjoyed a very pleasant day at Liverpool and on the Cheshire coast.

The usual votes of thanks were passed, and the members adjourned, with the exception of out-door meetings, until September.

The second out-door meeting took place on Saturday last, May 20th, this time to Gawsworth, *via* Macclesfield. About seventeen members arrived, some by rail from Manchester, whilst others, being nearer, walked or drove, and Mr. Brier exhibited what could be done on a tricycle. The day was not so suitable as it might have been, owing to wind. The light was at its best, and exposures were confined to subjects in which wind was not so objectionable. A capital tea, and a drive home, concluded the out-door meeting. One hundred plates were exposed.

The out-door meetings committee, since making up the list of meetings, have concluded to postpone the Bolton Abbey meeting from June 10 to June 17, in consequence of the former date coming so soon after Whitsun week.

Thursday Evenings for Photographers.

At the meeting held on the 18th inst., the chair was occupied by Mr. C. G. Collins.

Mr. A. Haddon exhibited the negatives of the sun taken during the eclipse the day previous, the first being taken at 6·30 a.m., and the second when the eclipse was at its maximum. In the negatives the eclipse was very clearly defined, and, by the aid of a glass, sun spots were distinctly visible in the same position in both negatives. He also exhibited three other negatives of the sun which he had taken that day, in order to demonstrate that the spots were not due to any imperfections of the plates, and in these negatives the spots were also visible. The lens used was the front combination of an ordinary cabinet lens. He also showed the shutter used. This consisted of a diaphragm to be placed in the stop slot of the lens, leaving an opening about a quarter of an inch wide; across this a narrow slot, of about one-sixteenth of an inch in width, was pushed, giving a very rapid exposure, the duration of which he promised to measure, and communicate to the next meeting.

M. Brown handed round prints from negatives of the same phenomenon. In his case, the exposure was estimated at about the twenty-fifth part of a second.

Mr. Cowan passed round two negatives, one being taken with a baby lens, and the other with a wide-angle rectilinear, the same exposure being given in each case. The stops used were cut after the plan advocated by Mr. Debenham, and were equal to F. 16. There was no perceptible difference between the pictures, both showing the same amount of definition. He then proceeded to demonstrate the method of dry mounting. The print, having been starched immediately on removal from the washing water, is allowed to dry, and then trimmed. The mount is then well damped with a sponge, and the print, being adjusted, is rolled through an ordinary two-roller press. One great advantage claimed for this method is, that the prints, being put on the cards dry, do not shrink and cause the mounts to curl. The prints mounted by Mr. Cowan, although they had been toned and starched for eleven years, yet adhered so firmly to the mounts that an attempt to separate them immediately after they had been through the press, caused them to tear and draw the card.

The Chairman exhibited a portable camera-stand of the Alpenstock type; it was made of bamboo rods sliding one into another.

Mr. Henderson passed round two negatives on plates from the same emulsion, one of the interior of a church, which had received twelve and a-half minutes' exposure, and the other, a landscape, taken with a drop shutter. He then opened a very interesting discussion on the reversed action of light.

Mr. Cowan did not think that the reversed action sets in till the exposure has reached some thousand times the correct one, and he instanced a sensitometer made by Mr. Warnerke, each tint of which was double that next preceding it, and by this instrument it was found that no reversed action was apparent until the exposure had reached several thousands.

It was announced that a special meeting of the new Club would be held on the 8th prox. (to be advertised in due course for the purpose of forming rules, &c.

Bolton Photographic Society.

The monthly meeting was held at the baths, on Thursday evening, the 4th inst., Mr. A. Harwood in the chair.

It was resolved that out-door meetings be held at Dibchester, Rivington, Clitheroe, and Hebden Bridge, on the third Saturday in each month; and at Furness Abbey, Bolton Woods, Windermere, Kirkby, Lansdale, and Matlock, on the Wednesday preceding the third Saturday in the month.

Messrs. Charles Williams, James Kildesley, and Edward Nashworth were elected members of the Society.

Talk in the Studio.

South London Photographic Society.—The usual monthly meeting of the above Society will be held on Thursday next, June 1st, at the Society of Arts, Adelphi, at 8 o'clock, when Mr. W. Brooks will read a paper on "Practical Experiences with the Alkaline Developer for Gelatine Plates." Should time allow, the following, from the "Question Box," will also be discussed: "What is the best Formula for Toning Ready-sensitised Paper?" The President will present the medal to the sucessful competitor in connection with last year's Artistic Competition, and the Presentation Print for 1881 will be ready for distribution. Several members having failed to claim the Presentation Print for 1880, they will oblige by doing so as early as possible.

A Royal Photographer for Deal.—The number of first-class photographers who reside out of London is shortly to be augmented by the secession from the metropolis of Mr. William Mayland, of Regent Street. It is in respect to her provincial photographers that Great Britain differs from the Continent; there, all the principal studios are to be found in the capitals, while with us many ateliers in the first rank are to be met with "far from the madding crowd." Mr. H. P. Robinson of Tunbridge Wells, Mr. Jabez Hughes at Ryde, the Sarony Studio at Scarborough, and Mr. John Fergus at Largs, are instances in point; and now Mr. William Mayland goes to Deal. Mr. Mayland's careful and artistic work is well known to all visiters to the Pall Mall Exhibition, where he has in several years secured medals for his tasteful photographs, the fine enamel portraits of the young princes and princesses of Wales having gained him one of these distinctions. Success, therefore, is already assured to Mr. Mayland in his new home, and we may hope that a change of residence to the seaside, away from the noise and bustle of London, will restore him again to the fulness of his health, to secure which is the principal reason of his retirement from town.

Cantor Lectures.—On the occasion of the last of Mr. Comyns Carr's Cantor lectures on "Modern Book Illustrations," he described briefly, and in a popular fashion, some of the photo-mechanical processes which are now in general use. Mr. Carr maintained that there is a certain superiority possessed by the wood-block which cannot be obtained by any mechanical process; but at the same time he admitted the probability of results being ultimately obtained such as the most delicate wood-block cannot rival. The silver print he would not admit to a place amongst book illustrations at all, and carbon came in for rather more severe animadversion. During the lecture a number of specimens illustrating the various applications of photography to wood-engraving were shown.

Society of Arts.—On Thursday evening, May 25th, a paper on "Recent Passages of Zulu-Kafir History" will be read by Robert James Mann, M.D., F.R.C.S., F.R.G.S. The chair will be taken at eight o'clock. The paper will be illustrated by an exhibition of photographs, which will be shown by means of the oxy-hydric light.

A Costly Telescope.—The great equatorial telescope, ordered by the Austrian Government in 1875 for the new Observatory at Vienna, is now in course of transit to its destination by the American Foreign and European Express. This instrument has been constructed in Dublin by Mr. Howard Grubb; it weighs about 30 tons, and is valued at £3,000. The mechanical portions were finished in 1878, but owing to the difficulty of obtaining perfect discs of optical glasses of the size required (27 in.) it has only recently been completed ready for delivery.—*Globe.*

A Photographic Poser.—Sir Henry Wolff has raised a curious point in regard to photographic copyright. In his objections to the Fine Art Copyright Bill he observed that a Professional Beauty might have a favourite attitude in which she sat to one artist; and was she not, he inquired, to be allowed to sit in that attitude to another photographer? Of course in time she would not be able to sit at all, and then she would undoubtedly have a *standing grievance.*—*Funny Folks.*

The Doctor his own Photographer.—Attention is called by the *Philadelphia Medical News* to a recent invention by means of which photographs may be made by the medical man. "Medical men very frequently want photographs in cases of injury, deformity, tumours, &c., but the trouble and expense have been serious bars to obtaining them; and many patients, too, cannot go to the photographer. Drawings are even more expensive, and labour under the disadvantage of possible inexactness. Recently, however, the introduction of the 'dry plate' process has so simplified the method, avoided the former dangers, and reduced the expense, that any one of ordinary intelligence and means can now take all the photographs he wants at a moment's notice. At the Cincinnati meeting of the American Association for the Advancement of Science, last August, Mr. Walker, of Rochester, New York, showed a 'pocket camera,' which, according to Professor Lattimore, supplies every want of the inexperienced amateur. Its weight is only two pounds. 'Dry plate outfits are now to be had at a cost of 10 dollars and upward, which are excellent. Provided with one of these instruments, the doctor would always be prepared to photograph any case he desires, at his office or in the sick room. Our hospitals, especially, should be provided with such an outfit, so that cases and specimens could be photographed at any time, even by a resident. Our microscopists would also find it exceedingly useful to make permanent many a transient preparation not suitable for preservation.—*Brit. Med. Journal.*

The Pope on Photography.—Mr. John Eastham is good enough to send us the following translation of the epigram by his Holiness Pope Leo XIII. It was written, we are glad to hear, after some successful pictures had been secured by Mr. Eastham at the Vatican:—

Photographic Art.

Sparkling likeness! swift touch of the sun!
By a ray instantaneously, splendidly done;
Minutely and truly reflecting each grace—
Noble brow, beaming eye, and beauty of face.
What a triumph of skill, as wondrous as new;
E'en the rival of nature. Apelles ne'er drew
More beautiful picture, or portrait as true.

Rules of the Artistic Competition of the South London Photographic Society.—1. That the competition be yearly. 2. That each year the President shall announce four subjects for competition, two landscape and two figure. 3. That each picture intended for competition, bearing a private mark only, accompanied by an envelope bearing a similar mark outside, and containing proper name and address, must be sent on or before October 1st, addressed to the Secretary, South London Photographic Society, Society of Arts, Adelphi, London, W.C. 4. That the size of the pictures (landscape or figure) be 12 by 10, or under, and that each picture must be mounted on a card, size 18 by 14. 5. That three artists, not being photographers, be appointed to judge the pictures. 6. That a diploma or award shall be given for the best picture of each subject, and a special award for the best picture of the year. 7. That the envelopes bearing the marks of winning pictures only be opened, all others to be destroyed. 8. That the exhibits become the property of the Society.

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News*" *Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed* "*Union Bank, Photographic News Co. Account.*"

*** We cannot undertake to return rejected communications.

*** Pressure on our space compels us to postpone the Lesson this week, together with an interesting paper by Dr. Fol, and other matter.

Emulsion.—1. The ammonium and potassium salts are about equally good for the purpose, but the latter is perhaps easier to obtain in a state of purity than the former; while, when the ammonium is used, crystallization on the plates is less likely to occur should the washing have been insufficient. 2. A mixture of Nelson's opaque and Coignet's has given excellent results in our hands. 3. Generally from undue application of heat when the mixture is alkaline. 4, 5, 6, 7, 8. Follow the directions given in the Year-Book. 9. Each one is quite neutral to test paper.

R. L. T.—Five grains.

Amateur.—You will find full particulars on p. 199 of the Year-Book.

Collotyper.—1. No satisfactory work can be done until the roller has been prepared or seasoned by repeated treatments with lithographic varnish; the usual method being to work thin or middle varnish on the slab each day for a period extending over several weeks, the roller being scraped as clean as possible several times during this period. 2. The best way is to have it built up on an iron stock or spindle, this being first covered with a thin layer of ebonite, outside which there is a thickness of nearly an inch of red rubber of good quality. To make the roller truly cylindrical it is caused to revolve at a high rate of speed on the lathe, when it is turned by a sharp file held in the slide rest, the finish being given by friction with fine glass paper. 3. It consists essentially of oxide of iron. 4. Experiments in this direction have not been very successful up to the present time.

Sulphur.—The idea was suggested in the Photographic News rather over two years ago.

Beginner.—1. Doubtless the result of using dirty plates. 2. Under such circumstances every trace of silver would be precipitated, unless a very large proportion indeed were added. 3. Dilute with a mixture of about two parts of ether and one part of alcohol. 4. You may regard it as practically valueless, as it would cost much more to replace the broken glass than the instrument is worth.

Telephone.—A wire having three times the sectional area of that on the coils of the instrument will serve very well for the distance you mention; but you should take care to protect the wire against rain; or, at any rate, mount it on the usual undercut porcelain insulators.

J. P. Coombes.—1. It consists entirely of carbon, hydrogen, and oxygen, and if heated to redness in the air, it burns rapidly and completely. 2. Full details will shortly be published in the Photographic News.

Urgent.—You had better merely acknowledge the receipt of the letter in the first instance, after which you can consider the matter at your leisure.

Copyright.—The point is open to a little doubt; but in most cases your view of the case would be taken.

Samuel Jones.—We are told that the law on this point is so ill-defined and doubtful, that it is difficult to judge in what direction the decision of a court would tend.

K. T. L.—It is extremely likely that sulphide of silver would be slowly formed in such a case.

T. W.—Yes, please.

A. Gardner.—Not at all; his success came like the success of most others: (1), good fortune or opportunity, which you will; (2), good health, and consequently good spirits; (3), a moderate amount of talent and application.

Gallow.—We don't think so. We decidedly prefer citric acid to acetic acid for the purpose you mention.

Chloride.—Because of the acid that is present; most samples of chloride of gold contain traces of acid.

Poor Printer.—If, as you say, there is a good deal of chloride present, then a good deal of the nitrate of silver will be converted. If it is a thick paper, the amount of solution taken up *mechanically* will be great, and practically, therefore, the silver bath will be sooner exhausted. But the silver in this case should be recovered in washing or toning the prints. Add a little common salt to your first washing water. The stoutness of the paper, amount of chloride it contains, and also the thickness of the albumen film, must all enter into the calculation if you want to know how much silver bath is absorbed, so that a practical answer cannot be given.

Cliche.—1. You mean the ferri-cyanide of potassium. 2. Since it is patented, of course you cannot.

Wellbank.—If you send your full address to our Publishers, they will furnish the information sought.

Propertius.—See Lesson in last week's News; carbon tissue impregnated with glycerine will answer your purpose.

P. G. M.—"Bigelow's Album" is out of print; Robinson's "Pictorial Effect" may be had of our Publishers, price 2s. 8d. per post.

Norman May.—Some of them were on sale in the print shops of London a few months ago; but you had better write to Messrs. Trübner and Co.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1239.—*June* 2, 1882.

CONTENTS.

A NOVEL METHOD FOR THE INTENSIFICATION OF NEGATIVES.

The intensification of line-negatives is, notwithstanding the many excellent processes which have been devised, still a matter which frequently causes some considerable difficulty to the photo-lithographer. When the subject to be copied consists entirely of clear black lines on a white ground, it is quite easy to obtain a satisfactory negative, and intensification by almost any good process becomes easy; but the real difficulties step in when an attempt is made to obtain a negative of a subject in which fine discontinuous lines have to be reproduced side by side with bold and solid black strokes crossed closely together, as in such a case the fine lines almost invariably tend to become blocked up during the process of intensification. The usual proceeding in such a case is to expose fully, so as to secure the finest and faintest lines, and to take care neither to develop nor intensify so far as to block these with a deposit of silver; after which the negative is shaded on the back over those parts where the blackest lines are crowded and the intermediate white portions are greyish and ill-defined. This shading is generally performed with blacklead and a stump on a sheet of transparent paper stretched over the back of the glass, and this is repeated until it is found that the whole of the negative prints at about the same rate on a piece of photo-lithographic paper. Such a process is troublesome and takes a great deal of time, and the outcome is always a negative in which the available contrast is so feeble as to tax to the utmost the skill of the photo-lithographer in making his transfer.

A proceeding which bids fair to be of great practical value to the photo-lithographer in the reproduction of difficult subjects has recently been introduced by Schlegel. After the negative has been fixed and washed, it is coated with a thin layer of bichromated gelatine, and allowed to dry in the dark. When dry the plate is laid, face downwards, on a black cloth, and is then exposed to the action of light. Under these circumstances those portions of the film immediately under the transparent parts of the negative become insoluble, and lose the power of swelling in water. After a sufficient exposure has been given the negative is soaked in water, and a suitable pigment is rubbed on—say permanent white, or any other substance which is fairly opaque—and this naturally only adheres to those parts which have become adhesive by the absorbtion of water. The great value of this method rests, however, on the facilities which it offers for local intensification, as the pigment need only be applied to those parts most requiring intensification, or which would have been shaded in the case we assumed just now.

Schlegel's process possesses a considerable value for treating ordinary gradated negatives, and those who wish to modify the relative degrees of light and shade in various parts of the picture will appreciate the power placed in their hands by this method.

Our readers will at once recognize the fact that the process of intensification just described is founded on the same basis as the Anthrakotype process of Dr. Sobacchi, which was described in the Photographic News early during the past year. A gelatinous solution of the same strength (1 and 30) may be used in each case; but for the intensification of negatives by Schlegel's proceeding it is better to add the necessary proportion of potassium bichromate (say one-sixth part by weight of the gelatine employed), rather than render the films sensitive after they have dried.

It will be quite obvious that any of the ordinary dusting-on mixtures may be employed instead of the bichromated gelatine, but in such a case the plate must only be very gently breathed on, or merely exposed to a damp atmosphere before the application of the pigment, and it would be necessary to coat the intensified picture with collodion, and soak in water, in order to remove the soluble materials used in the preparation of the so-called "dusting-on solution."

THE RELATION BETWEEN EXPOSURE AND DENSITY OF IMAGE.

Not long ago we placed before our readers some particulars of practical improvements in the gelatino-bromide process which are the outcome of experimental investigations by Mr. Plener; and we now propose to enter briefly into some theoretical questions which have recently been studied by the gentleman in question.

The laws which govern the proportionate reduction of silver on the various parts of a gelatino-bromide dry plate have not hitherto been so much studied as one would expect, considering the importance of the subject; and M. Janssen's recent experiments on the measurement of the light of the heavenly bodies by a photographic method, as detailed on p. 194 of our present volume, may be regarded as opening a new field for photographic experimentalists. As our account of M. Janssen's experiments has been so recently placed before our readers, it is unnecessary to enter into detail on the present occasion; but the collateral bearing of the points raised by M. Janssen are tolerably extensive, as a rational and accurate system of photometry appears likely to grow out of a study of them.

Mr. Plener contributed an important article bearing on this subject in our issue of last week, and he shows that the laws formulated by M. Janssen are not sufficient to elucidate all the phenomena attending the production of deposits of metallic silver in the gelatino-bromide film. He concludes that if the deposits were proportional to the intensity of the light—time of exposure being, of course, constant—a slow plate ought to have a more extended scale of gradations than a rapid plate. Practical observation shows, however, that the reverse obtains, and this led to an examination of M. Janssen's reasoning, when Mr. Plener found that by supplementing Janssen's laws by a fresh consideration, it becomes possible to reconcile practice and theory as regards the point in question; the supplementary note being to the following effect. In the case of a slow plate the deposit gains in density to a disproportionate extent as the action of light has been more prolonged or of greater energy. In other words, rapid plates yield a deposit which does not increase in vigour in so quick a ratio as the intensity of the light, while the reduction on a slow plate is greater in relation to the light when the exposure is considerable than when it is very short. These considerations enable one to understand why, in some instances, degrees of gradation which are invisible to the eye become, by the exaggeration of contrasts, well marked on the photographic plate; but in other cases, as when rapid plates are concerned, the reverse holds good, while in actual practice the two tendencies often may partially balance each other, so that the strict proportion between the intensity of the light and the density of the deposit holds good; or at any rate, an approximate expression of the actual condition of affairs is obtained by the method of Janssen. To the production of such plates the efforts of photographic experimenters should now be directed, and the method indicated by Mr. Plener towards the conclusion of his article should lead us into the way of recognizing such plates, and when this can be satisfactorily and readily done their constant production will become only a question of careful attention to details.

SOME APPLIANCES FOR GELATINO-BROMIDE WORK.

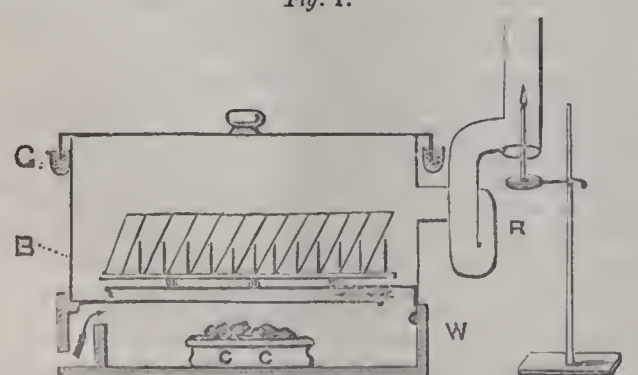
BY DR. HERMAN FOL.

A Drying Box for Gelatine Plates.

The first time I prepared my own gelatine plates, I borrowed two drying cupboards in order to dry them, but, after examining these rather cumbrous apparatus, each far too large to be put in my dark-room, I grew rather suspicious about their real darkness, and so began by putting a plate in each, and I left them to stand a few hours in broad daylight. After this I withdrew the plates with due precautions, and upon applying the developers found that both were considerably fogged.

My emulsion was ready, and seemed good; what was to be done? I had at hand a large zinc case with a lid of the same material, so I cut a long opening at one end of the bottom, and had another bottom soldered inside with an opening at the opposite end (see diagram). I then had a

Fig. 1.



B, zinc case; G, gutter filled with small shot; W, wooden tray; CC, calcium chloride vessel; R, Russian chimney.

so-called Russian chimney fastened on one of the sides, and fitted this with a gas-flame placed as shown, so that it might produce the necessary current of air. To make the cover fit air and light-tight was rather more difficult. This, however, I managed in the following manner. I had a rim soldered all round in the shape of a gutter, the edge of the lid sinking into the bottom of the gutter, and I then filled the latter with small shot, and thus obtained a most perfect closure. This box has been in use ever since, and, with the addition of a wooden tray and of an iron vessel full of calcium chloride, has done me very good service.

I should not have mentioned so insignificant a circumstance were it not that it led me to a method for shutting out light and air that seems to me to be new, and might be of service to some one or other of our confrères.

Washing Gelatine Emulsion.

I am much surprised, when reading photographic papers, to see what rough appliances are often recommended for performing delicate operations with the most fickle of all materials, viz., gelatino-bromide emulsions. None of us would use anything but porcelain vessels of suitable form for most domestic purposes, but as soon as photography is concerned, many are content with materials such as string, earthenware, canvas, and the like.

Now a good apparatus means saving of time, certainty in the operations, and the avoidance of endless annoyances. I have tried the different methods proposed for cutting up and washing my emulsions: forcing it through canvas, which is indeed a most disagreeable and unclean operation; cutting it up with a silver fork won't do, because the instrument tears rather than cuts.* I prefer a small roller with a number of sharp silver discs set up about a quarter an inch apart (Fig. 2), and all mounted by means of silvered

Fig. 2.

copper wire to a wooden handle. The discs are easily obtained by thinning out and sharpening small pieces of money. Having poured out the emulsion in a large porcelain tray, and let it set thoroughly, I pour clean water over it, and by rolling the above instrument to and fro, easily cut it up in long strips or ribbons.

For washing, I tried the washing-bottle system, but some pieces of emulsion stick to the bottom of the bottle,

Fig. 3.

and don't get washed at all, so I tried suspending it in a muslin bag in a vessel through which a stream of running water circulated. This is good, but very slow, and it is disagreeable to have to scrape the washed emulsion off the cloth, to which it adheres. Leading the water directly

* I have not tried forcing the emulsion through an iron grating, nor do I intend to do so, as the contact with metallic iron is too great an outrage to my sense of what is suitable.

into a canvas bag containing the emulsion is the worst of all methods, since the emulsion is apt to fill the pores of the cloth, and stop the flow of water, so that this frequently overflows, and causes other accidents. At last I procured a porcelain vessel pierced with numerous small holes—I might almost call it a porcelain basket. This I placed in a large stoneware jar with an arrangement for filling and emptying automatically with water (Fig. 3). The emulsion, cut up into ribbons, being placed in the porcelain basket, is easily and thoroughly washed without clogging the holes, since the water passes them alternately in opposite directions, and the operation of draining and collecting the emulsion is comparatively an easy matter.

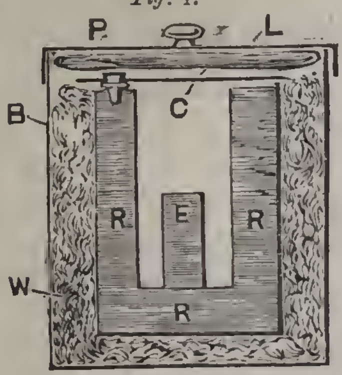
I find, by the way, that two parts of Simeon's Swiss gelatine, and one part of Nelson's No. 1, give a jelly that retains exactly its original volume, even after forty-eight hours' soaking in cold water. Simeon's gelatine alone under the same circumstances loses a part of its water, and contracts to a smaller volume.

My washing apparatus much resembles a common sponge-holder. Does not emulsion washing deserve a special vessel as well as the drying of a sponge? And if so, is it so very difficult to get a maker to alter the size and shape of his sponge-holders, and supply photographers with a most useful appliance?

Cooking Emulsions.

Some years ago I noticed in a Paris exhibition a most ingenious contrivance for cooking meat; it was termed a *cuisine Suédoise*. It consists of two vessels, fitting into one another and closing tightly; the space between the two being filled up with a non-conducting material such as wool or feathers (Fig. 4).* I had a similar apparatus made for

Fig. 4.



B, wooden box; L, lid to the same; W, space filled with wool; R, double-walled reservoir filled with warm water; C, cover to the same; P, pillow filled with eiderdown; E, emulsion.

my use; but with this difference, that the inner vessel had double walls and can be filled with warm water of a known temperature. When well closed, this temperature keeps unchanged for hours and days together. It proved a most efficient digesting apparatus. When I came to cook emulsions, I naturally used my Swedish kitchen, filling the reservoir with water of 70° C., and after a day and a half the cooking was completed with an ease and security quite unknown with any other contrivance. Seeing that many persons complain about the boilers actually in use, I venture to predict that my apparatus will shortly supersede them all.

* The meat or chicken thoroughly warmed on the fire is put into this inner space, and, after closing the lid, will be found perfectly cooked in a few hours, since the heat cannot escape.

By-the-Bye.

A UNIT OF LIGHT.

We have been accustomed so long to express the value of a light by comparison with the "standard candle," that it is very improbable we shall ever give up doing so, any more than engineers will desist speaking of engines in comparison with horse-power. Of the two measurements, that of horse-power is, perhaps, the more variable, for the discrepancies in candle-burning, large as they are, do not differ so widely as the observations in the power of horses. Watt was of opinion that the power of one horse was equal to raising 32,000 pounds one foot high in a minute; but a German engineer has placed it as low as 16,000 pounds, or just half the amount. Nowadays, as most people know, the nominal power of an engine in horses is not calculated upon the doings of any animal at all, but is based upon the effective pressure exerted by the steam against the piston. So in like manner, although we are not likely to give up measuring light by the standard sperm candle as a unit, we shall base that unit on some other data than that of a burning wick.

The standard sperm candle has long been doomed as a unit of light. Anyone who has given due attention to a burning candle knows hows how variable are its conditions of consumption. In the first place, since there is no single maker of the standard candle, no reliance can be placed upon its manufacture. It is made of spermaceti; but spermaceti is not a definite chemical substance. Spermaceti is a mixture of solid fatty ethers, containing a small quantity of oil. Again, standard candles are not made of spermaceti alone; manufacturers state that a proportion of beeswax must necessarily be added, and this amounts to from three to six per cent. Taken two standard candles of different dates or manufacture, their melting points rarely agree, a circumstance very natural, indeed, seeing that their constituents vary so much.

Again, the wick has a material influence in the burning of a candle—the number of its threads, the way it is plaited, and the treatment it receives prior to being put into the candle. But even were we to suppose that wax and wick are identical in two candles, it does not follow these would burn at an equal rate, giving out an equal quantity of light. A standard candle should burn away at the rate of about 120 grains per hour; but, as everybody knows, a certain consumption of material does not mean a certain light in candle-burning. The "cup" formed in the candle is of particular import, and so, too, is the way the wick bends over into this cup during the burning.

So unsatisfactory has been the standard candle in practice, much as it might be useful in theory as a convenient measurement, that for some time past steps have been taken to secure another unit. It is not only photographers who are interested in the measurement of light, but so important is it considered to the country to have a trustworthy standard, that the Government has given the subject attention. The Board of Trade, some time ago, nominated a committee of scientific men to address itself to the subject, this committee consisting of Professor Williamson, F.R.S., Dr. Odling, F.R.S., and Mr. Linsey.

These gentlemen are still engaged in experiment, and we have to wait another year, probably, before they make their final report on the subject; and whatever this may be, it is very certain that they will have no more to do with the standard candle as a practical measurement.

Indeed, from a preliminary memorandum this Phometric Committee has issued, we know that the members are at present inclined to employ a standard gas-burner instead of a candle. Obviously with a gas-burner there are many difficulties to contend with; but still the Committee appear to have surmounted these very satisfactorily. In the first place, the Committee does not suggest the employment of ordinary coal gas, but of a gas of a definite mixture, such as Mr. Vernon Harcourt has already recommended for taking photometric measurements. It is a mixture of petroleum vapour and air. Mr. Harcourt has taken the standard candle as his unit, and endeavoured to produce a light of about the same intensity with this air-gas, but which shall not vary like the burning candle. In a paper on the subject which he read before the British Association, Mr. Vernon Harcourt thus describes the arrangements for producing the light which the Committee contemplate adopting. "For the standard combustible I employ a mixture of air with that portion of American petroleum which, after repeated rectifications, distils at a temperature not exceeding 50° C.; this liquid consists almost entirely of pentane, the fifth number of the series of paraffins. The proportion which I propose to maintain is 576 volumes of air to one volume of pentane, measuring the liquid at, or near, 60° F., or, measuring both as gases, 20 of air to 7 of pentane." In the burner proposed to be used with the standard gas, the opening has a diameter of ¼ inch. The length of the brass tube, which the gas enters near its base, is 4 inches, its diameter is 1 inch, and the thickness of the disc which forms the mouth-piece is ⅛ inch. To this description we may add that the pressure of the gas is to be adjusted to give a flame 2½ inches high.

This, then, is the flame which the Committee, at the present moment, or, at any rate, a few months ago, had pretty well decided should be considered in the future to be a standard candle. Since then, however, electric lighting has become a household word with us, and the question arises whether a better and more unalterable standard of photometry could not be established by electricity.

Before the Electrical Exhibition at Paris closed, there was held—as most of our readers are aware—an electrical conference, at which some thoroughly good work was done. Electrical measurements had, before then, been in a very unsatisfactory state, and the Paris authorities, wisely taking advantage of the circumstance that so many electricians from all parts of Europe were present in their capital, decided forthwith to settle by an international conference the many moot points in existence. This was accomplished, and at the present moment we possess definite measures not only of the force of an electric current, but also of the amount that passes along a wire during a given time. Thus, to make a Swan lamp burn satisfactorily, we can say that it requires an amount of electricity equal to one ampère and a half per hour—we speak from memory only—exactly as one might say that an ordinary lamp required for its use a pint and a half of oil per hour. If the Swan lights were always the same as regards "resistance" they present to the electric current, and if, moreover, the carbon thread rendered incandescent were always of the same length, weight and diameter, then the amount of light produced by this ampère and a half should invariably be the same. Thus a standard of photometry would be at hand which should be easily under control.

Whether it would be possible to secure uniformity in these respects we do not know, but the difficulties in manufacture ought not to be insurmountable. To produce a carbon thread of a certain diameter is of course not very difficult, but the "resistance" it presents to an electric current is a matter not so readily under control. At the same time, the problem might easily be solved, we think, by simply choosing such carbon threads as indicate the required resistance, and employing these for the standard lamps. In our experiments with the Swan lamps, detailed in November last in these columns, we found the "resistance" of four lamps taken haphazard to be widely different. One of them gave a "resistance" equal to 67 ohms, another 59 ohms, a third 58 ohms, and a fourth 52 ohms, the result being, practically, that the first gave far less light than the fourth with the same amount of electricity. This indicates at once how necessary it would be, in the event of choosing an incandescent lamp for a standard, to see that the resistance of all standard lamps is the same.

Whether the air-gas flame or electricity is chosen, however, for measuring light in the future, it is very certain that we shall still reckon by standard candles. For this reason, it will be necessary to bear in mind that "standard candles," as we have shown, is only an arbitrary term, and no more to be regarded as a real measurement than horse-power applied to engines is to be taken to mean the power that a living horse is capable of exerting.

The "At Home" next week be "M. J. Ganz in the Rue de l'Ecuyer, Brussels"; the following "By-the-Bye" will be "A Plea for the Burette in Photographic Manipulations."

PHOTOGRAPHY IN AND OUT OF THE STUDIO

THE NEW COPYRIGHT ACT AND THE EXHIBITION OF SPECIMENS—A NEW PHOTOGRAPHIC SOCIETY—THE MEASUREMENT OF ACTINISM.

The New Copyright Act and the Exhibition of Specimens.—Though it is scarcely likely much will be done with the Copyright Bill this session, it would be well if the Photographic Society had something to say on the subject before the vacation begins. Clause 10 is one that affects the profession so keenly that, should it become law, it will lead not only to annoyance and inconvenience, but to positive injustice. The right to exhibit the photograph of a sitter is not one which the photographer can claim, nor does he ever seek to claim it. The practice of exhibiting specimens is coincident with the very commencement of the art as a means of livelihood, and no one who sits for his or her portrait can pretend to be ignorant of the fact that should this portrait prove to be a favourable example of the artist's process, he would like to exhibit it. But the barest hint on the subject expressing dislike to the exhibition is, as a rule, sufficient, and it would be difficult to point to a case where a photograph has been exhibited in opposition to the wishes of the sitter. Indeed, people generally feel flattered by the preference, and, practically, we believe that photographers exercise the greatest care in the selection of specimens so that tender susceptibilities shall not be wounded. But if clause 10 be read between the lines it will be seen that it is not so much the photographer as the photographic dealer who is aimed at—not that this is any consolation to the former. In a recent trial for libel the grievance which the prosecution most strongly commented upon was, that if your photograph became a commercial commodity and was exposed for sale, you had no remedy. We have no desire to enter into the motives which prompt a professional beauty to pass half her time in being photographed; but it is scarcely possible she can be so blind to her own celebrity as not to be aware of the risk she thereby runs of shop-window publicity. If so, has she not all the protection she desires in the honour of the photographer? An explicit statement that no use was to be made of the portraits would, we contend, be all-sufficient. It would be very interesting to know who are the thin-skinned people who require an Act of Parliament—and an Act of Parliament so monstrously stringent as this is—to shield them. Are they the actors and actresses, the poets, the novelists, the clergy, whose portraits are bought and sold by the thousand, who object? Can it be that the ladies of the ballet have suddenly evinced a desire to hide their faces? Or has Royalty determined to shed no more the light of its countenance on the loyal and gaping multitude? The general public, we are convinced, do not care a straw about the matter. It has never been made a crying shame on the part of Mrs. A. that her offspring formed the centre picture of a show case. Mr. B. has never considered that he was suffering a humiliation because his fine flowing beard made an effective picture for exhibition; and Miss C. is not altogether displeased when she is selected as "leading lady" in a similar capacity. The fact is, the power proposed to be given whereby a photographer's premises may be searched for copies of some particular photograph is oppressive and altogether unnecessary, and might, in the hands of a malicious person, be very easily abused. If there be any distinct grievance in the present practice of exhibiting specimens, photographers, we are certain, would be only too glad to remedy it; but until it can be shown that this grievance exists, the insertion of Clause 10 can only be regarded as an effort on the part of interested persons to inflict a blow on the photographic profession, for which there is not the slightest excuse. It is to be hoped the societies, and the Photographic Society in particular, will not allow the matter to be overlooked, as it is only by publicity and discussion that the real feeling of photographers can be elicited.

A New Photographic Society.—The cry is still they come. The existing societies not being able to find enough to talk about, it is, we presume, considered to be a favourable opportunity to form a new society. The proposed association has, however, features of its own, and as discussions, the reading of papers, and even meetings are not contemplated, the difficulty of finding matter for talk will not be felt. The principal objects of the Society appear to be stated in the first and second rules:—These are: That the purposes of the Society be for the circulation of prints, negatives, &c., for the advancement of the science and art of photography amongst its members, each of whom will be requested to send in one print of each quarter or half-plate he may take for insertion in a scrap-book, together with a few brief notes respecting its reproduction, kind of plate used, lens, exposure, light, locality, &c.; that a note-book be published to each scrap-book, in which members may jot down any useful hints or information, interesting experiences, &c., which may, if suitable, be compiled and published, each member receiving a copy. We gather that this Society is intended to take in the whole country, which is to be divided into districts, through each of which one scrap-book shall be circulated at a time when, having gone the round of members in that circuit, shall proceed to the next. The idea is certainly a novel one, but with good organization should prove perfectly practicable. Mr. F. C. Cowley, of 106, Western Road, Brighton, and Mr. W. B. Allion, of North Stuff's Infirmary, Hartshill, Stoke-upon-Trent, are the originators of the Society, and ask for suggestions on the subject.

The Measurement of Actinism.—The last annual report of Mr. Angus Smith, the Inspector under the Alkali Act, contains a series of experiments in relation to the measurement of actinism which will be found interesting to photographers. An important part of the duty of the Inspector is to determine the amount of vitiation which the air undergoes in consequence of the acid smoke emitted by certain factories, and as this vitiation naturally includes the effect which this smoke may have upon daylight, it was necessary to adopt some means to ascertain day by day the actinism of the light. The method employed was that of Dr. Albert R. Leeds, U.S., based on the amount of iodide of potassium decomposed by light in the presence of acid. The plan is stated to be extremely simple, the solution holding the iodide requiring only to be carefully measured, the amount of acid demanded carefully added, and the mixture stirred, and exposed to the light in a glass vessel, which, if at all covered, must not be filled so as to exclude the air. Mr. Angus Smith does not claim absolute accuracy for this method. He says: "One sees the great difference there is between the bright days of summer and the dark ones of winter; but it is also clear that the table is not perfect. The point of zero is reached frequently, and there is no doubt that there are many differences swallowed up in that one figure. There ought to be a gradation below this. To obtain such a result, it would be necessary to have more refined measures. These can be obtained by the same method, probably; but they have not yet been put in practice." The district selected for observations was Manchester, and the observations extended from May 1880 to July 1881. Two readings each day were taken, one of 2½ hours duration, extending from 9·30 a.m. to 12 p.m., and again until 3·30 p.m., the whole duration being six hours. It should be noted that the result has little relation to clear sunlight, the value of the total effective light being taken. The tables given are confessedly incomplete, and, as Mr. Smith remarks, "there is a great deal to do." Indeed, their full value can only be estimated by comparison with similar tables compiled in other districts, and this comparison Mr. Smith has not been able to establish. The observations are quite new, and no doubt they will be followed by similar ones elsewhere, and, as Mr. Smith remarks, "it would be interesting if many observers would take a similar trouble in towns and in country places." The general results are, however, as they stand, instructive. They show that in the first seven months of last year April was by far the brightest month, a total of 44·2 being placed to its credit. From the end of that month to the end of July there was a steady falling off to 25·4 against 55 for the July of the preceding year. December and January show the low total of 2·1, and November is 13·9, comparing very favourable with February, which only scored 6·8. The highest figure was reached in August, 1880, when 66·6 was recorded.

WHY AND HOW I PHOTOGRAPHED THE DERBY.

BY A. L. HENDERSON.

A few lines on the above subject may not be uninteresting to some of your readers. Having received a communication from a well-known fine art publisher, asking me to recommend someone who could or would take an instantaneous photograph of the Derby for an artist to paint from, I volunteered to do so myself, provided I got a properly arranged stand on which to place my camera. With the view of such a commission my first thoughts were, to prepare an emulsion sufficiently rapid, that no matter what light we might have on the Derby Day, I would get a picture fully exposed. The manner in which the said emulsion was made I append, should you think it of interest; suffice it to say that I have published the formula before, with a slight modification.

On the morning of the Derby I received a final reply to the effect that the artist could not get the stand for me. Nothing daunted, I determined to try on my own account, accompanied by my äerial friend Mr. Cobb, and several others. We made a rapid and pleasant journey to the Downs by rail, and although not a betting man, I could not resist the temptation of getting up a "sweep" by the way. I did not draw the winning number, yet I am still possessed of the stakes, no application having been made by the respective winners. Once at the Downs Station, the first thing was to moisten our throats and proceed to the course 'midst clouds of dust. My friend, never having seen a horse race or Derby course, will not attempt to describe his impressions; I may hear his ideas from his own lips in verse at some of our social gatherings. My next care was to ascertain which would be the best light and point of view. To get a panoramic picture, the middle of the Downs was undoubtedly the best. Here I engaged, for a major consideration, a four-wheeled van, over which boards were placed, I having previously inspected a site by climbing a ricketty ladder to the roof of a show caravan the ladder creaking under my weight making me somewhat nervous. My nerves got strung to the highest pitch at the top, when I heard the roof cracking under me, and not knowing but what I might drop through into perhaps a lion's cage. Descending at the request of the owner, I made my way further on, which proved little better. Leaving Mr. Cobb on the four-wheeler, I made my way to a refreshment stall. No! No! not for a legitimate purpose, but to ask the proprietor to allow me to get on the roof. His pert answer was, "No! I don't want you to come through on the top of me!" to which I replied that I would like to be possessed of all the gold that could be piled on the top over ten tons.

My next attempt was more successful. I enquired of a gate-keeper if he would allow me to enter the stand for a few minutes, and return me the amount (7s. 6d.) if I did not like the position. Having received a negative reply, I asked for the proprietor. I was informed that there were two, and he could not say when or where I could find them. Nevertheless I entered, got a top position, with my back to the wind, and a very good view of the grand stand and the race-course. My large frame, for once, was of use to me, as it kept the wind somewhat from the camera; yet during all the exposures, I had to hold my camera down behind, while a Scotch friend held the front leg of the stand.

I was very much afraid that, at the most important moment, some excited spectator would thrust his head in front of my lens, and eclipse the view. Here my Scotch friend's presence became a necessity, as I made him take up a position in front of my camera. By-the-bye, I may as well mention my friend's name: Mr. Dow, an old amateur, and who, I am informed, took a Daguerreotype portrait by electric light as far back as 1847). The camera I used is a 5 by 5, with six double slides, made for taking negatives for the lantern.

The lens, a Derogy-back, focus $5\frac{1}{4}$ inches, and rectilinear form $\frac{f}{11}$; a drop-shutter—opening of slit of shutter three-quarters of an inch—fixed on the front of the lens. I exposed in all twelve plates, and got eleven good negatives, the twelfth—an experimental plate—being very much over-exposed. I enclose you some proofs for inspection. In No. 1 you will perceive that the horses look more like ostriches, in consequense of the movement. This is not at all surprising, seeing that the horses run at from forty-five to fifty feet per second, and, as my drop-shutter worked at *about* one-tenth of a second, the movement must be at least five feet during exposure. No. 2 is the actual Derby finish, and to the shutter I added an elastic band to bring it down faster. I cannot say what the exposure was. Mr. Haddon, Royal Naval College, Greenwich, has kindly offered to test the speed, when, no doubt, the result will be published); but all the twelve horses are fairly sharp, and the wonder to me is that the Jockey Club should not photograph the finish of all races. No judge's eye can be so true as a photograph.

I am afraid I am wearying your readers. I will give something more photographic, viz., the formulæ.

I may say I do not believe in chemical fog in emulsion—*i.e.*, if there is a large excess of bromide used, and all the chemicals are pure.

No. 1.

Gelatine	20 grains
Water	1 ounce

I put into a 20-ounce jar, or larger, dissolve, and add—

Alcohol	$2\frac{1}{2}$ ounces
Ammonia (·880)	$\frac{1}{2}$ ounce

The ammonia and alcohol must be mixed before adding to the gelatine; then add—

Bromide of potassium	200 grains
Iodide of potassium	2 ,,

No. 2.

Nitrate of silver	200 grains
Water	$2\frac{1}{2}$ ounces

Both solutions must be warmed up to 120°. Add the silver to the gelatine and bromide, &c., in a fine stream, stirring all the time. Replace the jar in the hot water, and add of dry gelatine 6 drachms. As soon as the gelatine is all dissolved—say ten minutes' frequently stirring—add slowly, still stirring, alcohol 12 ounces, warmed to 90°. When the glass stirring-rod is taken out, it will be found that *no* emulsion is adhering to it, and yet no emulsion is felt at the bottom of the jar. The fact is that it is in a flocculent state of suspension. Remove the jar from the warm water, and substitute cold, and in a short time the alcohol may be poured off, and some cold water put on; the emulsion is then removed to wash. It will be found in a cake at the bottom of the jar, and if any difficulty should arise in removing it, a horn spoon is a useful implement.

I do not like breaking up the emulsion into too small pieces, as so much surface is exposed to the washing water, and a slimy deposit precipitated. I generally allow a small stream of water to play over the emulsion all night. I place the emulsion in a glass measure, pour in water till the bulk is 8 or 10 ounces.

Warm up and filter, when the emulsion is ready for use. It may not be generally known that the best preservative for emulsion I have tried is ammonia and alcohol mixed with the emulsion; 4 drachms of alcohol and 2 drops of strong ammonia will keep 10 ounces of emulsion a very long time. I have some by me that has been prepared for many months uncorked, and there are no signs of decomposition.

In conclusion, I must ask your readers, when trying the above formulæ, to use the utmost precautions as to light. I would suggest two thicknesses of ruby glass, two of yellow pot metal, a small paraffine lamp turned down almost half, and not to expose a plate within six feet of the light, and then not longer than necessary.

[Mr. Henderson's pictures are exceedingly interesting, and if they do not present quite so plain a representation of the race as Frith's "Derby Day," there is a life and reality about them which is unmistakable. The "crowd" is a wonderful picture, and so is the "finish," if only for the interest shown in the backs of the spectators. The horses and their jockeys are also well seen, but many of them appear to have past the post and done racing.—Ed. P.N.]

ROYAL CORNWALL POLYTECHNIC SOCIETY.

We have received the forty-ninth annual report of this Society (1881), and subjoin the section relating to photography.

Professional and Amateur.

The judges have great pleasure in congratulating the Society upon the success of this department—both as regards the high technical excellence displayed in most of the exhibits, and also in the great increase in the number of pictures in comparison with the past few years. And, again, the judges notice the rapid strides which the gelatine process has made during the past year, most of the present exhibits having been taken by this process.

Section I.—Professional.

The landscapes in this section are few in number. Mr. A. Hendrey takes the only award (second bronze medal) for a frame of charming little snow landscapes (No. 796), being beautifully rendered, and superior to anything of the kind we have ever seen, the generality of this kind of work being very hard.

Mr. J. Milman Brown contributes six pictures, which are somewhat dull and heavy, the best being "Osborne House."

Mr. John Bates Blow sends two frames. One, containing nine views, mostly of Newlyn, near Penzance, the subjects in themselves being most admirably treated, would have taken an award had it not been for the want of finish. In several are large dark spots, which might have been touched out in the negatives. Three of the prints show great artistic taste in the treatment of the fishermen's cottages and surroundings, and the groups of figures being well arranged. The other frame consists of a carbon enlargement of two dogs, which also possesses some good points from a photographic point of view.

Mr. W. G. Long forwards a frame of ships of the Royal Navy. These are good specimens of the different styles of naval architecture.

Mr. Reuben Mitchell sends two frames, "Elm Trees" (No. 815) being fairly good. "A Coast Scene" (No. 814) is an instantaneous view of the sea beach, which is not very interesting, compared with other instantaneous pictures in the exhibition.

Mr. J. G. Whaite again contributes this year four frames of charming instantaneous studies similar to those exhibited by him last year; but the fact of his having secured a medal in this section last year for the same class of picture debars him from taking a medal again. The judges, however highly commend his pictures.

Mr. C. R. Lenthall, of Reigate, sends four pictures—namely two interiors, which show clean and careful manipulation; the others are a landscape and a group, which are fairly good.

"Chester Cathedral" (interior) is a grand picture, forwarded by Mr. Silvester Parry, and is one of the finest photographs of its class ever exhibited. To this the judges have awarded their first silver medal. The same gentleman has two other pictures—one entitled "Canine Friendship," and the other "A Church, with River Scene," which possess good qualities.

No. 721—a frame of botanical studies, by Charles Henry Evans—would have been much improved if they had not been so black and cold in tone.

Mr. David Hedges contributes four frames—three being studies of animals—in his well-known style.

A very interesting collection of six instantaneous pictures is exhibited by Mr. Robert Harris (No. 772), taken on board the steamship *Arab* going full speed. To this series the judges have awarded a first bonze medal.

The Platinotype Company send a large collection of examples of printing by their process, one great charm being absolute permanency. The finest specimen is a frame of four "bas-reliefs."

Mr. W. Harrison exhibits a fine interior of "Antwerp Cathedral," which, in the opinion of the judges, would have been improved if it had been printed in silver instead of carbon, as they do not think the print exhibited does full justice to the negative.

In portraiture Messrs Byrne and Co., of Richmond, send some exceedingly fine examples of portraiture on china, which seem to have an elaborate finish. To these a first bronze medal has been awarded. The same firm also send some good examples of cabinet and promenade portraits.

Messrs. John Chaffin and Sons have been awarded a second silver medal for their excellent portrait study entitled, "The Signal," which is very artistically treated, and the composition well carried out. They also send several other pictures, notably "Going to School," "Annie's Birthday," "My Pet," &c.

Mr. Julius A. Kay sends "A Portrait" (No. 730), in the (so-called) Rembrandt style, of Mr. Perrini in character, which is well treated.

Messrs. E. Day and Sons forward six portrait studies of heads (vignettes), which are very soft and delicate.

Messrs. E. Denny and Co. exhibit six frames of small portrait studies. One is a coloured group, scarcely suitable for a photographic exhibition.

Mr. Arthur Debenham is again an exhibitor. His portrait studies are very fine. "Painting the Plaque," in the opinion of the judges, is the best. The one entitled "Summer" is also very good, representing a young lady with a lawn-tennis racket, and is easy and graceful in pose.

Messrs. W. T. Morgan and Co., of Greenwich, receive a first bronze medal for their enlarging process with argentic gelatino-bromide paper, the results exhibited being very fine indeed, and appearing to require but little working up.

Nos. 766-7, two portrait studies by J. T. Robinson, cabinet size—one entitled "Catchy-Catchy" (a little, laughing child in night-dress, which is very amusing); the other a portrait of a boy. Both these show great artistic taste on the part of the photographer.

The finest and one of the grandest composition pictures this year is exhibited by Mr. Gillard, of Gloucester, and is entitled "Reading to Granny" (No. 771)—a cottage interior, the figure of the old lady being admirable. In the opinion of the judges it is the most natural photograph of the kind they have ever seen, and they therefore award it a first silver medal. Another picture by the same artist, with some cattle crossing the stream, is very creditable.

Mr. Thomas Protheroe sends four frames of portraits, cabinets, &c., which are good, but with nothing special about them of interest.

Mr. F. Argall contributes six frames of portraits, some of which are very good.

Mr. F. A. Bridge sends a group of eighteen eminent musicians and composers who performed the "Toy Symphony." It is stated that this photograph was taken in an ordinary room. On the whole it is a very interesting photograph, and is highly commended.

SECTION II.—AMATEUR.

Mr. G. F. Williams sends one frame (No. 851) of instantaneous studies on Margate and Ramsgate sands. In the opinion of the judges these are the best and most perfect of examples of instantaneous photography they have ever seen, and they have awarded to them a first silver medal.

Mr. J. G. Horsey has been awarded a second bronze medal for four frames of photographs, some of which are perfect little gems.

Four frames by Cecil V. Shadbolt have been awarded a first bronze medal for their excellence of rendering and technical perfection.

Again this year Mr. T. M. Brownrigg contributes some of his well-known landscape studies, the smaller sizes being considered the best. The four larger ones are a trifle too soft. A little more force and brilliancy would have left nothing to be desired.

Mr. Andrew Pringle sends five pictures; but, in the opinion of the judges, they do not come up to his exhibits of 1879. At the same time his present contributions show great taste.

Mr. H. B. Berkeley sends nine small pictures printed in platinotype, which appear somewhat heavy. If printed in silver the results, upon the whole, would have been undoubtedly better.

Mr. W. J. A. Grant contributes two frames of views taken in Nova Zembla, which are full of interest.

Nos. 883-4, by R. N. Hormazdji, are two small studies, which are somewhat marred by being a little too heavily printed.

Mr. S. P. Jackson sends nine small studies—mostly on the River Thames—of boats and water in motion, which are clever and artistic.

SECTION III.—PHOTOGRAPHIC APPLIANCES.

No. 894, by Mr. Otto Mohr.—Improved lantern stand fitted with dissolving taps and valves. In the opinion of the judges this piece of apparatus has an amount of useless work about it in the way of screws, &c., the back pressure valves being very defective in construction, and perfectly useless for the purpose for which they are intended. No. 895, by the same contributor, is a piece of apparatus called "an improved oxygen-gas purifier." This is very elaborate, to say the most of it. The numerous screws, taps, &c., seem to make the simple method of washing the gas very complicated, which is not very desirable.

No. 896—an instantaneous shutter—is a clever contrivance by Messrs. Hunter and Sands, of London, and seems very effective. No. 897, a camera with swing back, contributed by the same firm, is a useful and portable contrivance; but several London makers besides the one in question adopt the same form of swing back. No. 898 is a frame of instantaneous pictures taken by the above shutter.

No. 899 is an instantaneous shutter by Mr. S. P. Jackson. This is the most simple and effective of its kind, and less likely to get out of order than many, and to it has been awarded a second silver medal.

Notes.

The Arctic yacht *Kara*, with Mr. W. J. A. Grant on board, sailed from the St. Katherine's Docks on Saturday.

Our "Photographic Studios of Europe" will be published this month.

A Society of Assistants has just been formed in Vienna, which already numbers a hundred members.

We are glad to hear that Mr. W. Brooks, of Reigate, has been elected on the General Committee of the Cornwall Polytechnic Society, in recognition of his services in promoting the yearly Photographic Exhibition of that body

We spoke the other day of Dr. Eder's new work on photography, which is likely to be the standard authority for many years to come, and one, therefore, that every experimentalist and photographic chemist must needs have upon his book-shelf. We hear Part II. is now published by Herr Knapp, of Halle, in Germany, and will be forwarded in return for a Post Office Order for half-a crown.

M. Janssen still leads the way in photo-astronomy. According to *Nature*, he has produced some magnificent photographs of the eclipse at Meudon, where his revolver was set into operation to determine the first and last contact. He seems to have employed the Daguerreotype method for some of his plates, this being the only photographic method that will yield trustworthy micrometric measurements.

M. Janssen, we are told, also took two series of photographs thirty-four inches in diameter, one negative, and the other positive, by direct exposure, with two large refractors. This is the first time that the whole photographic power of the Meudon Observatory has been set into operation. At the sitting of May 22 of the Academy of Sciences, M. Janssen presented the photographs of the last contact obtained with his revolver during the eclipse, on a Daguerreotype plate. He stated that the inspection of the several images proved the contact to have taken place at a later time than that calculated.

"It has been drawn especially by Mr. T. Scott, from a very excellent photograph," a contemporary told its readers last week in presenting them with a picture of Mr. George R. Sims. But Mr. T. Scott does not say who was the very excellent photographer; his name, evidently, was not worth mentioning.

Outdoor photography by means of the electric light is the last novelty. Liebrich, the New York photographer, has secured a stereoscopic picture of Perry's Monument, which is said to be in some respects as sharp and clear as a daylight picture. The electric light was 360 feet distant from the monument, and the exposure given was four hours.

In our account of the Arctic yacht *Kara* last week we mentioned that a chain of observatories was to be established around the Polar seas. A Swedish scientific exploring party left Stockholm yesterday, the first of June, for Spitzbergen, with a view to ascertain if an observing station could be established so far north as that inhospitable island.

At Messrs. Valentine's establishment at Dundee they adopt a very simple method of drying the many hundreds of prints that come out of the washing trough every morning. In a long apartment under the roof are upright supports, and these permit a series of wires to be stretched from one end of the room to the other. The wires are stretched three together in the same plane, about three inches apart, so as to constitute a shelf, when cardboard is laid upon the wires. The prints are brought up after draining, a sheet of blotting paper is put upon the card, and the prints then laid down to dry. The drying room is twenty-five feet long, and we counted seven treble-wire rows one below the other. As there is plenty of air, and it circulates freely between the open shelves, the operation of drying goes on apace.

M. Dumas, the perpetual president of the French Academy, has been instructed by the Minister of the Interior to make a return of all persons who have been killed or maimed in the pursuit of scientific research. It is the desire of the French Government to make some compensation for such casualties, which have hitherto been disregarded. Some time since we remember meeting M. Henri Pellet, whose blue-lined copying process is so well known, and sympathising with him on the loss of the fingers of one hand, which he had sustained through experiments with gun-cotton and nitro-glycerine. "I suppose you will give up explosives, now," was our remark. Our friend laughingly shook his head; "I have my other hand still," he cried, holding it up.

News comes to us from America that Mr. Eastman is manufacturing gelatine plates especially for the Tropics; on the other hand, as will be seen in another column, Major Waterhouse writes from Calcutta that he has no difficulty in working ordinary emulsion plates in India, provided a few simple precautions are taken.

Truth says this is a fact—an electric fact. An old couple went to the Crystal Palace; were charmed with the electric incandescent lights; asked the price, and found it moderate, the Swan lamps only costing 5s. each. Their means were limited, but the advantages seemed great, and they resolved to risk it, and invested in three or four Swan lamps. "Of course," said the intelligent clerk, who handed them the Swan circulars, "you know all about the engines and the different systems of producing electricity?" "Jist like these fellers, my dear," said the cautious old gentleman *sotto voce*, nudging his wife; "come along, Maria." He thought he was going to be wheedled into buying a lot more things by a pushing young tradesman, and so the two hurried off. They got home, and, taking a box of lucifers, applied match after match to the "filament," after removing the globe (a vacuum) with some difficulty. Still the thing would not light. At last, enraged, they appealed to the firm, and were—too late!—initiated one step further into the mysteries of electric lighting, which certainly seemed to them to be a case of "*lucus à non lucendo.*"

Some of our readers may be familiar with the simple plan adopted for hermetically closing certain parts of the continuous lime and cement furnaces. It is done by means of a sand-joint. Round the top of the kiln is an annular furrow or ditch, which is filled with sand; when, therefore, the cover is put on, its circular edge or rim fits deeply into the sand, and the kiln is closed. Dr. Fol, it will be seen, in his paper in another column, ingeniously makes use of this simple plan to close his drying closet, except that instead of sand he employs shot, which, being cleaner and more convenient, makes a capital substitute.

The conviction of Young for writing a threatening letter to the Queen rested entirely upon the identification of his handwriting. It is usual in such cases to call upon an expert to give evidence as to the similarity between the criminal document and the avowed handwriting of the prisoner, and in this instance M. Chabot was the witness. It is a pity the jury do not form their own conclusions, instead of listening to an outsider who, however skilful he may be, as a matter of course is always interested in proving what he has been called upon to prove. The only difficulty in identifying handwriting lies in the fact that the characteristic turns and twists in the letters are so small and insignificant; but this difficulty disappears at once if enlarged photographs are produced. Their cost would not be so great as the fees of an expert, and it would be much more satisfactory for the jury to draw their own inferences without the intervention of a witness.

When we visited the Police Detective Establishment in Paris, last year, we saw several interesting photographs of handwriting. The pictures had been used in securing convictions, enlarged photographs being so much more useful than the employment of a magnifier, for one juryman can then point out to another any characteristic resemblance without difficulty. Enlarged to four or five diameters of the original, the photograph shows formations in the letters which are otherwise only seen by the expert after much searching. In Paris, the enlargements we saw were sometimes mere initials upon a receipt stamp (these represented cases of embezzlement); but, limited as it was, handwriting thus placed under the fierce eye of the camera never failed to reveal truths which, without the aid of photography, would most likely have remained secret.

We saw a startling pose at Van Bosch's studio in Paris the other day. It was that of a youngster standing all alone at the very brink of a precipice. Of course, it was all "make believe," but still the picture drew a good deal of attention on the boulevards. The rock, with its sharply jutting shelf, stands in the studio about two feet high, and by placing behind it a cloud background with a low horizon, the effect of danger is at once produced.

The same ingenious effect is obtained by a masthead accessory we noticed at Liverpool in the studio of Messrs. Brown, Barnes, and Bell. By perching a youngster in sailor costume—very favorite apparel for boys now-a-days—upon it, and also using a clear background with low horizon, the same illusion of "giddy height" was the result. And yet the boy sits but a couple of feet from the floor when his portrait is taken.

Mr. Comyns Carr, who represents the high art school of engraving, can see but little to admire in anything photographic, and he considers that a mysterious something accompanies a wood-block, which photo-engravings or photo-type blocks cannot realise. If those who manufacture photo-mechanical blocks would have the courage to destroy all which are not first-class and do not truly represent the beauties of the original photograph, we are sure we should hear less about the inferiority of such work.

For some time past it has been customary to attach to embassies a military attaché, whose anomalous duty it is to make himself acquainted with any novelty introduced into the army of the State in which he resides; details of such improvement or modification he then transmits to his own Government. It has now occurred to Germany that perhaps information on matters connected with the peace and prosperity of a nation may be just as useful as news respecting warlike improvements, and so in the future there is to be a scientific attaché to the German embassy to this country. It will not be long, we may be sure, before other countries follow the same sensible course.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. XI.—Varnishing the Negative—Printing.

The photographer who has followed our instructions to the present point will so far have produced only means to an end; the end itself will be nowhere visible. He has made the materials for a picture, but the picture has still to be constructed from these materials. However delightful a negative may be to the photographer as containing infinite possibilities, it is to the common eye by no means a thing of beauty. Every shade is, as we explained, reversed; before a natural effect can be produced these shades must be re-reversed so as to represent those of nature. This is commonly done by resorting to the process of printing. This process consists in the placing in contact with the negative a sensitive film usually supported on paper, and allowing light to act on it through the negative—the effect being, as a little consideration will show, a reversal of all shades.

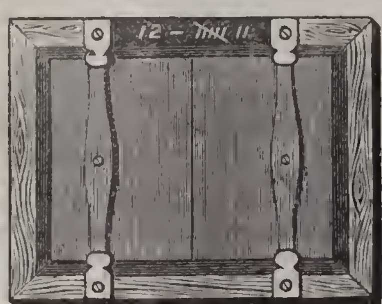
There are many printing processes, all of which may be studied with advantage by the amateur. Each one has certain advantages, and some are especially suited for certain purposes; but the process which, on the whole, has held its own against all others, and which for general purposes seems not likely to be soon superseded, is that known as "silver printing on albumenized paper." We propose to describe this, and to leave our readers to refer to more advanced or more special treatises for instructions in the various other processes.

"Ready sensitized" albumenized paper is now an article of commerce, and its convenience is so great that we should recommend its adoption by the beginner, and shall here describe the manipulation of such paper before we give instructions in the sensitizing of paper for immediate use. When the photographer has thoroughly mastered the process of printing, he will probably find that he can gain a higher degree of excellence by sensitizing his own paper; but certainly at first the contrary will be the case.

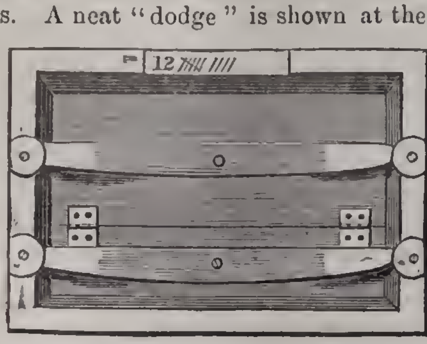
It is advisable to take a trial print from every negative before the process of varnishing is performed, and, in fact, if ready sensitized paper, which is always quite dry, be used, varnishing is not absolutely necessary. It is very advisable, however, and we shall describe the process before entering on the subject of printing.

After the negative is thoroughly washed and quite dry, take it by that corner which, were it a printed page, would be the left-hand bottom corner. Let it be warmed gently over a gas-burner till it feels just warm enough to be pleasant to the touch. If a gas-burner fixed above the level of the operator's head be used, a good criterion of the proper temperature is gained by watching the moisture which condenses on the plate from the water formed by the gas flame. When the moisture at first condensed is dispersed, and no more will condense on the plate, it is just at the right temperature. Let the plate be now held level by the corner mentioned between the finger and thumb of the left hand, whilst the varnish bottle is held in the right hand. Let a large pool of varnish be gently poured on to the centre of the plate. This pool should cover about half of the area of the plate. Let the plate be gently "tipped" so as to cause the varnish to flow first to one corner and then to another, beginning at that opposite to the one by which it is held. When the varnish comes round to the bottom right-hand corner, let the plate be tipped slowly up to a vertical position, so that all the excess of varnish may flow back into the bottle. The plate must be rocked from side to side during this part of the process to prevent the formation of crapey lines. When all the excess of varnish has flowed off, the plate must be again warmed—this time till it is about as hot as the hand can bear. When it is cold it is ready to be printed from. There is a vast difference between plates as to the ease with which the varnish will flow over them. The process is one which should in no case be performed over a choice carpet.

In printing with albumenized paper a printing frame is used. This apparatus is of various forms, but all these forms have the same object. They keep the paper in close contact with the negative, and are so constructed that one half of the print can be examined at any time, whilst the other is kept in contact with the negative to prevent it from slipping. In frames made at the present day the necessary pressure on the backs is gained by the use of springs. For small negatives, the frame is usually made exactly to fit the plate. In the case of large negatives—above whole-plate, for example—the frame is generally



made somewhat larger than the negative for which it is intended, and is fitted with plate glass, against which the negative is placed. The pressure of the springs would be liable to break a large negative were it not thus protected. In the case of large negatives it is also necessary to use a pad of felt between the paper and the back of the frame to ensure contact. We illustrate two of the forms of printing frames. A neat "dodge" is shown at the side of the



frame for registering the number of prints taken from any negative.

We shall suppose that our beginner has purchased a printing frame and a certain amount of ready sensitized paper. Let him cut the paper to about the size of the negative he has determined to print from. Now let him place a piece of the paper under the negative in the frame, and place the whole outside in a bright diffused light. It is not generally advisable to print in full sunlight. After the operation has gone on for a short time—say five or ten minutes—the result may be ascertained by taking the frame into a weak light on examining the print, one half at a time. The print must be made considerably darker than is required finally. The exact amount of depth that is lost in the after processes can only be learned by experience, but we may roughly say that it is necessary to print for about twice as long a time as that required to give a pleasing result in the frame.

When the desired number of proofs have been printed, the paper should be trimmed to the correct size. This is generally done with scissors, using "cutting moulds," or thin plates of glass, which can be had of any size. Many prefer to trim their plates after they have gone through the various processes of toning, fixing, and washing; but there are various advantages in trimming before toning. The clippings, if kept, become, when a large quantity has accumulated, of value; there is a saving of toning solutions, and the trimming is far easier to do before washing, as the paper lies flat; whereas, afterwards, it curls up in a way which makes it difficult to manipulate.

The following solutions should be prepared for toning:—

Chloride of gold	... ...	15 grains
Acetate of soda	... ...	1 ounce
Water	... ...	15 ounces

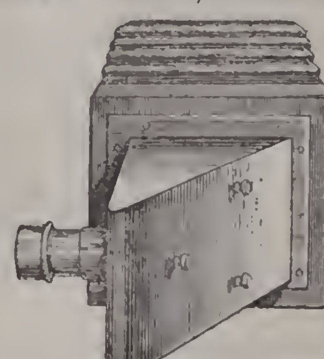
The chloride of gold is purchased in small sealed tubes holding fifteen or thirty grains each. One of these tubes is placed in a bottle capable of holding the whole solutions; when there it is broken by striking it with a glass rod, due care being taken not to break the bottle, which is quite possible. The acetate of soda is then added, and the water being poured in, the whole is shaken till the acetate dissolves. The solutions must be kept at least twenty-four hours before being used, and must not be exposed to a strong light. It should be labelled, "Toning solution, one grain to the ounce." The other solution which is required is one of three ounces of hyposulphite of soda to each pint of water, and should be labelled "Fixing solutions for prints."

NOTES ON REVERSED NEGATIVES AND SILVERING MIRRORS.

BY MAJOR WATERHOUSE B.S.C.,

Assistant Surveyor-General of India.

Reversed Negatives.—I have late been trying an arrangement made by Romain Talbot, of Berlin, for taking reversed negatives by means of a mirror placed behind the lens, instead of in front of it, as is usual, and find it answers very well indeed. It consists of a circular mirror about three inches in diameter, mounted as shown in the



figure, and is made for use with lenses with an aperture up to about $2\frac{3}{4}$ inches. I have not tried it with lenses of anything like this aperture; but with a Ross' No. 9 symmetrical it gives good definition over a 10 by 8 plate.

Another rectangular mirror about 8 by 6, belonging to the office, when fitted behind the lens, was found to give better results than when it was in front of the same lens, and altogether this arrangement seems to be an improvement over the ordinary one. A smaller mirror can be used, and the silvered surface is better preserved from dust and other chances of injury. It also seems more correct in principle, and less likely to cause loss of light and interference with the working power of the lens, that it should do its work before the rays are reflected, instead of afterwards.

I hope soon to make some comparative trials with negatives taken under similar conditions in both positions of the mirror, so as to ascertain more exactly the advantages of the new method.

Gelatine dry plates seem convenient for taking reversed negatives through the glass on the wrong side of the film; but the glass must be of better quality, and more free from blemishes, than that generally used by the makers of commercial plates; and the back of the plate must be quite clean and free from smears and patches of emulsion. There is no necessity for removing the spring of the dark-slide; a thickness or two of paper laid over the plate will effectually protect the gelatine surface from being rubbed or scratched.

While on the well-worn subject of gelatine dry plates, I may mention that I have been very agreeably surprised at the perfection at which the commercial manufacture of these plates has arrived, and the ease and comfort with which some kinds can be worked in the hot weather. We are now working with the thermometer inside a room generally in the nineties, and this even without the use of ice, though, as a matter of precaution, it is advisable always to use it for cooling down the washing waters in hot weather.

Silvering Mirrors.—Having recently to re-silver a reversing mirror, I thought that the formula given in Mr. Common's paper, "On Silvering Large Mirrors," published in the "Monthly Notices of the Royal Astronomical Society," vol. xlii., No. 2, for December, 1881, would probably be a good one, as he had used it for silvering a mirror thirty-seven inches in diameter; so I tried it, and found it exceedingly simple and efficient, more so than other methods I have used. It gives a fine strong coating of silver of good colour in about forty minutes.

Various silvering processes have been repeatedly published in the News and other journals, but a brief description of my successful experience with Mr. Common's formula may not be unwelcome to some who may be glad to know of a good method of performing this troublesome operation.

The solutions recommended by Mr. Common are three—

(1)	Nitrate of silver	1 ounce
	Distilled water	10 ounces
(2)	Caustic potash	1 ounce
	Distilled water	10 ounces
(3)	Glucose	½ ounce
	Distilled water	10 ounces

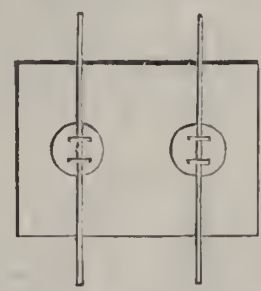
The above quantities are sufficient for 250 square inches, consequently an ordinary copying mirror 8 by 6 would require rather more than 2 ounces of each solution, and other sizes in proportion.

The caustic potash and distilled water must be quite pure. Ordinary caustic potash will not answer at all. The best to use is known as *pure by alcohol.*

The glass surface to be silvered is carefully cleaned with strong nitric acid, applied, as recommended by Mr. Browning, with a Buckle's brush, then well washed in clean water, and after rinsing with distilled water laid, face downwards, in a dish of distilled water till wanted.

Before cleaning the glass it will be necessary to arrange for supporting it face downwards in the depositing dish, so that the surface to be silvered may be quite horizontal, and just below the level of the fluid, which should be about half an inch above the bottom of the dish.

I have generally used a large cork, about four inches in diameter, cemented to the back of the plate, and fitted with three strings, by which it could be suspended in a level position and adjusted to any height by winding the string over a roller placed at a convenient height above the dish. As this arrangement was not available, I fixed on the back of the plate two ordinary wide-mouthed bottle corks of equal thickness in the positions shown in the figure, and to these corks attached thin slips of bamboo running transversely across the plate, and of sufficient length to rest on the sides of the dish, thus:—



The slips of bamboo gave the arrangement a certain amount of spring, by which the height of the plate could easily be regulated by putting on weights till the surface of the plate was just below the level of the fluid in the dish.

To prepare the silvering solution. A sufficient quantity of the silver solution No. 1 (2 ounces) is put into a perfectly clean glass. Ammonia is dropped in till the precipitate first formed is just re-dissolved. The same quantity of potash solution No. 2 as of silver is now mixed in, and the precipitate again dissolved by ammonia. A little more silver solution is then added to produce a distinct turbidity, and distilled water to make up the quantity necessary to fill the depositing dish to about three-eighths or half-an-inch, and the mixture is then filtered through cotton into another clean glass vessel.

The same quantity—two ounces—of filtered solution of glucose No. 3 as was taken of silver and potash is now mixed in, and the whole poured into a depositing-dish (which should preferably be of glass well cleaned with nitric acid).

The glass plate is then taken out of the distilled water, and laid face downwards on the silvering solution, being supported—as before described—just above the surface, so that the solution does not cover its back.

Mr. Common places the requisite quantity of distilled water in the dish, in which the mirror has been remaining face downwards, and then, having lifted the mirror up, pours in the undiluted silvering solution, together with the glucose solution, stirs well together, and then carefully lowers the mirror again into the dish.

Almost immediately after the immersion of the plate the silvering action begins, and, if things are going on well, a brilliant reflecting surface will be seen at the back of the plate; and in forty minutes, or even less, a good deposit of silver will be obtained. It is usually recommended to stop the action as soon as the silvering fluid appears clear and free from turbidity; but it is not always easy, I find, to see this.

After silvering, the plate is thoroughly well washed, finishing with distilled water, and dried off quickly. A slight cloudiness of the surface may appear, and must be removed by polishing before the mirror can be used. It is better to allow the mirror to remain a day or so before polishing, in order to harden the coating.

To polish the plate it should be slightly warmed, and perfectly dry, and rubbed very gently in small circles with a piece of very soft and dry chamois-leather, afterwards using a little jeweller's rouge.

Mirrors should always be kept in a dry place, and will require re-polishing from time to time.

It may be worth mentioning that, by mistake, the first time I tried Mr. Common's process, the potash solution was mixed at once with the silver solution, and the ammonia then added to dissolve the precipitate, followed by a little silver to produce turbidity. This did not seem to interfere much with the result, but the coating seemed to be rather brighter the second time, when Mr. Common's instructions were followed.

THE ENGLISH ECLIPSE EXPEDITION.

The eclipse is over, and the members of the different missions have arrived at Cairo on their return home, writes the *Times* correspondent from Cairo. They all seem satisfied with the result of their work, and it is probable that when their observations are properly discussed and reduced it will appear that this eclipse, although the shortest on record since the time that the value of eclipses has been properly recognized, has given us as great a harvest of fresh and important knowledge as was on former occasions secured during a much longer duration of totality.

It is difficult to give a description of the eclipse itself, and everybody who has had the good fortune to witness one will find that no description which he has read had in any way prepared him for the strange and exciting spectacle. In is indeed only when two or three eclipses have been witnessed that the phenomenon becomes sufficiently familiar to be completely enjoyed. Its distressing effect on animals has been often noticed, and it has always been found advisable to take strong measures for avoiding the intrusion of the easily excited population into the scientific observatories. Thanks to the efforts of Colonel Moktar Bey, aided by the local military authorities, soldiers were posted at intervals above the camp to prevent anyone who was not actually engaged in scientific work from approaching the observatories, and the cries which were heard during and immediately before totality proceeded from a crowd of spectators at a very respectable and safe distance.

The first contact took place a little over an hour before totality, and as the moon proceeded on her voyage across the solar disc, the air became cooler, and dark shadows were seen to cover the horizon. The observers, drawing each other's attention to the strange effects of illumination, involuntarily reduced their voice to a whisper. On went the moon, the darkness increased, a narrow strip of the sun only was left, and everybody silently withdrew to his post. A few minutes more and the corona shot out behind the dark edge of the moon, but a brilliant spark still showed that totality had not arrived, and that the last ray of the sun still found its way into our atmosphere. The spark is reduced in size; it has disappeared. The signal is given. The critical 70 seconds have arrived, during which every one is to do his work silently and steadily. There are moments, however, during which it requires a strong effort of the will to remain silent, and when, in addition to the corona for which everybody was prepared, a large brilliant comet was unexpectedly seen close to the sun, remarks were interchanged, and words passed which were not on the programme. Luckily, however, no serious disturbance took place, the totality was fully as long as was expected, and when the first ray of the sun had forced its way again over the edge of the retreating moon, all observers who could immediately judge of their results expressed themselves satisfied. It was some time before the photographic results were known, but they also proved satisfactory.

An approximate idea of the results which have been obtained cannot be easily given at present. The observations want reducing, comparing, discussing, and whatever is said at present may be subject to alteration or correction; but enough is known to show that all the trouble taken by the astronomers has not been wasted, and that all the kindness and hospitality shown by the Egyptians in the interests of science have been well rewarded. The French party consisted of Messrs. Trepied, Thollon, Puiseux. A great part of their work was done during the partial phase of the eclipse; the edge of the moon was carefully examined by them with two identical spectroscopes constructed by M. Thollon which unite great dispersion with good definition. Messrs. Trepied and Thollon express themselves with commendable caution as to their results; but there seems no doubt as to certain facts, and the only explanation which has at present occurred to them is the existence of the much discussed, often doubted, sometimes almost disproved, but always suspected, lunar atmosphere.

Professor Tacchini has also secured valuable observations of the spectrum of the corona. Little is known as to the results of M. Rauyard, who accompanied the French party. He confined himself to photography, and seems satisfied with the plates he has obtained. In the English camp, Mr. Lockyer, assisted by Mr. Lawrance, chiefly studied the uppermost layer in the solar surface, and he could utilize for this purpose several minutes before the total phase. His results are of importance, and in agreement with the phenomena predicted by him. Dr. Schuster, assisted by Mr. Woods, had charge of the photographic instrument. The plates used had been prepared by Captain Abney, who was, unfortunately, prevented from taking part in the expedition. As a sign of the great improvement which has taken place in the rapidity with which photographs can now be taken, it may be mentioned that when Mr. Brothers obtained an impression of the corona in 1870, during an eclipse which lasted over two minutes, it was considered a triumph of photography; while, during the present eclipse, a plate which was exposed for three seconds shows signs of over-exposure. The new comet appears distinctly on all the photographs. In addition, for the first time, a photographic record of the spectrum of the corona was obtained with a complete spectroscope. As some of Captain Abney's plates are sensitive in the red as well as in the blue, it may well be said that the day is close at hand, if not actually arrived, when every phenomenon seen during an eclipse can be photographed.

At a conference of the astronomers after the eclipse it was decided to give the new comet, discovered during totality, the name of the present Khedive, in recognition of the great help given by him to all observers. Three days after the eclipse the instruments were again in their cases, and only a few brick foundations remained as a memento of the important event which had brought astronomers from different parts of Europe to the village of Sohag, on the banks of the Nile.

ON THE EFFECT OF THE SPECTRUM ON THE HALOID SALTS OF SILVER, AND ON MIXTURES OF THE SAME.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

Three Parts of Iodide to One of Bromide.—When we take three equivalents of silver iodide to one of bromide the curves are somewhat modified. When washed paper prepared with the above proportions is allowed to print in the spectrum, we have the curve shown in fig. 54. When exposed damp in the presence of silver nitrate or other inoganic sensitiser, we have almost a facsimile of the curve in fig. 47.

Washed paper developed with acid developer shows that the proportion of iodido is so large in comparison to the bromide that the sub-iodide is not all destroyed, and we get the maximum corresponding with the maximum of pure silver iodide, fig. 55. The same paper developed with ferrous citrate shows a slight dip near G, fig. 56. The difference in 55 and 56 is seemingly due to the fact that silver iodide has more attractive power for precipitating metallic silver than has the bromide (a fact which is well known), and that the bromide is more amenable to reduction than is the iodide.

Figs. 57 and 58 are well worthy of attention. They are the results of the exposure of the same plate for different lengths of time to the spectrum. It was prepared in the silver nitrate bath, and exposed in the presence of free silver nitrate. Taking fig. 57 alone, it might be supposed that we had a similar case to that which we have recently considered, since we find an extraordinarily (apparent) greater sensitiveness in the green than in the violet, and yet we have the image formed in the presence of an excess of silver nitrate, which would be against the theory I have promulgated. Fig. 58, however, clears up the discrepancy; the maximum is found to be at G, and in this case the dip in the curve of fig. 57 is caused by the reversing action alluded to.

Fig. 59 gives the curve obtained by the above mixture of three parts of iodide to one part of bromide; when emulsified in gelatine the bottom curve shows a short exposure.

One Part of Iodide and Three of Bromide.—We now come to a mixture of one part of silver iodide to three of bromide. I have not described the printed spectra, since they correspond nearly with figs. 47 and 48.

If we compare the curves in figs. 60 and 57 we see a strange similarity between them; but if we take into consideration fig. 61, which is that due to a short exposure on the same plate, we shall

* Continue from page 295.

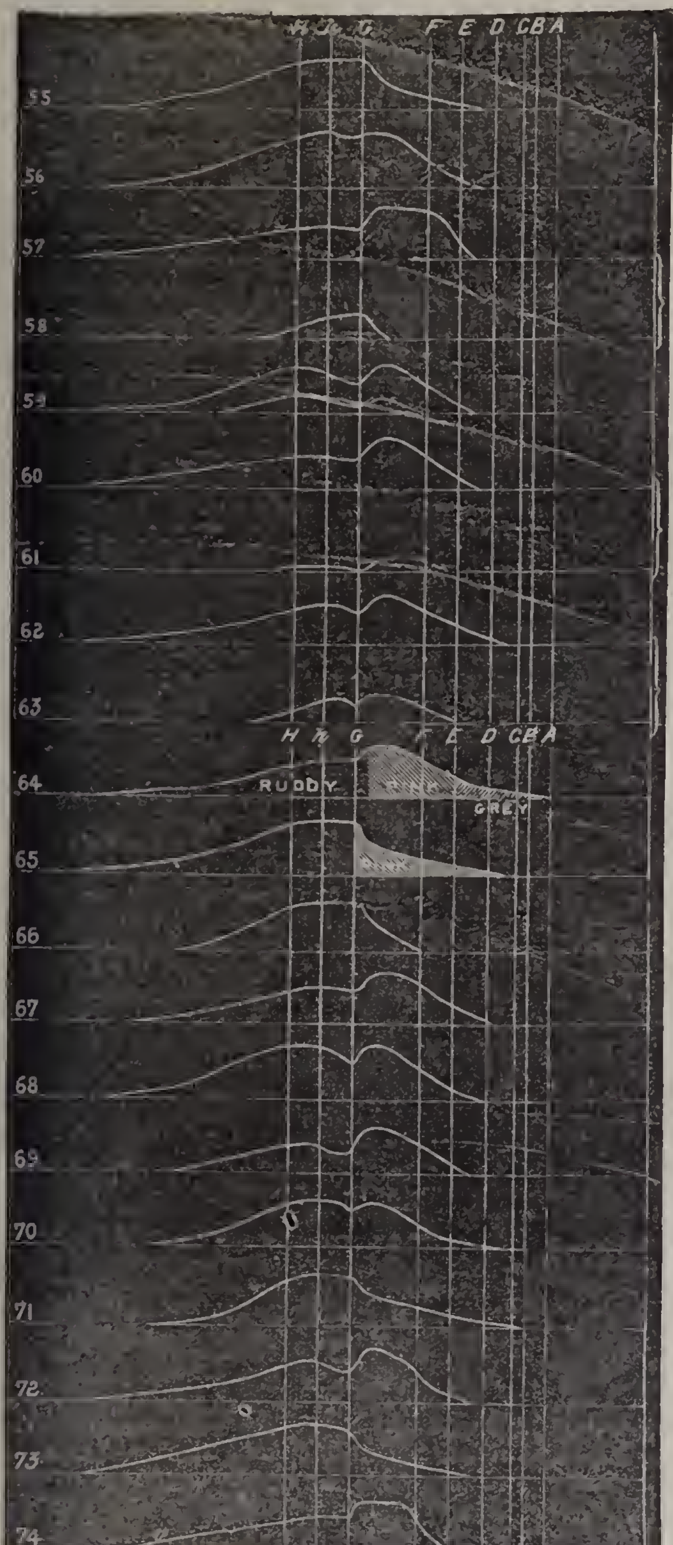
at once see that the dips about G are due to two different causes; the dip in fig. 61 is caused by the formation of the new molecule. Figs. 60 and 61 are also the curves shown by paper prepared with the above equivalents of iodide and bromide, and also of the same in collodion when developed by an organic ferrous salt. When developed by acid development, the curve in the more refrangible region is a little more pronounced in character.

Figs. 62 and 63 show the same equivalents emulsified in gelatine and developed by ferrous oxalate.

The different equivalent proportions of bromide to iodide, it will be noticed, show themselves in the curves more particularly when a comparison is made between figs. 51, 59, and 62.

Mixture of Iodide and Chloride.

Three Equivalents of Iodide to One of Chloride.—When paper is prepared with three equivalents of silver iodide to one of chloride, and washed and dried, or if exposed in the presence of dried silver nitrate or dried potassium nitrate, we have the curve shown in



$3AgI+AgBr$ on Paper developed gallic acid... ...	*Developed.*
Ditto, developed ferrous citrate...	*Developed.*
$3AgI+AgBr+AgNO_3$ collodion, wet plate, acid or alkaline developer	*Developed* (long exposure).
Ditto ditto	(short exposure).
$3AgI+AgBr$ in gelatine alkaline, or ferrous oxalate developer	*Developed* (long and short exposure shown).
$AgI+3AgBr$ on paper or in collodion, ferrous citro-oxalate developer	*Developed.* (long exposure).
Ditto ditto	(short exposure).
$AgI+3AgBr$ in gelatine, ferrous oxalate developer	*Developed* (long exposure).
Ditto ditto	(short exposure).
$3AgI+AgCl+AgNO_3$ on paper, or ditto washed, both dry	*Print.*
$3AgI+AgCl+AgNO_3$, wet, or $3AgI+AgCl+KNO_2$ wet	*Print.*
$3AgI+AgCl+AgNO_3$, or $3AgI+AgCl+KNO_2$ on paper, developed with gallic acid or ferrous citro-oxalate	*Developed.*
Washed $3AgI+AgCl$ on paper, ferrous citro-oxalate developer	*Developed.*
$3AgI+AgCl$ in gelatine developed ferrous oxalate...	*Developed.*
$AgI+AgCl$ in gelatine developed ferrous oxalate ...	*Developed.*
$AgI+3AgCl$ paper, washed	*Print.*
$AgI+3AgCl+AgNO_3$ wet	*Print.*
$AgI+3AgCl$ in gelatine or on paper, developed with ferrous citro-oxalate or acid developer	*Developed*
$AgI+3AgCl+AgNO_3$ acid developer	*Developed.*
$AgBr$ exposed to light, treated with I, exposed to spectrum	*Print and also developed.*

fig. 64. If, on the other hand, we have the same paper exposed moist, with silver nitrate or potassium nitrite, we have the curve shown in fig. 65. The reasoning applied to the mixture of iodide and bromide applies with equal force here, the results being modified for the shift of maximum of the chloride which lies about ½ Hh. In fig. 64 the most refrangible part of the spectrum as far as G is ruddy, between G and F a pink colour, and beyond that grey. This difference in colour indicates (as it does in all other photographed spectra where different colours are impressed or developed) a difference of compound acted upon. According to our theory the molecule acted on beyond G in the violet and ultra-violet would be $Ag_2I_2+AgICl$, and between G and E $Ag_2ICl+Ag_2Cl_2$ alone. The grey here is probably due to the organic silver compound formed in the paper.

Fig. 66 shows the same equivalents if contained in paper or collodion, and when exposed to light in the presence of moist silver nitrate or other inorganic sensitiser, and developed by acid or ferrous citro-oxalate developer, the slight modification due to the former developer noted above still holding good. Fig. 67 shows the same paper or collodion emulsion washed and developed with ferrous citro-oxalate. Fig. 68 shows the same when emulsified in gelatine and developed with the same ferrous developer.

There is a difference in the curves obtained with collodion and gelatine, but not more than is explainable by the fact that the former is essentially porous, and the latter almost continuous.

One Equivalent of Iodide to Three of Chloride.—When three equivalents of silver chloride are taken with one of iodide, we have, on printing a washed paper, the curve shown in fig. 70; exposing the same paper moist in the presence of silver nitrate we have fig. 71; the reasoning given when the mixture of bromide and iodide was under consideration holds good. Figs. 72 and 73 show the same equivalents of sensitive salts held in paper, the former showing the action of development on washed salts, and the latter on the same exposed in the presence of moist silver nitrate.

Fig. 69 shows the effect of the spectrum on equal proportions of the iodide and chloride when emulsified in gelatine.

Paper and also collodion films containing silver chloride were blackened in the light and treated with a solution of iodine till the darkening was obliterated, washed, and then exposed, with or without sensitisers; we had nearly the same results on printing and on development as shown in fig. 74; hence it was thought useless to repeat the curve there shown. (The same applies to darkened bromide treated with iodine, exposed to the spectrum and developed.) This appears to be a confirmation of the view already propounded regarding the formation of a new molecule, in the case of the chloride and iodide, the new molecule taking the form of Ag_2ClI, as already indicated.

From these results we may observe that to obtain a compound sensitive to the green a mixture of iodide and bromide, or iodide and chloride, should be employed, the former in preference to the latter, since it is more sensitive. The same sensitiveness to daylight with the former in gelatine plates can be obtained as when using pure bromide alone, the sensitiveness being preserved by a shift of the maximum to the green.

Mixtures of Silver Chloride and Bromide.

There is nothing special calling for remark in a mixture of these two sensitive salts. The printed spectrum and the developed seem to be a combination of the spectra impressed on each individually, a slight prolongation towards the least refrangible end taking place.

Mixture of Silver Iodide, Bromide, and Chloride.

When these three salts are combined together we have spectra which are very similar to the spectra produced on iodide and chloride, or iodide and bromide, with a prolongation towards the red.

Concluding Remarks.

In a paper read, in 1880, before the Photographic Society of Great Britain, I recommended the addition of a small quantity of iodide to the bromide used in the preparation of gelatine emulsion. On carefully examining spectra photographed on such plates (having $\frac{1}{12}$ part of iodide to $1\frac{1}{2}$ of bromide) I find traces of the loss of sensitiveness about G. I stated also that addition of iodide diminished the sensitiveness of the bromide to the red rays; an examination of curves given for the mixtures of bromide and iodide of silver bears out my statement.

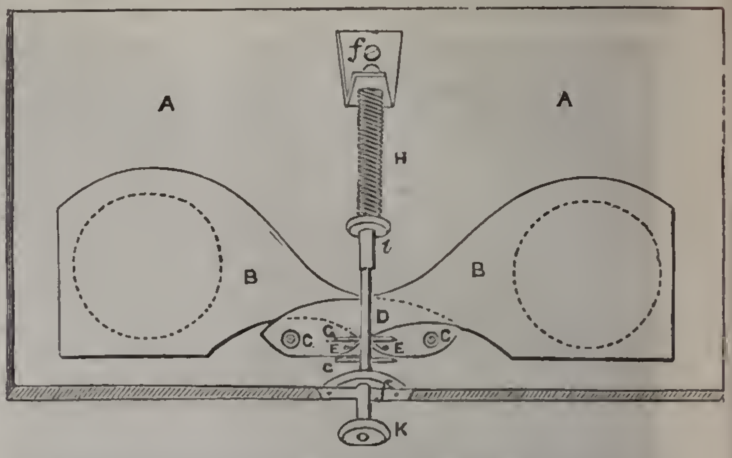
It will be noticed that I have not touched upon organic sensitisers of the haloids, prepared with an excess of silver and then washed, and such sensitiser applied. I have only treated of the haloids themselves, endeavouring to eliminate every extraneous effect which would modify the action of the spectrum.

REGULATOR SHUTTER FOR STEREOSCOPIC WORK.

BY P. H. PHILLIPS.*

In these days of rapid gelatine plates the necessity for some means of obtaining the minute and exact exposures required has led to the production of shutters, instantaneous and otherwise, truly bewildering in their number and variety. None, however, with which I am acquainted supply the want experienced in my own case, namely, a plan by which both halves of a stereoscopic plate could be exposed simultaneously, giving precisely the same exposure to each, and allowing any latitude desired in the duration of such exposure.

I consequently contrived and manufactured one for myself which I considered would fully meet the requirements of my own case. The following is a diagram and description of the shutter in question:—



A, base of wooden frame of shutter; B B, shutters made from thin sheet brass or ebonite; C C, screws acting as pivots for shutters; D, steel piston working up and down through bridges, *f f*; E E, two pins attached to shutters, working between the parallel bars, G G (which are in holes drilled through the piston), causing the shutters to rise and fall with the piston; H, cylindrical spring to aid in closing the shutter, the force of which may be regulated by raising or lowering the collet, *i*.

On lifting the piston, D, by means of the button, *k*, the lower bar, G, engages with the pins, E E, thereby raising the shutters clear of the lens aperture. The shutters fall by their own weight, assisted by the spring, H. A shallow box with the necessary apertures should be placed over the front of the shutter, to make the whole light-tight. By means of a small india-rubber bladder enclosed in a tube under the button, *k*, and inflated by a pneumatic syringe, the exposure may be regulated to any extent from about the fourth of a second to five minutes or more duration.

* A communication to the Liverpool Amateur Photographic Association.

Correspondence.

HOT-WEATHER TROUBLES.

Dear Sir,—I have, during the last nine months, made all my own plates, the formula being Dr. Eder's, as described in his book; and until three weeks ago everything went on successfully, when the plates frilled so much that it became impossible to develop them. Thinking a harder gelatine would prevent it, I used only Coignet's; but still they frilled. I then reduced the quantity of water, but the result was just the same. I then thought an emulsion which contained no ammonia might answer better. Accordingly, I tried the process described by Mr. W. K. Burton in his lecture at the Society of Arts, but with no better success. I prepared some plates one day by the latter process, in which six ounces of water were used instead of eight, and to which I also added two drops of a ten-grain solution of tannic acid in alcohol. This time I felt sure of succeeding, but, on developing next day, to my great disappointment, the defect still remained—the emulsion seemed perfect excepting this one grave fault.

The mode of drying the plates is exactly like that described by Mr. E. Phillips in the Year-Book for 1881. The weather down here is very warm, but I have experienced no difficulty in getting the plates to set: in fact, they set quite as hard as they did in winter. Is it the mode of drying? Do you think if I were to dispense with the lamp, and use sulphuric acid, the difficulty would be overcome? In trying Mr. Burton's process I used Nelson's No. 2 gelatine. Northumberland.

Proceedings of Societies.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held at the Free Library, on Thursday, the 25th ult., Mr. E. ROBERTS, President, in the chair.

The usual formal preliminaries having been transacted, Mr. T. Newall and Mr. J. Billington were elected members.

The CHAIRMAN then delivered an address upon instantaneous work, giving many useful hints and directions, especially for the photographing of animals.

A discussion took place as to the date and place of a proposed excursion. It was finally resolved, after many proposals had been discussed, to visit Storeton, near Bebington, on Saturday, the 10th of June, and Mr. B. J. Sayce kindly undertook the office of conductor on the occasion.

Mr. H. E. WOOD showed an "academy" camera and a small and portable stand made on Kennett's principle. The camera and changing-box excited a great deal of interest.

The HON. SECRETARY exhibited one of Lancaster's instantographs, with the new lens and instantaneous shutter. The apparatus was greatly commended for its combined lightness, portability, strength, and inexpensiveness. It was thought that the aperture of the shutter should be enlarged; but that in other respects the exposer was an exceedingly good one.

Mr. PHILIPS described a new and most ingenious shutter of his own make and invention, designed for two stereoscopic lenses (see page 318).

Mr. BOOTHROYD exhibited a fine enlargement of one of his negatives, made by Mr. Morgan.

Mr. SAYCE showed a print taken in mid-ocean on board the *Aconcagua*. The group could hardly have been more successful had it been taken in a studio.

The CHAIRMAN displayed a large number of excellent pictures of cattle, &c., in illustration of his address.

Mr. SAYCE having proposed a hearty vote of thanks to the Chairman for his valuable address, and for the interesting series of prints which accompanied it, the meeting adjourned to the last Thursday in June.

THURSDAY EVENINGS FOR PHOTOGRAPHERS.

AT the meeting held on the 25th ult., Mr. C. J. OLDHAM, of Graham's Town, Cape Colony, occupied the chair.

Mr. PRESTWICH exhibited a set of cutters for cutting the paper to the various sizes before printing. They consisted of steel frames, having knife edges, and were used in a hand-press, Mr. Prestwich stating that he was able by this means to cut from sixteen to twenty thicknesses of paper at one operation. The only drawback to their use was that the edges of the prints were liable to get ragged during toning, &c.

Mr. HADDON said he had measured the exposure given by the shutter he used to photograph the eclipse of the sun, and found it was between the 80th and 90th parts of a second.

Mr. BROWN passed round a solution made from a specimen of an article sold as Judson's *aurine*, which had been handed him by Mr. Debenham, but which, when examined by the spectroscope, was found to be perfectly unsafe as a dark-room medium, differing totally from any other sample he had tried. He also exhibited some plates coated with an emulsion made from a sample of Kennet's pellicle (some of the first made) handed to him by the Chairman at the last meeting. He found them rather slow and slightly fogged through the pellicle having been kept in the packet in an unsafe light.

Mr. HENDERSON passed round two negatives, both taken with a drop shutter under the same conditions, one by the Ampit and one by the boiling process; the Ampit was about six times as sensitive as the other.

The CHAIRMAN showed a model of a portable studio, made from designs by Mr. Cowan, which he intended to have constructed and take back to the Cape with him.

Several gentlemen then related their experience with Dr. Eder's new intensifying process as published in the NEWS of the 19th ult.

Mr. BROWN found it slow in action, and most dense in the yellow or first stage.

Mr. COLLINS had also used it successfully, he finding it very dense in the first stage.

Mr. HENDERSON exhibited a series of negatives taken at the Derby, one of the race being especially fine.

Mr. BROWN passed round a plate showing the reversed action of light.

Talk in the Studio.

MR. SAMUEL WALKER, OF REGENT STREET.—In speaking last week of Mr. Mayland's retirement from Regent Street, we should have mentioned that his valuable collection of negatives has been taken over by Mr. Walker. Mr. Walker, we believe, has for years past possessed an interest in the Houses of Convocation; at least, his fine series of portraits of the bishops and clergy might lead one so to suppose. Or, possibly, it is the new "Church and Stage Guild" with which he is connected, for a magnificent portrait of Mr. Irving, our *premier* actor, and another of Miss Ellen Terry, both emanating from Mr. Walker's studio, have recently found their way to our office. We have never given an "At Home" at Mr. Walker's for the simple reason that he is generally out, taking portraits "at home" on his own account; in fact, most of Mr. Walker's portraits are, we believe, not taken in a studio at all, but at the residence of the sitters themselves.

THE AUSTRALIAN CRICKET TEAM.—Messrs. Stilliard and Co., of Oxford, send us a series of portraits of the Australian team of cricketers. The pictures were secured on Wratten plates, and not a single film was spoiled in taking the series, says our correspondent. The series contains some very fine portraits, and none of them are anything but satisfactory.

THE PHOTOGRAPHIC CLUB.—At the last meeting Mr. White showed the old-fashioned "lamp without flame," in which a thin piece of platinum is kept incandescent by the slow combustion of alcohol vapour, and said that he had found it answer fairly well as a dark-room lantern. Mr. J. T. Taylor then made some remarks on the peculiarities of certain photographic lenses of American origin, and it was announced that at the next meeting he would exhibit several of the instruments, and describe them in detail.

THE ALEXANDRA PALACE.—On Monday last, several highly-successful photographs were taken in competition for the prizes offered, and the decision of the judges will shortly be given.

BICHROMATE OF POTASH DISEASE.—The corrosive action of the bichromates is well known, but the *Times* tells of other injurious influence. It says:—"It has been observed that the manufacture of bichromate of potash has a singular effect upon the nose, manifesting itself in a curious manner. A little hole is formed on the *septum* or partition of the nose dividing the nostrils, and increases gradually until the partition entirely disappears, with the exception of its lower part, so that to a superficial observer there is nothing the matter with the nose, except a little outward depression. It is noticed that as soon as the partition is destroyed the process appears to stop there, neither the lungs, air-tubes, nor throat being in the least degree affected. Some workmen at the chrome factory in Russia, where the disease has been chiefly watched, have been employed for ten years and remained unaffected, while with others the hole in the nose begins to be formed after one month's work. But that the disease is something more than an individual peculiarity is evident from the fact that an inspection of all the hands proved that more than 50 per cent. of the men had diseased noses. The early symptoms are a slight tickling of the part affected, followed by bleeding, but with no uncomfortable feelings, and, in fact, the destructive process is painless.

HANGING AT EXHIBITIONS.—A good many complaints have recently been made on the subject of hanging photographs at Pall Mall. But to judge from the following remarks in *Truth*, exhibitors at the Royal Academy have more reason to cry out. "Never was the grumbling at the hanging at the Royal Academy louder and deeper than it has been this year, and no wonder. No less than nine thousand contributions had to be inspected and the fate of each decided upon. Pictures and sculptures, &c., are sent in up to the end of March. The hanging committee sit for about five days to discriminate, and the rest of the month is devoted to hanging. This is at the rate of adjudication upon 1,800 works of art *per diem*. Say the working day is ten to six, with an hour for luncheon. This gives over two hundred and fifty-seven contributions to be inspected per hour, or less than fifteen seconds average for deciding the fate of what may be the making or marring of the struggling artist. Does anyone suppose that such cursory glances, even by experienced eyes, can fairly estimate the merits of the productions in competition?"

REMARKABLE EXAMPLE OF REFRACTION.—Herr Hakonsen-Hansen draws attention to a remarkable phenomenon due to refraction, observed by him at Trondhjem, on January 17, and similar in all respects to one witnessed by him at the same place on November 15, 1881. On both occasions, at 2.50 to

3 p.m. in the day, a rose-coloured stripe was seen to stretch across the sky from about north-west to east. From the middle of this rose a vertical column of a somewhat lighter red colour, and inclining on its western side to a shade of yellow, the whole being intensely luminous. After remaining visible for about ten minutes, the bright reds and yellows gradually faded away, leaving nothing but a blackish-grey streak across the heavens. The sudden and striking apparition of this vertical column recalled, as Herr Hansen observes, the descriptions given in past ages of bloody crosses seen in the heavens, and regarded as prophetic of coming wars and pestilence, and he remarks that if it had been seen at a later period of the day, it might have been taken to be a specially brilliant aurora.

Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed* "*Union Bank, Photographic News Co. Account.*"

*** We cannot undertake to return rejected communications.

Provincial.—There would be no difficulty in developing carbon prints on the articles in question, but the slight unevenness of surface would render it difficult to print by the ordinary methods.

T. E.—The best thing to do in such a case is to direct a letter of enquiry to the Inspector at the Police Station nearest ——— Street.

Bewildered.—Either you must have been misunderstood, or an attempt has been made to perpetrate a joke at your expense. The element carbon is said to be dimorphous, as it crystallises in two incompatible forms, the crystals of plumbago being six-sided tables belonging to the hexagonal system, while those of the diamond belong to the regular system, being derived from the cube. The peculiar crystalline carbon which has been found at Singbhom, near Calcutta, is neither diamond nor plumbago, and it may perhaps constitute a distinct form of carbon. Uncrytallised or amorphous diamond is of little value except as a cutting material when reduced to coarse powder; but the amorphous or non-crystalline plumbago is well adapted for the manufacture of the best pencils. The ordinary or crystallised plumbago yields a powder which consists of minute cleavage plates derived from the original tabular crystals, and it is of especial value in electrotyping, for protecting iron work, and as a lubricant. It is a curious circumstance that when carbon separates from a liquid it generally takes the form of plumbago, and not that of diamond. In the case of the recent artificial production of diamond, it is difficult to determine the exact conditions under which the deposition occurs.

Captain Turton.—You will experience no difficulty in removing it with a mixture of equal volumes of alcohol and ether.

Little Nemo.—We can trace two kinds of spot: one which looks as if due to the presence of hyposulphite in the mount, and the other appears to arise from contact with bronze powder. Try fresh mounts. Damp considerably expedites the mischief in either case.

X. Y. Z.—The cattle picture is the best of your series, and you had better submit this to a photographic publisher; but you will find it difficult to compete with the numerous excellent photographic scraps at present in the market.

A. M. M.—Your proportions are approximately correct, and we can only conclude that the negative was too much over-exposed.

Edward Ashby.—1. It should be grains, not minims. 2. We are under the impression that they have been advertised in the News. 3. In a few weeks.

Aqua Regia.—When in the form of wire it dissolves with remarkable slowness.

Novice.—1. Very much under-exposed. 2. A saturated solution. 3. Hardly sufficient to ensure perfectly equal resistance. 4. No.

Argent.—Although it is readily reduced under the circumstances, we would advise you not to attempt it as a working process.

Busy.—1. Under such circumstances the copyright of the picture should belong to the photographer. 2. Not unless a definite agreement was entered into at the time.

Erratum.—In Mr. A. Reimann's letter on "Developing with Soda," in our last, for "*hyposulphite* of soda," read "*hypophosphite* of soda."

T. E. G. G.—The description is quite correct; the bichromate serving to undo the work effected by exposure to light.

C. E. G.—Chrome alum is to be preferred.

Advertisements should be sent to Messrs. Piper & Carter, "Photographic News" *Office*, 5, *Castle Street, Holborn, E.C., not later than the 10th inst.*

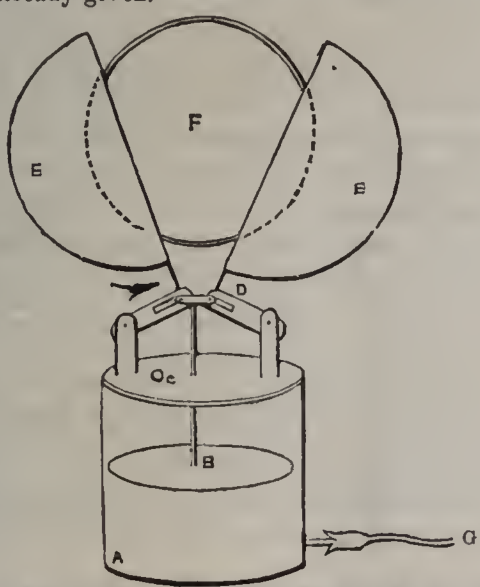
THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1240.—June 9, 1882.

CONTENTS.

MR. SPINKS' PNEUMATIC SHUTTER.

The novel and ingenious pneumatic shutter which we described on p. 194 of the present volume is the invention of Mr. Henry Spink, of Brighton, and we are now enabled to give our readers a sectional drawing of the working parts of the shutter as now found best in actual practice. No detailed explanation is necessary, a mere inspection being sufficient in the case of anyone who has followed the description already given.



Sectional diagram illustrative of Spink's pneumatic shutter; half open. A, cylinder; B, loose piston or plunger; C, hole in lid for escape or entry of air; D, cross head and crank action for moving flaps, E E; F, lens; G, flexible tube joined to pneumatic ball.

With regard to the practical working of the shutter, Mr. Spink writes as follows :—

Having been requested by the worthy Editor of the Photographic News to give some particulars regarding my shutter, I do so with pleasure, as I am confident it will be found a great help to any portraitist who tries it, especially as regards the attainment of what constitutes the greatest element of success in portraiture, viz., expression. Having been engaged daily for many years in the practice of photography, and often being obliged to deal rapidly with numerous sitters, I found the greatest causes of delay and failure were movements by the sitter from nervousness or ill ease. I therefore set to work to devise some means of making the exposure without the sitter knowing *exactly* when it was done, and, after many experiments, devised the simple little machine already described. It was first made many years ago so as to work with a string and balance weight. I afterwards, after trying electricity, adopted the air-ball, but the top arrangement, the idea of which was taken from a pair of scissors, remained the same. A very short description will render the arrangement clear to any one, and the apparatus can be readily made.

Suppose the shutter to be closed, a touch on the air-ball opens it, and all is ready for focusing. Another touch, and it closes ready for the exposure. Now you have a stiff and nervous sitter; face drawn, eyes rolling, convulsive twitching, and general uncertainty as to whether the hair cap, ribbons, coat, or tie, whatever it may be, is all right. The first thing I do is to show them their image in a small hand-mirror, and gently place the head in a suitable position, at the same time remarking pleasantly, "I should like you to look just like that; in fact, you look so well that any great change is likely to be for the worse. "This observation generally causes them to take pains to keep their position. I then make my little arrangement as to cuffs, chain, folds in dress or coat, &c., talking pleasantly all the time, which need not be many moments. I then step back and take a general view of the victim—the air-ball lies on the tail of the camera out of sight—so I then take an imaginary picture, perhaps two, saying, "Look here!" or "Look there!" in the meantime working myself towards the air-ball. When within reach—speaking slowly—I remark, "You have managed that very nicely indeed; I am much obliged." An easy and gratified expression steals over the face of the sitter. I go on slowly, saying, "But we will just try one more; I shall be ready in two seconds; many thanks to you for having so much patience to keep just so," &c. But before this time the real exposure is generally over. Again, in taking a dog, the shutter is very useful; any movement the dog can see makes him restless, as a dog generally watches the hand. I think it is because the hand feeds him, pats him, or thrashes him, as the case may be, and he looks after your hand: therefore, when you move your hand up to uncap, or if you open an outside shutter, the action causes him to move his head. In the case of my shutter, there is nothing he can see, and consequently a better chance of success.

In conclusion, I can only say that, being greatly indebted to many gentlemen of the profession for assistance in difficulties, and valuable information, I am only too happy if the shutter, or anything herein written, should be of any assistance to a generally painstaking and hard-working fraternity, in their endeavours to do good work and give satisfaction to that "many-headed monster," the public.

At Home.

M. J. GANZ IN THE RUE DE L'ECUYER, BRUSSELS.

Brussels may be said to be celebrated for two things; its dear hotels, and the absence of any great object to interest travellers. There is Waterloo in the vicinity, it is true; but the hot dusty fields require no little cool courage to face, and you must follow the advice of "the little marchioness," and pretend a good deal, if you are to realise the famous battle. The dear hotels are, of course, a relic of Waterloo—about the only genuine relic left, we suspect—and if the clean little capital is still to attract tourists, it will have to get rid of them; otherwise Paris, with its heavier metal and lighter cost, will draw off the visitors of the future.

We need not specify the name of our hotel, for an experience of several visits has shown them to be very much alike. But a quotation from the tariff "hung in every room" shows so well the relation between visitor and host, how the former must conform to this regulation and to that, under certain penalties, that we cannot refrain from alluding to it. The room might be a cell, and the visitor a convict, he could not be more in the power of the landlord when once he has unstrapped his portmanteau and taken possession of the quarters. As he walks uncomfortably up and down, he consults the tariff much as he would the prison rules. The price of this room is six francs a day, is the stern edict at the top; *but*, runs the first severe warning, if the traveller occupies it but one night, he will be charged eight. The charge exacted for your dinner, please to bear in mind, will be so much; *but* if you take it after prescribed hours, it will be so much more. The charge you will be mulcted for service is one franc; *but* if you do not take your meals regularly in the house, an impost will be made over and above this. What the amount of the penalty will be is not specified; no doubt it depends upon how you otherwise behave yourself, and whether the gold-capped porter below has other complaint to bring against you.

The Rue de l'Ecuyer is exactly like our Baker Street at home. It is narrow, crooked, and ill-paved, it is true, while Baker Street is a broad, straight, and even thoroughfare; but it contains an élite congregation of photographers. Here is the establishment of MM. Ghèmar frères; both brothers, alas! have gone to their long rest, but we remember forming one of a big group of volunteers sixteen years ago at the palace in Brussels, and being photographed by the firm, which then held the rank of court-photographers. Here, too, is Géruzet, one who has made a European reputation by the circumstance that he prints in permanent pigments, and in pigments alone. And here, too, is M. Ganz's noted little studio, which we have come to visit, and give some account of to our readers.

M. Ganz carries on his work very quietly. He would like to exhibit more specimens in the salon, only he cannot. He is perfectly satisfied with his *clientèle*, except in this respect: they refuse permission for their photographs to be exhibited. The aristocracy of small capitals is always more punctilious than that of larger ones, as anyone who has a knowledge of the little German dukedoms and their surroundings know very well. A princekin, let him be ever so microscopic, has a tremendous idea of his dignity, and his court ladies and gentlemen are naturally imbued with the same ideas. In Brussels there is to be found a good many representatives of *la vielle noblesse*, and from these, it seems, it is difficult to obtain permission to exhibit a photograph in the show-case, or even in the salon. Moreover, as the professional beauty does not occupy a place, as with us, among the upper ten, there is not even this source at the disposal of the photographer.

Boudoir and promenade pictures are in demand at M. Ganz's studio, and share with the cabinet equal favour. M. Ganz's work is especially soft and brilliant, and marked throughout with good taste. A fine picture of Listz, the famous composer and pianist, his soft white hair contrasting with his vigorous features, struck us particularly. M. Ganz studies a good deal from Meissonier's pictures, and in posing and grouping seeks to follow the example of this master of art. Our Brussels host, indeed, has courageously set himself the task of reproducing some of Meissonier's chef-d'œuvres, the French painter's "Brawlers" being here most faithfuly and successfully pourtrayed. The two combatants, one with drawn sword, and the other in the act of drawing, each held back by a group of friends, are wonderfully well set forth, and with a reality and truth that is astonishing; while the lighting, modelling, and posing represent very finished photography.

"In these group pictures," says M. Ganz, "I always find that the background employed appears too clear and prominent. To subdue this effect, and throw up the action of the picture, is therefore very necessary; to do this, thin tissue paper is put at the back of the negative, which is then stumped with graphite dust wherever this appears to be required."

We walk upstairs into the studio. It is a large, roomy apartment, with a lofty glass roof—"too lofty," our host assures us. There are two layers of curtains overhead, one above the other; the upper curtains, stretched immediately under the glass roof, are of blue linen, while six feet below is a horizontal curtain of brown holland. There is plenty of light at Brussels, but of course the two curtains are only employed in the height of summer. M. Ganz employs large backgrounds; those we see are not less than ten feet broad. He need not then change them so frequently, for two dissimilar pictures are at once produced by using different portions of the screen as background. He mounts the backgrounds on castors, so as to be able to move them without disturbing the sitter, and to slope them towards or away from the light as he may deem expedient.

Gelatine plates are in general use in the Ganz establishment, with oxalate development; but the silver bath has still a place on the premises, for it is employed for enlargements. M. Ganz agrees with Angerer in his process of producing enlargements, with one little exception, that, when it comes to making the carbon cliché, he makes use of red pigmented tissue, instead of black. M. Ganz takes from his negative an enlarged transparency upon a collodion plate, of the same size, in fact, as he desires his finished picture to be. He does a little retouching upon this collodion positive—but not very much—and then prints from it, in a pressure-frame, an impression in carbon, or, rather (as we have said), in red pigment. This is developed upon glass, and the huge reddish-brown negative thus obtained he again retouches. The red pigment seems to impart more vigour to the details in the shadows, which bid fair to be lost altogether in an enlargement if this is not very carefully handled. M. Ganz believes in maintaining his silver bath for these large transparencies at an equal and moderate temperature, and, for this reason, allows the bath to be lowered into a cupboard, the temperature of which may be regulated by the aid of a small Bunsen burner.

We ascend to the printing-room. M. Ganz employs albumenized paper with a slight roseate hue. "But I find you cannot always depend upon it, and therefore I never accept a supply without first practically testing the paper. Many samples, after toning and fixing, are apt to assume a yellowish tinge."

The printing room deserves a few words of description, for it is very practical and convenient. Imagine a square turret-shaped room; the interior is not very light, so that in the middle of the room the printing frames may be opened, and fresh paper substituted for the printed impressions. There are two large windows, or rather two openings, broad, but not high, in the room, facing different points of the compass, and here are the trays upon which the printing frames rest; in other words, there is a window facing north, and another east. The east window being much exposed to the sun, a light awning is used to protect the frames in glaring light. This awning is simply a light frame-work with tracing-paper stretched over it. As in most printing establishments, the trays may be pushed out, or drawn in, according to the nature of the light; but, besides this choice, the printer can make selection of the two aspects, for his negatives. While one window has light flooding into it, the other is in the shade, and hence delicate printinng can be conducted without difficulty. The printer has both batches of frames under his hands at the same time, and may, indeed, if he so chooses, change the printing of a negative at any moment. It is a question here, as in many high-class studios, not to get off a large number of prints during the day, but to print as carefully as possible, especially in the case of vignettes, to which too much attention cannot be given, and for this work the printing-room of M. Ganz appears especially fitted. Behind the printing room is another for sensitizing, toning, and washing the prints, but these present no point of interest.

The "By-the-Bye" next week will be "A Plea for the Burette in Photography"; the following "At Home" will be "M. Van Bosch on the Boulevard des Capucines, Paris."

STRAY NOTES ON DRY PLATES.

BY J. PLENER.

On a preceding occasion we arrived at the conclusion that in order to determine the quality of a given plate it is necessary to photograph upon it the scale of perceptible gradations. Now it remains to consider how such a scale may be constructed.

There are some theoretical considerations which we wish to point out as likely to be of help in practical solution of the question. Let us suppose that we got such a scale, the reflected light from the shades of which we designate by—

$$A_1, A_2, A_3, A_4 \ldots\ldots\ldots\ldots A_{n-1}, A_n,$$

where A_1 represents black, A_n white, and n the number of shades.

When we go through the psychological process of comparing two shades, we accomplish an action similar to that of dividing the reflected light from one shade by that of another. The physiologists express this thus: they say that our sensations vary as logarithms of the causes that produce them; for instance, the difference in the sensations produced by the reflected light from A_2 and A_1 will have for expression—

$$\log A_2 - \log A_1, \text{ or } \log \frac{A_2}{A_1}$$

Considering that we have a scale of equal differences between shades, the relations below must be equal too; thus—

$$\log\frac{A_2}{A_1} = \log\frac{A_3}{A_2} = \log\frac{A_4}{A_3} = \ldots\ldots \log\frac{A_{n-1}}{A_{n-2}} = \log\frac{A_n}{A_{n-1}}$$

Hence

$$\frac{A_2}{A_1} = \frac{A_3}{A_2} = \frac{A_4}{A_3} = \ldots\ldots\ldots \frac{A_{n-1}}{A_{n-2}} = \frac{A_n}{A_{n-1}}$$

If we take for unity the very small amount of light reflected from black A_1, and designate the relation

$$\frac{A_2}{A_1} \text{ by } \rho$$

then

$$A_2 = \rho,\ A_3 = A_2\rho = \rho^2,\ A_4 = A_3\rho = \rho^3 \ldots\ldots A_n = \rho^{n-1},$$

and the reflected light from each shade will be respectively

$$1, \rho, \rho^2, \rho^3, \rho^4 \ldots\ldots\ldots \rho^{n-2}, \rho^{n-1}.$$

Suppose, now, we have two powders, some white and some black, and want, by mixing them, to construct the scale of perceptible gradations. To begin with, we must find the relative value of the intensity of the reflected light from black, which we took for unity, and from white, which we will designate by W. To do this we must make the supposition that the reflected light from a mixture of two powders will be equal to the sum of the reflected lights of its component parts, thus designating by r the volume of black, by r_1 that of white, while the mixture will have the unity for volume; the reflected light from black will be r, from white r_1W, and from mixture $r+rW$.

Now we add to the black as much of white powder as to make the difference in colour perceptible. Let us designate by r the volume of added white powder to the unity of mixture's volume, then

$$\rho = 1 - r + rW.$$

$1-r$ represent here the reflected light from the black in the mixture.

Next we add in the same way black powder to the white, and let it be the volume r_1 of the former that produced the marked change in the white, consequently we receive another expression for

$$\rho = \frac{W}{W - r_1W + r_1}$$

hence

$$1 - r + rW = \frac{W}{W - r_1W + r_1};\ \text{or } (1 - r + rW)(W - r_1W + r_1) = W$$

Thus

$$W^2 + W\left(\frac{2rr_1 - r + r_1}{r - rr_1}\right) = -1,$$

and

$$W = -\frac{2rr_1 - r + r_1}{2(r - rr_1)} \pm \sqrt{\frac{(2rr_1 - r + r_1)^2}{4(r - rr_1)^2} - 1}$$

When the value of W is known, we calculate ρ from the formula $\rho = 1 - r + rW$.

To prepare the mixture for ρ^2 we must replace in the mixture for ρ a certain quantity of it by white powder; thus if we designate by χ this quantity, we have—

$$\frac{\rho - \rho\chi + \chi W}{\rho} = \rho;$$

hence

$$\chi = \frac{\rho^2 - \rho}{W - \rho}$$

For the number of shades we have the equation

$$\rho^{n-1} = W,$$

because of the last shade being white. From this we receive

$$(n-1)\log\rho = \log W;\ n = \frac{\log W}{\log\rho} + 1.$$

Besides the above method, the definition of the quality of the plate might be made with the aid of any sensitometer à cliché, provided the relation between the transmitted light by two contiguous divisions are of due value; but the construction of such a sensitometer might involve considerable difficulty. Let us at first consider the rules that govern the construction of a sensitometer à cliché, like Mr. Warnerke's.

If the thicknesses of the film in various divisions stand in the ratio of numbers

$$1, 2, 3, 4, 5 \ldots\ldots\ldots\ldots 24, 25,$$

then the transmitted light by each division will be respectively

$$i\lambda, i\lambda^2, i\lambda^3, i\lambda^4 \ldots\ldots\ldots\ldots i\lambda^{25}$$

when i is the standard light, and λ a fractional co-efficient variable with the nature of the film and with that of standard light. If we so arrange the sensitometer as to give for λ comparatively considerable value, then the scale will be long; should λ be made very small, then the scale will be very short. Now the question arises, what value must λ have, so as to give n gradations, supposing n to be the number of perceptible gradations between black and white?

Let us have a print on albumenized paper from Mr. Warnerke's sensitometer. If for the densest tint we have received N°m, then for the faintest we have $m+n_1$, where n_1 is the number of gradations. The sensitometer we want to construct would have m and $m+n$ respectively. But the densest and the faintest tints receiving the same amount of transmitted light in both prints, consequently we have two equations—

$$i_1\lambda_1^m = i\lambda^m;\ \text{and } i_1\lambda_1^{m+n_1} = i\lambda^{m+n}$$

hence

$$\log\lambda = \frac{n_1}{n}\log\lambda_1$$

Now, in Mr. Warnerke's sensitometer, n and λ_1 are known, and n being the number of perceptible gradations, the corresponding to it λ will be found from above.

But for our purpose it is not enough to know the value of λ; we must determine the quantity of Indian ink to be added to gelatine, so as to obtain a film having λ for its co-efficient. To be able to do this, we ought to find the exact relation between two variables, λ and the Indian ink in gelatine. This must be done by experiments. Theoretically, we will examine only one, and the most simplified case of the above problem, viz., if, instead of the quantity p of Indian ink, we add double quantity, $2p$ of it to the gelatine, will λ_1 of the new cliché, be > or < than λ^2 of the original cliché, provided we have made due correction for the different amount of gelatine in both films? It is evident that the amount of Indian ink will be the same in both films, corresponding to λ_1 and λ^2, with the only difference that in the second case it will be distributed in a film of double thickness. These two cases are quite identical with those of two gelatine plates, one dry and another soaked in water till swollen twice its original thickness. Hence their importance.

Now we have to examine the two above-named films, which we will designate as films λ_1 and λ^2. Let us consider a very small element on the surface of the film λ_1, so small that its thickness will be equal to the diameter of the particles of the carbon in the Indian ink. Suppose that before the amount of Indian ink was doubled, this element transmitted the quantity $\frac{l}{a}$ of light, where $a > l$. In this case the absorbed light will be equal to $l - \frac{l}{a}$. When we have doubled the amount of ink, the absorption will be doubled too, and the transmitted light will be equal to—

$$l - 2\left(l - \frac{l}{a}\right) = \frac{al - 2al + 2l}{a} = \frac{2l - al}{a}$$

while in the film λ_1 the light passes through one element, it must pass through two elements in the film λ_2, consequently the transmitted light in the latter case will be $\frac{l^2}{a^2}$. It remains to compare the two values—

$$\frac{2l - al}{a} = \frac{a(2l - al)}{a^2} = \frac{2al - a^2 l}{a^2} \text{ and } \frac{l^2}{a^2}$$

their relative value depends on the relation between

$$2la - la^2 = l(2a - a^2) \text{ and } l^2, \text{ or } 2a - a^2 \text{ and } l.$$

We said above that $a > l$, consequently we may put it thus—

$$a = l + \beta,$$

substituting this for a, and taking l, the standard light, as unity, we receive

$$2(l+\beta) - (l+\beta)_2 = 1 - \beta_2 < l = 1.$$

This shows that the transmitted light by the first element of λ_1 is smaller than that transmitted by two elements of λ^2. If we designate the first by i, and the second by i_1, the amount of light transmitted by the films λ_1 and λ^2 will be respectively—

$$i^m = \lambda_1 \text{ and } i_1{}^m = \lambda_2,$$

where m is the number of elements in the film λ_1. As we have found, $i < i_1$, consequently,

$$i^m < i_1{}^m \text{ and } \lambda_1 < \lambda^2.$$

That is the reason why a gelatine plate in dry state is more opaque than when wet. On the other hand, a moist plate, transmitting more of incident light and absorbing less, must of necessity require more exposure.

We have said above that the relation which we designate by λ between the transmitted light by two contiguous divisions of Mr. Warnerke's sensitometer can be easily found; indeed, considering that

$$\frac{s_1}{s_{11}} = \frac{i_{11}}{i_1} = \lambda$$

we have only to divide the value given for the sensitiveness of one number by that of another; thus dividing No. 1 by No. 2, we receive $\frac{1}{1318}$. The importance of the correctness of this value cannot be too much insisted on, because if λ be incorrect, then all calculations of relative sensitiveness of the plates will fall to the ground. Mr. Warnerke, in his paper read last year before the Photographic Society of Great Britain, said that the relative values of the various tints, or numbers representing them, were carefully calculated and verified by a system different to that which was used for calculation. It is much to be regretted that he should have withheld from us the two methods he spoke of. Nevertheless, in his paper we find some data, though given for a different purpose, but which are quite sufficient to enable us to calculate for ourselves the value of λ, and to compare it with that to be found in the sensitometer.

There are two tables given by Mr. Warnerke.

No. 1.

A phosphorescent plate was illuminated with one inch of magnesium ribbon, and, after a lapse of two seconds, put in contact with the sensitometer, and a sensitive gelatine plate placed behind. Similar experiments were repeated, giving continually increasing rest to the luminous plate up to 900 seconds. All these plates were afterwards simultaneously developed, and the following results obtained :—

After	a rest of	2	seconds,	last number	developed was	20
,,	,,	10	,,	,,	,,	18
,,	,,	20	,,	,,	,,	17
,,	,,	30	,,	,,	,,	17
,,	,,	60	,,	,,	,,	16
,,	,,	90	,,	,,	,,	15
,,	,,	120	,,	,,	,,	14
,,	,,	150	,,	,,	,,	12
,,	,,	300	,,	,,	,,	9
,,	,,	600	,,	,,	,,	8
,,	,,	900	,,	,,	,,	6

No. 2.

The sensitive plate was cut in six parts, and after a phosphorescent plate was exposed to the magnesium light, and had one minute's rest, it was used to act through the sensitometer on to these several plates during varying periods of time, as per table, and simultaneously developed with the following results :—

After	5	sec. exposure	No. 12	was developed
,,	13	,,	15	,,
,,	20	,,	17	,,
,,	40	,,	18	,,
,,	80	,,	19	,,
,,	160	,,	20	,,

To the table No. 2 we can add some numbers, and it will stand thus—

After	5	sec. exposure	No. 12	was developed
,,	13	,,	15	,,
,,	20	,,	17	,,
,,	30	,,	$17+\chi$	,,
,,	40	,,	18	,,
,,	60	,,	$18+\chi$	,,
,,	80	,,	19	,,

To calculate λ from these tables, we have equation

$$y = asti\lambda_e,$$

where y represents deposit, a the smallest deposit perceptible to the eye, t time, i intensity of standard light, and e the thickness of the film. If we apply this equation to the last developed number, then we have $y = a$, and e equal to the developed number. Thus

$$a = asti\lambda^n, \text{ or } 1 = sti\lambda^n \text{............(1)}$$

From the table No. 2 we have for 30 seconds' exposure N17$+\chi$, and for 60 seconds No. $18+\chi$. Substituting these values in the above equation we receive—

$$1 = s.60.i_1\lambda^{18+\chi}$$

$$1 = s.30.i\lambda^{17+\chi}$$

hence

$$\lambda \frac{i_1}{i} = \tfrac{1}{2} \text{............(2).}$$

Now we must find the relation $\frac{i_1}{i}$, where i_1 is the intensity of light of the phosphorescent tablet between 60 and 120 seconds after exciting, and i between 60 and 90 seconds. Let us designate by t_1 the intensity between 30 and 60 seconds, by t_2 between 60 and 90 seconds, and by t_3 between 90 and 120 seconds. Then from the tables No. 1 we have—

After a rest of 60 seconds, last number developed was 16
„ 30 „ „ „ 17

We can put it otherwise—

$$\frac{t_2+t_3}{2} \text{ gave No. 16, and } \frac{t_1+t_2}{2} \text{ gave No. 17.}$$

Substituting this in the equation (1) we receive—

$$1 = s.30(t_2+t_3)\lambda^{16}, \text{ and } 1 = s.30(t_1+t_2)\lambda^{17},$$

hence

$$\lambda = \frac{t_2+t_3}{t_1+t_2}; \text{ and } t_1 \text{ being greater than } t_2,\ \lambda < \frac{t_2+t_3}{2t_2}$$

On the other hand, i_1 being equal to

$$\frac{t_2+t_3}{2}, \text{ and } i = t_2$$

the relation—

$$\frac{i_1}{i} = \frac{t_2+t_3}{2t_2} > \lambda, \text{ or } \lambda < \frac{i_1}{i}$$

Now we take the equation (2)

$$\lambda \frac{i_1}{i} = \tfrac{1}{2}$$

and substitute in it

$$\lambda \text{ instead of } \frac{i_1}{i}$$

As

$$\lambda < \frac{i_1}{i}$$

consequently the first part of the equation will become smaller than the second, or

$$\lambda_2 < \tfrac{1}{2}, \text{ and } \lambda < \frac{1}{\sqrt{2}} = \frac{1}{1{\cdot}414}$$

We see that λ as calculated here differs considerably from what value Mr. Warnerke has found for it, viz., $\frac{1}{1{\cdot}318}$; still more so if we compare (say) λ^8, or $\frac{1}{15{\cdot}98} > \lambda^8$ with $\lambda^8 = \frac{1}{9{\cdot}147}$ as given by Mr. Warnerke. The corresponding values for sensitiveness when N9 is the last developed, from Mr. Warnerke's sensitometer will be 9·147, while as calculated here more than 15·98. This difference is too wide to be left unexplained, but we are unable to do this, as we do not know the methods which Mr. Warnerke followed.

FRENCH CORRESPONDENCE.

POITEVIN MEMORIAL—SOLAR ECLIPSE—PRINTING PROCESS ON ZINC—CELLULOID PELLICLES.

The Committee for the Poitevin Memorial.—The committee for organizing subscriptions in aid of the Poitevin memorial has been definitely constituted; of this committee, M. Davanne is president, M. Lévy vice-president, M. Londe secretary, and M. Léon Vidal treasurer. At the next meeting of the committee printed circulars will be issued, and the lists of subscriptions drawn up. The committee will appoint corresponding members everywhere, to receive subscriptions and transmit them to the central body in Paris. Although the memorial is to be one in honour of a Frenchman, the work ought by no means to have a national character only; the object is to do honour to the name of one who was a light of photographic science, without reference to the country of which he was a native. For my own part, I should like it to be generally admitted that the photographic profession is not divided into distinct groups, each belonging to a different nation, but that it forms one great whole, belonging to the entire world. So far as Poitevin is concerned, the initiative would naturally belong to France, just as, if the memorial referred to Talbot, it would belong to England: but, when once the start has been made, it is only a question of honouring the memory of a man whose services to photography are appreciated in every land. It is, therefore, to the whole world that an appeal can be made for subscriptions. The memorial itself is assured; what we have still to look forward to is that the contributions in its favour may be as general as possible. Large individual subscriptions are not necessary, but the smallest sum will be sufficient to prove the sympathy we each of us feel with the labours of a man who was as modest and retiring as he was earnest and devoted to the cause of photography. Those of our readers who wish to take a part in the work of the central committee at Paris should send their subscriptions to the Editor of the PHOTOGRAPHIC NEWS, who has kindly consented to transmit them to us.

Photographs of the Solar Eclipse.—At the June meeting of the Photographic Society of France (we were glad to welcome at this meeting Mr. Wilson, the editor of the *Philadelphia Photographer*, who is paying a visit to Paris) M. Janssen, member of the Institute, exhibited a fine print of the recent solar eclipse, which was partially visible at Paris. He drew attention to the fact that the outline of the moon on the solar surface was very clear and distinct, showing that if the moon has an atmosphere, it cannot be one of any appreciable importance, since its interposition in front of the sun produces no effect. This would not be the case if we were able to take a photograph of a partial occultation of the sun by the earth; the terrestrial atmosphere, by its power of absorption and refraction, would produce effects which would be correctly rendered by photography. It is generally held by astronomers that the moon has no atmosphere, and the result obtained by M. Janssen confirms the correctness of this view. M. Janssen is at present engaged in experimenting with the photographic revolver, using a sensitive plate to which a continuous motion is communicated; he proposes shortly to show some proofs of the correctness of his views. So far as I am concerned, I am quite convinced that for objects strongly illuminated it is completely useless to proceed by means of successive stoppages. What difference can it really make, since the object to be reproduced is already in more or less rapid motion?

Printing Process on Zinc.—M. Janssen, at the same meeting, described a process for printing on zinc which is used in the Ministry of Public Works, and of which I already have had occasion to speak. Let me give a brief *resumé* of it:—The zinc plate is first prepared by cleaning, and there is then a solution of gallic acid and gum flowed over it; this is wiped off, and when the plate is dry it is coated with a solution of bitumen of Judæa in benzine; it is exposed behind the original drawing—that is to say, a positive—and the bitumen which has not been rendered insoluble by the action of light is dissolved out by means of spirit of turpentine. The lines of the drawing appear everywhere where the metal has been laid bare. It is next treated with water acidulated with acetic acid, a solution which restores to the zinc the property of retaining a fatty substance—that is, the property of which it had been deprived by the solution of gallic acid. A roller charged with fatty ink is then passed over it, producing a picture in black, and the whole plate is then cleaned up with essence of turpentine. Impressions can now be immediately taken in the lithographic press from the zinc, and we obtain positive prints identical with the original drawing. It stands to reason that this process is only applicable to the reproduction of line drawings.

Improvement in Celluloid Pellicles.—M. David pursues with perseverance worthy of complete success his endeavours to find a use for celluloid in photography. At the meeting above alluded to, he showed some very thin pellicles, obtained by passing with a brush over glass a film of varnish, which is nothing more than liquid celluloid. He hopes to be able to work with a varnish of this kind in the same way as collodion, and thus to obtain more regular films than those produced with a brush. The varnish thus spread over the glass he coats with gelatino-bromide, and the whole is then capable of being stripped off very readily. Celluloid in sheets, when it is wetted, stretches like paper. Without having arrived at perfection, from which he is yet at some distance, M. David has, at all events, made some improvements in his previous methods.

Leon Vidal.

THE ECLIPSE.

The actual work of the observers is thus described in the *Daily News*.

In an eclipse there are four critical points: the first, second, third, and fourth contacts, so called—the first when the moon makes its appearance on the sun, the second when it first totally obscures it, the third when the sun again reappears, and the fourth when the sun is quite clear of the moon again. It is of course with the totality—that is, the time that the sun as we know it is invisible between the second and third contacts—that the physical astronomer has almost exclusively to do; but as some of the phenomena are visible slightly before totality, the time has to be carefully watched. During totality this has to be done in the most steady manner, and the observer upon whom this duty falls has a most responsible task. In the English Observatory, to which I shall now confine myself, this fell upon Mr. Buchanan; and as the arrangement adopted this time was new, I will describe it. It was devised by Mr. Lockyer as the result of his Indian experience, when the timekeeper found it so difficult to keep the time and to observe the eclipse, which he had come 600 miles to see, that he resolutely turned his back upon the sun lest he should fail in his self-imposed task, and so disturb the work of others. What one wants to know at any moment during an eclipse is for how many seconds the phenomenon is yet to be visible, and when each ten seconds of the totality have flown away, as each observer has generally more than one thing to do, and the announcement of the timekeeper is the signal for changing his instrument. On this occasion a clock used for testing gas metres was employed, with a seconds pendulum set going at the moment of totality, and with a large dial marked 65, 60, 50, 40, and so on to 0; 65 being the number of seconds which it was thought would leave a safe interval for covering the lenses of all the cameras before the actual termination of the eclipse. The plan answered admirably. Mr. Buchanan sang out the times shown on the dial, and sketched the eclipse with perfect ease.

While the land was darkening and the sky and the Nile were beginning to put on those indescribable hues round which so much of the terror of eclipses is centred, and while the whispers on the hill at Sohag were beginning to surge into a sound—half roar, half moan—some eight minutes before totality, Mr. Lockyer announced the appearance of bright lines, indicating that our atmosphere was already dimly illuminated enough to permit of the atmosphere of the sun being seen through it, and it was easy to see by the rapid pencilling on a copy of Angström's map, which was arranged on a stand under the eye-piece of his spectroscope, that observations in earnest had commenced. This went on, the image of the retreating cusp of the sun being carefully kept on the slit of the spectroscope by Mr. Lawrence until Dr. Schuster, as had been arranged, announced the instant of totality. At this signal Mr. Buchanan said, "sixty-five seconds," Mr. Lockyer left the spectroscope to study the structure of the corona with the telescope, and Dr. Schuster uncovered all the lenses of his cameras—all four of them arranged on a single stand—and to all, except the observers, the sun's atmosphere shone out in all its splendour and majesty, and the roar increased on the hill. In the telescope the verdict was that the solar conditions of 1871 were again present; and at the signal "forty seconds more," the information to be gathered by the naked eye and the grating was to be sought by one observer, while the photographic plates had to be changed by another. At this moment the silence in the observatory was broken by shouts calling attention to a strange object among the fainter exterior details of the corona itself, which were more suspected than seen. There, one solar diameter to the right and one solar diameter long, was an exquisitely formed comet, complete with nucleus and tail, sweeping in a beautiful curve, in brilliancy almost, if not quite, equalling that of the very corona itself—a real photometer, in fact, of which we have not yet heard the last. As in the naked eye view, there was a struggle with the comet, so with the grating there was a struggle of another kind. A prism or a diffraction grating used without lenses forms what is called a slitless spectroscope. The coronal ring is really used as a circular slit, and according to the substances present in the solar atmosphere we shall have rings or no rings; and if rings are seen, then their presence in certain definite positions will tell us what substances are present. Now in 1871 rings were seen, and they were very bright. In 1878 no ring whatever was seen. The question to be decided, then, was, Did this year's eclipse resemble in this respect the eclipse of 1871 or 1878? The result of the inquiry was that there were rings, but that they took time to see. This indicated a solar condition more resembling that presented in 1871 than in 1878, but stopping short of it.

Owing to these difficulties, hardly had Mr. Lockyer time to pass back to the telescope by means of which the spectrum of the corona was to be studied, when the clock showed that sixty-five seconds had elapsed, and Mr. Buchanan's "over" filled all with regret that the phenomenon, so rare and beautiful, and full of such precious knowledge, which each was doing his "level best" to secure, should be so ephemeral. So the caps were put on the cameras by Dr. Schuster and his assistant, Mr. Woods, lest the precious records which it was hoped might have been secured should be spoiled by the first beam of the re-appearing sun. It turned out, however, that so admirably had the eclipse been calculated, and so exactly had the French party hit upon the central line, that the totality really lasted 7 seconds more, that is, the full 72 seconds. The spectrum of the corona, therefore, was studied for a second or two under, perhaps, better conditions than had ever been present before, excepting during the memorable observation of Janssen in 1871. There were the red and green and blue lines stretching right across a wide field of view, and although no obvious dark lines were seen in the momentary glimpse, it was obvious that the spectrum was not truly a continuous one. There were variations of intensity here and there, and not the equal toning generally observed. So then ended the totality in one of the observatories. Dr. Schuster and his assistant at once proceeded to the extemporised dark room on board the steamer to develop the photographs, while those members of all the parties who had made telescopic or spectroscopic observations retired to the solitude of their tents to write down their results while they were still fresh in their minds.

A NON-ELECTRIC INCANDESCENT LAMP.

A bright light, easily obtained and sufficient for projections has frequently been regarded as a desideratum where it has been impracticable to procure either the electric or the lime-light. The French Minister of Public Instruction lately appointed a special commission to indicate the apparatus most suitable for projection in primary schools; and it appeared that while there was no lack of simple arrangements for the projection proper, the problem of easy production of an adequate luminous source was hardly solved.

Dr. Regnard has lately conceived the idea of getting a bright light by burning on platinum gauze a mixture of air and petroleum vapour. The intense heat which results raises the platinum to bright incandescence, giving a light equal to about half the lime-light.

The apparatus is very simple. There is an ordinary Bunsen burner, terminated by a small cage of platinum wire. The mixture of air and petroleum vapour is admitted below, in place of the gas; it is produced by a familiar method, and the current is generated by means of a pair of bellows or a Richardson "pear." With a ventilator or "trompo," several of the lamps may be maintained in action at once, for lighting halls, workshops, &c., where there is no gas. The aspect is that of electric incandescent lamps. In this case it is well to augment the volume of the carbonator, so that the supply of petroleum vapour is abundant. To send all the light in one direction, the Bunsen burner may be fitted with a bent trumpet-shaped nozzle closed with platinum gauze. One has merely to regulate, with the ring of the burner, the admission of the mixture of air and vapour, to have, whenever the current is produced, an extremely bright light.

With a large loaded bag of air under the table the lamp may be kept in action for several hours without requiring attention.

The expenditure is very small, only a few centimes an hour, with maximum action.—*Nature*

PRACTICAL EXPERIENCES WITH THE ALKALINE DEVELOPER FOR GELATINE PLATES.

BY W. BROOKS.*

IT always has been a common remark that "more plates are spoilt in developing than by any other operation connected with photography." Now in the days of rapid gelatine plates it applies more than ever it did in the days of wet collodion with the nitrate bath. For instance, it is possible at times to get a passable result by proper development from an indifferent plate, and with improper development with a good plate the worst result is sometimes obtained; therefore I consider that too much attention cannot be paid to development. My first trial with gelatine plates was with Mr. Kennett's on their introduction, and these at that time were as sensitive as many of the plates now in the market. In those days the alkaline developer was not so well understood as it is now, when I considered the failure was that the alkali was not sufficiently restrained, and fog was the result. Following these came Messrs. Wratten and Wainwright with their commercial plates; the developer recommended for the plates contained more of the restraining bromide than the former, with a better result, and the same developing formula is in use at the present day. In my hands it is somewhat slow, so I have given it up in preference for another containing a larger amount of bromide. With Wratten's developer at first the great complaint was, that it did not give sufficient density. Many attributed that to over-exposure. In many cases I know it was so, and in others where proper exposure was given, intensity was very difficult to get without a great deal of forcing. I still use their form of developer, generally for testing the rapidity of plates with Warnerke's sensitometer. It may be remembered by many of our members, that Mr. Cowan used to bring up to the meeting at various times some excellent results, and on one particular occasion the difficulty of getting sufficient density was discussed. I well remember him saying that to get density he commenced with a very strong solution of pyrogallic, about six grains to the ounce, and sometimes more, using about five drops of the bromide and ammonia solution, which was

Liquor ammonia	1 ounce
Bromide of potassium	1 dram
Water	2 ounces

I have used this system of development for years with success, but for the last eighteen months I have used the following:—

Solution P.

Pyrogallic acid	2 grains
Water	1 ounce

Solution A.

Bromide of ammonium	6 grains
Liquor ammonia	20 minims
Water	1 ounce

This developer was first brought to notice about twelve months since, Mr. Debenham being the first to use it. To develop (say) a $7\frac{1}{4}$ by $4\frac{1}{2}$, I take one and a-half ounces of solution P, and half an ounce of solution A; this I pour over the plate at once without any soaking, and if the exposure be correct, the image at once flashes out and gains sufficient intensity in about two minutes. It will be seen that the developer contains ten minims of liquor ammonia, but is well restrained; there is not the slightest fear of fogging unless from over-exposure. Some few months since I took the trouble to try it on several makes of plates, and in each instance I found it to give far better results than those recommended by the makers. I will give a few names of the plates I tried: Swan's, Wratten's, Mawdsley's, Cobb's, Fry's, Britannia, Miall's, and several other makes by private people; in every instance the development was more rapid than that given with the plates. Now, if we compare these three developers I have mentioned, it will be found that the bromide is increased, and I have noticed that with the increase of bromide, less pyrogallic is required to obtain sufficient intensity (I not long since made an experiment by increasing the bromide still further, and was surprised how little pyrogallic was required to give intensity; I found that one grain per ounce was quite sufficient).

I was so satisfied with this developer that I thought it was as perfect as it well could be, and several friends said to me, "Have you tried sulphite of soda?" My reply was, "No, I can get all I require without it," and thought so until one evening when in conversation with Mr. England, when he asked me the same question, and he strongly recommended me to give it a trial, which I did, and, as I think, I never did finer negatives by any process. Before I made up my mind to employ it, I made several experiments with it as regards exposure, and I am inclined to think that it gives more latitude in exposure than without it. It slightly increases the length of time in developing, but the gradations are far finer, and I am sure those who will once give it a trial will never develop another plate without it. One experiment I tried was how far I could force an under-exposed plate without producing chemical fog, or the blacking that comes with forcing, that is so common in forced plates. The plate I now hand round was the one I intentionally under-exposed; it was in the developer nearly half-an-hour, without the slightest trace of fog, as you will see; and the developer contained 40 minims of the strongest liquor ammonia, 12 grains of bromide of ammonium, and only three grains of pyrogallic, and I must not omit to mention 16 grains of re-crystallized sulphite of soda. This was a plate of my own preparation containing a chloride, and, when I use a chloride in "the emulsion," I use a certain portion of citric acid in the developer. It not only helps to keep the pyrogallic solution clear, but, with a chloride in a plate, the citrate of ammonia that is formed materially assists in developing the image. Now I make up my solutions as follows:—

Solution P.

Pyrogallic	2 grains
Sulphite of soda	8 „
Citric acid...	1 grain
Water	1 ounce

Solution A (*same as before*).

Bromide of ammonium	6 grains
Liquor ammonia...	20 minims
Water	1 ounce

Using it in the same proportions as before.

I now pass round for your inspection some half-a dozen negatives developed by this formula, with prints from same, and I think you will agree with me that they are as near an approach to wet plates in look as possible; the extreme shadows are bare glass, and the general image grey in colour, so that there is no difficulty in judging as to their printing value. At first I thought I could make up any quantity of solution P that would keep (say) a week or ten days; so it does to all appearance without changing colour. A few days before I developed these plates I had some of the solution P left over, and when about to develop these plates I made up some fresh in another bottle, and I found that the fresh solution worked in about one-tenth the time of the old, which had not been made up more than five days at the outside. Of two of the negatives that are of the same subject, one was developed with the fresh solution, and the other with the old, and it is impossible to tell one from the other; all that I can find is that the time in development was only protracted, but the finished result was the same.

I now keep an old solution by me which I find very valuable in this way. At times I have to develop a great many plates for amateurs, and have but very little knowledge of the exposure that has been given; so when such is the case, I commence with the older solution, and with a much over-exposed plate the image makes its appearance very slowly, so there is plenty of time to see whether the correct exposure has been given without risking the plate. Of the plates I have passed round, some I do not wish you to look at in an artistic point of view, but only from a photo-chemical standpoint, as they were taken when out with an amateur gentleman pupil of mine, showing him what won't look well, and what will, in a photograph. In one batch of plates I made I tried to get a little more sensitiveness, and over-cooked it, and the result was green and red fog when developed with ammonia. Having seen it mentioned in one of the journals that plates that gave this green and red fog were quite free when developed with carbonate of soda instead of the ammonia, I tried it, and the result I now pass round. The only alteration I made in the developer was the substitution of half an ounce of a saturated solution of common washing soda for the ten minims of liquor ammonia. I find it is not quite so quick in its action as the ammonia, but the result is about the same. I know several operators who cannot stand the fumes of ammonia without feeling a pain in the chest. To those so affected, by using the soda all this is avoided; it is very easy to substitute one for the other, calculating that one ounce of the saturated soda solution is equal in effect to twenty minims of strong liquor ammonia.

In conclusion, I wish to say that I have only given my own system of working, and I hope those who hold different opinions will not omit to express them.

* Read before the South London Photographic Society.

Notes.

Mr. J. T. Taylor is editing a new edition of "Hardwich's Photographic Chemistry."

The army estimates this year include a sum of four hundred pounds for "photographic services" for the army.

The Copyright and Works of Art Bill before Parliament has been blocked; there is, consequently, no chance of it becoming law this year.

Berlin is to have a retouching school. The proposed fee is thirty marks (shillings) per month, and a month is to be the minimum term of attendance. The Society for the Advancement of Photography seems inclined to take the matter under its wing.

According to Schlegel, gelatine negatives acquire the character of wet plates if a few drops of a solution of cyanide of silver in cyanide of potassium are added to the developer.

A monument to the memory of Poitevin is to be raised. Of the committee appointed to carry out this object, M. Davanne is president, and our esteemed Paris correspondent, M. Léon Vidal, the treasurer. Already the list of subscribers is a lengthy one.

Dr. Vogel, of Berlin, confirms the practical value of Eder's new intensifying process; the Vienna photographers seem also well pleased with it.

Dr. Vogel immerses the negative first in a solution of bichloride of mercury (water 50 parts, mercury 1 part) until a whitish veil appears, and the plate is then transferred to the Eder intensifier. The film first grows yellow, then brown, and then very intense. Afterwards the action is reversed. Dr. Vogel speaks highly of the smooth and gradual change that comes over the negative.

According to the yearly report of the Astronomer-Royal which he made to the official visitors last Saturday, the number of hours of bright sunshine recorded by Campbell's sunshine instrument during 1881 was 1,301, or more than 100 hours above the average of the four preceding years.

Another interesting fact in the report is, that out of 365 days, it was possible to take photographs of the sun on 200 of them; and, curiously enough, only on two days out of this 200 did photographs show that the sun was free from spots.

Sun-spots on the face of the sun have recently been studied, as everybody knows, with much care by scientific men, and endless theories have been built on the phenomena. Whatever the nature of these speculations may be, it is obvious that the first thing is to secure trustworthy records, and in doing this photography renders invaluable service. The evidence of the camera, it seems, is to the effect that sun-spots have increased materially of late, and the area covered daily in 1881 is found to be nearly double that covered in the preceding year.

Garibaldi's death reminds us of his visit to this country in April, 1864. We had the pleasure of taking his portrait on that occasion; the general's aversion to being lionised, as well as his irritability just then occasioned by his wounded foot, were reasons for believing that he would not sit still very long, and in these circumstances arrangements were necessary to make the posing as short as possible.

A semi-circle formed by five converging lenses consequently awaited the patriot when he arrived in the studio. The posing chair was immovable, and a sitter had been focussed in position immediately before Garibaldi entered. It was only necessary, therefore, for the general to sit down for a period of some twenty seconds. In his grey toga, worn over a red shirt, the grizzled warrior sat as firm as a rock, and not one of the five portraits betrayed a movement. "I never faced such a battery before," cried Garibaldi, jokingly, in French, as he rose.

Platinotype printing is attracting the attention of the Vienna Photographic Society. Under the anonymous name of "Platina," a photographer has submitted some fine platinum impressions, produced by a method he describes in confidence.

One would scarcely have thought to find electricity and burglary coupled, but in these days of electrical progress nothing occasions surprise. At Liverpool, two housebreakers were smartly captured the other day by one of the inmates, who received intelligence of the visitors through the medium of an electric bell attached to the door. One of these days there will be a detective camera in the doorway, and burglars will find their portraits forthcoming at the trial, to be used, as constables say, in evidence against them.

The American photographic journals seem to be without their editors just now. Mr. E. L. Wilson, of the *Philadelphia Photographer*, and Mr. J. T. Taylor, of the *Photographic Times*, are both of them in this country. Nevertheless, the journals do not lack interesting matter; the latter last month published a series of excellent lessons in dry plate photography, which are really so good we should have reprinted them, only that they originally appeared in these pages.

History repeats itself. In the chronicles of the Pickwick Club it is recorded how the astute Pickwickians dug up near Cobham an historical stone, apparently of great antiquity, the marks upon which, however, turned out in the end to have been made by a prosaic individual named William Stubbs. A similar disclosure is now made in respect to the lacustrine canoe which was discovered two months ago in an excellent state of preservation near Bex, in Switzerland. The fact that this hollowed-out, Robinson Crusoe-like craft was found 3,000 feet above the Valley of the Rhone made the discovery all the more interesting, since no other relics of the lacustrines —that strange pre-historic people, who lived in habitations on piles above the lakes—had been met with at such an elevation.

Photographs of the canoe were made for distribution to the learned societies, and antiquaries in the neighbourhood paid speedy visits to the spot. The result is that Dr. Forel, whose experiments on the penetration of light below the surface of the water were recently recorded in our pages, has pronounced the lacustrine canoe to be nothing more than a water-trough made from the trunk of a tree, such as one meets with in every mountain village.

The electric studio of Stagel and Eckel, in Vienna, has closed for want of patronage. The reasons given are that during the present winter and spring the weather has been exceptionally fine, and hence artificial illumination was uncalled for, and that only the wet process was employed, necessitating long exposures. In London, on the other hand, we hear that two new electric studios have just been established.

"Twelve Lessons in Elementary Photographic Chemistry," will follow our dry plate lessons, which are now coming to an end. We shall follow the same plan of adapting our remarks to the beginner, and shall not omit the explanation of a single change or reaction merely because it happens to be simple or well-known. For we hold that those unacquainted with a fact will be glad of the information, while those who possess the knowledge already will not be ungrateful for having it once more impressed upon them.

The electric light that streams forth into the dark night from the big black hulls of our ironclads seems to have produced a scare at Alexandria. Nearly every one of our first-class battle ships is now provided with this vivid means of illumination, and some of them, like the *Inflexible*, are fitted with incandescent lamps between decks as well. One of the principal uses of the electric light in war vessels is to sweep the seas at night to prevent the approach unseen of any torpedo launch or other nocturnal visitor. At Alexandria our war ships are so near that men busy at the earth-works at night are at once discerned by throwing the electric beam on shore.

"When I was in London, window cleaning was a trifle," said a Manchester photographer to us the other day; "but here all the glass must be cleaned each day, or my exposures are nearly doubled." In Manchester, therefore, there is plenty of scope for beginners to learn the rudiments of their art.

La Grande Chatreuse. Everybody has heard of the famous golden green *liqueur* prepared at the monastery, and most of us have tasted it. The monks are said to make an income of a million francs a year by their Chatreuse, the secret of preparing it from aromatic herbs within the walls having been religiously kept from time immemorial. But of late the cells have been the scene of other work than that of liqueur-making; they have been converted into photographic laboratories.

Came the prior of la Grande Chatreuse recently to Paris to acquire instruction in the ways of photographers, for the monks desire to be adepts in the art. For some time past, it appears, they have been working the wet collodion process in the vicinity of their monastery, taking pictures of the wild inhospitable country around, and securing photographs of monastic life. It is the wonders of the gelatine process which have now tempted them to seek outside help, and hence the temporary descent into the world once more by the reverend father.

Mr. Spinks' method of dealing with nervous sitters, as detailed in another column, is calculated to prove of more value to the portraitist who wishes to secure a natural and easy expression, than to the youth who would rather die than tell or act a falsehood.

MOUNTAIN PHOTOGRAPHY IN NEW ZEALAND.

MR. BURTON, of the photographic firm of Burton Brothers, has recently returned, the Otago papers tell us, from what appears to have been a most interesting though difficult trip among the mountains inland from Milford Sound, New Zealand. This spot and its surroundings have been frequently photographed, and the beauties of the neighbouring scenery are tolerably well known; but Mr. Burton has, on this occasion, pushed his way up the Arthur River, making good use of his time meanwhile, and reaching the Poseidon River, at the head of Lake Ada--spots where foot of photographer has never hitherto been set. The goal aimed at—viz., Mount Balloon—time did not enable the party to reach; but the already rich collection of views of New Zealand mountain scenery has received many most valuable additions from Mr. Burton's trip. Mr. Burton's diary presents so many points of interest, that we have not hesitated to reproduce it. To judge from some fine pictures he also sends us, the little expedition was a very successful one.

It was to be a month's trip, says the hardy photographer, but there must be deducted two days' steaming from Port Chalmers to Milford Sound, and two days for the return trip; so that there remained just twenty-two days net—that is, if the Union Steam Ship Company's steamers kept exact time. This Company arrange for several of their vessels to call at the Sounds, both to and from Melbourne. The last of these callers for the present season was to be the *Rotomahana*, leaving Port Chalmers on February 2nd; and t'other way the *Rotorua*, leaving Melbourne on the 21st, being due at Milford Sound about five days later—namely, the 26th. An application for a return-ticket for Milford Sound was met by the bland explanation that the Company did not give return-tickets on such occasions, as they could not guarantee that their steamers would call in at Milford Sound at all. This was refreshing intelligence, truly, as, in case of weather preventing the last steamer from calling in, the only thing would be to patiently wait for the visit of the Government steamer *Stella*, on one of her lighthouse inspection trips, and then be carried, some time in the course of the autumn, away to Wellington. However, a "single" ticket was taken, the resolve being to "risk it." It was to be the writer's fourth trip to the Sounds; but, on this occasion, it was not to be merely the Sounds that were to be photographed, but a long-cherished design was to be carried out, and this was to make way into the mountains, striking into the interior from Milford by way of

Arthur River. There had been a standing challenge from Mr. Donald Sutherland, who has lived four or five years in the Sounds, to pilot the writer into a district of weird beauty and surpassing grandeur, by ways only known to himself and his mate. The programme of the scenic entertainment promised included a waterfall more than 4,000 feet high, appropriately named, after its discoverer, Sutherland Falls. Visitors to Milford Sound, who have noted with admiration the Bowen Fall, are invited to imagine its height multiplied by eight! Another wondrous item was Mount Balloon, a mighty monolith cut by nature's own hand, which standing as on a vast base, upon a range of hills 4,000 feet above the sea, towers, in shape like an enormous Cleopatra's Needle, 1,200 feet higher into the heavens. Mount Balloon it is fittingly named, as by no other means will it ever be topped by man. The most distant of these wonders was about thirty miles from Milford, and to those whose ideas of travelling reach only to railways or turnpike roads, it may seem absurd to make a fuss about such a distance; but eight days of fine weather would be needed for the trip, and, in our variable climate, it can be seen how easily these eight days might be doubled, or even trebled, ere head-quarters can be reached again. Ample employment for the camera would be found in Lake Ada and on the Poseidon River, through which the way to Mount Balloon lay. Now, then, to begin—diary fashion.

February 2nd.—Depart Port Chalmers in the *Rotomahana*, Captain Underwood. There is no need to "bombast out" this account with details of "board-steamer" life, though, as our fellow-passengers included a venerable bishop and veteran actor, there would be some excuse for indulgence in penny-a-lining, especially when the bishop gravely informed us that he had once passed a night in a lock-up on the West Coast! As to the "veteran," he was amiable enough to allow himself to be drawn out upon two most interesting topics—his early Colonial experiences, and Shakespeare. He related a story of a successful digger, who, calling for a case of champagne, arranged nine of the bottles as skittles, and hurled the remaining three at them in lieu of balls. The total cost of this lavish gentleman's "spree" was the respectable sum of £850. Another reminiscence must be related. The "veteran" was acting as money-taker for a benefit entertainment. Front seats, 5s.; back seats, 3s. Enter four diggers. "Back seats, gentlemen?" he asked with great suavity." "Back seats? No, you(so-and-so). Front seats!" clapping down a £5 note and passing in. "Your change, sir!" called out the "veteran." Said the digger, "(So-and-so) the change! Keep it, you hungry-looking beggar!" Veteran pocketed the affront and carried the change to private account. Of course, everyone has heard many such stories; but it is pleasant to hear them again from one who was an actual eye and ear witness; now especially, as those early diggings times seem to belong to a very remote and misty past.

February 3rd.—Made the usual call at the Bluff, leaving again at 4 p.m. Genial veteran again delighted us with his reminiscences, drawing from the rich storehouse of his memory anecdotes of actors and actresses, living and dead, able and unable. Especially was it refreshing to hear him, when talking of "acting editions," express his utter contempt for those beings—such as Colley, Cibber, Tait, and Garrick—who had dared to "improve" upon Shakespeare.

February 4th.—All was anxiety this morning as to the weather, for we were due in Milford Sound early in the afternoon. The writer was lifted into a position of fictitious and temporary importance on the strength of his previous visit, and especially as being "the man who was to be left at Milford." Martin Chuzzlewit, it will be remembered by all readers of genuine history, was complimented by a levée at Colonel Kedgick's hotel on his departure for the new settlement of Eden; but it only came out afterwards that the excitement among the citizens whom he "received" arose from the fact that, as the Colonel put it, "he was not like emigrants in general. . . . Nobody as goes to Eden ever comes back alive." If the presumption involved in such a comparison may be forgiven, there is some parallelism in the cases. Early in the morning there seemed some likelihood of fine weather, but as the day wore on the sky became more and more leaden-hued, until we entered Milford in a steady downpour. But few of the marvels of this most marvellous of the Sounds were the *Rotomahana's* passengers privileged to see. Just a few hundred feet of perpendicular cliff on either side, with countless cascades rushing down; above the rolling mist, through which ever and anon the summit of Kemberley would appear for a few moments; but the Mitre remained hidden, and of glorious Pembroke there was not a sign. "Now, sir," called out the chief officer, "boat's all ready; will you point out your traps?" In a few minutes the "social hall" of the *Rotomahana* was exchanged for No. 1 Kennedy Street, Freshwater Basin, and the steamer resumed her voyage to Melbourne. The city of Milford makes quite an imposing show from the water, no less than three buildings revealing themselves to the astonished gaze of those who had imagined that there were no signs of civilisation in this out-of-the-way spot.

February 5th.—A glorious day! The camera was soon at work, and eight "exposures" made before breakfast. To see Milford Sound in perfection, the day should not be too clear. A perfectly cloudless sky seems to minify the heights of the mountains, and to render somewhat reasonable the incredulity of visitors unused to mountainous regions when they are told that such-and-such a peak is nearly a mile and a-quarter in perpendicular height. But let fantastic masses of cloud wreathe the giant mountains, or hang like a belt around the peaks, always leaving the actual summits clear above; then let the spectator wander away until he has lost sight of every indication of human companionship, and he will realise the combined immensity and beauty around him.

February 6th.—Another change. A pouring rain, a gale of wind, the spray from the Bowen Falls—hidden from us by Cemetery Point—driving across the Sound, and the Cleddau River rushing down with great violence a few yards from our doors, and in the worst of it the *Te Anau*, from Melbourne, made her signal by whistle. The whole of the (permanent) inhabitants of Milford put off in a boat to the steamer, taking with them a gentleman of Invercargill, who had just finished a sketching tour. On its return the progress of the boat was followed with anxiety by the eyes of the solitary observer on the beach. Duly rounding the point, it shot out of the driving mist, and then—suddenly disappeared! Rapidly through the watcher's mind passed the thoughts—"Alone, the steamer gone, no boats, no sign of human beings, and no communication with the outer world for three weeks." On the other hand, there were plenty of provisions and a good roof. And here a selfish thought would obtrude itself. Could the survivor be regarded as the inheritor of the property around? However, there was no need, happily, to pursue that subject, as the boat reappeared as suddenly as it had vanished. It had merely been hidden by the branches of a large tree that had been carried down the Cleddau by a recent freshet, and now was fixed in mid-stream.

February 7th.—Another wet day, clearing up towards evening; took advantage of this to get some negatives, with delicious "effects." Rigged up one of the huts as a developing-room, covering up windows and fireplace, shutting out the evening light, which would steal in at the crevices in door and floor. The result of this first batch of "developing" was highly encouraging.

February 8th.—Showery, but managed to get a few negatives.

February 9th.—Wet; but stole a couple of negatives just before dark.

February 10th.—Showers occasionally, and leaden sky all day defying photography.

February 11th.—Showery again, but with occasional peeps of blue sky; so managed to dodge the weather and secure a dozen negatives. Had a grand "medicine talk" this evening as to the probability of getting to Mount Balloon. Out of the twenty-two days seven were already gone. The guide (Sutherland) said we must have two fine days before it would be prudent to start, as the bush would not otherwise be fit to travel through. Still there was as yet a margin of four or five days, so "turned in" hopefully.

February 12th.—Wet, oh, so wet!

February 13th.—A grand day. Pulled down to Harrison's Cove, and did a great stroke—exposing no less than twenty-nine plates from all parts of the beach; secured some grand views of the "Lion" and Pembroke Peak. While the photographer was "taking" the peaks, the other two of the party were "taking" the fish, and at midday a most appetising *al fresco* meal was discussed. A four-mile pull home; then tea; then developing till midnight; then a consultation as to probability of reaching *ultima thule*—in our case, Mount Balloon. Turned in at 1 a.m., hoping that the next, or rather that, day would be as fine as the preceding one. But, oh!—

February 14th was just a damper. Spirits very low; hopes of reaching the mountain now very slight.

February 15th.—A grand day. Photographer in his glory—hard at work all day "bagging" negatives in all directions; ditto all night developing.

February 16th.—Clambered up the "slip" above the huts a few hundred feet, and was gladdened with a distant view of Lake Ada, and made six successful shots at it and the surrounding scenery. Spirits, which in the morning had been buoyant, were depressed, in sympathy with the weather; in the afternoon—dark—lowering.

February 17.—Wet once more. "Crushed again." Thirteen days had now gone, and reluctantly the truth had to be faced that Mount Balloon would for this time escape the trying ordeal of being "took." To get to Lake Ada was now the extreme of our ambition, even if that modest goal could be reached.

February 18th.—Wet once more, and, to vary the monotony, hail and thunder in addition.

February 19.—Very much the same; rather more so, if anything.

February 20th.—The morning opened deliciously. What had been rain to us we found had been snow on the heights, and Mitre Peak especially was a glorious object. To watch the changing hues on its brilliant summit—first blue grey, as the light of early morning struck it; then golden, as it caught the first direct rays of the sun; then dazzling white, against a background of brilliant blue—surely nothing earthly could be more beautiful. Our practical photographer became rapturous, till he recollected that his mission was not to poetise, but to depict, and forthwith he was "up to his eyes" in negatives. For only a part of the day, however. Once more the clouds gathered, showers fell, and hopes of reaching the lake fell likewise. There was still a chance, though. If to-morrow were fine, then—

February 21st.—And it was fine. "Explored" all day; packed up for Lake Ada; then "developed" all night.

(*To be continued.*)

ON THE CAUSE OF THE LIGHT BORDER FREQUENTLY NOTICED IN PHOTOGRAPHS JUST OUTSIDE THE OUTLINE OF A DARK BODY SEEN AGAINST THE SKY; WITH SOME INTRODUCTORY REMARKS ON PHOSPHORESCENCE.

BY PROFESSOR G. G. STOKES, SEC. R.S.*

An observation I made the other day with solar phosphori, though not involving anything new in principle, suggested to me an explanation of the above phenomenon which seems to me very likely to be the true one. On inquiring from Captain Abney whether it had already been explained, he wrote:—"The usual explanation of the phenomenon you describe is that the silver solution on the part of the plate on which the dark objects fall has nowhere to deposit, and hence the metallic silver is deposited to the nearest part strongly acted upon by light." As this explanation seems to me to involve some difficulties, I venture to offer another.

1. I will first mention the suggestive experiment, which is not wholly uninteresting on its own account, as affording a pretty illustration of what is already known, and furnishing an easy and rapid mode of determining in a rough way the character of the absorption of media for rays of low refrangibility.

The sun's light is reflected horizontally into a darkened room, and passed through a lens,† of considerable aperture for its focal length. A phosphorus is taken, suppose sulphide of calcium giving out a deep blue light,‡ and a position chosen for it which may be varied at pleasure, but which I will suppose to be nearer to the lens than its principal focus, at a place where a section of the pencil passing through the lens by a plane perpendicular to its axis shows the caustic surface well developed. A screen is then placed to intercept the pencil passing through the lens, and the phosphorus is exposed to sunlight or diffuse daylight, so as to be uniformly luminous, and is then placed in position; the screen is then removed for a very short time, and then replaced, and the effect on the phosphorus is observed.

Under the circumstances described there is seen a circular disc of blue light, much brighter than the general ground, where the excitement of the phosphorus has been refreshed. This is separated by a dark halo from the general ground, which shines by virtue of the original excitement, not having been touched by the rays which came through the lens.

2. The halo is due to the action of the less refrangible rays, which, as is well known, discharge the phosphorescence. Their first effect, as is also known, is, however, to cause the phosphorus to give out light; and if the exposure were very brief, or else the intensity of the discharging rays were sufficiently reduced, the part where they acted was seen to glow with a greenish light, which faded much more rapidly than the deep blue, so that after a short time it became relatively dark.

3. This change of colour of the phosphorescent light can hardly fail to have been noticed, but I have not seen mention of it. In this respect the effect of the admission of the discharging rays is quite different from that of warming the phosphorus, which, as is known, causes the phosphorus to be brighter for a time, and then to cease phosphorescing till it is excited afresh. The difference is one which it seems important to bear in mind in relation to theory. Warming the phosphorus seems to set the molecules more free to execute vibrations of the same character as those produced by the action of the rays of high refrangibility. But the action of the discharging rays changes the character of the molecular vibrations, converting them into others having on the whole a lower refrangibility, and being much less lasting.

4. Accordingly, when the phosphorus is acted on simultaneously by light containing rays of various refrangibilities, the tint of the resulting phosphorescence, and its more or less lasting character, depend materially on the proportion between the exciting and discharging rays emanating from the source of light. Thus daylight gives a bluer and more lasting phosphorescence than gaslight or lamplight. I took a tablet which had been exposed to the evening light, and had got rather faint, and, covering half of it with a book, I exposed the other half to gaslight. On carrying it into the dark, the freshly exposed half was seen to be much the brighter, the light being, however, whitish, but after some considerable time the unexposed half was the brighter of the two.

Again, on exposing a tablet, in one part covered with a glass vessel containing a solution of ammonio-sulphate of copper, to the radiation from a gas flame, the covered part was seen to be decidedly bluer than the rest, the phosphorescence of which was whitish. The former part, usually brighter at first than the rest, was sure to be so after a very little time. The reason of this is plain after what precedes.

A solution of chromate of potash is particularly well suited for a ray filter when the object is to discharge the phosphorescence of sulphide of calcium. While it stops the exciting rays it is transparent for nearly the whole of the discharging rays. The phosphorescence is accordingly a good deal more quickly discharged under such a solution than under red glass, which along with the exciting rays absorbs also a much larger proportion than the chromate of the discharging rays.

5. I will mention only one instance of the application of this arrangement to the study of absorption. On placing before excited sulphide of calcium a plate of ebonite given me by Mr. Preece, as a specimen of the transparent kind for certain rays of low refrangibility, and then removing the intercepting screen from the lens, the transmission of a radiation through the ebonite was immediately shown by the production of the greenish light above mentioned. Of course, after a sufficient time, the part acted on became dark.

6. I will mention two more observations as leading on to the explanation of the photographic phenomenon which I have to suggest.

In a dark room, an image of the flame of a paraffin lamp was thrown by a lens on to a phosphorescent tablet. On intercepting the incident rays, after no great exposure of the tablet, the place of the image was naturally seen to be luminous, with a bluish light. On forming in a similar manner an image of an aperture in the window-shutter, illuminated by the light of an overcast sky reflected horizontally by a looking-glass outside, this image, of course, was luminous; it was brighter than the other. On now allowing both lights to act simultaneously on the tablet, the image of the flame being arranged to fall in the middle of the larger image of the aperture, and, after a suitable exposure, cutting off both lights simultaneously, the place of the image of the aperture on which the image of the lamp had fallen was seen to be less luminous than the remainder, which had been excited by daylight alone. The reason is plain. The proportion of rays of lower to rays of higher refangibility is much greater in lamplight than in the light of the sky; so that the addition of the lamp-

* A Paper read before the Royal Society, May 25th, 1882.

† The lens actually used was one of crown glass which I happened to have; a lens of flint glass would have been better, as giving more separation of the caustic surfaces for the different colours.

‡ The experiments were actually made, partly with a tablet painted with Balmain's luminous paint, partly with sulphide of calcium, and other phosphori in powder.

light did more harm by the action of the discharging rays which it contained on the phosphorescence produced by the daylight, than it can do good by its own contribution to the phosphorescence.

Correspondence.

THE MOON'S ATMOSPHERE.

Dear Sir,—You no doubt have lately read in the newspapers an account of the discovery recently made by the French savants of the Egypt expedition respecting a special atmosphere to the moon.

I take the liberty to recal to your memory that in 1870 my partner in business, Mr. E. Ogier, had arrived at the same conclusion by photographic means. Your journal, as well as those of Paris and America, received Mr. Ogier's communications on the subject, and his discovery caused much wonder and surprise in both the Old and New World.

Unfortunately, M. Ogier has abandoned photography, which he had taken to temporarily, to retake his old profession, that of author. Perhaps, after having referred to your journal of the 19th August, and following in the years 1870 and 1871, and re-read the articles therein on the luminous power of the moon and its photosphere, you will think it advisable to affirm the discovery made by photographic means eleven years ago, and recognised as a fact at the present day.—Yours, &c., Godfray.

[Those of our readers who have the News for 1870 and 1871 will doubtless turn with interest to M. Ogier's letters of that period.—Ed. P.N.]

MY TENT.

Dear Sir,—Seeing in your journal of last week's issue descriptions of dark-tents, it occurred to me your readers may feel interested, and perhaps find something useful, in another form. Should you think so, you are at liberty to let them have, through the medium of the News, the following description of my dark-tent :—

It is made of three thicknesses of black twill calico ; its shape is that of an inverted bag (square), and measuring two yards high ; each side measures a yard. In one of the sides is cut an oval-shaped opening, measuring 8½ by 6½ inches. A square piece of calico is sewn over this opening, on the inside, like a pocket, in which is cut an oval opening the same size as the outer oval. The size of this square piece is 10½ by 8½ inches ; the top edge is not sewn, so that a plate of ruby glass, 10 by 8 inches, can be slipped down, like one would drop a large card into his coat pocket. There is a flap over the top edge, sewn on to the outer calico, like a pocket flap, which falls over the top edge of the glass, and thus completely preventing any white light from entering. The oval is prevented from opening too wide, or from losing its shape, by five or six cords laced across from side to side, like miniature cross-bars of a window. Across the top of the tent are placed two sticks in the form of an X, four feet long, one inch thick, having a nick cut out of each end. Four strong brass curtain-rings are firmly sewn outside on each corner at top, into which the nicks are inserted. The two sticks are just long enough to keep the top extended, allowing a little sag to the calico. They are held together at the centres, where they cross by means of a running loop of good stout cord or rope. This rope is seven or eight yards long, and is intended to suspend the tent by throwing it over the limb of a tree, and hauling on it. By this means the tent can be raised or lowered. On the top of the tent is laid a square yard of india-rubber cloth, through the centre of which passes a short brass tube, having a flange outside, and another inside. The india-rubber cloth and calico are of course thus held between the two flanges, which can be secured tight together, thus making it perfectly water-tight. In this manner I have a very good water tank on the roof. The india-rubber tube is slipped over the brass tube, then carried into one of the angles (that is, left of window) by means of tape loops, and terminated by a small brass tap. I have three small pockets sewn on right-hand side, to hold bottles for developing. I cannot describe my table better than saying that it is a large camp stool with a stout piece of coarse canvas on top, and kept tight by a twine tying down the legs. As you will perceive, there is no door. The only means of egress is by raising the tent at one side, and getting in and out underneath. When inside, the bottom edges of the calico are trampled with the foot, so as to exclude all white light. I generally pitch my tent on an incline, so that the water may run off from under the feet. This tent has, like all dark tents, its disadvantages, but after trying other forms I find it the best. It is very portable, as it can be folded up into a small space, tied on to the camp stool, and will not take long to put up, provided you have a tree or some other suitable support from which to suspend it. If not, it cannot be used. I have used it many times in different parts of Ireland, and have never been disappointed in finding a peg from which to hang my tent.

T. O'Connor.

THE RECENT ECLIPSE OF THE SUN.

Dear Sir,—The paragraph which you quote from the *Times* refers to the great improvement in photography since 1870, and says : "It may be mentioned that when Mr. Brothers obtained an impression of the corona, in 1870, during an eclipse which lasted over two minutes, it was considered a triumph of photography ; while during the present eclipse, a plate which was exposed three seconds shows signs of over-exposure." This would lead anyone to suppose that in 1870 it required the full duration of the eclipse to produce the photograph referred to. The fact is, that during the 104 seconds I exposed *five* plates ; but owing to the partially clouded sky during the greater part of the time, only one of the photographs was of any scientific value, and this was obtained in *eight seconds*. The comparison, then, is really between *eight* and *three* seconds ; and when we consider the difference between the collodion plates as I used them, and the gelatine plates employed lately, the comparison is not so favourable to gelatine as might have been expected. I should have supposed that less than *one* second would have produced the picture referred to.—Yours truly,

A. Brothers.

HOT WEATHER TROUBLES.

Dear Sir,—If your correspondent will refer to the description of my "drying box," &c., in the Year-Book for 1881, he will find I there state that I have had the same experience as he has, but found a remedy in the use of plenty of cold or cool fresh air for drying, instead of that which is heated by the lamp. He can easily try this by putting his lamp on top of the box, and letting it draw its air supply through it—or possibly, if the room in which he uses the box is not very well ventilated, an increased supply of air to the room itself might relieve him.—Yours truly,

Richard Parr.

Dear Sir,—I notice that "Northumbrian" mentions, in connection with the formula for gelatine emulsion which I gave at the Society of Arts, troubles which he has had on account of the frilling of plates. Experience which I have had of this nuisance, and the conclusions to which I have come with regard to the cause of it, may possibly be of use to "Northumbrian" and others.

The cause of frilling is, I believe, in nine cases out of ten, an insufficient quantity of air through the drying-box, or an unevenly-distributed current and too high a temperature. Very few of the drying-boxes which I have seen have nearly large enough air-passages. With an insufficiently-ventilated box, and a high temperature, frilling is almost sure to occur. With a brisk current of dry air, and no artificial heat, frilling never occurs. In winter, a little artificial heat seems to be quite necessary; but in summer it is neither necessary nor desirable.

I may say that I do not consider the gelatine used by "Northumbrian" to be by any means the least prone to frilling. I should advise him to try the gelatine specially made by the Autotype Company for dry-plate purposes.

W. K. Burton.

PS.—I may say, in connection with the formula which I gave at the Society of Arts, that I have since then found an advantage in increasing the amount of chloride to two or three times what I at that time gave. This will not alter the composition of the emulsion, as it is intended that there should be no chloride in it, but will allow the boiling to be performed in the presence of a greater excess of soluble chloride, and sensitiveness will be more rapidly gained.

PHOTOGRAPHING THE DERBY.

Sir,—I think you will pardon me if I let your readers into the secret that you have never witnessed a Derby race, or your ideas of locality are somewhat at sea. This I infer from your criticism of my Derby race photograph, where you say, "The horses and their jockeys are also well seen, but many of them appear to have passed the post and done racing." Now, as a matter of fact, none of the horses have passed the winning post, although within a few yards of it. We all know that in front of the Grand Stand the final struggle takes place. The horses at this point must have been running at over fifty feet per second. A photographic friend (expert) who I showed the picture to, exclaimed, "Why, they are standing still!" Did he expect to see them move in the photograph? I admit that had a slight movement during exposure taken place, it would have given a better representation of the race as presented to the eye. This is very apparent in some photographs I took at the Alexandra Palace a few days ago (copies of which I will have pleasure in sending you in proof of the above statement).

I will thank you to find a place for this letter in your next issue, as I believe that the photograph in question is the first successful Derby race that has been photographed. Please also correct a typographical error that has crept into your report of the Thursday Evenings for Photographers. I am represented as exhibiting a negative taken by the "Ampit" process; it should read, ammonia nitrate process.—Yours truly, A. L. Henderson.

Proceedings of Societies.

South London Photographic Society.

The ordinary monthly meeting of this Society was held at the house of the Society of Arts, John Street, Adelphi, on Thursday evening, the 1st inst.

A communication was read from the Rev. F. F. Statham, M.A., President, regretting his inability to be present, and the chair was then taken by Mr. P. Mawdesley, Vice-president.

The minutes of the previous meeting having been read and confirmed,

The Treasurer read a communication he had received anonymously, commenting upon a practice indulged in by the members, during the reading of papers, of conversing in loud tones. The writer seemed to think that this was to a great extent the cause of the unwillingness of members to contribute papers.

Mr. W. Brooks, who has been lately elected on the Council of the Royal Cornwall Polytechnic Society, with which he has been many years connected, drew the attention of members to the Fiftieth Annual Exhibition and Jubilee of this Society, which takes place in September next, and urged upon th Society to assist in making it a success.

A number of prize lists were distributed amongst the members, and Mr. Brooks expressed his willingness to supply any further information that might be needed.

Mr. Brooks then read a paper entitled "Practical Experiences with the Alkaline Developer for Gelatine Plates" (see p. 327), and handed round for inspection some negatives, and also prints from the same.

At the conclusion of the paper Mr. E. Dunmore agreed with Mr. Brooks' opinion that sulphite of soda was a valuable addition to the developer.

Mr. Brooks remarked that many persons thought sulphite of soda prevented green fog; in his experience the reverse was the case. He thought all green and red fog was due to sulphur in some form, and believed that a great deal of green fog was owing to the decomposition of gelatine through boiling.

Mr. Dunmore thought that with regard to sulphur being the cause of green fog, in his experience he did not find any trace of it until after the plate was put into the hyposulphite.

Mr. Brooks had often seen it before being placed in the hyposulphite.

Mr. Mawdsley was very doubtful about negatives in which the shadows remained perfectly pure; where the shadows retained their pristine brilliancy there was always in his experience green fog.

Mr. Dunmore thought that might possibly be the result of not washing the negative sufficiently before putting into the hyposulphite bath.

Mr. Brooks said he had endeavoured to get the neutral tint more commonly obtained with wet plates; it took him a long time to get this colour, and it was done by using an emulsion containing chloride, and a large proportion of citric acid in the developer.

Mr. Henderson thought Mr. Dunmore was quite correct in saying that an imperfectly washed picture is more likely to give green fog. He had made an experiment with a plate which he developed in the usual way. One-third of the plate was then immersed in weak acid, the opposite end being immersed in a weak solution of ammonia for two minutes, the centre portion receiving no further treatment. When fixed, the portion treated with acid was perfectly free from green fog, the other portions showing it more or less.

Mr. J. Nesbit thought it would often be found that green fog was the result of the action of ammonia upon the gelatine in some way; it seemed to him that this would point to the action of ammonia upon the pyrogallic developer, and not to anything in the hyposulphite or pyrogallic. He would like to ask if any one had ever noticed green fog after using the ferrous-oxalate developer.

Mr. Dunmore had often found it so.

Mr. Brooks remarked that by substituting carbonate of soda, you did away with green fog altogether.

Mr. Nesbit thought it seemed strange to get green fog with the ferrous oxalate developer, and that an excess of ammonia must be the exciting cause of it.

Mr. Henderson said it had nothing to do with the gelatine whatever, but was caused by the bromide.

Mr. Bolas remarked that opinions were so diverse on the subject, that it was difficult to arrive at any conclusion whatever. He thought the green fog arose in some cases from gelatine in a state of decomposition, and said that when Mr. Plener changes the gelatine, the green fog disappears.

Mr. Brooks said some gelatines would stand more cooking without giving green fog than others.

Mr. Coles had found sulphite of soda to be a valuable preventive of green fog.

Mr. Brooks said that many photographers, instead of getting sulphite of soda, got sulphate. In his hands sulphite was more a producer of green fog than otherwise, but those plates that gave it thus had not a trace of it when common washing soda was used. In place of ten minims of liquid ammonia he used a saturated solution of soda. He had not tried carbonate of potash, but had tried chemically pure carbonate of soda; he found, however, common washing soda preferable. Ammonia affected the chest of some operators, which was not the case with soda. He did not find soda caused "frilling"; he generally used a very hard gelatine, and had actually developed with water at 90° temperature without "frilling."

The Chairman then remarked that the general opinion seemed to be in favour of the use of sulphite.

Mr. Bridge informed the meeting that there was a question in the box, "What is the best formula for toning ready-sensitized paper?"

Mr. Henderson thought this was a very difficult question to discuss until they knew how the paper was prepared.

Mr. Bridge had found it better to make a new bath than to strengthen the old one. In buying paper, you perhaps got one sheet perfectly good, and the next one might be of no use at all. A gentleman had told him it was a good plan to soak the prints in a weak solution of soda.

Mr. Foxlee had met with great success with an obstinate sample of paper by immersing the prints in a weak solution of washing soda.

Mr. Dunmore thought it was the introduction of acid into the toning bath that caused prints to go "mealy," and would recommend a fresh bath.

Mr. Brooks had been using a chloride-of-lime bath, but found it better to introduce acetate of soda. After washing the silver out of the prints, he recommended letting them lie for a few minutes in a weak solution of carbonate of soda, putting them in singly, to make sure of the action taking place equally, and then taking them out and filling up the dish with water. He would have the bath made up of double strength, and get about the same bulk of hot water. When he did not raise the temperature of the bath above that of the atmosphere, he found the toning to go on slowly. He used 15 grains of gold, ½ drachm of chloride of lime, 1 ounce of acetate of soda, and about ¼ ounce of chalk. He had not the slightest difficulty, and could tone three sheets of paper with 2 grains of gold. He had great difficulty in toning until he neutralized the acid with an alkali.

Mr. Cowan recommended the following:—

Borax	2 ounces
Boiling water	80 "

and

Chloride of gold...	10 grains
Water	80 ounces

using 8 ounces of each solution to tone a sheet of paper. If used at a temperature above that of the atmosphere, the prints would be mealy.

Mr. Nesbit found the gold go down more readily with durable sensitized paper than with ordinary.

Mr. Mawdesley believed it was false economy to use a bath a second time.

Mr. Bridge found less markings with ready-sensitized paper. For some years he had used a composition called York's salt of gold, and found that the bottle would tone twenty-four sheets of paper. Since he had used ready-sensitized paper, he could get the same result.

The Chairman then presented Mr. E. Dunmore with the Society's silver medal, won by that gentleman in the Artistic Competition.

This being the last ordinary meeting of the season, a discussion ensued as to the rendezvous for the usual outdoor meeting, and it was eventually decided that the first should take place at Jack Straw's Castle on the first Saturday in July, tea being arranged for six o'clock.

The Chairman then called the attention of the Society to the presence in their midst of Mr. J. Traill Taylor, formerly one of their members, and remarked that he was sure that they would all be glad to see him.

Mr. Taylor, who was heartily received, said he had great pleasure in appearing amongst them again; he came as a representative of the Congress of Photographers' Associations of America to be held in August next, and said he had a very great desire to see English art well represented on that occasion. He would be very glad to take charge of the pictures of intending exhibitors, which he would have placed in the most favourable positions possible, and would return them safely. Any pictures addressed to him in the care of either of the weekly journals would reach him, and he would like them to be sent not later than the first week in July if possible, as he would be leaving England about the 13th to 20th July. The pictures need not necessarily be large, and he would like to see landscapes of subjects out of the ordinary beaten track of portraiture.

The Chairman having called for a vote of thanks to Mr. W. Brooks for his able and interesting paper, which was heartily responded to, the meeting closed.

Thursday Evenings for Photographers.

At the meeting held on the 1st inst., Mr. Alexander Collier occupied the chair.

Mr. Henderson passed round a negative which he had, with a view to reduce the density, treated with a solution of iodine and cyanide; this removed most of the silver, but left an opalescent stain, apparently caused by some insoluble compound left in the film.

Mr. Coles exhibited a transparency that had been reduced by immersing it in a solution of permanganate of potash; but it having been left exposed to light behind a negative for a week or ten days, the negative image was printed on it, showing that negatives so treated darkened by exposure to light.

Mr. Brown said he had frequently used a solution of permanganate of potash as a stain for wood; it darkened by exposure to light, giving quite as good a stain as that obtained with bichromate of potash.

Mr. Henderson exhibited a number of instantaneous negatives taken at the Alexandra Palace on Whit Monday.

Mr. J. Traill Taylor, in the course of a few remarks upon photography in Amercia, said that at present there is an enormous number of amateur portrait makers (not photographers) in America, and that he estimated there were more cheap sets of apparatus disposed of in one day in New York than by all the English makers in three months; and he exhibited a specimen of the dark slides issued with these cameras; it was machine-made, the plates sliding into grooves; the slides, which were made of stout milboard, drew right out, a light-trap closing after them.

Mr. Le Fevre introduced M. De Fonville, president of the French Aeronautical Society, &c., to the meeting, and he gave a most interesting acount of the progress of balloon photography in France, stating that on his next trip he intended using the photographic revolver invented by M. Janssen, and he was very sanguine of success.

Mr. Ashman said it had been stated that immersion in the hyposulphite bath reduced the intensity of negatives; in his experience the result was quite the reverse, and he passed round a negative, half which had been left for twelve hours in the hyposulphite solution, and was much more dense than the other half.

Mr. Debenham thought the negative was stained by sulphide of silver, for which he knew no solvent.

Mr. Ashman had been able to remove the stain by treating the plate with hydrochloric acid, boracic acid, and alum.

Talk in the Studio.

Photographic Society of Great Britain.—The last meeting of this Society for the present session will be held on Tuesday next, June 13th, at 8 p.m., in the Gallery, 5a, Pall Mall East, when papers will be read by C. R. Woods, "With the Eclipse Expedition," and by J. Cadett, "On the Comparative Efficiency of Various Instantaneous Shutters."

Glass Roofs and Ceilings.—M. Arthur Morin, director of the Conservatory of Arts and Trades at Paris, writes on the influence of glazed roofs and ceilings during the winter:—"If in the summer season the glazed roofs of stations and covered courts present the inconvenience of producing a heating effect, which it is necessary to overcome, in winter they have the contrary defect, which often leads to very disagreeable results. The conductibility of thin glass then leads to a considerable cooling of the interior layers of air in contact with the glass; this air, becoming denser than that below, descends, and is constantly replaced by more, which is likewise cooled, and by this continued movement the rooms thus covered become very difficult to warm. To these troubles is added that of the motion of the cold air, which naturally flows towards the chimneys, or the discharge openings, if there are any, so that the occupants feel a descending current of cold air, the more unpleasant the nearer they are to the chimney or the discharge openings. If the glass roof is single, and has, as is almost inevitably the case, joints, through which the external air—much colder than that in contact with the internal surface—penetrates into the room, the effects which have been mentioned become more sensible and disagreeable. There is also the danger that water will enter during rain storms. It is, then, necessary in occupied buildings, when similar plans are adopted for lighting, to place under the roof a glass ceiling with as few joints as possible, and in the loft thus formed and limited above and below, to provide heating arrangements which will prevent the cooling of the ceiling, and thus to avoid the cold air currents which have just been referred to".

NEW ZEALAND SCENERY.—We have received from Messrs. Burton Brothers, of Otago, New Zealand, some charming views of lake and mountain, secured on a visit to a remote portion of the island, of which an interesting account appears in another column. We cannot give higher praise to Messrs. Burton than to say that their productions remind one of a series of Mr. W. England's Swiss views. There are here placid lakes, snowy mountains, lofty crags, and magnificent cloud pictures, proving that not only are the antipodes blessed with magnificent scenery, but also with photographs of taste and culture capable of doing justice to it.

ALBUMENIZED AND SENSITIZED PAPER.—Speaking of Mr. William England, we may mention that that gentleman, or rather we believe one of his sons, is occupying himself with the manufacture of albumenized and sensitized papers. Mr. England has never used any but paper of his own preparing in producing the vast number of prints which, for a quarter of a century past have made their way out of his studio into every corner of the world, and hence we may take it there is plenty of knowledge and experience at hand for undertaking the manufacturing work in question.

ROYAL CORNWALL POLYTECHNIC SOCIETY.—The next Exhibition will open on Tuesday, September 5th, and the following regulations affect photographic exhibits. In all cases state whether the work is professional or amateur, and name process of production. All works sent for competition must have been executed within eighteen months of the date of this Exhibition. Carte-de-visite portraits are excluded from Exhibition except when illustrating some special process or novelty. *Professional Photographers*—Medals are offered by the Society for meritorious productions in the following subjects:—1, for landscapes; 2, for portraits; 3, for composition pictures; 4, for instantaneous pictures; 5, for dry plate pictures; 6, for pictures by improved processes; 7, for enlargements. *Amateurs*—Medals are offered for meritorious productions in this department. *Photographic Appliances*—Medals are offered for improved apparatus and appliances, including magic lantern work. All exhibits in this department must be accompanied by a written explanation of their specialities. Further information respecting the photographic department may also be obtained from Mr. W. Brooks, Warren Road, Reigate, who has kindly undertaken to assist the Society. All paintings, drawings, sketches, and photographs must be framed; and if left at one of the following places on or before Tuesday, August 22nd, will be conveyed from these depôts to and from the exhibition free of charge, namely:—Mr. W. A. Smith, 20 and 22, Mortimer Street, Regent Street, London, W.; Messrs. Worth and Co., Cathedral Yard, Exeter; Mr. T. T. Bartlett, Ebrington Street, Plymouth; Mr. H. M. Harris, Union Street, Plymouth; Messrs. Thomas Solomon and Co., King Street, Truro.

ATMOSPHERE DE LA LUNE.—Les journaux de France annoncent que les savants de l'expédition d'Egypte viennent de découvrir que la Lune avait une atmosphère. Il y a dix ans que nous connaissions à Jersey ce que ces savants ignoraient il y a quelques jours. Qui ne se souvient ici des photographies lunaires de M. E. Ogier, et du tapage qui se fit en Angleterre à l'occasion de sa découverte? Nous voyons encore ces images obtenues par l'atmosphère lumineuse de la Lune à La Collette; nos confrères de Jersey publièrent la plupart des articles de la presse Anglaise de 1870 à 1871, surtout ceux du *Photographic News*. Un an après, si nous avons bonne souvenance, M. Baudoux, photographe, de Jersey, exposait un cadre de photographies lunaires au Collège; donc, pour rendre le communiqué des savants français tout-à-fait amusant, il serait à désirer que leur preuve ait été acquise par la photographie; ce serait un comble. M. Pegot-Ogier a quitté la photographie pour reprendre les travaux historiques et littéraires, mais nous qui connaissons son mérite et l'antériorité de sa découverte, nous croyons devoir l'engager à réclamer l'honneur qui lui appartient. On ne saurait assez remarquer combien est grande la part des amateurs dans le progrès des sciences et des arts. Est-elle moindre que celle des hommes de profession? Non; mais justice leur est bien rarement rendue.—*Jersey Chronicle.*

LONDON RELICS.—The issues of the Society for Photographic Relics of old London, now ready for forwarding to subscribers, comprise twelve large photographs by Mr. Dixon, of Albany Street, and two sheets folio size of letterpress descriptions, furnished by the hon. secretary, Mr. Alfred Marks, of Long Ditton, Surrey. The series of interior and garden views of Ashburnham House are especially interesting and apropos. With these is the old Buckingham Water-gate, whose fate it is in these latter days to be entirely separated from the river whose waters once washed its stone steps; and the Banquetting Hall, Whitehall, immortalised as the scene of King Charles's execution. The remaining photographs are views of fine old mansions on the west side of Lincoln's-inn-fields, regarding the history of which Mr. Marks furnishes some interesting particulars. The past year, we learn, has been fatal to more than one of the few works of Inigo Jones which but a little while ago yet lent beauty and interest to London streets. This circumstance yields an additional ground for satisfaction in the fact that the labours of this celebrated architect furnish most of the subjects of the present series of the Society's issues.—*Daily News.*

ACTION OF LIGHT ON FERRIC-OXALATE.—M. Jodin writes, in the *Comptes Rendus*, that the sensitiveness of ferric-oxalate solutions varies with their composition. If one takes a solution containing half molecule of ferric-chloride and half molecule of oxalic acid to each litre, and compares it with a solution containing three molecules of each, the photo-chemical sensitiveness of the former is about six times greater than that of the second. This decrease of sensitiveness with increase of strength seems connected with a certain complexity of the photo-chemical and photo-thermic properties of ferric-chloride.

OXIDATION OF PYROGALLOL IN PRESENCE OF GUM ARABIC.—Ph. de Clermont and P. Chautard.—The authors, following the indications of H. Struve, obtain purpurogalline by causing aqueous solutions of gum arabic to react upon pyrogallic acid, likewise dissolved in water. They dissolve 10 grms. pyrogallic acid in a little water, and add to the solution 500 c.c. of a solution of gum at one-tenth. The whole is introduced into a wide flask containing 2 litres. In a few moments the mixture becomes pale yellow, and shortly afterwards brown. After some hours the purpurogalline begins to be precipitated; the deposit increases daily, and in two months the operation is terminated. They add then an excess of water to remove the gum; the precipitate is let settle, and washed several times by decantation, and then filtered. The purpurogalline is thus obtained in crystalline needles of a fine golden-yellow, which are freed from traces of gum by being dissolved two or three times in alcohol.—*Chemical News.*

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. PIPER & CARTER, "*Photographic News*" *Office*, 5, *Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. PIPER & CARTER, *and crossed* "*Union Bank, Photographic News Co. Account.*"

*** We cannot undertake to return rejected communications.

AN IGNORANT AMATEUR.—1. The substance in question adheres most persistently, even such solvents as chloroform and carbon disulphide only removing it with extreme slowness. 2. We think you have made some mistake in the figures: write again. 3. It is principally a difference of name, the proportions not being very considerably altered. 4. Just so.

INSPECTOR.—1. The firm referred to undertook its manufacture over six months ago, but after several trials have failed to finish a single instrument, the very easy adjustments required proving too much for them. Any philosophical instrument maker can make the apparatus if you furnish him with the description and drawing which appeared in the PHOTOGRAPHIC NEWS, or with the Specification issued by the Patent Office, and you cannot do better than apply to the maker of the lens to which you refer. We are told that a simplified form is sold by the Photographic Stores Company, but we have not seen one. 2. Shortly.

STUDIO.—What you wish for can be easily attained by hanging curtains obliquely across, so as to shade the end at which you have placed the camera. The tint mentioned is as suitable as any.

A. B. C.—A notable degree of cold is produced when hyposulphite of soda is dissolved in water, and if the solution is used when cold, its solvent power is proportionately reduced. No doubt this is the cause of the irregularities you notice.

H. H. B.—1. They must be mounted before removal from the glass, and moderately thin glue answers extremely well. 2. The so-called albumen colours are very suitable, or a little of the pigmented gelatine taken from the surface of carbon tissue may be used. A good method is to place a small piece of the tissue on a warm plate, and work a little of the pigment off with a brush moistened with a two per cent. solution of potassium bichromate, this latter serving to quickly render the spotting insoluble.

E. A. M. (Barnet).—A mere trace is present; but one never can know how little may do mischief.

G. M. Redaway.—As you require nothing larger than 10 by 8, you had better take your pictures direct, except in special cases. The most suitable lenses are those of the symmetrical or rectilinear type, and for the two sizes you mention you might commence very well with a wide-angle rectilinear or portable symmetrical of six inches focus, and a rapid lens of the same character having a focus of eleven inches. In each case the lens may be divided, should you require to approximately double the focal length; but the marginal lines will suffer a little as regards straightness. An ordinary bellows camera will be most suitable, and it is very questionable whether it is advisable to have one fitted with a swing-back.

A Query.—Mr. George Breithaupt, of the Bank of Madras, Bellary, writes:—"I should like to place the following question before you and the many readers of your paper for an opinion, and shall feel greatly obliged by your kindly giving it a place in one of your issues. Is it usual with respectable trading firms to advertise that they are prepared to supply all articles at manufacturers' prices (as also advertised by them) less 5 per cent. discount for cash, and when receiving an order to add on to the manufacturer's prices in their invoice, and then grant the discount on the *increased sum?* Is this a perfectly fair and equitable transaction, and the usual practice of London firms? To the instance in point. About September last, I received from Messrs. Blank and Co. a rapid rectilinear lens, 12 by 10, by Dallmeyer, in *rigid setting* (I asked for one with rack-and-pinion). Mr. Dallmeyer's price for this lens is £11, as per his and Messrs. Blank and Co.'s catalogue. Messrs. Blank and Co., however, charge me £11 10s. in their invoice, and then allow me 5 per cent. on the £11 10s. Presuming it was an accidental error, I wrote to them on the 25th August last, but my letter was ignored. I wrote again on 21st March after a lapse of seven months, and am now told that I only paid £10 18s. 6d. for the lens, and that that "answers my query *re* price." Their logic is beyond me. I *have* paid only £10 18s. 6d. (*i.e.*, with 5 per cent. off £11 10s.); but as the original and correct price of the lens was only £11, and not £11 10s., I ought not to have been charged more than £10 9s., *i.e.*, 5 per cent. off £11, in lieu of £10 18s. 6d. As Messrs. Blank and Co. do not appear inclined to act fair by me in the matter, and refused the over-charge of 9s. 6d., it's a duty I owe to myself, and to others out here, to ask you to publish this letter in common justice. Messrs. Blank and Co's. conduct in this matter has surprised me; but what follows will, I think, surprise you and your readers. They conclude their letter to me by saying that they "think that our Mr. Blank's friendly relationship with the heads of the two journals (even if other reasons do not interfere) will prevent your troubles (if such exist) having any outlet from those sources." In plain language, Blank and Co. have the assurance to insinuate that their "friendly relationship" with yourself and the editor of the *Photographic Journal* (?) would interfere with your positions on which we rely, and would prevent your doing an outsider an act of justice in making public the unfair treatment I have been subjected to. If Messrs. Blank and Co. care to admit that the invoice at £11 10s., in lieu of £11, was a clerical error, and refund the overcharge with that explanation, I shall certainly have a better opinion of them than I can possibly have now. [We have personally dealt with Messrs. Blank and Co. for several years prior to our connection with this journal, and must avow that we always found the firm straightforward and courteous. We cannot but think a little "friction" must have here come between buyer and seller, and no doubt, ere this, a satisfactory ending has been made to the little quarrel. As to the reference to ourselves, it is amusing, certainly, but nothing more.—Ed. P. N.]

W. Paton.—Certainly; use a little bromide of potassium.

T. W.—We should advise you to purchase the sulpho-pyrogallol from the Platinotype Co.; see our advertising columns. If you cannot make that answer, let us know again; but we have had no difficulty in getting negatives both *clear* and *vigorous*.

An Old Dry Plate.—1. Probably the developer would no longer develop; anyhow, you might try it. 2. Let us have further particulars, especially as regards the advantages over the old method.

Big Nemo.—We have observed something similar in the case of a badly albumenized paper with which we met some time since, when an irregular reduction of silver took place.

THE PHOTOGRAPHIC NEWS.

VOL. XXVI. No. 1241.—*June* 16, 1882.

CONTENTS.

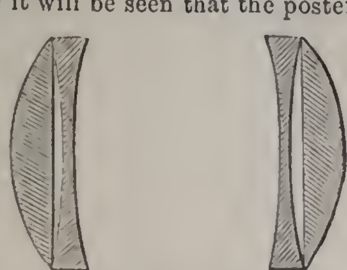
CERTAIN MODIFICATIONS IN THE CONSTRUCTION OF PHOTOGRAPHIC LENSES.

Mr. J. TRAILL TAYLOR has recently given most interesting demonstrations of certain modifications of the forms of photographic lenses which are common in America, but which are so little known in this country that such recollections as we can give of Mr. Taylor's remarks may be interesting to our readers.

The first modification illustrated has reference to portrait lenses. A demand was made for a lens similar to that known as the carte-de-visite lens; that is, one which would cover with full aperture a considerable plate. The desired effect was brought about by allowing a small air-space between the two lenses forming the front combination. These were ground to slightly different radii, so that, while they touched at the edges a little, they were parted at the centre.

The next modification, and a far more important one, is that made in the class of lenses of the "rapid rectilinear" or "symmetrical type." The object which the American optician who introduces the changes has in view is the minimizing of the thickness of the optical glass used, as such glass is subject to an enormous duty in transmission to America. All those who are familiar with our English and Continental rapid lenses know that each combination consists of a very deep meniscus made up of two lenses, one a deep converging meniscus, the other a deep diverging meniscus. Those who are not familiar with the lens may refer to our recent illustrations, although in them we do not show the separate lenses of each combination.

The deep form of lens involved thick glass before grinding, and Mr. Morrison, an American optician, found that he could get the same result by the use of flatter lenses if an air-space were left between them as shown in our illustration. Here it will be seen that the posterior surface of



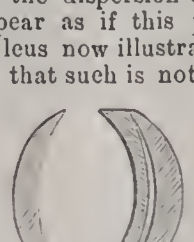
the front lens is a plane, whilst the anterior surface of the back lens is slightly curved, so as to touch at the edge, but not at the centre.

By comparing this sketch with that of one of our Continental or English lenses it will be seen that the American form involves far thinner glass than the other. Mr. Taylor tells us that as regards definition and covering power the one seems to be as nearly as possible equal to the other. A great drawback is to be found, however, in the two extra reflecting surfaces. It is true that the loss of rapidity from many reflecting surfaces is small. There is a reason for this. It must be taken into consideration that every reflecting surface is also a diffusing surface, sending light in all directions; and also that every reflecting surface sends light not only back from the lens towards the object, but also re-reflects the light reflected from every surface behind it, and also the light falling on the sensitive film. All this inclines to increase the dispersed light in the camera, whilst it slightly diminishes the direct or useful light. The diffused light acts somewhat as the "auxiliary" exposure which used to be permitted in collodion days, and counteracts the slowing action due to the loss of direct rays; but it is at the sacrifice of quality, and, to a still more notable degree, of latitude of exposure. This applies, of course, specially to rapid dry plates, which require such care in working. With such the greater latitude afforded by a single lens than that afforded by one having several combinations is very marked.

The next modification referred to is a still more remarkable one. It is made in the lens known variously as "globe lens," "wide-angle rectilinear," "wide-angle symmetrical," &c.

The usual form of this lens is well known. It consists of two very deep menisci opposed to each other, and so placed that the outer surfaces very nearly form parts of a sphere.

By a well-known principle in optics, when two uncorrected deep meniscus lenses are thus placed with a small stop between them, all oblique rays will be achromatized, the back lens correcting the dispersion of the front. At first sight it would appear as if this principle were taken advantage of in the lens now illustrated; but a little consideration will show that such is not the case. The front



lens of this combination is the usual one—that is, it is achromatic, whilst the back one is uncorrected. It is evident that in such a case there must be considerable chromatic aberration. It is impossible for rays already achromatized to pass through an uncorrected lens without suffering chromatic aberration. The fact, however, remains that the lens works in practice; the explanation must be that given by Mr. Taylor. He points out that the achromatism in a photographic lens is always but a compromise, and it is likely that in the case of the lens in question, which works with but a small aperture, the aberration is in reality less than it is in a large aperture lens, which is nominally fully corrected.

Several American "dodges" were shown besides these modifications in construction which we have described, such as vulcanite diaphragm, peculiar arrangement of the rackwork of the portrait lens, a shutter in the form of a diaphragm dropping through the lens, &c.; but as all these have been already described in our columns, they do not call for particular notice here.

Mr. Taylor's excellent demonstration suggests to us many reflections, principally the one made by himself. He asks why photographers should leave themselves so completely in the hands of the opticians as they do? Why should they not take the matter of their lenses in their own hands, and experiment for themselves? Every photographer is a chemist; how few are opticians! Yet the one is nearly as easy as the other. It is generally supposed that to have any knowledge of optics, deep skill in mathematics is necessary. How little true this is, is shown by the fact that some of our most successful practical opticians have been but ingenious workmen who have arrived at most useful results by simply trying the effects of different combination of lenses. It is true that without a deep knowledge of mathematics no man need expect to perform a master stroke such as Petzval did, when he turned out the portrait lens in such a form that for a third of a century no improvement but in details has been made in it. But a little experimenting combined with some common sense will show the photographer that he has in most of his lenses powers he has little dreamed of. The optician makes a lens; he says, "This is a landscape lens." The photographer obediently uses it for landscape, and landscape only. Yet were he to venture to enlarge the aperture which the optician has provided for him, we know that he has a lens for portraiture superior, under certain circumstances, to the most expensive instrument marked by the optician "portrait lens;" whilst in the latter, did he dare to unscrew one combination, he has a perfect "landscape lens."

How great a power the photographer who gives the subject his consideration has, is shown by an example given by Mr. Taylor. This gentleman, having a globe lens of the ordinary pattern, with two combinations, and wishing a pair, unscrewed the back combination, and, fixing a deep meniscus spectacle glass behind each combination, had a pair of lenses similar to the one sketched above, and working, he says, admirably!

The remarks which were made at the meeting referred to bring up to our minds forcibly the necessity, which we have often urged, for a *standard of definition*. In astronomical work there is such a standard, and we do not have such terms as "perfect definition," "sharp as a die." That photographers are inclining to take the matter of their lenses into their own hands is shown by the fact that our advice, given more than a year ago, as to the advisibility of a standard of rapidity, seems likely to be put in effect. Let us hope that it will be the first of a series of standards, one being a *standard of definition*.

RECENT RESEARCHES ON ALBUMENOID BODIES.

A tolerably exhaustive monograph on bodies of gelatinous nature has recently been published by M. Béchamp, and the great importance of this subject from a photographic point of view renders it necessary that photographers should know something of the work of this able investigator.

Those complex organic bodies ordinarily known as albumenoids and gelatinous substances, whether liquid and coagulable, as white of egg and vegetable albumen; or solid, as in the case of the fibrous and horny constituents of the animal organisms, are, perhaps, at the same time the most interesting and the least known of organic compounds. As they are neither volatile nor crystallisable, the greatest difficulties are experienced in obtaining them in a pure and isolated state, and it not unfrequently happens that what appears at first sight to be a new body turns out to be a previously-known substance in an impure condition. Up to the present those distinctive properties which should enable us to draw sharp lines of demarcation between the various albumenoids are obscure and ill-defined, and a study of their elementary composition presents unusual difficulties, while when formulæ are deduced, they offer so much complexity as serves to put them almost outside the pale of the systematic organic chemistry of the present day. Notwithstanding this, there is some hope that before long the true composition of these bodies may be unfolded by patient labour and investigation.

Notwithstanding the amorphous nature of these bodies and their non-volatility, there is one characteristic which enables us often to judge of their purity, this being their rotative action on a bundle of polarized rays; and, by taking advantage of this characteristic, M. Béchamp has classified these bodies into well-defined groups, and it is to be hoped that further work in this direction will yield abundant and valuable results.

The white of egg appears to contain no less than three albumenoid bodies, one of which is precipitated by acetate of lead, another which is thrown down by basic acetate of lead, while the third is not coagulable by heat, is soluble in water, and insoluble in alcohol. The two first-mentioned offer the general characteristics of albumenoid bodies, while the third is rather of the character of a ferment, and it possesses the property of liquefying starch. These three bodies rotate the polarized ray to the left, their powers in this respect being 34°, 52°, and 78° respectively, and they appear to unite with acids almost as if they possessed basic properties.

The ferment thus discovered in the white of egg explains certain phenomena incident to the process of incubation, and there can be but little doubt that this substance will be found to have an important bearing on the process of silver printing, especially with reference to the permanency of the pictures.

Among the remarkable chemical re-actions which modern research has brought to view, may be mentioned those of a so-called catalytic nature in which a substance seems to induce decomposition by its presence without in itself undergoing any change, and the decomposing action of fibrine on peroxide of hydrogen is of this nature, the peroxide splitting up into water and free oxygen. When fibrine is treated with dilute hydrochloric acid the greater part dissolves, but an insoluble residue always remains, and Béchamp has demonstrated that it is this insoluble body which induces the decomposition of hydrogen peroxide.

The insoluble body in question is a true albumenoid, and, when heated to the boiling point, in contact with water, it loses its decomposing influence on peroxide of hydrogen. When, however, it has been dried at a low temperature, it retains its catalytic properties unimpaired for a length of time.

The investigations of M. Béchamp are being extended to the decomposition products of albumenoids, and we shall not fail to present to our readers full particulars of those points which appear likely to have a very direct bearing on photographic progress.

SOURCES OF FAILURE IN PHOTOGRAPHIC WORK.

An interesting article on this subject, from the pen of Dr. H. W. Vogel, appears in the *Notizen*, the substance thereof being as follows:—

It is frequently my lot to give counsel and advice to photographers who come to a dead block with their chemicals, or otherwise get into difficulties; but to always give useful and practical advice through the medium of a mere verbal or written communication is not by any means easy.

On one occasion a collotypic printer informed me that he had been troubled for some weeks with roundish spots on his negatives, and these had remained master of the situation, notwithstanding changes of collodion, bath, and developer. He sent two negatives for my inspection; these being taken from the same original (a map), but on a different scale. When I came to examine them I soon found that the relative position of the spots was identical in each negative, clearly proving them to arise from some peculiarity in the original map; and an examination of the batch of maps which the collotyper was engaged in reproducing showed the presence of yellowish iron stains, so faint as to be scarcely visible to the eye, but of sufficient intensity to notably influence the photographic reproduction.

In another case a photographer was troubled with faint, cloudy markings, concerning the origin of which it seemed by no means easy to form an opinion. The silver bath was changed, and the trouble immediately ceased; yet the defect was rather in the developer than the bath, this preparation containing enough alcohol to work well with a new bath, but not sufficient to enable it to flow smoothly over a plate sensitized in an old bath. Collodions differ much as regards the amount of alcohol which it is necessary to add to the developer, the use of horny kinds often necessitating the addition of a considerable proportion.

I could give many instances of troublesome failures arising from a careless reading, or insufficient study, of clearly-expressed printed directions; and these failures have, in many cases, had very serious consequences for the photographic practitioner, besides often occasioning much loss of time to the originator of the directions, who may write letter after letter without touching on the real cause of the failure. On one occasion I recommended a manufacturer to practise Liebig's process for silvering by the chemical process, as I had found it to yield most excellent results. He, however, instead of adding the potash gradually, as ordered in the directions, added the whole quantity at once to the silver solution; and this failure to comply with plain directions caused him to lose several months of time. On the other hand, we sometimes meet with those who fail to read the current photographic literature because they consider their knowledge so complete as to render such a proceeding unnecessary. Not long ago, a person of this class, who receives my journal, but seldom cuts the leaves, asked me for information on a point which had been repeatedly discussed, upon which I of course referred him to my journal.

There are also some eccentric people whose proceedings are such as to confound every kind of instruction; and one of these, who had lately removed to Berlin, was much concerned when he found that the water in which he first washed his prints did not become milky as he had usually seen it, the fact being that the Berlin town water is unusually free from chlorides. This intelligent individual could not rest until he had found a water which would become milky; he fancied that his work was unsatisfactory when done with the Berlin water. At last he secured what he wanted by digging a well at a considerable expense.

MR. PLENER'S PHOTOMETRICAL INVESTIGATIONS.

In our issue of last week Mr. Plener resumed his study of the relation between exposure to light and density of deposit in the case of dry plates, and he has raised points which are likely to call forth a considerable amount of discussion; moreover, his argument will doubtless lead to numerous experimental investigations, which may be undertaken with the view of further elucidating the subject.

Mr. Plener's idea of constructing a scale of perceptible gradations by the intermingling of definite proportions of white and black powders is ingenious, and appears to be thoroughly practicable if carried out with sufficient care and attention to detail; while it appears that two careful and accurate experiments with definite pigments will afford the data for constructing a scale of any required extent and completeness by the admixture of the pigments in question.

Mr. Warnerke's sensitometer is next brought under consideration, and it is pointed out that this might have been constructed so as to give the scale of perceptible graduations rather than a series of varying stages of opacity having a highly complex ratio to each other.

A wet gelatine plate, having its film thickened by the absorption of water, transmits a larger proportion of the incident light, and, as a consequence, it absorbs less, and therefore requires a longer exposure: and something similar will necessarily hold good in the case of two of the Warnerke screens having the same amount of Indian ink, but distributed through different thickness of gelatine. Mr. Warnerke's sensitometer numbers are next brought under consideration, and it is found that, assuming No. 9 to be the faintest tint, the real sensitiveness rather corresponds to 15·752 than to 9·147.

By-the-Bye.

A PLEA FOR THE BURETTE.

The photographer is usually deficient in chemical apparatus, and, truth to tell, he can get on very well with a limited supply of it. But if there is no need for a complete chemical laboratory in connection with the dark room, it is important he should have proper utensils at hand when he does want to perform an experiment or make some simple assay. Where space is limited, our advice is to keep one corner of the work-room, or of the dark-room, if it is large enough and light enough for the purpose, for a laboratory corner; all that is absolutely necessary is a shelf near at hand, where a few pieces of apparatus may be kept clean and orderly, a small firm table or ledge for working on, and an adjacent sink. It is well to have a gas main with flexible gas tube and burner, but this is not indispensable, as a spirit lamp answers most purposes.

A few glass beakers, test-tubes, and wide-mouthed stoppered bottles, always kept clean, some filters and a filter stand, a flask or two, and iron ring-stand for boiling, one or two porcelain evaporating dishes, and perhaps a retort, represents a stock of apparatus that most photographers would consider luxurious. Yet its cost is only a few shillings, and any photographer who desires to learn the why and wherefore of this or that reaction can scarcely do without it. But we are about to advocate a still further addition to the modest outfit of a photographer, an item more expensive still than any just enumerated; we mean the burette.

The burette, however, is not a very costly piece of apparatus, after all. We show two kinds of burette here (fig. 1), either of which will suit the photographer, though we advise him to use the one having a glass stop-cock. They are termed Mohr's burettes, and are to be obtained of any dealer in photographic and chemical apparatus. Supposing the photographer to be satisfied with a burette containing 50 cubic centimetres, he can obtain one with a glass stop-cock for five shillings, while that with the pinch-clamp costs four. For this amount he will receive a vessel graduated not only into cubic centimetres, but into tenths of these as well.

For use, the burette, after being filled with liquid, is made fast to a firm stand—the iron ring-stand will do—in such a way that it hangs over the table before the experimentalist, its tap ready to hand, and its scale more or less on a level with the eyes. The tap should be some inches above the table, so that any vessel destined to receive the liquid from the burette can be placed underneath without difficulty. The tap is turned and the liquid runs from the burette in a small stream. To control the amount of liquid issuing forth is the easiest thing in the world, for you have simply to observe the scale on the burette, and

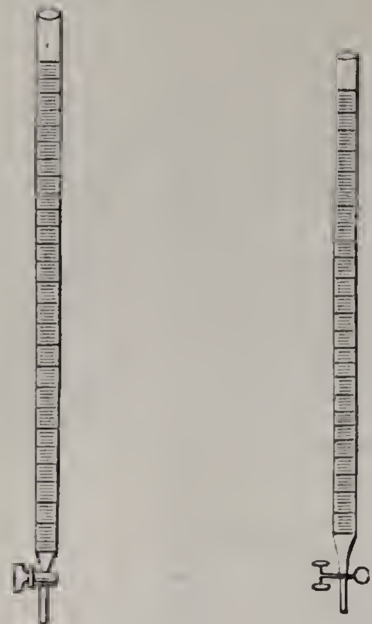


Fig. 1.

to turn the stop-cock as soon as the liquid has sunk to a certain degree. Thus it is easy not only to read off cubic centimetres, but also tenths of cubic centimetres, without much difficulty. To aid in reading off, chemists generally employ a little screen, half white and half black, which is put behind the scale, and so shows the level of the liquid at a glance (fig. 2). This screen, of course, is easily made out of a bit of cardboard.

Fig. 2.

For some purposes the pinch-cock—a pincers pinching a little bit of rubber tube—is more handy than the glass stop-cock, which, by the way, usually wants greasing a little to make it work smoothly and to prevent leakage; but for photographic purposes we think the latter is preferable. The rubber tubing contains sulphur, which is objectionable, and cannot well be cleaned; at the same time this form of burette is more quickly used, and the liquid flows more freely.

It is difficult to say for what photographic operations the burette may not be used with advantage. In the first place, it may be employed as a simple measure, or converter of English drams and ounces into cubic centimetres. All calculation of fractions is at once avoided; to turn a fluid ounce (English) into cubic centimetres (French), we simply turn the liquid out of the ounce measure into the burette. To measure off cubic centimetres accurately again, there can be no more simple plan than that of filling the burette, opening the stop-cock, and reading off as the liquid descends in the scale.

A burette divided into tenths of cubic centimetres allows of the measurement of very small quantities, and the measurement of small quantities is usually not gone into by the photographer, because in ordinary circumstances it is troublesome. But, as soon as he finds that it is as easy to make small and accurate measurements as to make haphazard guesses—and with a convenient burette this is so—the photographer will be ready to adopt the more rational mode of proceeding. The fraction of a cubic centimetre may appear very small to write about, but when familiar with the burette, the measurement of tenths is a very simple matter. In fact, it is almost impossible to make such measurements without it.

We have found it convenient to employ the burette to hold the warm solution of silver in emulsion making. The fine stream of silver can be regulated with the greatest nicety in a burette. The eye watches the scale as the liquid gradually runs down, and both hands are at liberty for mixing the emulsion. If coming too fast, the stream may at any moment be cut off, and the dose of silver increased or diminished to the tenth part of a cubic centimetre with exceeding accuracy.

Other similar uses will suggest themselves for the burette, but its existence in the photographic laboratory is called for, if only because of the means it furnishes of testing the strength of silver solutions. This may be done roughly, as most photographers know, by employing a floating argentometer, which is immersed more or less according to the gravity of the silver bath. But silver solution, if it has been employed, say, for sensitizing paper, contains other bodies beside nitrate of silver which interfere with its gravity, such as nitrate of potash and ammonia. Its strength may have been exhausted by the formation of haloid salts of silver, or the amount of nitrate of silver in solution may have been uncertain from the first. To discover, then, the actual contents of silver in a solution by chemical means should be in the power of every photographer, and, without a burette at hand, the process is both a long and tedious one.

We have made use, for some time past, of the scale given by Dr. Lagrange some years ago, which is one of the most practical the photographer can employ for testing the value of silver solutions. He has simply to note in his laboratory-book, or hang up in his work-room, a series of numbers, which show how much salt solution is required to neutralize silver solutions of certain strengths, and then a simple laboratory experiment proclaims at any moment the strength of any silver solution he may be called upon to examine.

A standard solution of common salt is prepared with distilled water. If the photographer desires to be very accurate, he may purchase pure crystallized chloride of sodium for testing purposes; but this is hardly requisite for every-day work. The standard should be made up of—

Chloride of sodium	1 part
Water...	10 parts

and this may then be put into the burette. To test your silver solution, put a cubic centimetre of it into a test-tube, add about twenty times as much distilled water, and a few drops of nitric acid.

The silver solution is now ready for bringing under the burette; turn the tap, and let the standard solution of salt flow for awhile. A white cloud of chloride of silver will be produced, and this whitening of the solution will proceed as long as there is silver left in it. The salt solution should be added with care, too little rather than too much being employed. In fact, it is well to make the addition twice, thrice, or even oftener, the solution being carefully filtered in between every addition. As soon as no more chloride is formed, the amount of standard salt solution emptied out of the burette is read off. If, say, the reading is 5·7, which means that five cubic centimetres and seven-tenths of a cubic centimetre of salt solution have been expended, then the photographer knows he has a solution of silver under examination of a strength equal to one part of nitrate of silver dissolved in ten parts of water. If the salt solution expended amounted to 4·8, then the silver solution would be shown to be of a strength of 1 to 12.

But here is a table, which the photographer would do well to note as showing the amount of standard salt solution required to neutralize silver solutions of various strengths. It is one of the most important of tables for the photographer, for however quickly photography progresses in these days of new processes, silver solutions are still to him of the utmost importance.

Of a standard solution of salt,—

14·00	c. c. neutralise one c. c.	of silver solution of	1 : 4	strength.

FRENCH CORRESPONDENCE.

Undried Bichromatized Gelatine—Exposure with the Drop-Shutter—Camera for Sensitive Pellicles—The Photographer on the Tramp.

Mr. Woodbury and Undried Bichromatized Gelatine.—My excellent friend, Mr. Woodbury, is vexed at some remarks which I made in my last letter on a subject in which he claims priority of invention, a claim which I had never the least intention of disputing. He refers to the description of the action of light on undried bichromatized gelatine which I gave in my last letter. So long ago as 1864, Mr. Woodbury says that he obtained reliefs on undried gelatine coated on sheets of mica; it was a further step to produce luminous photographs by the dusting-on process. Mr. Woodbury was the first to describe this in the News, at a time now sufficiently distant, in an article entitled "Ephemeral Photography." I am quite willing to admit that Mr. Woodbury is the original inventor of these two methods, and I am glad to have the advantage of being corroborated in my views by the authority of so competent an observer of facts, which I only desired to recal to notice without the slightest pretence of being the original discoverer. It has often happened to me to recur to old ideas or to processes already known, though not sufficiently so; since it is not enough that a thing should have been spoken of only once for the whole world to become acquainted with it. Besides, it may very well occur that I may hit of my own accord upon an idea, without knowing that the same has presented itself to some one long ago, and that I may then publish it, although I am quite ready to resign any pretension of being the original discoverer. And this is what I now do with pleasure with regard to Mr. Woodbury.

To Obtain Fixed Time of Exposure with the Drop Shutter.—MM. Londe and Mauduit have been occupying themselves with the difficulty there is in fixing the length of the exposure with quick moving shutters, and they describe a method of graduating a drop shutter for given exposures. They have arranged so as to vary the duration of the exposure for an invariable length of drop by separating more or less the two plates between which is situated the opening for the admission of light. Evidently, with the same velocity of drop, the duration of the exposure will be less in proportion as the opening is narrower. On this point I may observe that, like everyone else, I also have designed an instantaneous shutter on the drop principle, but situated behind the lens, and moving upwards by means of spiral springs. This is of course not a drop, but the motion produced by the two springs is very regular. There is a slit in the shutter which can be made narrower at pleasure, and can be reduced to a breadth only limited by the necessity of avoiding interference. This shutter may be employed in the interior of any kind of camera immediately behind the lens; it moves upwards, because in taking landscapes when the exposure is of comparatively long duration, as the sky will be printing for about a half of the duration of the movement, the motion is kept more regular and free of all vibration, unless this were produced at the commencement, which I do not think possible.

M. Martin's Camera for Sensitive Pellicles.—The camera maker, M. Martin, showed one which he has arranged for portfolios to carry pellicles, in which may be exposed papers like those of Mr. Morgan, or Mr. Stebbing's pellicles. There is no frame outside the camera except these carriers, so that the weight is considerably reduced. The apparatus is very well made. There is at the present day much to be done in this direction in order to save the tourist photographer from the burden of heavy and cumbersome weights. Glass plates are in any case too heavy, so that we must have recourse to pellicles, and these must be capable of being carried in the hand twenty-five or thirty at a time without being exposed to the light, and arranged in some kind of frame which shall replace the dark slide, so that the pellicles may be exposed successively in the camera. It is surprising that an apparatus of this kind is not more largely used.

The Photographer on the Tramp, by Mr. O'Madden.—MM. Gauthier-Villars have just published a little brochure, entitled, "The Travelling Photographer," being a description of the apparatus and photographic equipments necessary for the photographer when travelling, by the Chevalier O'Madden, a distinguished amateur photographer, to whose works I also have had occasion to refer.

Leon Vidal.

Review.

Cours de Reproductions Industrielles, Exposé des principaux procédés de reproductions graphiques, héliographiques, plastiques, hélioplastiques, et galvanoplastiques. *(Par M. le Professeur Leon Vidal, Paris, Librarie, Ch. Delagrave, 15, Rue Soufflot.)*

[second notice.]

In fulfilment of the promise made when recently noticing the above work, we now briefly summarise the chapters relating to the commercial reproduction, in several colours, of polychrome subjects, water-colour and oil paintings, enamels, &c., or subjects from nature herself.

Engraving in colour dates back to the commencement of the seventeenth century, when Lastmann, a Dutch painter, made the first essays in this direction by placing the different colours successively on a plate engraved in mezzotint and stipple. A little later, in 1704, Leblond sought to apply Newton's theory of colour to painting. His first attempts not being satisfactory, he came to England, where he succeeded in obtaining the advances requisite to put his ideas into practice. Starting with the principle that the primitive colours were reducible to three, he thought that it would suffice to engrave three copper-plates in order to obtain the intermediate or combined shades; but his attempts in this erroneous direction were not more fortunate than those which had preceded. Thus more than a century and a half ago Leblond's essays had for starting point the same ideas as those adopted by MM. Cros et Ducos du Hauron in the present day for their process of natural héliochromy.

About the same time Gautier came to Paris with a similar idea, employing, however, a fourth colour—black—in addition to the three primitives of Leblond, and his processes were adopted and practised. He moreover found that it was desirable to employ different shades of blue, yellow, and red, according to the subjects to be rendered. For anatomical and antique subjects, works of the old masters, &c., he used a palette composed of pure, or German black; dull, or Prussian blue; clear yellow ochre, and cinnabar. For silk draperies, velvet, stuffs, and bright-coloured works, he employed ultramarine, a golden yellow, and carmine; having likewise a third scale of colour with a mixed blue and a mixed yellow. His first plate was engraved for all the black tones to be reproduced, this colour, with the white of the paper, rendering all the grey tints. Having printed the black, he proceeded with the blue, then the yellow, and, lastly, the red.

Following these first attempts many others were made with a greater or less number of colours, and at the end of the 18th century many prints were coloured by engraving; but with the invention of chromo-lithography this method was gradually abandoned, and is now rarely used.

In the same manner that coloured impressions are obtained from the sunk lines of the copper plate, so can they be taken from typographic, or raised clichés, and though each separate colour must be formed by lines or dots, these become lost in the superposition of several colours, and a chromo with even tints is produced. Excellent typographic clichés can be made by transfer to zinc of monochromes, in line or stipple, executed with a pen on the lithographic stone; or a series of wood blocks can be prepared by an engraver using the same tracing on each block. There is, however, a degree of dryness and hardness about works produced by the preceding methods, that they will not bear comparison with a drawing in colour by a skilful artist on the lithographic stone.

There is next a short account of chromo-lithography, much too large a subject to be fully entered into in such a treatise, and of steno-chromy, in which latter process it is sought to obtain a many-coloured impression with a single printing. This end is attained by the formation of a kind of mosaic work, or matrix, in solid colours; the required colours, incorporated with a soapy matter soluble in spirit of turpentine, being cut to shape by the aid of patterns, and placed in position. An unsized paper moistened with turpentine is used for receiving the impression, and a short contact under pressure allows of a certain quantity of the colour being brought away. The process is suitable for impressions on silk and velvet stuffs and on leather.

M. Vidal now approaches the deeply interesting question of natural heliochromy, or the art which, in his own words, *would* consist in the reproduction of natural colours by photography, for there exists as yet no method of accomplishing this directly, the tentative essays not having reached a practical application, though theoretically offering great interest. Important experiments, commencing in 1838, were made by M. Edmond Becquerel, and eventually he succeeded in obtaining the colours of the spectrum, using the violet sub-chloride of silver formed on a metal plate by the action of chlorine. Of these experiments Hunt, in his Researches on Light, says: "I cannot learn that such impressions were ever rendered in any respect permanent; consequently we may regard this result as a slight advance only upon what Herschel had previously done with the chloride of silver."

The attempts of M. Niepce de St. Victor are dismissed by our author with a notice of only four lines, as differing little in method or result from those of Becquerel. This was not, at the time of their publication, the opinion of many competent judges, who thought that they marked a considerable advance upon the efforts of previous workers. He, however, was unable to fix the colours, which, though not so evanescent as on the earlier plates, eventually became of one uniformly reddish tint. In a memoir entitled "Upon the relation existing between the colours of certain coloured flames with the heliographic image coloured by light," he has indicated his method of operating, and the conditions which seemed involved in the production of colour. A plate of silver, previously connected with a voltaic battery, is plunged into a bath of chlorine water to which has been added the salt essential to give predominance to any particular colour, the selection of the salt being determined by the colour which it imparted to the flame of burning alcohol. The circuit being completed, the plate becomes covered with a dark coating, probably of subchloride of silver mixed with the particular salt used. After remaining in the bath some minutes, the plate is washed in a large quantity of water, and dried over a spirit lamp. The surface thus produced is of a dull neutral tint, often almost black. The sensibility of the plate appears to be increased by the action of heat, and when brought to a cerise red colour the plate is in its most sensitive condition, which even then is but low, two or three hours being required to produce a decided effect in the camera. Very lively colours are obtained with a bath composed of all the substances giving separately a dominant colour, but it is difficult to mix the salts in such proportion as to give equality to the tints. All the colours of a picture have been obtained with a bath of dento-chloride of copper, which salt, says M. Niepce, produced a variegated flame.

In 1865 M. Poitevin succeeded in obtaining coloured images on paper, which Niepce had failed to do, the end being accomplished thus: to paper coated with violet subchloride of silver, produced by the reduction in light of white chloride in presence of a reducing salt (usually protochloride of tin), and well washed, is applied a mixture composed of equal proportions of a solution of bichromate of potash, of saturated solution of sulphate of copper, and of a 5 per cent. solution of chloride of potassium. The paper is allowed to dry, and must be kept in the dark. By an exposure of five to ten minutes to the sun's rays, under a painted glass, all the colours of the spectrum may be reproduced; but the paper is not sufficiently sensitive for use in the camera. After being passed through certain chemical solutions, and well washed, these coloured impressions may be preserved in an unaltered condition in an album away from the light.

M. Cros and M. Ducos du Hauron, on the 17th of May, 1879, by a curious coincidence, communicated simultaneously to the French Photographic Society a method of heliochromy similar to each other, accompanied by specimens. M. Ducos' theory, like that of Leblond (previously mentioned) was, that all colours are comprised in three, reasoning from this, first, that it was necessary to take three negatives of the coloured object, interposing successively between the lens and the object a green, an orange, and a violet glass. That each negative would differ from the other, the first being formed by the yellow and blue light of the model, as the green glass, absorbing its complementary colour, red, allows only the blue and yellow to pass, and so with the orange and violet glasses; second, that by the aid of coloured tissues (carbon process), proofs would be obtained of a colour complementary to that of the glass which served to produce the negative, the cliché made behind the green glass giving a red positive proof, that behind the violet screen a yellow positive, and that with the orange screen a blue positive; third, that these three pellicles, superposed, will give the colours of the natural object to be reproduced.

Of this process M. Vidal, in one part of his work, says: "The reasoning is erroneous, its execution impossible. The solution of the problem of héliochromy by these means may be ranged with squaring the circle, or perpetual motion." But we find this sweeping assertion afterwards somewhat modified, and the specimen shown would, we think, impress favourably most of those who see it. The process has been taken up commercially in Paris, and M. Albert and M. Obernetter, of Munich, have produced coloured impressions by it.

M. Vidal, while seeking to obtain coloured prints other than by manual or chromo-lithographic processes, denies the possibility of doing so in a direct manner as M. Ducos desires. From a transparent positive M. Vidal makes as many negatives as are required, and stops out certain portions of each; he then prints on coloured tissues from each negative the positive proofs, which are afterwards superposed; the whole is finally covered with a carbon print of neutral tone, to give exact drawing and vigour in the shadows. This method is evidently one requiring great care, and not easy of execution, so the first portion of the work is now, in general, purely chromo-lithographic, the impression of the separate colours being taken mechanically from the lithographic stone in the usual way, a photographic image being lastly printed by phototype or photoglypty over the coloured impression.

M. Germeuil-Bonnaud has likewise devised a method of photographic printing in colours; but as these must be capable of withstanding the chemical agents and manipulations involved in the process, his plan seems scarcely practical.

"At present," says M. Vidal, "we can only produce photographs in colours by using certain artifices. Possibly a day will come when we may be able to obtain the images with their colours as seen on the ground glass of the camera; but everything seems to indicate that this day is, at least, very far distant."

ON THE CAUSE OF THE LIGHT BORDER FREQUENTLY NOTICED IN PHOTOGRAPHS JUST OUTSIDE THE OUTLINE OF A DARK BODY SEEN AGAINST THE SKY; WITH SOME INTRODUCTORY REMARKS ON PHOSPHORESCENCE.

BY PROFESSOR G. G. STOKES, SEC. R.S.*

7. The other observation was as follows:—The same tablet was laid horizontally on a lawn on a bright day towards evening, when the sun was moderately low, and a pole was stuck in the grass in front of it, so as to cast a shadow on the tablet. After a brief exposure the tablet was covered with a dark cloth, and carried into a dark room for examination.

It was found that the place of the shadow was brighter than the general ground, and also a deeper blue. For a short distance on both sides of the shadow the phosphorescence was a little feebler than at a greater distance.

This shows that, though the direct rays of the sun by themselves alone would have strongly excited the phosphorus, yet, acting along with the diffused light from all parts of the sky, they did more harm than good. They behaved, in fact, like the rays from the lamp in the experiment of § 6. The slightly inferior luminosity of the parts to some little distance on both sides of that on which the shadow fell, shows that the loss of the diffuse light corresponding to the portion of the sky cut off by the pole was quite sensible when that portion lay very near the sun.

All this falls in very well with what we know of the nature of the direct sunlight and the light from the sky. In passing through the atmosphere, the direct rays of the sun get obstructed by the very minute particles of dust, globules of water forming a haze too tenuous to be noticed, &c. The veil is virtually coarser for blue than for red light, so that in the unimpeded light the proportion of the rays of low to those of high refrangibility goes on continually increasing, the effect by the time the rays reach the earth increasing as the sun gets lower, and has accordingly a greater stretch of air to get through. Of the light falling upon the obstructing particles, a portion might be absorbed in the case of particles of very opaque substances, but usually there would be little loss this way, and the greater part would be diffused by reflection and diffraction. This diffused light, in which there is a predominance of the rays of higher refrangibility, would naturally be strongest in directions not very far from that of the direct light; and the loss accordingly of a portion of it where it is strongest, in consequence of interception by the pole in front of the tablet, accounts for the fact that the borders of the place of the shadow were seen to be a little less luminous than the parts at a distance.

8. The observations on phosphorescence just described have now prepared the way for the explanation I have to suggest of the photographic phenomenon.

It is known that, with certain preparations, if a plate be exposed for a very short time to diffuse daylight, and be then exposed to a pure spectrum in a dark room, on subsequently developing the image it is found that while the more refrangible rays have acted positively, that is, in the manner of light in general, a certain portion of the less refrangible have acted in an opposite way, having undone the action of the diffuse daylight to which the plate was exposed in the first instance.

It appears, then, that in photography, as in phosphorescence, there may in certain cases be an antagonistic action between the more and less refrangible rays, so that it stands to reason that the withdrawal of the latter might promote the effect of the former.

Now the objective of a photographic camera is ordinarily chemically corrected; that is to say, the minimum focal length is made to lie, not in the brightest part of the spectrum, as in a telescope, but in the part which has strongest chemical action. What this is depends more or less on the particular substance acted on; but taking the preparations most usually employed, it may be said to lie about the indigo or violet. Such an objective would be much under-corrected for the red, which accordingly would be much out of focus, and the ultra-red still more so.

When such a camera is directed to a uniform bright object, such as a portion of overcast sky, the proportion of the rays of different refrangibilities to one another is just the same as if all the colours were in focus together; but it is otherwise near the edge of a dark object on a light ground. As regards the rays in focus, there is a sharp transition from light to dark; but as regards rays out of focus, the transition from light to dark, though rapid, is continuous. It is, of course, more nearly abrupt the more nearly the rays are in focus. Just at the outline of the object there would be half illumination as regards the rays out of focus. On receding from the outline on the bright side, the illumination would go on increasing, until on getting to a distance equal to the radius of the circle of diffusion (from being out of focus) of the particular colour under consideration the full intensity would be reached. Suppose, now, that on the sensitive plate the rays of low refrangibility tend to oppose the action of those of high refrangibility, or say act negatively, then just outside the outline the active rays, being sharply in focus, are in full force, but the negative rays have not yet acquired their full intensity. At an equal distance from the outline on the dark side the positive rays are absent, and the negative rays have nothing to oppose, and therefore simply do nothing.

9. I am well aware that this explanation has need of being confronted with experiment. But not being myself used to photographic manipulation, I was unwilling to spend time in attempting to do what could so much better be done by others. I will, therefore, merely indicate briefly what the theory would lead us to expect.

We might expect, therefore, that the formation of the fringe of extra brightness would depend:—

(1.) Very materially upon the chemical preparation employed. Those which most strongly exhibit the negative effect on exposure to a spectrum after a brief exposure to diffuse light might be expected to show it most strongly.

(2.) Upon the character of the light. If the light of the bright ground be somewhat yellowish, indicating a deficiency in the more refrangible rays, the antagonistic effect would seem likely to be more strongly developed, and, therefore, the phenomenon might be expected to be more pronounced.

(3.) To a certain extent on the correction of the objective of the camera. An objective which was strictly chemically corrected might be expected to show the effect better than one in which the chemical and optical foci were made to coincide, and much better than one which was corrected for the visual rays.

It is needless to say that on any theory the light must not be too bright or the exposure too long; for we cannot have the exhibition (in the positive) of a brighter border to a ground which is white already.

P.S.—Before presenting the above paper to the Royal Society I submitted it to Captain Abney, as one of the highest authorities in scientific photography, asking whether he knew of anything to disprove the suggested explanation. He replied that he thought the explanation a possible one, encouraged me to present the paper, and kindly expressed the intention of submitting the question to the test of experiment.—*Chemical News.*

* Continued from page 332.

Notes.

Mr. Maxwell Lyte was cordially greeted as an old friend, when installed as Secretary of the Photographic Society of Great Britain on Tuesday last; but all present at the meeting felt the loss of Lieutenant Darwin, who shortly leaves for Australia.

In a somewhat less mathematical form the whole subject matter of Mr. Cadett's paper on "Shutters" appeared in the NEWS during the autumn of last year; but in our leaders it was pointed out that a well-designed shutter opening and closing at the centre is practically better, and nearly as good theoretically, as any other form.

Still, for convenience of handling, the simple drop shutter is often preferable, as each complication in a shutter considerably increases the chances of failure, and when the drop shutter is made according to the principles which we laid down, its theoretical effectiveness is only a fraction behind that of the best.

The lens Committee seem to have worked altogether on an English basis as regards screws; but there can be no question as to the convenience of having stops so marked that the numbers shall indicate relative exposures.

Strong ammonia and pure water act with about equal energy on glass, says Mr. Cowper; but mix one volume of the former with five volumes of the latter, and it will be found that this dilute ammonia acts on glass with something like sixfold force.

"The Photographic Studios of Europe" will be published at the end of next week. An edition will be published in Germany by Dr. Liesegang, of Düsseldorf; another in America by Messrs. Anthony & Co., of New York; and a fourth in French, by the firm of Gauthier-Villars.

Many of our sea-painters are becoming expert photographers. Mr. Brett, Mr. Henry Moore, and Mr. Colin Hunter, whose pictures are always conspicuous on the Academy walls now-a-days, are all well versed in camera work and the development of dry plates. The camera is usually taken on board a yacht, that instantaneous views may be secured of passing craft, which are rapidly depicted in every phase of sailing by the ready yachtsman.

The photographs are put away in the portfolio with other study sketches, to be used hereafter, as occasion serves, in picture making. It is in this way the painter acquires the wide experience one often marvels at in his productions. Whether he is called upon to depict the seashore, the highlands, a street in Cairo, a Tyrol village, an Irish cabin, or a Russian market place, the painter, if he has travelled, as he assuredly has, finds no difficulty in filling up all details in his studio at home, since his well-filled portfolio furnishes him with just the life and character he wants.

We had a long chat with Mr. E. L. Wilson, of the *Philadelphia Photographer*, on the subject of photography as a profession in the United States, and were glad to hear from his lips that our art was taking a higher standard in America than it had hitherto done. From small towns and remote districts he received pictures displaying art and skill that showed unmistakably a generation was now engaged in the work who had been properly tutored and trained to it. If finer pictures are not produced, they are, at any rate, much more general than was the case twenty years ago.

The ex-carpenter, ex-tailor, ex-butcher and baker, and candlestick-maker are no longer the general practitioners of photography, but thorough-going men who have education, taste, and a good knowledge of photographic chemistry. In a word, they are men who are photographers by profession. The charge made for cabinet portraits in the best studios in the States is from ten to twelve dollars a dozen, or, say, from forty to forty-eight shillings.

We begin to think that photographers will really find it worth while to take Mr. Francis Galton's advice, and set about making composite portraits. Even if it is only to produce something quaint and interesting, something to talk about, this new feature of photography is worth attention. A gentleman possessing three daughters placed in our hands a composite the other day, which was most perplexing from its definite likeness to all three. He had taken three negatives, all full-face and of the same size, and forwarded them to Mr. Francis Galton, in reply to that gentleman's general invitation given in these columns. The result was most diverting to those acquainted with the originals, and gave rise to endless fun and controversy. In our YEAR-BOOK appear full details as to method of securing these composites, but Mr. Galton, as we have said, is prepared to make them, if provided with suitable portraits.

There is one serious difficulty in the way of getting all the portraits in a series to impress themselves equally upon the sensitive film so as to produce a fair composite picture, and that is the vigour of the various original prints. If it were possible to present before the sensitive plate a number of personages one after another, all equally lighted and all equally exposed, a well-balanced result might be forthcoming; but when the negative is secured from a series of photographic prints, the vigour of these must surely exert some influence. Thus, to take an extreme instance, if a soft vignette and a hard over-printed impression were exposed one after another, the latter would obviously impress itself more vigorously on the film, and the composite in this case would present more distinctly the features of No. 2 than No. 1.

Dr. Wright, of St. Mary's Hospital, has long been engaged in important physico-chemical researches, and, considering that that he has recently estimated with great accuracy the feeble thermic and electric energy developed on mixing solutions containing different proportions of the same body, we may hope this investigator will soon turn his attention to the dynamical changes occurring during the exposure of sensitive bodies to the light. Such investigations would place photographic operations on a firm scientific basis; and we may hope that Dr. Wright's labours will lead to the framing of a notation which shall render complete account of the play of forces accompanying chemical reactions, just as the usual chemical symbols express the weights of the reacting bodies.

Photographic records of the pulse, similar to those taken by Dr. Luys, are employed to some purpose in the education of the medical student, for the pictures tell, perhaps more than any other medical record, of the vitality of the human system at different ages. The photographs, as most of our readers are aware, are in the form of wavy lines, the waves or curves being impressed upon a sensitive film by the action of a column of mercury in a glass tube, rising and falling with the pulse. If the pulse is vigorous, the mercury rises and falls quickly, and in a great degree; while if the pulse is feeble, the movement of the mercury is also feeble.

We have before described the process of photographing the pulse. The reservoir of mercury in a flexible bag is simply placed upon the wrist of the patient, the glass tube dipping down into the mercury, and thus it comes about that the movement of the pulse moves the mercury in the tube. The photographic film is kept moving along behind the head of the mercury column, and thus the up-and-down motion of the mercury is made to impress a wavy line upon the film. These waves vary with the age of the patient. Thus the pulse of a boy five year sold, beating eighty to the minute, forms a line of sharp zigzags; in a man in the prime of life there are not so many ups and downs—that is, not so many pulse beats—but the waves are represented by sharply pointed spires, double as high as the zigzag marks made by the child's pulse. In old age, to take a third photographic illustration, we find vitality has indeed fallen off; the picture here is of a series of low rising curves, as rounded as a mole-hill, and in a fair way of ceasing to be waves at all.

Those who have never tried it, have no idea of the value of a sheet of ground glass in the process of enlarging transparencies in the camera. The negative or positive upon glass, to be copied, is usually fitted as a sort of window, and then the camera adjusted, so that the enlarged image falls upon the focussing screen. If, while looking upon this image in the camera, an assistant is instructed to place a sheet of ground glass in front of the original negative—that is, between the source of light and the transparent window—it will be seen that the focussed image is at once perceptibly lightened up.

The tiny facets on the surface of the ground glass reflect the light coming to the negative equally in all directions, and thus it is more evenly distributed over the surface of the enlarged image in the camera, which is otherwise inclined to be brilliant in the centre and dull at the margins. But we repeat, unless anyone has tried the experiment, interposing and withdrawing the ground glass two or three times while the focussed image is under observation, he will fail to realise the full advantage of the modification.

Viscount Cranbrook recently narrated a telling anecdote when distributing some science prizes to working men. He begged the medallists and prize winners not to be puffed up with their own importance because they had answered certain questions in chemistry and physics without a mistake. It was most gratifying to know that they, as hardworking handicraftsmen, were well grounded in science; but, for all that, they were not yet chemists. An old cobbler of the Viscount's acquaintance was exceedingly proficient in the subjects taught at science classes; he knew pretty well every star in the heavens by name, his knowledge of inorganic chemistry was profound, and he was one of the best draughtsmen in the village. But, after all, his great pride was to make a sound pair of boots.

An idea to illustrate "Edwin Drood" by photography has been mooted. It is, of course, well known that Dickens laid the scene of his last novel principally at Rochester, Cloisterham being none other than that Cathedral city. "The Nun's House" is a veritable building; the river and the bridge spoken of are the Medway and Rochester Bridge, while the Close described is that of the old Kentish pile. It is not unlikely that a large edition of such an illustrated work would be sold if the photographs were taken with taste and skill.

There is, indeed, no reason why a realistic author, such as Dickens proved himself, should not be further connected with real life. Dickens exaggerated many of his personages, but his localities were very true to nature. It would therefore add a new interest to a book like "Pickwick," if illustrations of the places spoken of—which are rapidly fading from our eyes—were produced by means of photography. The Marshalsea is no more, and the Fleet Prison is pulled down; Goswell Street, the abode of Mrs. Bardell, is rebuilt, and the "Saracen's Head" has been levelled to the ground.

But the "Bull Inn," where Alfred Jingle made love to the buxom widow at the ball, is still extant, and a photograph of the ball-room might be taken to-morrow. The "Leather Bottle," at Cobham, whither Mr. Tupman retired from the world after his unlucky love escapade, is still open for the reception of travellers; the old inn in the Borough, with its court-yard and gallery where Mr. Pickwick first fell in with Sam Weller, is probably still to be found; and the "White Horse" at Ipswich, famous for the lady with the yellow curl-papers, as well as the "Angel" at Bury, are to this day well-known hostelries. We ourselves secured a photograph not long ago of Dotheboy's Hall, with the identical well from which Nicholas Nickleby and his charges drew their supply of washing water. Indeed, Dickens's works suggest both to professional and amateur photographers plenty of interesting objects for the camera.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. XI. (*Continued*).—Printing.

It will be noticed that the prints as they come from the frames are of a more or less unpleasant colour. The operation which is to be described, and which is called toning, is intended to correct this defect, and to give them the pleasing colour which we are accustomed to see. The process consists in covering the image with an exceedingly thin film of gold.

Toning may be said to be at once the easiest and the most difficult photographic process. Nothing is easier than to *tone*, nothing more difficult than to tone *well*. Anyone can change the colour of a print to a sort of slatey grey; there are not very many who can be sure of getting at all times a pleasing tone and the exact tint required. The difficulty lies in the direction so common in photographic operations. A certain result is gained, but the after processes modify this result, so that great experience is necessary to know beforehand what will be the final appearance of the subject.

We shall describe as exactly as possible the operations, and for the rest, as in so many cases, the beginner must look to intelligence and experience for success.

The toning solution mentioned in the first part of our lesson is too concentrated to use as it is; it must, therefore, be diluted. The common practice is to use a large quantity of toning solution, and, if it is not exhausted, to keep it for after-use. This is very well for the professional who tones at regular intervals, but in the case of the amateur we think it is not advisable. The solution once used is very liable to "go bad," the gold being deposited at the bottom of the bottle. We therefore recommend that the beginner estimate the amount of toning that will be necessary, allowing a little margin, and after he is done, throw it away. The waste will be very small—so small that it will not be found worth while to keep the liquid as residue. If the prints be trimmed before toning, one grain of gold is amply sufficient for each sheet of paper measuring 17 inches by 22 inches. Let, therefore, one ounce of the stock toning solution be taken for every sheet of paper, and let it be diluted with six or seven times its amount of water.

Now let the prints be taken one by one, and placed in any dish which is suitable for washing them in; a common small wooden tub is the best of all. Let the prints be kept from sticking to each other, and be moved about by hand. It will be seen that the water becomes milky from the nitrate of silver in the paper forming chloride and carbonate of silver with the salts in the washing water. The water must be changed several times till this milkiness disappears entirely, or almost so. Now the prints are ready for toning. The washing is best done by the light of a candle or lamp, as such will not affect the paper. The toning must be done in feeble white light, as it is difficult to judge of colours by yellow light. It is best performed in a flat white dish at least an inch larger each way than the prints.

Let one print be taken from the washing water, and placed in the toning, first face downwards, then turned face up, then down, once or twice, so as to allow the solution to act evenly on it. Now let another print, and perhaps two or three more, be similarly placed in the solution. It will be noticed that the prints, during washing, turn to a brick red. In the toning they will turn to a brown, and gradually to a sort of violet or purple. They must be kept in constant motion. The best plan is to keep continually lifting the undermost print, and placing it on the top. At first, only a few prints should be attempted; after some practice, a dozen or two may be in the solution at once. When many prints are toned together, it is a good plan to have two dishes of toning, side by side, and keep lifting the prints out of one into the other, the whole of the prints being turned over in a mass when they are all in one dish.

The difficulty is the one indicated before, viz., at the time of toning to discount the change which will take place during the after processes. The difficulty is greatly increased by the fact that every brand of paper acts in a somewhat different manner from any other. Very few ready sensitized papers will stand being pushed to the purple stage; that is to say, if the toning is continued to the purple, the final result will be disappointing, although the prints will look beautiful before fixing. It is usually advisable to remove the prints from the toning solution whilst they are still of a very warm brown in the shadows. It is a good test to watch the half-tones, and when these begin to become purple or violet, to remove the print. The prints when removed are placed in another dish of clean water. They must be moved about for a short time after first placing them here, so as to get rid of the greater part of the toning solution which is in the pores of the paper, and which would make the toning proceed after it was desired to stop it. When all the prints have passed through the toning bath they must be washed in several changes of water, being kept moving for about five minutes during each change. Now comes the fixing; the prints are removed from the washing water, and are placed in a flat dish. Sufficient fixing solution to quite cover the prints is poured in, and they are kept moving for about twenty minutes; more than one change of colour will be noticed during this time. The first will be an almost total loss of tone; afterwards the colour will return to something like its former self. A further change will take place when the prints are dried. After fixing, it is necessary to wash the prints most thoroughly for not less than twenty-four hours. This is best done in running water, but if this cannot be had, then frequent changes will do. The smallest trace of hyposulphite in the prints will cause them to fade.

The prints, after washing, are allowed to dry spontaneously, being placed on any clean surface; or they may be mounted wet on cardboard. In either case they should be afterwards rolled. A rolling press is an expensive article; but the amateur can generally find some neighbouring photographer who will roll his prints for a small consideration.

The great convenience of ready-sensitized paper is that it will keep for a very considerable time, either before printing, or between printing and toning. The means of preparing such paper is at present a trade secret, and when the amateur prepares his own paper, he will find that it will turn brown after about twenty-four hours. He must therefore do his sensitizing and toning all in one day. If he has time to do this, he will probably be rewarded by superior results. We shall therefore describe the process of sensitizing.

"Salted" albumenized paper is purchased—that is to say, paper coated with albumen which is impregnated with soluble chlorides.

A "silver bath" is prepared by dissolving nitrate of silver in distilled water. The strength of the bath varies with the paper used. Every dealer in albumenized paper will state what strength of bath is best to use for the particular brand. One containing sixty grains of nitrate of silver to each ounce of solution will suit most papers. Enough of this must be prepared to cover the bottom of the flat dish to be used in sensitizing to a depth of at least ⅛-inch. The dish should be half an inch larger than the paper in each direction. If much paper is to be used, it is best to sensitize in large pieces, and cut it into sizes before printing. Professional photographers usually sensitize a whole sheet at a time.

A room lighted by a lamp or gas is the best to carry on the sensitizing process. Strings should be stretched in convenient position for hanging the paper on to dry. American clips are useful for fixing the paper to the strings.

Let the silver solution be poured into the bath, and let a piece of the paper be taken by opposite corners, and with the albumenized side downwards. Let the paper be so held that it will first touch the surface of the solution in a line between the two corners not held by the hands. We again take the *simile* of a printed sheet. Suppose the paper held by the right-hand upper and left-hand lower corners. Now let the left-hand upper corner touch the surface of the solution, and let the paper be lowered till it touches in a line from the left-hand upper to the right-hand lower corners. Now let the two corners held in the hands be dropped, first one and then the other. This sounds elaborate, but is very simple in practice. If it be carried out properly, there will be no air-bells under the paper, but it is best to lift it from the solution after about a minute and look, to make sure. If there are any, they can be broken by gently moving about the paper whilst one-half is held out of the solution.

The time of floating varies with different papers and different strengths of baths. It should be ascertained when the paper is purchased. With a 60-grain bath from three to five minutes is usually ample. If the paper curl out of the bath at the edges, it may be caused to lie flat by blowing on it.

After the specified time has elapsed, let the paper be removed from the bath by drawing its surface over one edge so as to drain off most of this silver solution. It is only necessary now to bring it up by one corner to dry. A small fragment of blotting-paper should be caused to touch the lower corner immediately that it is hung up. This will adhere by capillary attraction and collect a drop or two of solution which would otherwise fall on the floor.

If the room be warm, the paper will dry in ten minutes or a quarter of an-hour.

When it is dry, printing, toning, &c., are performed as described for ready-sensitized paper. Good paper sensitized as described may be toned to a far deeper purple than the paper purchased ready sensitized.

The silver solution becomes weaker through use, and it is necessary to strengthen it at intervals. Its strength can be ascertained by the use of an "argentometer," which is a cheap form of hydrometer specially graduated for grains of silver per ounce of water.

The solution must be filtered every time it is used.

ODD JOBS.

BY THE AUTHOR OF "LOOKING BACK."

No. 9.—Copying.

When the dull season has begun to set in along with the short days, and sitters have as gradually dwindled away as the bright sunshine, the photographer turns his attention to filling up time. He arranges his negatives, washes old plates, burns residue, and, among other necessary labours, when the light will permit him, works off his accumulation of "copies," that were not wanted in a hurry; indeed, I believe many houses will not take anything to copy unless it is left entirely to themselves when it may receive attention. Still, despite this cavalier way of treating the subject, copying is a very remunerative branch of the business. I have frequently arranged in the evening before I left six C.D.V.'s that had to be copied the same size, fixing them on a board by means of drawing pins three in a row, so that they could easily be covered by an 8 by 10 plate; then in the morning using a Kinnear camera and a Ross C.D.V. lens, and using a small stop, I make a negative of the lot at once, thus at "one fell swoop" making as good money as if I had six sitters. One thing I would mention to the inexperienced in this way of doing copying, and that is they must be careful in the picking the six—viz., have them either all vignettes, or full printed pictures; for it is easy to see you could never render justice to a dark plain printed picture and a faded vignette on the same plate.

I have found the above mentioned lens very serviceable in copying; either enlarging or reducing. I have found it to do almost everything; it will enlarge a carte to 20 by 15, or reduce the same to a locket; it will do everything except copy a 15 by 12 the same size; it will do a whole plate, or, at a stretch, a 10 by 8 with a very small stop, covering well to the corners the same size; but if a 20 by 15 or 25 by 20 be required, the best lens to use, in my estimation, is a Dallmeyer group and view lens. Triplets are very good to copy plans or letter-press with, but they have two objections to copying photographs—they give a startling vividness to the grain of the paper, and take an awful time in exposing. Yet, when pushed once, I made a couple of remarkable enlargements with a Dallmeyer triplet. So good were they that silver prints with a little working up (of course a good deal of work on the negative first) defied the inspection even of professionals to tell whether they were copies or direct photographs.

In the way of copies we meet with very "Odd Jobs." Not long ago a lady in deep mourning, with a crape veil so thick that I could not see her features, stepped from a closed cab, and, after a stately bow, asked if the artist could make a photograph of some flowers that she had brought with her, at once, and in her presence, as she could not allow them out of her possession. Upon being told that our time was fully taken up, and that it was not usual for us to do copyings during the hours of sitters, she asked the price of a sitting. £1 1s.! She immediately laid two sovereigns on the desk, and producing a card, requested that it should be taken to the next sitter with her compliments. The name was the "Countess C——, Aberdeenshire." She spoke to the next sitter, and almost at once got permission to take the appointment. In the studio the Countess produced a small curiously carved little box, and opening it took out a small bouquet of faded flowers; her hand trembled, and her breast heaved as she looked at them. Seeing this, I at once disappeared in the dark room. I made a cabinet picture of them—allowing her to arrange them as she thought fit—never once dreaming to touch those faded little memories of the past with my rough hands. In this case I had to use the triplet, else I would not have got the back leaves in focus at all—using a small stop and giving about fifteen minutes' exposure. I remember that same week that the Countess came with her faded flowers, I had a bride's cake to photograph—a case of Alpha and Omega—and I had the same lens to use and cut a smaller stop of cardboard blackened with ink so as to make all the little Cupids and sprays that hung around it as sharp behind as in front.

The next instance of "Odd Jobs" in copying is rather of an amusing nature. One dull November day, when everything felt damp and everybody miserable, the studio was hurriedly entered by a little shabby old man carrying a brown paper parcel under his arm. He lifted his hat in a most solemn manner, and at once proceeded to business. "Sir," he commenced, "I have a parcel here of great, very great importance!" Here he looked at me as if expecting the word of denial. He then proceeded to open it. After numerous wraps of newspapers had been undone, he produced a faded water-colour profile of a lady—one of those curiosities that were the fashion just before the Daguerreotypes.

"This is number one," quoth the little man; "my wife, sir!"

"Yes," I answered, "she is very pretty but (and it struck me that if she were still alive, they might be comparing the picture I should make of her in the flesh with this half century old thing), but she must be greatly altered since this was done?"

"She is dead, sir!" was the solemn answer, as he proceeded to unwrap the rest of the parcel. "This is number two," he continued, as he produced a coloured cabinet photograph of a sharp, shrewish, old-maidish-looking female, that looked business all over; indeed, one of the sort that may be expected to exclaim, "Never say die!" I made sure that she was above ground.

"Of course, you mean this is your second wife?" I asked.

"Yes—yes—my wife, sir, my wife!"

"Ah! it is very good; taken some time since, I see. I shall have no difficulty in making a better picture than this, when she does me the honour of granting a sitting." This I spoke with my pleasantest smile.

"She is dead, sir!" was the remark of the little man, spoken more solemnly than before. I was swamped.

"Now, look here! continued my customer; "now we come to number three!" Then he produced from the depths of an inside pocket a small carte of a very robust female. I commenced to think that I had dropped upon a modern Bluebeard, and I could not help looking at the thin face, scranny whiskers, and seedy-black coat, and wondering how many more "numbers" he would pull out.

"My third wife, sir!"

"Of course, she is dead?" I suggested, making sure I was right this time.

"What!" shouted the little man; "what do ye take me for? What do you mean, sir?" And he stamped his feet with wrath, and foamed with fury.

I begged his pardon, which appeased him; then he explained that number three was still his partner in this life, and he wished a family picture to be got up (all cabinets), himself in the centre, and his wives all round him, "with their names underneath," he added. "Ah!" I could not help exclaiming; "No. 1, No. 2, and No. 3. Eh?"

"What! What!!"

The shouts that he gave made me think I had gone too far; but a long face and a supernaturally earnest manner pulled things straight again. So I set to work upon them next day, and had the satisfaction of getting good results off each by means of the Ross C.D.V.

MOUNTAIN PHOTOGRAPHY IN NEW ZEALAND.*

February 22nd.—Weather all that could be wished, and with every probability of continuing so. The first part of the journey was by boat up the Arthur River, and delicious pictures were revealed at every bend of the stream. These were duly "spotted" by the operator, and a day's work hereabouts planned should there be time on the return. As we pulled up the river the navigation became more and more difficult, the utmost exertions of our two powerful and skilful oarsmen being unable to stem the current which rushed by "Manœuvring Rock" until the tide had risen sufficiently to counteract it. Now came the second phase of the trip. Blankets, food, and photographic paraphernalia, previously divided into three swags (the photographer, in consequence of his "youth" and inexperience, having been considerably made light), were now shouldered, and the march through the bush and over the boulders in the river bed began. The bush part was the more preferable, as a capital track had been cut by Sutherland and his mate; but the boulder part was "a caution." A short "blow" was allowed at "Smoke ho!" (half-way), and another good long spurt carried us to the foot of Lake Ada. At the end of the track we duly found the canoe (17 feet long) which our explorers had "dug out" of a birch tree two seasons ago. Swags were slipped from the shoulders and stowed in the little craft to the great relief of one of the party, and Sutherland and the photographer paddled their, or rather the former's, own canoe up the lake. The third member of the party (Mr. Malcolm) returned to the boat, engaging to meet the others on the Arthur River on the evening of the next day but one. Lake Ada is some eight miles long by an average breadth of about a mile and a-half. It is by no means deep; indeed, in comparison with other Otagan lakes, it may be considered remarkably shallow, being only about ten or twelve fathoms in the deepest part. It is the opinion of "the guide" that the judicious expenditure of a few charges of dynamite among the boulders where the Arthur River leaves the lake would reclaim a large portion of its surface, leaving just a channel for the stream. And how fertile would be the banks of the stream then! Though a stranger might be incredulous, it is a fact that there is a considerable amount of level land in the valleys and gullies, with soil of a rich chocolate, and often of great depth. The height of Lake Ada above the Sound is about a hundred feet. There is no part of the lake which does not abound in points of beauty, scarcely a turn or an islet which does not "make" a fresh picture; but the completest effect is gained from the centre. Then you have on the right-hand Sheerdown Hill (how unobstrusively is this mighty mass named!), which is so grand an object at the head of the Sound, and the peculiar peaks of Camp Mountain; next, the Wick Mountains, with a glimpse of the Sinclair chain through the gorge of Joe's River; next, right ahead, the imposing Castle Mountain, only a very few feet short of 7,000; then, more distant, and still loftier, Mount Danger Mountains, and range after range cut apart by deep defiles. On our right hand the fantastic Terror Peaks, with the strangely-shaped summit, to which the restful appellation of the "Devil's Armchair" has been given. Lastly, behind us are Mount Phillips (beautiful here, but the only ugly mountain as seen from the Sound), the Barren Peaks, and even a glimpse of the far-off monster, Mount Titoko. One of the most noticeable features of the locality must not be omitted. On the west side of the latter a densely-wooded sweep, like an inverted arch, one side descending from a spur of the "Devil's Armchair," and the other reaching up to a companion peak a mile or more away to the south, forms a mighty wall, behind which and far beyond rise the Terror Peaks spoken of above. In the very centre of this inverted arch—if that term conveys a clear idea to the reader's mind—is a vast rift, narrow, but something like 1,200 feet deep. This defile is impassable, and the hidden wonders of the huge ampitheatre, of which only glimpses are obtainable, can only be discovered by climbing the mighty forest-covered screen itself. What startling effects of glacial action that enormous basin would exhibit can only as yet be conjectured. However, the rift itself, called the Giant's Gate, is an earnest of what may fairly be expected to be revealed. Sutherland, the guide, has determined to solve this question when other more pressing matters of exploration and prospecting will allow him sufficient leisure. On reaching the head of the lake a well-pitched tent was found, in good order, and while one attended to matters culinary, the other made the best of the daylight that remained, taking six negatives—the only difficulty being to make a choice amongst the wealth of scenery spread around. A few drops of rain falling while at supper, filled both with fear as to the morrow. Had we then but reached thus far to be tantalised with a sight of what might be done if only the weather would allow? Even though the floor of the tent was as elastic as a spring mattress, occasional showers through the night made sound sleep impossible; for should wet weather be likely to set in in earnest, we must start back without delay of an hour.

February 27th.—All forebodings vanished, for this morning was simply delicious. The lake was without a ripple; the snow-clad peaks were mirrored with startling exactness—a slight belt of fog just hiding the water-line, while fleecy clouds developed the shoulders of the mountains. Needless to say the camera was "at it"—a coo-ee to breakfast was felt as almost a nuisance. The meal despatched, we paddled up the Poseidon River, "working" the country as we went. In photographing such a country as this, a billhook is almost as necessary as a camera, for while one (the photographer-in-chief) spots and "composes" the view, the other clears away the undergrowth that would have blocked up the pictures, and thus "opens up the country." We were now floating up the upper lake or lagoon out of which the Poseidon River runs, and one could not suppress a feeling of self-gratulation at being the first to depict such scenes as those among which we were revelling. As many as twenty or thirty persons may have seen Lake Ada from the foot, but those who have reached the head might be numbered upon the fingers of one hand, while even fewer than these had ever found themselves on the spot where we now were. But we had now reached our farthest point, and with a longing glance in the direction where Sutherland Falls and Mount Balloon lay, we took the back track. Still four or five "subjects" tempted us ashore, until we had to tear ourselves away, lest we should be benighted far from our camp.

February 24th.—Another day such as gladdens a photographer's heart, and on our downward journey we made even better work than yesterday. Some sweet views were found from an island—some very telling ones of the Giant's Gate, and so down to the foot of the lake. One cannot live upon photography alone, however, and a long and exciting day deve-

* Continued from page 331.

loped an appetite such as only a mountaineer or a bushman knows. The meal we sat down to was not to be despised. It consisted of a delicious stew of four teal, a weka, and a pigeon. Not amiss, this, for two persons. But, sharp as was the appetite, and savoury as was the meal, it was with the utmost difficulty it was discussed. Oh, those sandflies! People complain that they are sometimes "bad" at the Bluff, when two or three settle on the face or hands. They are troublesome in the Sounds generally. They are irritating on Lake Manipori. But for thorough-going, temper-destroying, blasphemy-producing, temporary-insanity-engendering little demons, the sandflies about that swampy camping-ground at the foot of Lake Ada knock spots out of all creation. Swags were again packed. This time, however, there were only two backs to bear them instead of three. Like consideration as to weight for age again marked the apportionment of the burdens. Evening was fast falling, and bush-tracking and boulder-climbing had to be done at a small pace. Malcolm with the pack was duly on the watch, and by-and-bye we were fighting our battles over again over a billy of tea in Freshwater Basin.

February 25th.—This was to be the last day with the camera, as the steamer might be expected in the afternoon, or next day at latest. The Arthur River was accordingly chosen as the scene of our last "shots," and the views noted three days before were duly secured. After half a day's work, we felt we had earned the "usual Saturday half-holiday," so knocked off and began, not to chop wood, but to pack up.

February 26th.—A steamer's signal started the "inhabitants" out of their bunks soon after day-break, and quickly a gun from "Sutherland's Battery" boomed a welcome to the *Rotorua*. Sutherland and Malcolm pulled off in their boat, speedily to return with the intelligence that Captain Tozer could only give the photographer "five minutes!" This was news indeed, as it had been understood that the day would be spent in Milford. A "round-robin" had been concocted, it would seem, requesting the captain to run through other of the sounds, instead of making a stay a Milford. Remainder of packing was done in a rush, and in a very short time the photographer had bidden good-bye to his hosts and guides, and his trip to the mountains was virtually over. As "the man who had been a month at Milford," a transient popularity again awaited him; but truth compels the admission that the attention of the lady portion of the passengers was devoted more to a certain case of flowering Alpine plants—a nice specimen of the *Ranunculus Lyellii* among them—which formed a portion of his baggage. A timely suggestion by the chief officer that these floral treasures should be put into one of the boats relieved any embarrassment which gallantry, struggling with pardonable selfishness, might have produced. In at Thompson Sound; out at Doubtful. In at Breaksea, through Anchor Passage, and out at Dusky. Thus the *Rotorua* threaded her way; weather delightful; passengers in ecstasies; photographer alone moody and discontented. Lovely scenes were passing before his eyes, and not a "shot" could he take at them.

February 27th.—The Bluff. Expended the last five plates in taking views of the town and shipping, and groups of the captain and officers of the *Rotorua*.

February 28th.—Port Chalmers at daylight.

EXTRACTS FROM THE REPORT OF THE ASTRONOMER-ROYAL TO THE BOARD OF VISITORS OF THE ROYAL OBSERVATORY, GREENWICH,

Read at the Annual Visitation of the Royal Observatory, 1882, *June* 3.

BY W. H. M. CHRISTIE, ASTRONOMER-ROYAL.

In the year ending 1882, May 20, photographs of the sun have been taken on 200 days, and of these 352 have been selected for preservation. Since the end of last August photographs have been taken on Sundays as well as on week days. There were only 2 days out of 200 on which the sun's disc was observed to be free from spots. There has been a large increase in the number and size of spots and faculæ, the mean of the daily area for each in 1881 being nearly double of the corresponding quantities for 1880, and the increase is still continuing, though with well-marked fluctuations. A very remarkable outbreak of spots occurred in April last.

As regards the photographic reductions:

The photographs have been measured in duplicate, and the measures entered, to	1882, May 9
The areas of spots and faculæ have been completely reduced, so as to exhibit areas in millionths of the sun's visible surface, to	March 19
Radii of the sun, corrections for zero of position-circle, and heliographic elements, have been computed to... ...	May 9
Distances from the sun's centre and position-angles of spots and faculæ, corrected for distortion and refraction, have been formed to	March 19
Heliographic longitudes and latitudes of spots have been computed to	March 19

In order to save labour, without appreciable loss of accuracy, the reductions, since the beginning of this year, have been carried only to tenths of a degree instead of to minutes in position-angles and heliographic longitudes and latitudes, and to thousandths of an inch instead of ten-thousandths in measures of distance from sun's centre. To facilitate the computations, tables of sines and log sines, cosines and secants for degrees and tenths have been printed on a card, and the time occupied in the reductions is thus very materially shortened.

We are troubled at times in the magnetic basement with discolouration of the photographic sheets, apparently caused by want of ventilation in a room which has to be kept from the influence of changes of temperature in the external air. Possibly the adoption of one of the newer photographic processes might meet the difficulty, or it might be removed by the construction of a subterranean channel of sufficient length to bring the air entering the room through it to the temperature of the soil, which at a depth of a few feet is sensibly constant.

As regards the magnetic reductions, the eye-observations of the upper declination magnet and of the horizontal and vertical force magnets, giving zeros for the ordinates of the photographic curves, are reduced to the end of the year 1881.

The time-scales for declination and horizontal and vertical forces are complete to the end of 1881, and the base line values are formed. These are entered on the photographic sheets, and new base lines laid down.

The hourly ordinates of the photographic curves are read out to the end of 1881 for declination and horizontal force, and the taking of hourly and monthly means is complete. The time-scales for the earth-currents are laid down for 1881. The observations of dip are completely reduced; those for horizontal force are reduced to the end of 1881.

On four days during the year—viz., September 12 and 13, and April 16 and 19—magnetic storms have occurred. Those of April were of more marked character than any that have taken place since the great storms of the year 1872, and it is a significant fact that exceptionally large spots made their appearance on the sun shortly before—viz., on April 11 and 17. Smaller magnetic movements are now also much more frequent, the traces exhibiting a marked contrast to their general appearance some two or three years ago.

The number of hours of bright sunshine recorded by Campbell's sunshine instrument during 1881 was 1,301, which is more than 100 hours above the average of the four preceding years.

As regards solar photography, the value of our results would be very greatly increased if the gaps in the Greenwich series were filled up by the help of the photographs taken in India and elsewhere under the auspices of the Solar Physics Committee, so that the areas and positions of sun spots and faculæ should be given for every day. I am in communication with the Committee on the matter, and am in hopes that the saving of labour recently effected in our photographic reductions will enable us to undertake the work with our existing staff.

Royal Observatory, Greenwich, 1882, *May* 20.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The last meeting of the session of this Society was held on Tuesday evening, the 13th inst., at 5A, Pall Mall East, the President, JAMES GLAISHER, Esq., F.R.S., in the chair.

Before opening the proceedings, the CHAIRMAN expressed his conviction that they would all feel much pleasure at seeing in their midst an old friend, Mr. J. Traill Taylor, of New York, and called upon the members to give him a hearty welcome.

The minutes of the previous meeting were then read and confirmed.

The Chairman stated that the Council had received a letter from Mr. Darwin, informing them with much regret that he was compelled to give up the secretaryship of the Society, as he was leaving for Australia in September; he (the Chairman) wished to take the opportunity of bearing testimony to Mr. Darwin's faithfulness to the interests of the Society, and his agreeableness in his intercourse with the members. He stated that the council had elected Mr. Maxwell Lyte, one of the oldest members of the Society, to fill the vacant post, and called upon that gentleman to take the secretary's place.

Mr. Henry Stevens was duly elected a member of the Society.

Mr. T. Sebastian Davis read the report of the committee appointed by the Society to consider the establishment of a standard of rapidity for lenses; this report would be circulated as the standard of the Society.

Captain Abney then gave a brief abstract of Mr. C. R. Wood's paper on the recent eclipse operations, the paper itself being taken as read.

Mr. Cadett was next called upon to read his paper on "The Comparative Efficiency of Various Instantaneous Shutters." In introducing the subject, he pointed out the importance of utilizing to its fullest the effect of the action of light. It was usual to work with lenses of large aperture, though it was true there were instances on record of seascapes having been successfully rendered with the aperture as small as $\frac{f}{18}$; but these were exceptional cases. Mr. Payne Jennings was continually complaining that he could not get plates rapid enough. If the sensitiveness of plates for ordinary work was a matter of such importance, it was surely equally important to utilize the light to the fullest advantage. He stated that the best position for the shutter was undoubtedly immediately in front of the plate. After that, a shutter immediately behind the lens utilized the largest portion of the light which passed the latter, and he showed that, with the shutter placed in front of the lens, the greatest loss occurred. He demonstrated, by means of a diagram, the amount of light wasted by different forms of shutters. The ordinary drop-shutter, with square aperture the height of the opening of the lens, wasted exactly one-half of the light which ought to pass from the lens during exposure; while in using the shutter opening from the centre, loss of three quarters of the total light occurred. He alluded to the method adopted by Mr. Warnerke and himself in estimating the duration of exposures of various shutters, and stated that Mr. Warnerke had since improved upon the plan by constructing an arrangement consisting of a revolving disc of metal in which was a small aperture. This was placed in front of a bright light, such as the sky or light reflected from a sheet of paper, and the disc caused to revolve at the rate of once per second. A photograph was then taken while it was in motion, and by measuring the arc formed on the plate by the moving aperture, the duration of the exposure could be calculated exactly. With the simple drop shutter the duration of the exposure could be calculated without the assistance of any special appliances, and he showed on the blackboard a simple formula by which such calculations could be worked. He alluded to the influence which friction produced on the working of the drop shutter. Ignoring friction, he pointed out that the speed of the drop is continually accelerating; but Mr. Warnerke had found that after a certain speed was attained, the influence of friction intervened and prevented any further acceleration.

Mr. Addenbrooke then exhibited and described an arrangement he had devised for the purpose of measuring exposures, similar in general principle to Mr. Warnerke's, the chief point of difference being that the plate itself was caused to revolve. The duration of exposure was estimated, as in Mr. Warnerke's case, by measurement of the arc described upon the plate; it had the advantage of enabling ten or a dozen measurements to be made on the same plate by simply altering the centre of revolution of the latter. A negative bearing several measurements was passed round for inspection. A description of the apparatus will be given in a subsequent number.

Mr. Payne Jennings, in referring to Mr. Cadett's remarks to the effect that plates which were very rapid should of necessity not be of so good a quality, said, that in his experience, the more rapid a plate was, the better was the quality. He might say that he did not know how those who recommended that a plate should be slow base their arguments, and that he certainly thought they would be going a step backward if they gave out that slowness must be compatible with quality in results. They all knew that tide, water, foliage, &c., were constantly moving, and whatever they might wish to depict, it must be done as rapidly as possible, from which he concluded that the whole energy of plate makers ought to be directed towards the attainment of the utmost rapidity possible. With regard to small stops, he himself liked sharpness.

Mr. W. K. Burton said Mr. Cadett's remarks appeared to him to be thoroughly sound, and to cover the whole of the ground; but he would like to add emphasis to one or two of the points touched upon, points which had been brought to the notice of photographers times out of number. Firstly, with a shutter which worked close to the lens, the object was to have it very long, otherwise there was an enormous loss of light without any of the advantages accruing. Another point was that of the shutter working between the lenses of a combination; if the shutter opened and closed at the centre, there must be a loss of light under any circumstances; but it must be remembered that the shutter acted as a stop, and enabled you to use a lens of larger aperture. Mr. Cadett had said that there must always, theoretically, be a motion in a shutter; this was quite true respecting shutters with only one moving piece; but in shutters with two moving pieces, opening and closing in the centre, there was, theoretically, no motion.

Colonel Stuart Wortley said that from his experiments, he found he only lost one-sixth or one-seventh of the rapidity with a shutter just behind the lens. Some people thought it was not necessary to have a rapidly moving shutter for an instantaneous picture, but he could not agree with those who favoured a slow shutter. He produced and exhibited a shutter which he said might be classed as a very rapid one, and with which he had last year worked while at Niagara, to get a view of the falls from a very short distance, but he only succeeded after having strengthened the spring and thereby rendered the shutter five times as rapid.

Mr. Addenbrooke remarked that with breaking waves, the sea, streams, &c., one-fifth of a second was ample, and that the best way was to work with as slow a shutter as possible. Trees on a breezy day might easily be got with an exposure of one-tenth of a second.

Mr. Peek said some views he took of the seashore at Brighton were exposed by hand, and were perfectly sharply defined.

Mr. Maxwell Lyte agreed with some of the speakers that the use of a very small diaphragm is sometimes desirable in order to give sufficient definition to the picture; but he thought that an extreme diminution of the diaphragm might, if carried to a very great extent, greatly injure the balance of the picture.

Captain Abney thought that Mr. Cadett, in his diagram, had only taken into account shutters in which the height was equal to the diameter of the lens. In the case of a drop shutter, in front or behind the lens, the loss of light was one-half; but with the shutter he used himself and which he recommended, the length of which was equal to three times the diameter of the lens or more, instead of there being a loss of one-half of the light, there was really only a loss of one-eighth of the light. He disagreed with Mr. Jennings insomuch as he thought that if you had a moderately rapid plate, that was all you need desire. Except for special work, he thought a plate that took a good picture within a second was all that was to be wished for, and that Mr. Jennings' best work had hardly ever taken less than five seconds. He agreed with Mr. Burton's remarks respecting two opposing shutters, and had found that with this arrangement you had no motion on the camera at all. When at Scarborough he took two pictures of a sea-piece, in one of which he uncapped the lens with his hand, and in the other gave an exposure of $\frac{1}{20}$ part of a second. An artist, on seeing the former, said, "Oh! you have been copying a picture!"; but, on being asked his opinion of the other, thought it was a photograph, because, he said, "even an artist never saw ripples on the water, like that."

Mr. Cadett remarked that he thought a rapid plate would aid them towards progress in the future. Mr. Burton, he said, favoured a shutter which opened and closed in the centre, as it acted as a diaphragm. He (Mr. Cadett) thought this a mischievous practice; he preferred to use a more efficient shutter, and put a diaphragm in his lens. He said that Mr. Burton forgot that the period of time that shutter was open was exactly the same as occupied by a more efficient shutter. As Captain Abney pointed out, every shutter ought to have several times the aperture of the lens itself.

The Chairman called for a vote of thanks to those gentlemen who had taken part in the discussion, which was responded to.

Mr. Ackworth showed a conveniently fitted tourist's camera.

The Chairman then made the following announcements :— The exhibition would open on the 7th October, and would remain open every day, Sundays excepted, until the 16th November ; the *soiree* would take place on the 7th October. The latest date for receiving packing cases will be the 29th September, and nothing can be received after 9 o'clock on that evening The Council have also resolved that the exhibition should be open on three evenings in the week instead of two—viz., Monday, Wednesday, and Saturday ; also to have season tickets this year, the prices being £3 for one person, and £5 for two. The usual judges will be appointed.

The next Technical Meeting was announced for Tuesday, June 27.

The Chairman having remarked that the present meeting closed the session, and expressed a hope that they might have an interesting session next year, the meeting was brought to a close.

Sheffield Photographic Society.

The usual monthly meeting of the above Society was held in the Freemason's Hall, Surrey Street, on Tuesday, the 6th inst., Mr. Dakin in the chair.

Messrs. Pawson, Mallham, and J. Pilley were unanimously elected members of the Society.

The report of the last excursion (to Welbeck) was then presented by the Secretary, who stated that, owing to the persistent rain, very few plates were exposed, and those only in the Riding School, of which some good negatives were obtained, though a very difficult subject to photograph. Prints and negatives were brought to the meeting, to compare results, &c. It was proposed that the next excursion be to Matlock, on Friday the 23rd inst.

Mr. Dickenson showed a fine enlargement, 15 by 12, from a half-plate negative, taken by him at Hadden Hall, on gelatino-bromide paper, executed by Mr. Pumphrey, of Bradford.

A very interesting discussion took place on the merits and demerits of sulphite of soda in the developer, and also of the sulpho-pyrogallol, one member stating that, in his experience, it was unnecessary, as he always developed his plates very quickly, and so avoided staining the film, which, he contended, was always the result of prolonged development. He said he always got clear shadows by that method. The general opinion, however, was that the use of the sulphite was an advantage ; but the solutions should be used fresh, otherwise the pyrogallic lost its strength, and the negatives their pluck and vigour.

Thursday Evenings for Photographers.

A general meeting of the members and others interested in the formation of the new society arising out of these meetings was held on the 8th inst., Mr. W. E. Debenham in the chair.

The Chairman, in his introductory remarks, pointed out why it had been decided expedient to form a new society, and the special advantages it was proposed to confer. It was intended that the reading of papers should not be the chief object of meeting, although they would gladly welcome any papers on new discoveries or investigations ; but it was not possible to obtain such papers for every meeting. During the whole of the Thursday evening meetings, he, the Chairman, did not remember one meeting at which something fresh had not been been brought forward, or one at which he had not learned something. In the new society it was intended that the meetings should be occupied after the plan of the Thursday evenings, viz., by the exhibition and explanation of new apparatus, the communication of new formulæ, the result of investigations, and the discussion of matters of photographic practice, on which any of the members had met with difficulties. This latter point he considered a most important one, and one which was calculated to be especially useful to young photographers, amateurs, and assistants, who would all be welcome on an equal footing. It was believed that, with the large number who would appreciate the advantages offered, the subscription—which it was intended should be 5s. per annum—would suffice to pay all expenses ; but, as this was necessarily an experiment, two gentlemen had come forward as guarantors, in the event of there being any deficit in the funds for the first year.

After some discussion, and many suggestions from those present, it was resolved to name the society "The London and Provincial Photographic Association."

The Hon. Secretary *pro tem.* is Mr. C. B. Cutchey, 62, Gracechurch Street.

Bury Photographic Club.

Several gentlemen, photographers and amateurs, having a love of photography and the fine arts, met together on April 29th, May 10th, and May 16th, to form a Club, which it was agreed to call the Bury Photographic and Arts Club, its object being to provide a means of social intercourse amongst its members, and to foster and develop the application of photography to the arts and sciences. The following gentlemen were elected officers :—

President—Mr. J. E. Mellor.

Vice-Presidents—Messrs. W. S. Barlow and Edward Eccles.

Council—Messrs. F. W. Cooper, James Shaw, Daniel Mellor, Rushton, and H. Dearden.

Treasurer—Mr. John Nelson. *Secretary*—Mr. F. W. Livsey.

After the members had confirmed the rules and minutes of previous meetings,

Mr. Rushton introduced the question of drop and instantaneous shutters, and showed one of his own construction of a simple and very efficacious form.

Talk in the Studio.

Green Fog by Ferrous Oxalate Development.—When Mr. Dunmore seemingly confirmed Mr. J. Nesbit's remarks at the last South London meeting he did not intend to convey the notion that his experience was altogether identical with that of Mr. Nesbit. What Mr. Dunmore did say, so he informs us, is this, "that I had seen green fog after ferrous oxalate development, and that if, as Mr. Brooks thought, green fog was caused by sulphur, it might possibly proceed from the hypo. bath itself, green fog being invisible prior to fixing."

A Family Album.—A French photographer residing at Tangiers has just received a most interesting order from the Sultan of Morocco. He is commissioned by his Highness to photograph the 364 wives of this modern Solomon. The portraits will be contained in an album, of which the Sultan alone will have a key. If the photographer could only manage to strike off some duplicates from the negatives, they would doubtless command a considerable sale.—*Truth.*

Electrolytic Deposition of Copper from Alkaline Solutions.—In order to deposit a satisfactorily compact film of copper on iron, it is generally necessary to work with an alkaline bath, and cyanides have generally been employed in the preparation of the fluid. Weil has, however, found it advantageous to replace these poisonous salts by organic acids or by glycerine. Such a bath dissolves oxide of iron, leaving the metal bare and clean. Either the single-cell method may be employed, or a separate source of electricity can be used ; but, in the former case, the porous cell in which the zinc plate is placed must be charged with a solution of caustic soda, instead of the usual dilute sulphuric acid.

The Electric Light and the Growth of Plants.—Further details of Dr. Siemens' researches have been published. Two 4,000 candle lamps were used, one being enclosed in a glass lantern and placed outside a greenhouse, while the other lamp was placed inside a greenhouse. The result was not satisfactory in the case of direct exposure to the uncovered arc ; but under the influence of the protected lamp, which was only kept in action during the night, peas which were sown at the end of October were gathered in the middle of February ; strawberry plants placed in the greenhouse on December 16th yielded ripe fruit on February 14th. The interposition of yellow or red glass between the light and the plants retarded their progress notably, and, strange to say, blue glass exercised a still more injurious action.

To Correspondents.

*** We cannot undertake to return rejected communications.

Major R. Gordon.—1. Doubtless ; but the sample sent is so far peroxidised by exposure to the air, as to be practically useless. 2. You cannot do better than adopt the proportions given by Dr. Eder on p. 35-37 of the current Year-Book. 3. It makes no difference whatever.

H. Spink.—We have not heard of the application you mention, but would suggest that you should make a trial, and, if successful, let us have a description of your mode of working.

F. Cowley.—1. The best method is to tightly roll on a cylinder of moderately hard wood, and then cover with a few thicknesses of stout brown paper. If the picture is one of considerable value, a sheet of very thin sheet brass—or, better still, German silver—may be placed between the layers of brown paper. Mounted prints must be placed between packing boards. We do not know of any method of mounting which allows of the print being folded or rolled to a small radius without damage. As regards the scrap-book, the only point is to make it as light as possible consistently with sufficient strength. 2. We have asked Mr. Brooks to send you a prospectus.

Dark Room.—1. The best form of bichromate battery for the purpose is that which was described in the Photographic News about three months ago; while the worst is one made up like a Bunsen battery, but with a mixture of bichromate and sulphuric acid instead of nitric acid. Considering everything, the ordinary Bunsen battery is generally preferable.

C. R. F.—1. In all probability it was written several months before the close. 2. Simply ludicrous.

T. E. Forrest.—It is probable that your trouble arises from the reflection of light from some portion of the mount or tube, rather than from "flare" in the usual sense of the term. Mix some starch paste and lamp black, and with this mixture carefully cover any portions of the inside of the tube which appear to reflect light. The rapidity with different stops varies approximately with the squares of these diameters, and the relation would be absolute were it not for certain slight disturbing influences.

County Amateur.—1. Probably from over-exposure or the accidental access of light. 2. A very undesirable proceeding. 3. Nothing of the kind exists. 4. By itself it is a little too brittle, but this can be remedied by adding a little thin solution of india-rubber in benzole. 5. Certainly; but we should prefer to employ the wet collodion process for the purpose. 6. Dr. Eder's work on "Modern Dry Plates," published at our office.

J. M. Nisbett.—Look well to the camera and lens with a view of ascertaining if anything partially obstructs the light; or perhaps the lens is not placed centrally with regard to the plate. With respect to halation, you may either adopt the plan of squeegeeing a piece of carbon tissue softened in a mixture of glycerine and water against the plate, or you may paint the backs of your plates with a bitumen varnish.

Eta.—Not just at present. See notice of the Royal Cornwall Polytechnic Society, in the Photographic News of last week.

An Amateur.—The quantity first used is so much in excess of that theoretically required, that it is seldom requisite to add more. Yes, add a new bath.

W. E. D. Jones.—1. As regards the spotting, the principal thing is to obtain a sable brush of good quality, so that a fine point can be readily kept. 2. The result is very good. 3. We will devote a leader to the question shortly.

Amateur (Islington).—The back lens alone will not give a good picture, but if you unscrew the back lens and leave the front lens in position, very good views can be obtained. There are, however, advantages in using the front lens behind the stops, and with its convex side next the sensitive plate.

Mr. Spink's Shutter.—We have received a letter from Mr. Volk, of Brighton, in which he claims to be the true inventor of the shutter in question. Mr. Spink, in one of his communications to us, mentioned that his idea had been carried into practice by an electrician residing in Brighton; but no name was mentioned, and we must regard this as one of the numerous instances in which it is difficult to exactly apportion the merit of an invention between two individuals. Here, however, is Mr. Volk's view of the case:—"The facts are these. Some three years ago, Mr. Spink asked me if I could contrive a shutter for him, and I agreed to do so. All he suggested in the matter was, that it opened down the middle. I constructed it, and submitted it to Messrs. Marion and Co., with a view to patenting and publishing it. The patentee of a pneumatic shutter they supplied, however, stated that he claimed all pneumatic shutters, and, to avoid all trouble, I gave Mr. Spink the single and only one I ever made, without fee or reward, telling him why I did so. I may say that I have since been advised that I could have manufactured them without infringing the other patent. Had Mr. Spink acknowleged me in any way, I should have been satisfied; but seeing my indentical apparatus, I take the opportunity of explaining how matters stand."

Vexed.—1. We believe not. 2. We think you must, if you wish to obtain the best results.

H. H.—There is no such book; but information will be found in back numbers of the News and in the Year-Books.

R. M. L.—Our "Twelve Lessons on Dry-Plate Photography" will be shortly reprinted in book form; but you should also obtain Eder's work on "Modern Dry Plates," which is published at our office.

C. T. B.—If regarded from your point of view, it is an admirable practical joke.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1242.—*June* 23, 1882.

CONTENTS.

RECENT RESEARCHES OF DR. EDER ON GELATINO-BROMIDE.

Dr. Eder has already demonstrated that a bromo-iodide emulsion containing one-twelfth of silver iodide, and which has been emulsified in a neutral or slightly acid state, is less sensitive and gives thinner images than is the case with a pure bromide emulsion, provided that oxalate developer has been used, and that neither emulsion has been digested at a high temperature. The same holds good in the case of a bromo-iodide emulsion prepared with ammoniacal silver solution, and digested for about half an-hour at 35° to 40° C., the difference being very noticeable when the proportion of iodide ranges from one-twenty-fifth to one-twelfth of the bromide. In both these cases, then, the iodide exercises an injurious action.

It must not be lost sight of that the distinction—as regards properties—between a pure bromide emulsion and a bromo-iodide emulsion depends largely on the duration of the digestion and the degree of heat to which the preparation may have been subjected. As an illustration of this, it may be mentioned that a bromo-iodide emulsion containing one-twenty-fifth part of iodide, and boiled for half an hour while slightly acid, was hardly less sensitive than a similarly prepared bromide emulsion, although the former did certainly give thinner and weaker negatives than the latter, and more time was required for developing them.

The bromo-iodide precipitate is ordinarily flocculent and cheesy, when (as in the case of an emulsion containing about one-tenth of iodide) the gelatine, soluble bromide, and soluble bromide are first dissolved, and the silver nitrate is subsequently added, even though the gelatinous liquid may be dilute. Hence it frequently becomes necessary to first prepare a bromide emulsion, and to subsequently iodize it by the addition of iodide of potassium, so as to partially convert the silver bromide into iodide. When this expedient, due to the investigations of Abney, is adopted, a longer digestion is necessary than when the iodide is formed in the first instance, or it will frequently happen that the sensitiveness is less when the silver iodide is subsequently formed by the reaction of silver bromide with potassium iodide.

It has been proved by experiment that iodide of potassium exercises a very slow decomposing action on silver bromide when a considerable excess of potassium bromide is present. In one instance a washed and decidedly foggy emulsion was warmed for a short time with iodide of potassium, and afterwards well washed, the result being to considerably reduce the tendency towards fogging; but the sensitiveness was less than that of an ordinary clear working bromo-iodide emulsion containing one-fiftieth of silver iodide.

Iodide, to the extent of one-fiftieth, in the boiled or non-ammoniacal emulsion, tends, then, towards greater thinness of image and retards the development, but in the end the same details are obtained in the shadows. When, however, the proportion is increased to one-twelfth there is a loss as regards sensitiveness and vigour; this being more noticeable when oxalate developer is used than when pyrogallic acid is employed. An emulsion of bromo-iodide (containing one-fiftieth iodide) which has been boiled, and then digested with ammonia in the usual way, gives clear and vigorous negatives, which possess an exceptionally wide range of contrast; and, in some cases, the addition of iodide offers decided advantages.

The various emulsions may be arranged according to the vigour of the image obtainable with equally long exposures; and in the following statement the least vigorous is placed first:—

1. Boiled bromo-iodide emulsion.
2. Boiled bromide emulsion.
3. Bromide emulsion boiled, and subsequently digested with ammonia.
4. Bromo-iodide emulsion boiled, and subsequently digested with ammonia.

Lunge has recently made the observation that the action of dilute acids on easily-attacked substances, such as metals or ultramarine, is materially diminished by the presence of inert bodies, such as gum, glycerine, or lamp-black, and it is possible that the comparatively inert iodide may act in the same kind of way in relation to the developer. The thinness of image obtained when a considerable proportion of iodide is present may merely result from its non-actinic colour, and certain yellow colouring matters produce a similar effect. The retarding action of the iodide may, to some extent, be imitated by adding glycerine, sugar, or dextrine to the developer.

If the above considerations are correct, the presence of a silver salt which is difficult to reduce must diminish the chances of fogging, and, if present to a moderate extent, render the development slower, but without reducing the sensitiveness.

Taking this view of the case, some highly sensitive bromide emulsion, which rather tended towards fogging, was mixed with some immature or unripe emulsion, and the result was highly satisfactory, sensitiveness, vigour, and clearness being the result, proving that unripe bromide emulsion may replace iodide as an addition; and it was found that from two to five parts of the unripe bromide may advantageously replace one part of the iodide.

The addition of a small proportion of silver chloride to the bromide emulsion tends to favour the production of detail in the shadows, and it is probable that this action may be rather due to the ease with which the chloride is attacked by the developer, than to any extra sensitiveness of the bromo-chloride film. It is probable that the most perfect control over the quality of emulsion will result from the proper admixture of ready-prepared bromide, chloride, and iodide emulsions.

A remarkable fact which recent experiments have proved is that a very high grade of sensitiveness results when silver bromide is boiled with not less than ten times its weight of water and a considerable proportion of gelatine. The following proportions yield a highly sensitive preparation:

Bromide of potassium	24 parts
Gelatine	20 ,,
Water	200 ,,
mixed with	
Nitrate of silver	30 ,,
Water	125 ,,

Boil thirty to forty minutes, and add to 20 parts gelatine in 400 parts of water.

In the case of this emulsion it is easy to take advantage of the known remarkable effect of ammonia or carbonate of ammonia for increasing the vigour of the emulsion, and a very advantageous method of working is to only boil nineteen-twentieths of the whole quantity; the remaining one-twentieth being added after the boiled portion has been cooled to 40° or 50° C. Twenty parts of a ten per cent. solution of carbonate of ammonia are now added, and the whole is digested for half an-hour at 40° to 50°, after which the final addition of gelatine is made (20 parts gelatine and 300 of water).

RELATIVE POWER OF ANTISEPTICS.

The photographer, who deals so frequently with substances like albumen and gelatine, which are much prone to decomposition, will be glad to note the results of some exhaustive experiments on the subject of antiseptics recently made by M. Salan de la Croix. It was M. Croix's object to ascertain the relative value of the various well-known substances usually employed to prevent decomposition, as well as of others known to the chemist, and the issue of his work he has now published in the form of a table. Photographers are in the habit of using alcohol, phenol or carbolic acid, as also thymol to mix in their solutions of albumen or gelatine, but they will see by reference to the results below that the first-named has a comparatively very small protective power.

M. de la Croix's plan to ascertain the value of a substance in preventing the development or evolution of the microbia of putrefaction was a very simple one. He placed finely-divided boiled or raw meat in water, and ascertained the maximum and minimum quantities of each substance that were effective. The figures in the following table indicate the number of grammes of water in which one gramme of the substance mentioned prevents the development of microbia:

Substance employed.	Maximum dose in which development is not arrested.	Minimum dose in which development is arrested.
Alcohol	30	1·77
Chloroform	134	1
Soda biborate... ...	107	14
Eucalyptol	308	14
Phenol...	1,002	10
Thymol	2,229	20
Potash permanganate	3,041	35
Picric acid	3,041	100
Borated soda salicylate	3,377	30
Benzoic acid	4,020	50
Ethereal oil of mustard	5,734	40
Sulphurous acid ...	7,534	72
Alum acetate	7,535	478
Salicylic acid	7,677	343
Mercury bichloride ...	8,358	2,525
Lime hypochlorite ...	13,092	109
Sulphuric acid ...	16,782	135
Iodine	20,020	410
Bromine	20,875	493
Chlorine	34,509	431

From which it will be seen that chlorine, the hypochlorites, and perchloride of mercury are very effective, while alcohol is comparatively impotent.

At Home.

M. VAN BOSCH ON THE BOULEVARD DES CAPUCINES, PARIS.

The name of Van Bosch has been growing quite familiar during the past two years. Dashing portraits of French and German actresses and lady celebrities of the opera, all executed with a considerable amount of chic and "go," have lately been seen in our shop windows, both in town and country, bearing the quaint Dutch signature, and at some of the recent European exhibitions, medals—in one case a gold one—have been awarded for the pictures. As many of our readers are aware, Van Bosch earned for himself a name in Frankfort before his studio in Paris was opened, and in the old free town on the Main he still presides over a large establishment. But it is in Paris that he has made his mark, and hence it is to that capital we journey in order to set down an "At Home" in these pages.

Van Bosch has opened his campaign in Paris with vigour. It is always a bold thing to carry the war into a foreign capital, but Van Bosch has proved himself a bold man. In the best part of the Boulevards, where that magnificent thoroughfare is broadest and brightest, just between the Grand Opéra and the Madeleine, the favorite promenade of every fashionable visitor to the French metropolis, he has secured magnificent premises. A large emporium to the sign of "Old England" will have been remarked by many visitors to Paris, and it is above this establishment that Van Bosch has organized his studio.

As in the case of ninety-nine photographers out of a hundred, the studio itself is up many pairs of stairs, and not very far from the roof. The *porte cochère*, or broad doorway of Paris houses, affords an ample and favourable locality for the display of specimens, and on either side of the roomy recess are charming examples of work. Van Bosch does not, however, employ frames; he simply pins the card mounts against walls of handsome plush, and in this way secures a very fine effect. The bright photographs with their dark, rich tones, harmonise well with the soft amber background, and no valuable space is taken up by the gilder's art. There are cartes-de-visite, cabinets, promenades, and huge mammoths, which go by the name of Cartes Van Bosch, the last measuring twelve inches by eight, with a head frequently five inches in height. The price of the Van Bosch portraits is fifty francs, or £2 for the first, and half that price for copies; while cabinet portraits are sixty francs a dozen. The last-named figure may be taken as a standard for houses *du premier rang* in Paris just now. When the visitor gets to the end of this broad passage, and has seen the specimens, it may be that he is inclined to have a portrait taken; in this case he opens the door at the end, and in many establishments is directed by a notice to mount "*au cinquième*," or some such lofty elevation. The visitor looks up the vista of broad, shining stairs, and if he has been pacing the hot flags for some time, the chances are he will feel scarcely equal to the exertion; he shuts the door again, and postpones his call. M. Van Bosch has arranged matters differently, however, displaying not only common sense, but a knowledge of the public. A tiny piece has been cut off the end of the broad passage and made into a neat little office—there is hardly room for a writing table and a couple of chairs—and here on the ground floor the visitor may make enquiries, see further specimens, and make an appointment without further trouble.

When the sitter afterwards comes by appointment, he is shown upstairs to the second floor into a magnificent salon.

The busy boulevard is at your feet, and through the windows you can glance up and down the lively thoroughfare for a considerable distance. This room measures no less than forty feet in length, its breadth being about thirty. The furniture is "old German" and Flemish, with many examples of costly carving and rich tapestry, as attractive almost as the wonderful view to be seen from the windows. But there is no time to linger here; we proceed to an ante-chamber, from which, right and left, rises a handsome staircase. That to the right leads to a smaller salon, set apart for lady visitors; that to the left brings you into the studio.

The dimensions of the studio are unlimited; that is to say, when you have mounted you may look back over the balustrade, down upon the stairs again, and the ante-chamber you have left; or you may cross over to the ladies' salon without going down stairs; or you may walk past screens, among cameras and backgrounds. The working studio, in fact, is only an enclosure of a part of this apartment, in which visitors may tarry while still their presence is unnecessary before the camera.

There is plenty of light here where the portraits are taken; there is clear glass looking on to the boulevard ten feet high, which rises from a skirting board of eighteen inches. Then there is another ten feet of sloping glass roof, while the reverse side of the studio is, as we have just explained, simply made up of upright screens, which can be moved to any distance. These screens are covered with grey or slate-coloured fabric, while on the floor are light rugs of soft buff or light grey. "I like to work with plenty of light," says our friend the manager, who, with M. Van Bosch, junior, is good enough to accompany us on our round of inspection. Curtains of dark-blue pulling upwards provide for screening off too much glare, but these are not used when subsequently, obedient to command, we sit down to be posed; and it is noon, albeit there was no direct sunshine.

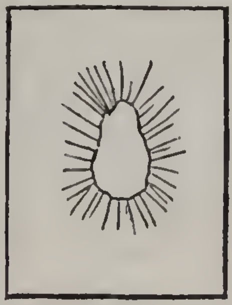
For vignettes, Van Bosch employs a revolving chair—a solid one, of course—and uses a parti-shaded background; this latter is darkly shaded at one extreme, the shading growing less towards the middle, until at the centre it disappears altogether. So simple a background has a good effect in giving relief to the vignette, and by means of the revolving chair the drawback of disturbing the sitter is reduced to a minimum.

It is the rule of the studio to take two pictures of every pose, one smaller than the other, a step, of course, easily taken, by retiring the camera a foot or two between the exposures. "Sitters so frequently complain that a head is too large or too small, that we now always submit two sizes," explains the manager.

A "rock-work" accessory in the studio deserves a few words of description. It is made up in three pieces, one main portion and two minor pieces. These latter may or may not be used to alter the shape of the pile, but they permit the placing between of pots of growing flowers and plants, which in the photograph appear springing out of the rock. In the picture, the flowers appear natural, as indeed they are, and for this reason the rock seems natural too.

In speaking of his *clientèle*, our friend informs us that nine-tenths are visitors to Paris, while one half are English. A sore subject he broached upon, which has already been ventilated both at Berlin and Vienna, although we have heard no complaint upon the subject in this country: we mean the giving of commissions to agents—douceurs, we believe, is the right name—who may secure the sitting of celebrities. This matter of douceurs is evidently becoming a great nuisance, and it prevails not so much in the case of great celebrities, as in mediocrities. "We are growing wiser now," says our friend, "but we have had to put up with douceurs, in some cases of a thousand francs, for the honour of receiving a visit, the profits of which to us, from portraits sold, have not amounted to a thousand centimes." Of course, these fees are accepted—to use a mild term—by agents, who may be perfectly unauthorized: but, in any case, it would seem that the greater personages—those whose portraits are really worth having—are free from the suspicion of requiring commissions of this kind.

A glance at the printing, which is done on a convenient flat roof, teaches us two little things: firstly, that only albumenized paper purchased ready sensitized is employed; and, secondly, that, in the delicate vignetting work, neither cotton-wool nor serrated cardboard openings are used. An opening is cut in a piece of card of the



shape desired, and then the "softening off" of the vignette is produced by simply making cuts into the card with a pair of scissors. There is no forcing open of the cuts thus made, which permits quite enough light to penetrate without further manipulation.

The work of the studio is much subdivided—the artist who poses, and has nought to do with developing the plate, the studio, so to speak, being under one management, and the dark-room under another; albeit, there is, of course, an *entente cordiale* between the two. Only gelatine plates are in use, and only oxalate development Another characteristic in the working is that there is no saving of waste. Residues are considered too insignificant to be taken care of.

The Van Bosch establishment has now existed in Paris for three years, and so successful has this branch of the Frankfort House proved, that there are whispers of further branches to be established in other capitals of Europe.

The next "By-the-Bye" will be "About Photographic Societies"; the following "At Home" will be "Picture-making with Mr. H. P. Robinson at Gwysaney Hall, North Wales."

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

PHOTOGRAPHY AT THE ROYAL ASTRONOMICAL SOCIETY—PHOTOGRAPHING PUBLIC BUILDINGS—A NEW METHOD OF TESTING NITRATE OF SILVER—THE ELECTRIC LIGHT AND THE INSURANCE COMPANIES.

Photography at the Royal Astronomical Society.—At the last meeting of the Royal Astronomical Society, a paper by Dr. Henry Draper on his photographs of the nebula in Orion was read. The negatives (photo-lithographic enlargements from which were exhibited) were taken on the 14th of March last, an eleven-inch refractor being used, and the exposure being one hundred and thirty-seven minutes. In consequence of this lengthened period, the stars were much over-exposed, and were somewhat altered in form, in consequence, so it was stated, of a slight movement of the telescope during the long exposure. One notable feature of these photographs was that certain small stars, which are almost invisible when looked at through the telescope, were brought out so that, as Dr. Draper remarked in his paper, it would appear possible, by still further increasing the exposure, to photograph stars which are invisible to the eye. It was also stated that photographs of the spectrum of the nebula taken without a slit show that two of the condensed masses preceding Trapeziums give a continuous spectrum, and therefore contain either gas under pressure, or liquid or solid matter. It was noticeable that the photographic experience of Captain Abney, who was present at the meeting, furnished a reasonable explanation of the increase in the size of the stars. Captain Abney pointed out, in contradistinction to the statement of Dr. Draper, and also to the opinion of one of the members, that this increase in diameter was due to reflection from the back of the plate, and he suggested that this might have been prevented by backing the plate with asphaltum, which was the method adopted for the photographs of the recent eclipse, and which was suggested last year in these columns. According to Lord Rosse, photography fails to reproduce drawings containing faint details. This statement was made in consequence of a suggestion that a singularly perfect drawing of the nebula made by Mr. Lassell, of the Royal Society, should be reproduced by means of photography. Did Lord Rosse mean that faint detail cannot be photographed, or that it cannot be reproduced in photo-zincography or photo-lithography? If he meant merely the reproduction, he was quite right; but it is almost too much to say that faint detail cannot be photographed.

Photographing Public Buildings.—It may save some trouble to photographers to know that public buildings under the charge of the Office of Works cannot be photographed without an order. A photographer recently attempted to photograph the sculpture at the base of the Albert Memorial, but was peremptorily stopped by one of the keepers for the reason just stated. Of course it is quite reasonable that certain structures, such as fortifications, should not be photographed without permission; but one fails to see on what ground an order is necessary for the photographing of the Albert Memorial. The point suggests the question whether the owner of a house can prevent its being photographed. If he cannot, it may come to pass that some ultra-sensitive person of influence will, before the passing of the Photographic Copyright Act (if it ever comes to be law) get the insertion of a clause making it a criminal offence to photograph a house without permission. Who knows?

A New Method of Testing Nitrate of Silver.—Hydro-fluo-silicic acid is recommended as a test for the purity of nitrate of silver. The silver salt is first dissolved in the smallest possible quantity of water, filtered, and hydro-fluo-silicic acid is added drop by drop. If turbidity is produced, an alkaline salt is indicated; but should the solution remain clear after several drops of acid have been added, the liquid is mixed with an equal bulk of alcohol, when any alkali is at once precipitated. To detect nitrous acid and nitrites, the liquid is evaporated as much as possible, and a solution of one-hundredth per cent. of magenta in glacial acetic acid added. If nitrous acid or nitrites are present, the liquid changes colour, running from violet to yellow. Free mineral acids also cause a similar change; but if water is added the red colour is restored.

The Electric Light and the Insurance Companies.—The Electrical Exhibition at the Crystal Palace has settled satisfactorily the question of the insurance of buildings lighted by electricity. When the Exhibition was first opened at the Palace, the insurance companies immediately were alarmed, and intimated their intention of raising their premiums; although why electricity should be considered more dangerous than gas, it is difficult to see. The experience of the last six months has, however, proved that there is very little to fear from the use of the electric light, at least so far as "extra risk" is concerned, and the companies now intimate that they will insure buildings lighted by electricity at the ordinary rates, provided certain conditions and stipulations are fulfilled with regard to laying the wires. By the way, it is to be hoped that at the next photographic exhibition, photographers will have an opportunity of seeing what the electric light can do in the way of untouched photographs. The specimens of a well-known photographer now to be seen in many shop windows are admirable as pictures, but they are so worked up on the negative that it is quite impossible to judge of what electricity is capable.

Ignorant Photographers.—We can call to mind a parallel case of ignorance to the one instanced last week by Dr. Vogel, in which an intelligent (?) photographer used a water unusually free from chlorides for washing his prints, and thought there was something wrong because no milkiness followed. In the incident we are about to relate, however, the photographer was a lady, and her ignorance of chemistry was, therefore, more excusable. This lady had heard of the amount of silver which could be recovered from the washing waters, of which she had hitherto taken no notice. She determined for the future to be much more economical; accordingly, she carefully hoarded up the water in a number of winchester quart bottles, and threw away the chloride of silver deposited as being perfectly useless. The delightful unconsciousness that she was doing anything ridiculous reminds us of the simplicity of a photographic dealer in the early days of the art, who, when asked in what consisted the superior qualities of a certain collodion, replied, with a very wise look, "Oh! it's so much *stronger* than anybody else's!"

FRENCH CORRESPONDENCE.

The Photographic Exhibition in August next—Photographic Photometry—Husnik's Sensitive Bitumen—Photo-engraving by Bichromated Albumen.

The Photographic Exhibition in August next.—The coming photographic exhibition of the Union Centrale promises to be one of great interest and importance. There are already enough photographs to fill two large galleries of the Palais de l'Industrie, and fresh applications for space are still being received. Let me remind my readers that this exhibition is not to be exclusively a French one; foreign productions will be admitted. Applications for space may be addressed up to the 15th of July next to the Union Centrale, 3, Place des Vosges, Paris; or to the President of the Photographic Committee, 20, Rue Louis-le-Grand.

Photographic Photometry.—Great attention is being paid to the question of establishing a luminous standard. Our esteemed colleagues, Mr. Warnerke and Dr. Vogel, are studying the subject with great care, but they have not yet succeeded in mathematically solving the problem with sufficient accuracy. The difficulty is to find a unit of light which is really constant, and next a means of determining scientifically the greater or less number of these units. This problem has nothing to do with the investigation with which I myself am at present engaged; the object of that investigation is to establish a method of photometry by which the length of exposure of a photograph, whether negative or positive, may be fixed and known. Up to the present I have successfully employed a graduated scale of tints each of which is pierced with a hole at its centre. Underneath this scale is placed a piece of sensitive albumenized paper, and after a minute's exposure in diffused light the degree of luminous action is found by the number of the tint which matches best, so far as depth is concerned, with that of the sensitive paper. We can then deduce the necessary duration of exposure in the camera, having given the focal length of the lens, the diameter of the diaphragm, and the sensitiveness of the film. Silver chloride paper answers very well for operations in the open air, because at the end of a minute, even in diffused light, there is always obtained an appreciable change of tint, whatever may be the weather. But this is not so in the case of dark interiors, where sometimes no change is observed even after ten minutes' exposure, and it may be necessary to continue the exposure to fifteen or twenty minutes. For this reason I have made the attempt to substitute for chloride-of-silver paper, a gelatino-bromide paper like that of Mr. Morgan. To effect this I increase the sensitiveness by dipping the paper, just before exposure, in a bath of nitrate of silver of not more than 4 or 5 per cent.; I then wash it, and let it dry. This paper only gives a slight change of tint; but its rapidity is four times as great as that of the chloride-of-silver paper. Gelatino-bromide pellicles can also be used extremely well for this purpose. The iodide-of-silver paper, which Mr. Warnerke used to prepare at one time, gives a more strongly-marked discolouration in a lapse of time less than two-thirds of that required for chloride of silver. I am endeavouring to fix accurately the different relations between these facts, in order that a photometric standard for the different circumstances which may arise may be readily obtained.

Husnik's Sensitive Bitumen.—I have been trying with success the liquid bitumen prepared by Husnik's method, which is much more sensitive than the ordinary bitumen of Judea. It can be procured from M. Moll, of Vienna Bitumen of Judea is a substance which, though possessing many valuable properties, is not generally distinguished for its sensitiveness to the action of the luminous rays; it is, therefore, of importance to discover any means by which this substance may be rendered more sensitive.

Photo-engraving by Bichromated Albumen.—I have in previous correspondence spoken of a process of photo-engraving in which bitumen of Judea is advantageously replaced by bichromated albumen, on account of the much greater sensitiveness of this latter product. This process I have studied with great care, and I have drawn up a detailed account (see page 363) of it which, as I think it will be of use to my readers, I have sent for publication in the News. It will, I think, be found to be of great use to those engaged in photo-engraving. No account with full details has yet been given of the process, and for this reason I think that my paper will be of interest to anyone who may wish to experiment with it.

Leon Vidal.

THE MODERN PHOTOGRAPHER: HIS POWER AND APPLIANCES.

BY J. M'KEAN.*

We have seen and heard much of what has been done in the progressive art of photography in this the gelatine era of its existence, the unlimited rapidity of the modern dry plate, and its application to almost every branch of science. Amongst the mysterious orbs of heaven and the rolling clouds, from Alpine heights to the deepest caverns of the earth, the camera is capable of revealing to the eye of man a mighty store of knowledge meet for his most profound contemplation.

As professional workers in this interesting field of research, we owe a deep debt of gratitude to those noble pioneers of the art who have placed in our hands such a marvellous power in so simple a form as that of the gelatine dry plate. Yet, simple and reliable as we find it, how few of the profession have mastered the process of making such a plate to their entire satisfaction, contenting themselves with simply exposing and developing those of commercial fame under whatever name they are known, though differing chemically in a very small degree. That photographers should thus allow a most important weapon to be taken out of their hands is not, to my mind, as it should be. We are neglecting to fortify our position, and so profit by what we have learned. Let me therefore direct your attention to the stern realities of our calling, and, if possible, open the eyes of some who have not, as yet, fully recognized the great power we now possess of bettering our position in the eyes of the public, calling forth that artistic skill without which no man need hope to succeed as a modern photographer.

Apart from this, however, there are other qualifications none the less needful, and to these in particular I shall briefly refer, presuming you all know wherein lies the beauty of the sun picture—how that, by the lighting and posing of the model, effects may be produced according to your ideal or artistic conception of it.

* Read before the Edinburgh Photographic Society.

Taking, then, in our hand a modern dry plate and holding it between us and "the light of other days," let us weigh its advantages over its many predecessors – first, with regard to its simplicity of preparation; second, its extreme rapidity; third, its certainty and convenience in the studio or field.

Under the first head, namely, its simplicity of preparation, I intend this evening to give you a practical demonstration of my mode of working; and I venture to say that after two years' work without a negative bath, and daily using my own plates, there is no reasonable excuse for even the humblest in the profession not becoming their own plate makers. I have said the humblest in the profession, and refer to those who, in the hand of iron fortune, are swimming but slowly with the stream of progress, with the risk of being swamped by that great revolutionary wave we call gelatino-argentic-bromide.

The appliances before you, with the exception of the drying cupboard, are, of their kind, familiar objects to you all. Two bottles, a bowl, and jam pot contain the simple ingredients for the production of ten ounces of emulsion. In the first bottle we have:—

Silver nitrate	200	grains
Distilled water	$1\frac{1}{2}$	ounces

In the second bottle:—

Ammonia bromide	105	grains
Ammonia chloride...	5	"
Ammonia liquor (·880)	6	drops
Water	$1\frac{1}{2}$	ounces

The jam pot contains:—

Gelatine (Nelson's No. 2)	40	grains
Potassium iodide	5	"
Water	$1\frac{1}{2}$	ounces

We now place in the bowl one-half ounce of gelatine (I use equal proportions of German and Nelson's No. 2), and covering it with water, leave it to swell till we have mixed and digested our emulsion, which we will now proceed to do.

Placing our two bottles and jam pot with their contents into a pan of sufficient size, along with an ordinary bath thermometer and a little water, we raise the temperature to 140° Fahr. over a fire or Bunsen burner, and shutting out all actinic light from the room, we take in our hand the bottle containing the silver nitrate, and in the other a glass rod, or glass or silver spoon. I have used them all with good effect, though for the last twelve months I prefer a horn spoon for this as well as coating plates with emulsion. The following are its advantages:—It never breaks, and soon gets seasoned for the work; in washing it parts with the emulsion freely; for coating plates it is light and easy to handle; with Scotchmen, at least, it is no stranger, from its long association with "the halesome parritch, chief of Scotia's food." In its new capacity, then, as an aid to science, and, if you please, a promoter of the fine arts, we begin operations by using the handle to agitate the solution of gelatine and iodide. We next introduce in a gentle stream our solution of silver nitrate, *a la* Captain Abney. We have now our old friend the iodide of silver in contact with our new love gelatine, though they do not seem quite to agree with each other, the iodide clinging to the handle of the spoon as if anxious to avoid the hot treatment to which it shall shortly be subjected. But immediately we introduce the solution of bromide and chloride, harmony is restored.

Our emulsion is now in its first stage of sensibility, and may, after a thorough wash and the addition of the rest of the gelatine, be considered in its infancy, capable of receiving impressions of the outward world, though a little too slow for these days of spring shutter and photographic revolvers. We have, however, a simple and effectual means of attaining this desirable degree of sensitiveness, namely, the process of boiling. Before doing so it is well to withdraw a few drops of our emulsion, and spreading them on a glass plate we may, by tranmitted light, mark the difference between its youthful bloom before, and its grey maturity after boiling.

So far we have accomplished our task in making what we would term a modern emulsion. We will now cover with a lid the dish containing it, round which I place a cloth to keep it from coming in contact with the sides of the pan in which we intend boiling it. Covering all with the lid of the pan, and relighting our Bunsen, and the room if necessary, leave it to "cook" as long as in the present occasion we may find it convenient. I usually allow it thirty minutes.

Meanwhile let me ask if there is anything so far as we have gone to debar any one with moderate intelligence from the independent position of having at his command, not only as quick plates and reliable as any in the market, but plates suitable for all circumstances? This is a desideratum with every photographer.

We know that in the wet collodion process it was necessary to modify not only the silver bath, but the state of collodion for certain kinds of work. For example, in copying we desired an impression that would bear any degree of development without fogging; preferring to use an old collodion and acid bath. And for a so-called instantaneous photograph, the very opposite would be our mode of treatment. Now to accomplish all this it was necessary to be daily surrounded with an innumerable multitude of bottles, baths, and fumes that were injurious to the health, and worrying to the mind. It is only those who have passed through such a fire of affliction that can hail with pleasure the present revolution. My desire is to lift the veil from the seeming mystery that shrouds the process of making a gelatine dry plate, but can add little more than what has already been done by abler hands than mine. It is much, however, to be brought face to face with the naked truth; to divest a process of many of its encumbrances and technical phrases in which men of science delight to revel. To this end I have employed nothing but what is in the immediate reach of all.

The formula I prefer, after trying many others, is one by Mr. Bedford, though, as you see, I have made some modifications, and it is right that I should give you my reason for so doing. First, I have replaced five grains of iodide with five of chloride, thus reducing the yellow colour of the film with an increase of rapidity. Second, I add in the first instance twenty grains more of gelatine, as by this quantity the haloid salts are held in better suspense during the process of boiling. I have also found it necessary to increase the quantity of water. The German gelatine, though excellent in other respects, is too hard to be used alone, and absorbs less water in the course of washing. My mode of mixing and digesting is reduced to the very verge of simplicity. My object in making these modifications was to lessen the risk of failure through want of skilful manipulation, not always to be found within the secret precincts of the dark room.

Thus far it may be said the process is casy and clearly understood; but our task is not yet done, nor is the contents of the pot sufficiently cooked. So to sharpen your appetites till that is ready, I will say a little on a dry subject; though this in reality should be the first matter for consideration with those who have not made a beginning in the process of emulsion—namely, a quick and ready means for drying your plates after they are coated. This has been the subject of much study, and many and various plaus have been adopted. After carefully weighing one with the other with regard to simplicity and expense, consistent with the object in view, I plied the tools to the formation of the drying-cupboard now before you. It may be thus briefly described:—

Made of dry pine, it measures 3 feet 4 inches high, 32 inches wide, and 1 foot deep from front to back. It contains eight shelves of the same materail, capable of holding twelve quarter or three whole plates each. The top and bottom are double, with sufficient room for the entrance and exit of air without light. From the upper air chamber rises a metal chimney, inside of which is a gas-burner at the end of a brass tube, through which, from the side of the cupboard, is led the supply of gas for the purpose of rarefying the air, and causing a draught. From the bottom right-hand side runs, in a horizontol position, an oblong square tube, through which passes, perpendicularly, a Bunsen burner. For cooking my emulsions I light the gas in the usual way outside the wire gauze; but when drying plates, the gas is lighted inside the tube of the "Bunsen," causing, with a small peep of gas, a sufficient heat to dry the air as it enters the cupboard, and winds its way over the shelves, the latter being open alternately at back and front. The principle, as you see, is not new, though the design is, perhaps, a little novel. It has been in constant use for these last two years; in fact, I would feel a little out of my element were it not before me on the present occasion. It stands in a convenient position in the dark-room, and takes the place of the negative bath; and to its credit be it said, it has never been the worse for alcohol (as we often find our bath), even after treating the emulsion to a "wee drap" with no apparent advantage. As I said, various plans have been tried in the formation of a drying cupboard, and, as there is always a desire to strike out something original, I may advise you that, whatever plan you may adopt, experience will teach you that there is nothing like wooden shelves. They are always dry, and the moisture from the plates has a tendency to be drawn thereto, which, in its course, is expelled from the cupboard by the current of air. I usually coat my plates after business hours, and they are ready for use the next morning; and so confident am I of the success of each batch of plates, that I never think of trying a plate before using it for a sitter in the usual course of business.

This brings me to a point which I must not pass without some observations, as I know that in this particular my experience differs from some of my professional brethren. Let us reason. I gave you my formula, and have shown you how to treat it in making an emulsion. You observe the conditions necessary to secure the best result, and have succeeded, we shall say, to your entire satisfaction. You repeat the process, and observe the same conditions as regard time and temperature. Is it unreasonable, then, to expect anything but the same result? If the contrary has been the experience of some, I am pleased to say it is not mine, therefore can prescribe no remedy. I may, however, point to a few causes and their effect, which in the course of a few experiments I have discovered. I have, for example, tried the effect of adding more bromide, iodide, and chloride to the same proportion of silver, and in every case it has lessened the rapidity of the plate, though greatly improving it as regards grain and clearness of shadows in the resulting negative. From this fact I have come to the conclusion that, for a suitable plate for landscape work, we must look in this direction, as such a plate will bear any amount of development without stain or fog. Another cause for slowness will be found in the nature of the gelatine; the harder that is, the slower the plate, unless the washing of the emulsion is prolonged accordingly. There are many other causes for slowness which must be apparent to all, as insufficient digesting, &c.

I need hardly say that to secure the most rapid plates we must work in the opposite direction. There is a way of increasing the sensitiveness of emulsion which may not generally be known. I have found that by keeping the emulsion (after washing and draining) for several days before coating, there is a considerable improvement in this respect. In any case the material is in our own hands, and it is capable of being moulded to suit any circumstances, without, as I have said, half the complexities and perplexities common to the wet collodion process. It it certainly more congenial to our feelings to look upon a boiling pot with the assurance that there is something good therein; but let us see.

Previous to stopping the boiling operation, we shall drain the water from the bowl of gelatine, and, turning out the gas under the pot, withdraw the dish of cooked emulsion, and replace it with the bowl. After stirring the emulsion for a little, we shall examine a few drops through a glass plate, and, comparing it with the first, we find it has changed from orange to a grey-blue colour—a change which I do not pretend to explain. It is enough for our purpose to know it has become more sensitive to light, and in this state I decant it right into the bowl, and in a few minutes the gelatine is dissolved. I now leave it to "set" all night, and, in the morning, squeeze it through coarse canvas into a can of water, over which I tie a piece of finer material. At the bottom of the can is drilled a small hole, through which is passed a rubber tube, forming the simplest and cheapest washing apparatus yet invented. We have only to connect the tube with the water tap, and cover the mouth of the can with a light-tight lid, turn on the water, and leave it till you are ready to coat plates in the evening. I usually finish up by inverting the apparatus a few minutes previous to turning off the water. I then disconnect the tube, and blow through it; by this means the water is rapidly expelled from the emulsion.

We now begin the operation of coating plates by getting everything in position. Into our pan, filled with hot water, place a bowl, into which the emulsion is transferred from the washing apparatus, when it will quickly be dissolved. Over a second bowl I stretch two plies of fine cotton, through which I filter the emulsion, and it is ready for use. For this operation, the only addition to our appliances will be two levelling-stands and two plates of thick glass. Placing one on the table at the left, and the other within arm's length of the cupboard, and with horn-spoon in hand, proceed. Many plans have been tried to secure uniformity in coating plates. I have tried many, but like none so well as this. The spoon contains perhaps three times the quantity of emulsion necessary to cover the quarter-plate in my hand; but pour it all on, and you require no glass rod to conduct it to the edges of the plate; pour off the surplus into the spoon, and return it to the bowl. By this means the coating is conducted smoothly and more quickly than coating a plate with collodion. You have not to wait till the film sets in your hand, but placing it on the level glass go on with another till that is filled, after which pass it over to the other stand next the cupboard, and begin filling the next plate as before. By this time the first plates will be thoroughly "set," and may be placed in the cupboard. In this way the shelves are speedily filled, after which the door is closed, and the gas lit above and below. Thereafter you may retire to rest, with the satisfaction of knowing that a batch of cheap and reliable plates will be ready for the first sitter in the morning.

This is my experience in making a modern dry plate, and so ends the first part of my paper, namely, "its simplicity of preparation." We have to consider in the second place, "its extreme rapidity," but fearing I have trespassed already too far on your time and patience, I must for the present forbear. I shall at a future occasion take up this part of the subject, when I hope to give it more justice than would be possible under present circumstances. I know that I have been treading on the toes of commercial plate makers, but I do it in the interest of the photographic profession; indeed, I question the application of the word "photographer" to those who do not make their own plates—artist, if you will, but no more like our fathers in this respect "than I to Hercules."

PHOTOGRAPHY AS A HANDMAID TO THE SCIENCES, AND AS A RECREATION.

BY W. DOUGALL.*

The following short paper may not be without interest to the members of the Edinburgh Photographic Society, as it is a reminiscence of one who acted for some time as secretary to the Photographic Society of Scotland, the predecessor of our present society.

The late Dr. Joseph Dougall, F.R.C.P.E., was educated at the University of Edinburgh, and was a keen student of many subjects beyond the usual studies pertaining to his profession. Being a phonographer as well as a photographer, he took a great interest in the work of the old society, and made notes of its proceedings in shorthand, which were extended in the official minutes. He spent twenty years in the Indian Medical Service, and travelled a great deal over India, Burmah, and China, and received the medal and clasp for the Chinese War of 1860. In 1864-65, he first made photography do service in assisting the proper illustration of very important surgical operations. At this time he had under his care a case of *Elephantiasis Scroti* which he photographed carefully before operating on it, and after removing a tumour of 24lbs. weight, he again photographed the patient after he had sufficiently recovered. The fame of this operation soon brought six or seven more cases from different parts and great distances, all of which were successfully treated, and photographed in the same manner as the first, thus affording a permanent illustration of the cases both before and after cure. These photographs were sent home and presented to the late Dr. Warburton Begbie, of Edinburgh, who considered them of great importance.

At the Andaman Islands, in 1873-4, Dr. Dougall made a discovery of a very successful method of treating leprosy and other skin diseases. Some of his patients were in a most wretched condition, having fingers and toes eaten off by the disease, and here again he photographed them all at different stages of his treatment, these pictures giving incontrovertible proof of the exact changes which occurred. The great value of photography in such instances is that it gives a true and reliable representation of the cases, and affords no room for the exaggeration or romancing which might naturally occur were the sketches made only by the hand. Again, Dr. Dougall was enabled to take many fine views of the aborigines of the Andaman and Nicobar Islands, a diminutive and little-known race, very low in the social scale. He also obtained skeletons of these people, and presented the University of Edinburgh with two, and the Hunterian Museum of the Royal College of Surgeons, London, with ten, a contribution to anthropological science which was highly prized, and was acknowledged by a special vote of thanks of the college. These skeletons and photographs enabled Professor Flower, F.R.S., to publish a memoir on the osteology of the Andamanese, which was read before the Anthropological Society of London, and published with illustrations.

Dr. Dougall also made a valuable collection illustrative of the conchology of India, and photographed the shells and corals to a scale, which views were exhibited at the last exhibition of the Photographic Society in Edinburgh, and are now here for the members to examine. Passing from the purely professional advantages to be derived from photography as a handmaid to science, it may be remarked that Dr. Dougall, when at Vizagapatam, taught Nursing Rao, a wealthy and highly educated native gentleman, the photographic art, in which he very soon became a proficient operator. This gentleman has since become a member of the Royal Astronomical Society of England, and no doubt his photographic skill will be employed as a handmaid to astronomy, as he has a highly equipped observatory at his residence in India. While resident medical officer at the Court of Burmah, Dr. Dougall photographed the king's sons, one of whom is the present celebrated King Theebau, of bloodthirsty notoriety. In 1875 Dr. Dougall took a holiday to visit his friend General Sir Donald M. Stewart, now Commander-in-Chief in India, in the course of which he travelled 4,000 miles, and photographed some of the scenery of Northern India. When the Duke of Buckingham and Chandos, Governor of Madras, accompanied by the Ladies Grenville, paid a visit to the Andaman Islands as part of an extensive tour, they were collecting photographs of every place visited, and were at first disappointed at the prospect of having no views of these beautiful islands; but Dr. Dougall had a call from the Governor, and showed him his collection of views, from which he gladly selected a large number for himself and daughters. After His Excellency returned to Madras, his daughters sent a splendid large album to Dr. Dougall in remembrance of his kindness, and in appreciation of the views they received to complete the illustration of their interesting tour. Numbers of these views have been printed by the Woodbury Company from the original negatives, some of which will be shown to-night. These remarks, I think, have proved that in the experience of a single individual, a knowledge of the art of photography has greatly assisted in illustrating important medical and surgical cases, and has given an additional charm to the study of anthropology, conchology, and astronomy. They also show that a very great amount of pleasure can be enjoyed by a true artist in getting up a variety of fine pictures, and that this pleasure is enhanced by his being able to impart a share of it to others in presenting them with some of those things of beauty which are a joy for ever.

* Read before the Edinburgh Photographic Society.

Notes.

"The Photographic Studios of Europe" will be published to-morrow.

Major Waterhouse, B.S.C., the Assistant Surveyor-General of India, will shortly contribute a series of papers on photo-lithography.

A committee has been formed, with M. Davanne at its head, to collect subscriptions for a monument to Poitevin. We shall be happy to forward to the Treasurer, M. Léon Vidal, any sums that may be entrusted to us for the object in question.

To those who have not yet trusted themselves to prepare an emulsion, we commend the simple formula published to-day in No. 12 of our Elementary Lessons. It is possible to make an emulsion of higher sensitiveness than the one there indicated, but we cannot point out a more straightforward method of working to ensure success.

The *foyer* of the Prince of Wales' theatre, where "The Colonel" has been playing for the past two years, is about to be re-modelled and re-decorated. One of the chief features of the new salon will be a collection of pictorial photographs by Mr. H. P. Robinson, of Tunbridge Wells, selected from the series which received medals at the last two Pall Mall Exhibitions.

We learn that Mr. W. J. A. Grant, in the little yacht *Kara*, reached Promso, in Norway, on Tuesday afternoon, after a stormy passage. The *Hope*, with Sir Allen Young on board, which is to join the *Kara* in her search after Mr. Leigh Smith, left Gravesend yesterday. They will meet, probably, on the Nova Zembla Coast, which has been made familiar to Arctic voyagers and stay-at-homes through the medium of Mr. Grant's photographs.

A serious fire broke out at the studio of Mr. W. G. Wilson at Queen's Cross, Aberdeen, on Wednesday in last week. The Queen, who was in Scotland at the time, and has always shown a high appreciation of Mr. Wilson's delightful pictorial photographs, forwarded a telegram expressing a hope that none of his valuable negatives were injured; fortunately, the fire did not reach the storeroom where these are kept, and Her Majesty was duly informed of this fact.

Touching one of our "Notes" last week, a correspondent suggests the formation of a Pickwick Club among photographers; the members to exchange prints of such photographs as they may take in illustration of Dickens' works.

According to *Harper's Magazine*, two of our recent literary celebrities have never been photographed, viz., George Elliot, and Edwin Arnold, the editor of the *Daily Telegraph*. Certainly photographs of the author of "Adam Bede" were on sale shortly after her death, but whether they were true camera pictures we cannot say.

The portraits in *Men of Mark* will in future, we are told, be all taken by means of the electric light in Mr. Mayall's studio.

The well-known Italian photographer, Carlo Naja, of Venice, whose work is so largely purchased by travelling Britons, died on the 29th ult.

Professor Henry Draper, of New York, never lags behind in the matter of photo-astronomy; he has followed Dr. Huggins' footsteps, and successfully photographed the spectrum of the nebula of Orion.

We should have mentioned last week, by the way, that Dr. Huggins successfully obtained a photograph of the spectrum of the comet (Wells) on May 31. He found a strong continuous spectrum, but could secure no Fraunhofer lines, owing to the great relative brightness of the continuous spectrum from the comet's own light. There were no cyanogen bands visible in the ultra-violet, he tells us, but at least five groups of bright lines between F and H, both in the light of the nucleus and of the coma on the side next the sun.

Two yards of Turkey-red calico folded in three serve to immediately transform a lavatory, such as we find on most of the North Western main line trains, into a dark room. A small apartment with a well-fitting door, hanging baskets suitable for bottles, a wash basin set in the middle of a bordered pewter table, a good water supply, and several clean towels, is attached to each first-class compartment having six places.

It is generally supposed that the most exalted state of sensitiveness in gelatine emulsion is more quickly reached when the latter contains but a small proportion of gelatine at the time of boiling; but Dr. Eder has just found out that he can produce the most highly sensitive emulsion by boiling for ten minutes with the full dose of gelatine added.

Another recent observation of Eder's, according to the *Mittheilungen*, is that if a gelatine plate, after exposure, is dipped into a dilute solution of nitrate of silver, and then dried before development, a very considerable increase in the sensitiveness of the plate will be remarked. In this case the nitrate of silver obviously performs, as an accelerator, a different rôle than when present at the time of exposure.

Has any photographer tested the light of a glow-worm upon a sensitive plate? We captured two shining little creatures last week, but, unfortunately, were a hundred miles from home, and their brightness waned two days afterwards, when we desired to make the experiment. We have little doubt a quarter of an hour's sojourn upon a gelatine plate would have produced an effect, and we would ask any of our readers who may have the opportunity to carry out the interesting experiment. The glow-worm should be permitted to make its mark from the reverse side of the plate, first of all, so that the action of its phosphorescence may be placed beyond doubt.

Those who wish to develop without staining the fingers should look back to page 301, where a drawing of Mr. W. J. Williams' trigger is given. Mr. Dunmore speaks well of a similar arrangement which he recently exhibited at the Photographic Club.

Although not quite equal to M. Nadar's picture of the roofs of Paris, Mr. Cecil V. Shadbolt's view taken near Stamford Hill is undoubtedly the best specimen of balloon photography which has been done in this country. It is a cabinet picture, taken with a rapid symmetrical, full aperture, and the portion which is fairly sharp evidently corresponds with the rotation axis of the balloon.

How much there is still to improve in photo-engraving may be seen from a glance at "Academy Notes" of this year. Had the blocks been executed by the Klic process, no doubt more satisfactory reprints would have been forthcoming than are produced by the photo-etching method which is chosen, and which we have several times described in these columns. A pen sketch with Indian ink executed upon smooth white cardboard will give the best results, we may mention, by the photo-etching process.

To get a painting photographed prior to its being sent to the Academy is now an established custom, and many photographers have a busy time of it the week before sending-in day. With apparatus carefully packed in a four-wheeler, the photographer goes the round of the studios, and does his work as expeditiously as he can. The painting is fixed up in the back garden where there is plenty of light, and within a quarter of an hour—for both to painter and photographer time is precious—three or four plates have been exposed, and the photographer and his camera have disappeared once more.

The photographing of paintings is, indeed, a flourishing business now-a-days. No painter paints an important picture who does not desire to keep a copy of it, and, as a rule, orders come not only for silver prints, but for impressions of large dimensions printed in pigments. Some painters, in fact, are following the example of their French brethren, and publishing photographic copies of their pictures.

Dr. Vogel confirms our recent remark that the dryness of a gelatine plate materially influences the time of its development. "The other day," says the doctor, "I prepared some emulsion with hard gelatine, and this was declared on trial to be very insensitive. But on closer investigation, it turned out to be simply a matter of slow development, for my film, when fully developed, was found to possess quite as much detail as one of the quickest commercial plates. Only, the hard film required an immersion in the developer for six minutes, and the other but three minutes.

Slow development, when it is not too slow, is frequently an advantage, particularly in landscape work. The judicious employment of hard gelatine in emulsion making is, therefore, to be commended.

When the Astronomer-Royal makes his yearly report, the question again and again suggests itself whether Greenwich is, after all, the best place in the world for heavenly observations. Especially does this misgiving arise in one's mind when the Astronomer-Royal speaks of the photographic work and records of bright sunshine made in the midst of the thick vapour and murky clouds that come over from the Isle of Dogs opposite. Indeed, to anyone acquainted with the normal atmosphere of Greenwich Hill, and who has seen the lurid sun time after time stifled in yellow mist long before it reaches the horizon, the taking of solar photographs seems little less than ridiculous; while to tell us how many hours of bright sunshine the factories and docks in the neighbourhood have been blessed with may be of interest to those residing within the borough, but has, obviously, little scientific value. That there have been 1,301 hours more sunshine this year than last, may mean simply that the Smoke Abatement Act has been more rigidly observed in the S.E. district; and if, as the Astronomer-Royal tells us, the photographs of the sun were taken on 200 days, the fact merely proves that the borough was extremely fortunate in its freedom from fog and smoke this year. That the record of sunshine would have been greater, and the solar photographs clearer and more defined, had the observations been made in a purer atmosphere at a distance from town, no one will gainsay. There is no need for us to abolish Greenwich as a geographical station, but to constitute it a photographic observatory is worse than absurd, since the results are without that accuracy which alone constitutes their value.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. XII.—Making Gelatine Emulsion.

We gave it as our opinion, when commencing these lessons, that the amateur will generally find it best to purchase plates from the manufacturer. He will probably find it both cheaper and more satisfactory to do so than to manufacture them himself, unless he has at his disposal considerable time, and unless he has great patience and a happy temperament, which will enable him to bear frequent disappointment, when, after going through the tedious process of making an emulsion and coating the plates, he finds that the latter are, from some unknown cause, useless.

Nevertheless, we believe that the photographer who makes himself acquainted with the process of the manufacture of dry plates, and knows how to make an emulsion, will have a more thorough mastery of the working of them than those who have never made their own plates. There are some few who, for the love of the work, prefer to make their own emulsion. These are the real enthusiasts to whom we look to further our knowledge of photography, and with such the manufacture of plates pays, if it be only in the satisfaction they have in relying on themselves alone.

The subject of gelatine emulsions and plates is one on which volumes might, and in fact have been, written, and here of course we can but give the briefest instructions. If the photographer succeed with these, he may with advantage take up the study of the advanced works which have been written on the subject.

We do not propose to give the formula which has given the highest sensitiveness in our hands, but shall give one which has given us plates of fair rapidity, and of the very highest quality.

The principal piece of apparatus necessary for making any number of plates is a drying cupboard or box. This is a box arranged so that the plates may be placed in it in such a position that a current of air passes rapidly over the surface of all of them. There are various designs of boxes, some of which are so arranged that the current of air is heated. This is not desirable if a fairly dry place can be had for the drying-box. The motion of the air is usually ensured by burning a gas jet at the lower end of a small chimney or flue. The defect in almost all drying-boxes that we know, is that the air-passages are too small.

The other apparatus necessary is as follows:—

A large slab of plate glass, marble, or smoothed slate, levelled accurately, so that the plates can be laid on it to set. The larger the slab the better, as more plates can be placed on it at once.

A piece of coarse canvas or "scrim," such as ladies do worsted work on—say two feet square.

Several glass beakers or jam pots for mixing and boiling solutions in. The latter are preferable, as glass is very likely to be broken in the dark-room.

An ordinary hair sieve.

A vessel of such a size and shape that the sieve may stand in it, and that when it—the vessel—is full of water, the upper edge of the sieve will stand (say) half an inch above the surface of the water.

A large glass filtering funnel.

Several hock bottles. These, from their deep red colour, are useful for performing the various manipulations in.

An ordinary saucepan.

A Bunsen ring burner, on which this may stand to boil.

Let the following solutions be prepared, and each mixed in one of the jam pots.

A

Nitrate of silver	100 grains
Distilled water	2 ounces

B

Bromide of potassium	85 grains
Nelson's No. 2 gelatine	20 ,,
Distilled water	$1\frac{1}{2}$ ounces
A one per cent. mixture of hydrochloric acid and water ...	50 minims

C

Iodide of potassium	8 grains
Distilled water	$\frac{1}{2}$ ounce

D

Hard gelatine, such as that sold by the Autotype Company for dry plates	120 grains
Water	several ounces

Let B and D stand till the gelatine is thoroughly soaked as indicated by its being quite soft. Let all the water be poured off D, and let as much water as possible be squeezed out of the gelatine.

The pots containing A and B must now be placed in hot water till the solutions are at about 120° Fahr., when B is poured into one of the hock bottles.

From this time all operations must be performed in the most feeble ruby light possible.

A little of B is now added to the solution already in the bottle and the whole shaken. Small additions of B are made so that it is poured in five or six stages into A, the whole being shaken at each addition, and a very thorough agitation being given at the end.

C is added, and the solutions, now forming an emulsion, are again shaken.

The whole is poured into one of the jam pots. This is placed in the saucepan, the lid is placed on the latter, and the water brought as rapidly as possible to the boil. A loose cover of some sort should be placed over the jam pot during this part of the process to prevent condensed water from dropping off the lid of the saucepan into the emulsion. The emulsion is allowed to remain for half-an-hour in the boiling water. If, at the beginning of the process, a drop of the emulsion be placed on a piece of glass and a gas flame looked at through it, the flame will appear very red. The emulsion is said to be red by transmitted light. At the end of the boiling it will be a more or less near approach to blue in colour.

At the end of the half hour the gelatine D is placed among the emulsion, and the whole stirred to mix it. The can is then put in a cool and dark place to allow the emulsion to set. It will do so in from one to two hours on a moderately cool day, but it may be left for days if it be desired. This is the best period at which to break the process, which is somewhat lengthy to be performed at one time.

When the emulsion is set quite stiff the jam pot is dipped for a few moments in hot water. If it be inverted the emulsion will now fall out of the vessel in the same manner that a jelly for the table drops from its shape or mould. The sieve must meantime have been placed in its appropriate vessel full of water. The lump of emulsion is placed in the canvas, the whole is placed under water in the sieve, and the canvas twisted up so as to cause the emulsion to pass through it in fine shreds into the water. It must now be washed for half an hour, either by allowing water to run into the sieve, or by frequently changing the water in the vessel.

The object of this washing is to get rid of the soluble nitrates and bromide, whilst the insoluble bromide and iodide of silver—the sensitive salts—remain in the emulsion.

At the end of half an hour the sieve may be removed from the washing vessel, and placed in any convenient position with one side somewhat tipped up, so that all superfluous water may drain off. The draining should go on for at least half an hour. At the end of that time the emulsion is finished, and only requires to be filtered. We have found nothing better for this than several folds of cotton such as pocket handkerchiefs are made of.

Three-quarters of an ounce of methylated spirits or alcohol is now added, and the emulsion is ready to be used for coating the plates. The quantity will be about six or seven ounces. It may be kept in one of the hock bottles, wrapped in brown paper. A small earthenware teapot is the best thing to pour the emulsion on to the plates from. It should be very small; such an one as holds a few ounces, and is used by children at a "doll's tea party," will do. The smallness of this allows a constant check to be put on the quantity of emulsion given to the plates by counting how many are coated by each fill of the teapot.

The glass plates must be thoroughly cleaned before being coated. This may be done by dipping the plates in a 5 per cent. mixture of nitric acid and water, then rubbing them under the tap with a wet cloth, and afterwards drying with a dry cloth. If they have been coated with emulsion before, they should be left at least twenty-four hours in the dilute nitric acid, and then rinsed with hot water.

Let us suppose the plates ready to coat. The dark-room lamp is placed within a few inches of the right-hand end of the levelling-shelf, and at the back of it. To the left of the lamp is the pile of plates; to the right a glass measure or jam pot, or other convenient vessel, in which to stand a glass rod to be ready to hand. The glass rod should be about two inches longer than the breadth of the plates to be coated. Immediately in front of the lamp is placed the teapot full of melted emulsion. A plate is taken from the pile. It is placed as far forward on the levelling-shelf as possible, and in front of the lamp.

A pool of emulsion, about half covering the plate, is poured from the teapot. The glass rod is taken between the fingers and thumb of each hand, and dipped into the pool of emulsion right across the plate. The emulsion will run between the rod and the plate to each edge of the latter. By a motion of the finger and thumb of each hand the rod is lifted the smallest possible distance from the plate, and is rapidly moved first to one end, then to the other, the tips of the finger and thumb resting on the level table as a guide. This, if properly done, will cover the whole plate with emulsion; and if the plate be small—under whole-plate size—it is sufficient to slide it to the far end of the table to set. If the plate be large, the coating will not be evenly spread unless it is lifted, balanced on the tips of the fingers of the left hand, and gently rocked for a few seconds. By this method plates may, after a little practice, be coated with great rapidity. There is no need to wipe the rod each time it is used.

Each ounce of emulsion must not be made to cover more than six or seven quarter-plates or three half-plates.

The plates will "set" in a few minutes—that is to say, the emulsion will stiffen like a jelly—and will not run off the glass, whatever position it is placed in. They are now transferred to the drying-box. They will take from six to forty-eight hours to dry, according to circumstances. When dry, they are ready for use.

If a very rapid emulsion be desired, the boiling may be continued for from one to two hours, the emulsion, after washing, be rendered neutral or slightly alkaline by the addition of about twenty drops of the ten per cent. mixture of ammonia and water, and be kept for a couple of days before coating the plates. We would strongly advise, however, that the beginner confine himself to a slow emulsion.

PROCESS OF PHOTO-ENGRAVING ON ZINC OR ON COPPER BY MEANS OF BICHROMATED ALBUMEN.

BY LEON VIDAL.

This process is similar in many respects to the one which was some time ago communicated to the Photographic Society of France by M. Stroubinsky, of St. Petersburg, but in a much improved and complete form. An account of it was given by M. Gobert, at the meeting of the same Society, on the 2nd December, 1882. The following are the details, as demonstrated by me at the meeting of the 9th May last:—

Sheets of zinc or of copper of a convenient size are carefully planished and polished with powdered pumice stone. The sensitive mixture is composed of—

The whites of four fresh eggs beaten to a froth	100	parts
Pure bichromate of ammonia ...	2·50	,,
Water	50	,,

After this mixture has been carefully filtered through a paper filter, a few drops of ammonia are added. It will keep good for some time if well corked and preserved from exposure to the light. Even two months after being prepared I have found it to be still good; but too large a quantity should not be prepared at a time, as it does not improve with keeping.

I find that the dry albumen of commerce will answer as well as the fresh. In that case I employ the following formula:—

Dry albumen from eggs ...	15 to 20	parts
Water	100	,,
Ammonia bichromate ...	2·50	,,

Always add some drops of ammonia, and keep this mixture in a well-corked bottle and in a dark place.

To coat the metal plate, place it on a turning table, to which it is made fast at the centre by a pneumatic holder; to assure the perfect adhesion of this holder, it is as well to wet the circular elastic ring of the holder before applying it to the metallic surface. When this is done, the table may be made to rotate quickly without fear of detaching the plate by the rapidity of the movement. The plate is placed in a perfectly horizontal position, where no dust can settle on it; the mixture is then poured on it, and distributed by means of a triangular piece of soft paper, so as to cover equally all the parts of the plate. Care should be taken not to flow too much liquid over the plate, and when the latter is everywhere coated, the excess is poured off into a different vessel from that which contains the filtered mixture, or else into a filter resting on that vessel. The turning table should now be inverted so that the sensitive surface may be downwards, and it is made to rotate at first slowly, afterwards more rapidly, so as to make the film, which should be very thin, quite smooth and even. The whole operation should be carried out in a subdued light, as too strong a light would render insoluble the film of bichromated albumen.

When the film is equalised the plate must be detached from the turning table and placed on a cast iron or tin plate heated to not more than 40° or 50° C. A gentle heat is quite sufficient to dry the albumen quickly; a greater heat would spoil it, as it would produce coagulation. So soon as the film is dry, which will be seen by the iridescent aspect it assumes, the plate is allowed to cool to the ordinary temperature, and is then at once exposed either beneath a positive, or beneath an original drawing the lines of which have been drawn in opaque ink, so as to completely prevent the luminous rays from passing through them; the light should only penetrate through the white or transparent ground of the drawing.

I say a *positive* because I wish to obtain an engraved plate; if I wanted to have a plate for typographic printing, I should have to take a *negative*. After exposure the plate must be at once developed, which is effected by dissolving in water those parts of the bichromated gelatine which have been protected from the action of light by the dark spaces of the cliché; these parts remain soluble, while the others have been rendered completely insoluble. If the plate were dipped in clear water it would be difficult to observe the picture coming out, especially on copper. To overcome this difficulty the water must be tinged with some aniline colour; aniline red or violet, which are soluble in water, answers the purpose very well. Enough of the dye must be dissolved in the water to give it a tolerably deep colour. So soon as the plate is plunged into this liquid the albumen not acted on by light is dissolved, while the insoluble parts are coloured by absorbing the dye, so that the metal is exposed in the lines against a red or violet ground, according to the colour of the dye used.

When the drawing comes out quite perfect, and a complete copy of the original, the plate with the image on it is allowed to dry either of its own accord, or by submitting it to a gentle heat. So soon as it is dry it is etched, and this is done by means of a solution of perchloride of iron in alcohol. Both alcohol and iron perchloride will coagulate albumen; their action, therefore, on the image will not be injurious, since they will harden the remaining albumen still further. But to get the full benefit of this, the alcohol and the iron perchloride must both be free from water; it is therefore advisable to use the salt in crystals which have been thoroughly dried, and the alcohol of a strength of 95°.

The following is the formula:—

Perchloride of iron, well dried ...	50 gr.
Alcohol at 95°	100 ,,

This solution must be carefully filtered so as to get rid of any deposit which may form, and must be preserved in a well-corked bottle, when it will keep for a long time. The plate is first coated with a varnish of bitumen of Judea on the edges (if those parts are not already covered with albumen) and on the back, so that the etching liquid can only act on the lines to be engraved. It is then placed, with the side to be engraved downwards, in a porcelain basin, into which a sufficient quantity of the solution of perchloride of iron is poured, and the liquid is kept stirred so as to renew the portion which touches the plate; but care must be taken not to touch with the brush the parts where there is albumen remaining. The length of time that the etching must be continued depends on the depth required to be given to the engraving; generally a quarter of an hour will be found to be sufficient. Should it be thought desirable to extend the action over half-an-hour, the lines will be found to have been very deeply engraved. When the etching is considered to have been pushed far enough, the plate must be withdrawn from the solution, and washed in plenty of water; it must then be forcibly rubbed with a cloth so as to remove all the albumen, and after it has been polished with a little pumice, the engraving is complete.

It will be seen that this process may be used with advantage instead of that of photo-engraving with bitumen, in cases where it is not advisable to use acids. One of my friends, M. Fisch, suggests the plan—which seems to deserve a careful investigation—of combining this process with that where bitumen is employed; it would be done somewhat in the following way. The plate of metal would be first coated evenly with bitumen of Judea on the turning table, and when the bitumen is quite dry, it should be again coated with albumen in the manner as described above. In full sun-light the exposure need not exceed a minute in length; then the plate would be laid in coloured water, dried, and immersed in spirit of turpentine. The latter will dissolve the bitumen in all the parts where it has been exposed by the removal of the albumen not rendered insoluble by the action of light. But it remains to be seen whether the albumen will not be undermined in this method; therefore, before recommending the process, it ought to be thoroughly studied. The metal is now exposed in all the parts that have to be etched, while all the other parts are protected by a layer of bitumen coated with coagulated albumen. Hence we may employ as mordant water acidulated with 3, 4, or 5 per cent. of nitric acid, according as it is required to have the plate etched with greater or less vigour.

By following the directions above given, any one wishing to adopt the process cannot fail of obtaining good results. One of its greatest advantages is that it is within the reach of every one engaged in printing operations.

THE RIVES PAPER MANUFACTORY.

Five hundred and sixteen kilometres southeast from Paris, between the great silken city of Lyons and the old walled town of Grenoblo, in the department of Iseie, is located a little market town of about 2,300 inhabitants, which is of more importance to the art of photography than perhaps any other one place in Europe. I allude to the town of Rives, where is located the manufactory of the plain paper so well known to every photographer in the world, I might safely say, and bearing the name of the place I have named.

As one nears Rives by rail the peaks of tho Colline de Parmenie loom up in the distance, and presently we run along the crest of a hill which, with the mountain, forms a deep cut or ravine, in which is located the object of our visit—the manufactory of Rives paper. It is a beautiful spot, and although seemingly at our feet as we approach the station, we must drive nearly two miles to reach it. So, landing at the station, a quaint, rattletrap of a carriage is offered us by tho sturdy driver, the circumference of whose hat is equivalent to that of his stomach and appendages; and we take it for the drive. We pass through the main street of the village, and wish at every turn for our '76 camera, so plenteously did the picturesque bits present themselves.

Arriving at the office of the manufacturers, the presentation of our card at once secured us the best of attention and every courtesy the heart could desire. After our special business had been transacted, we wero shown about the premises, and the entire process of manufacture explained to us by M. Klebe, a member of the wealthy firm who conduct the immense business hore. It seems that these gentlemen also manufacture writing and blank-book paper very extensively, but for this they have an entirely separate establishment, perhaps a quarter of a mile away from the other. We were shown through this, but no description of it need be given here, so we will proceed at once to the mills, which interest us the most. As wo walked along, the great sluices which conveyed the water to the mills were seen for at least half a mile. These were all covered in, to prevent contamination by thoughtless or mischievous hands. The water is brought from a mountain lake called La Fure du lac Solodin by means of the Riviere du Beaumont, and is received at the mills in ponds or tanks. These latter are first given a hard, artificial bottom of washed gravel, which in turn is covered by layers of pebbles, which are most carefully washed before they are allowed to be placed in the tank, and before the water enters the tanks it is carefully filtered, so that it is very clear and clean, and the pebbled bottoms of the tanks may be clearly seen. But this is not the only means taken to secure the purest possible water for the manufacture of the paper. As it enters the mills it is received into separating pipes, which pour their crystal contents forth into troughs lined with thick woollen or flannel cloth, thus securing a second and most careful filtration. After this the water runs into small stone tanks lined with cement, from which it is drawn as needed for the manufacture of pulp. Now we pass on and behold the various processes followed for the manufacture of the paper, which in nearly all their details are similar to those adopted in the manufacture of the best writing paper.

Great tiers of bins were shown where tons of clean rags were stored for future use. Then came the grinding mills, the bleaching process, the washing of the pulp in circular tanks, where it was kept in motion by a system of spiral wheels of great diameter, provided with automatic blankets similar to those of an Egyptian irrigating machine. Around and around these travelled, catching up the pulp and emptying it out again in a different place, never tiring or stopping until the desired end was accomplished. Thus, too, the "size" was intermixed with the pulp, and finally it entered the tank at the end of the giant machine with its hot cylinders and jiggling cranks and sieves, which were to assist in forming the hard sheets of proper thickness, as ordinary paper is produced. The paper comes from the machine in what are called "endless rolls," and is received upon a cylinder provided for the purpose. Just before it is thus received other cylinders drop automatically down upon it for a moment. At proper distances apart, upon these, the brand of the factory is engraved, and by gentle pressure, as the roll revolves, imprints the trade-mark upon what will, when cut to size, be the margin of each sheet. After the receiving rolls are full they present to the cutting machine, where the paper is rolled off, cut to size, sent to the inspecting-room, and after inspection to be calendered. In the inspecting-room are long counters or tables, with many windows opposite. At each window sits a woman with a pile of sheets before her, and she is required to carefully inspect each one, throwing out any that are perforated or spotted. Her eyes must be those of an eagle, for her work is done rapidly. She seems to cover the whole surface of a sheet at one time, and must use a wide-angle Morrison lens in her eye and expose the sheets by means of the J. C. B. plates, aud certainly her "drop" of each sheet is "instantaneous."

After the sheets are inspected they are carried to the calendering machine. This is the most magnificent machine of the kind I have ever seen. The rolls are about 9 inches in diameter, and, I should think, about 48 inches long—long enough for two sheets of paper to pass side by side at one time. There are three double tiers of these rolls. Each tier is attended by two women, who feed and receive the sheets. Three times each sheet must submit to the very affectionate squeezo of these calenders before it is considered sufficiently glossy and hard for the rough treatment to which it must be subjected by the photographer. If it bears all this well, it is allowed the honor of a place in some honestly counted ream, and wrapped up with its 479 confrères and sent with sealed orders to one part of the world or another. America is certainly the largest market for this kind of paper, 3,600 reams going to New York during the past year—in a little less than a year, I was informed.

From the rag to the finished sheet there are nine operations, and ten days aro required to produce a sheet of paper. About 500 people are employed at Rives, and the large proportion are women. They all wear the huge wooden shoes so much used in France aud Belgium, aud the clatter of them upon the stone floor and pavements is something noisy. I saw a pair of these shoes hung up to-day, which were almost large enough for one of the receiving water tanks. All through the several departments the most conscientious care was apparent, lest something should occur to cause impurity or failure. Ten years ago we all remember that Rives paper was not only pestiferous on account of tiny metallic specks all through it, but it was so tender that one could scarcely bring it through the necessary manipulations without tearing it. All such annoyances have disappeared, and to-day papier Rives is the leading paper of the world, because it is the very best, and because the skilful manufacturers have persisted until they have produced a perfect article. My visit was very interesting to me, and well repaid me for the thirty hours it cost. A drive with Mons. Klebe ended the happiness of the visit, and then a whirl down to Brindisi, Italy, whence I took the steamer for the Orient.—Edward L. Wilson in the *Photographic Times.*

MICROSCOPIC PHOTOGRAPHY APPLIED TO CHEMISTRY.*

Although the microscope renders the greatest services to the natural sciences, the use of the instrument proves of no less value in the physical sciences, especially that of chemistry. The microscopic examination of certain substances permits in a manner of making an analysis of them with a rapidity and certainty that would not be afforded by methods based upon the use of reagents, especially as regards organic matters. If, for example, the chemist has to satisfy himself of the purity of a specimen of commercial starch, he throws a small pinch of the substance that he desires to examine into a little distilled water,

* From *La Nature.*

stirs it with a glass rod, and then transfers, on the point of the latter, a drop of the solution to a glass slide, which he submits to a microscopic examination. He can thus obtain a general view of the starch grains, which all have a characteristic ovoid form. If the adulterator has mixed with the substance a certain amount of powdered gypsum, for instance, the latter will betray its presence at once under the form of angular grains having a crystalline aspect.

Coffee, chocolate, milk, pepper, &c., thus examined under the microscope, are immediately analysed by an observer accustomed to study in this manner the different kinds of these substances, as well as the products which are most commonly used for adulterating them. It is the microscope that permits of detecting trichinæ in pork, and it is this instrument also that frequently serves for determining the nature of a salt that is observed to crystallize in a drop of water placed on a slide under the objective.

A microscopic inspection made directly as we have just indicated, however, presents the inconvenience that it leaves no durable trace of the observations. The importance of a photograph of the enlarged image of an object submitted to examination will be therefore at once understood. If a chemist has observed trichinæ in pork meat, he will thus not only be able to assert that the observation was made by the microscope, but it will be possible for him to show photographic proofs of the negative that he has obtained directly; and thus, by fixing them permanently, to multiply the material proofs of his analysis.

We recently visited the Municipal Laboratory of Chemistry, where, thanks to the politeness of Mr. Charles Girard, the director, and of Mr. Pabst, we had occasion to see in operation several micro-photographic apparatus, which are, we believe, the completest of the kind known in the way of this sort of arrangement. The system is a new one, and may be employed for microscopic studies of all kinds; so it seems to us that it will prove of interest to make it known.

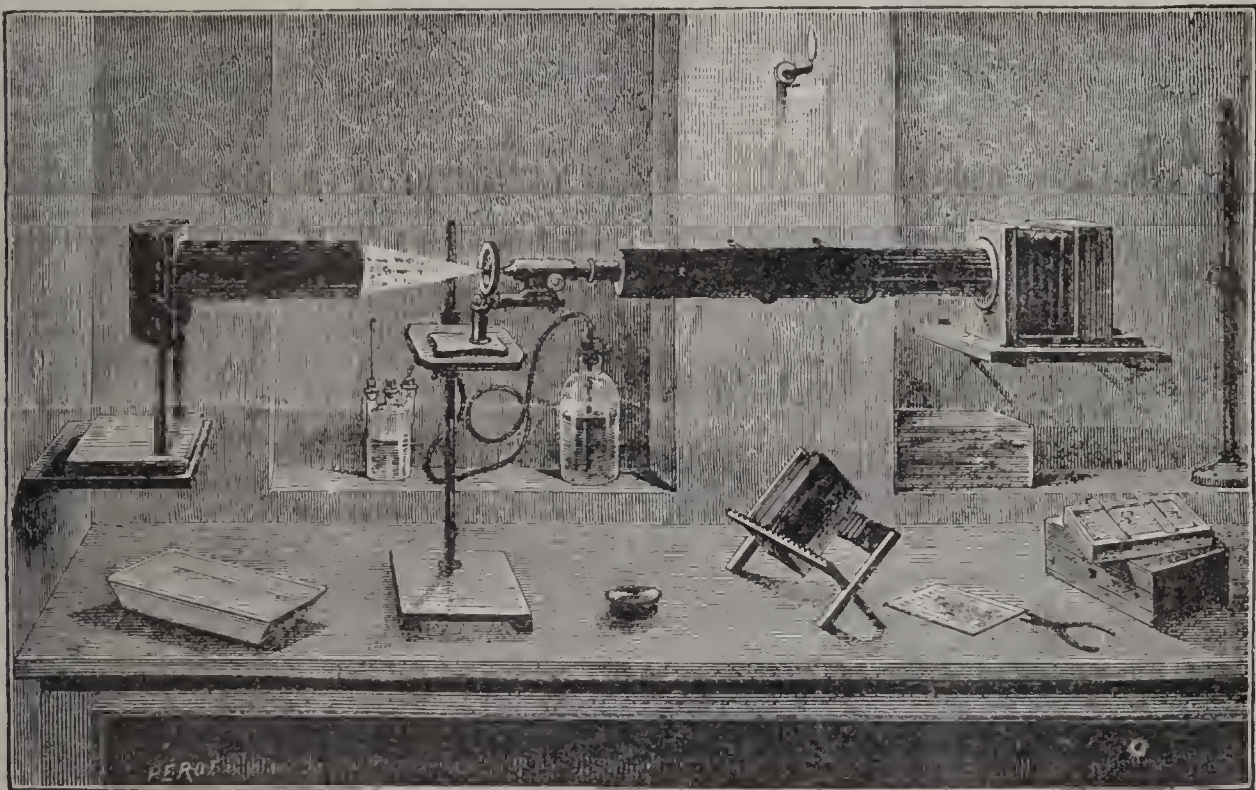
The simplest system of micro-photography consists in applying a small dark chamber directly to the eye-piece of a microscope standing vertically as during direct observation, the illumination being obtained by means of a ray of light, from an oxyhydrogen or an electric light, projected on the mirror.

The virtual image is first transformed into a real image by displacing the eye-piece. In the microscope, the image furnished by the objective forms in the interior of the eye-piece, in front of the lens, between it and its focus. If the eye-piece be drawn out so that the image formed by the objective is between the focus of the ocular lens and its centre of curvature, the image then forms on the other side of the lens and becomes real, and it may be received on a piece of ground glass. The dark chamber is then adjusted and the focussing properly done.

Another method, due to Mr. Vogel, of Berlin, consists in seeking the virtual image situated in the microscope by means of a dark chamber and an objective of short focus. We know that the image forms virtually in front of the eye-piece, at about 0·12 m. or 0·18 m., according to the magnification of the ocular lens. The photographic objective is almost in contact with the eye-piece of the microscope.

These two methods are applicable to any ordinary microscope, placed in any room whatever—work-room or laboratory.

The third system which we are about to describe, and which is represented in the annexed figure, necessitates a special organization in a dark chamber made for its operation. It permits of taking the photograph of an object in several planes, and is especially applicable for obtaining photographs of histological sections, trichinæ crystals, &c.



MICRO-PHOTOGRAPHIC APPARATUS AT THE MUNICIPAL LABORATORY OF CHEMISTRY, PARIS.

The microscope, which is placed horizontally, is represented in the centre of the engraving. To the right is the photographic dark chamber, whose objective is connected with that of the microscope by a long tube. To the left is affixed to a shelf the oxyhydrogen or electric light. The oxyhydrogen light will answer for obtaining negatives with magnifications of 300 diameters; but, beyond this, up to 800 diameters, the electric light is employed.

The apparatus under consideration is based on the principle that the pencils of light, with a great distance of conjugate focus, become almost parallel, and that the points situated in the planes contiguous to the focal plane are reproduced by points scarcely larger than those of the focal plane. The apparatus is installed in a dark room which is provided with all the accessories necessary for photographic operations, such as tanks, water-faucets for washing, &c.; and the operators who make use of it obtain excellent results by the new gelatino-bromide of silver processes.

In the Laboratory of Chemistry we have looked over a remarkable photograph album, in which were to be seen very good proofs of micro-photographs of chocolate, coffee, pepper, milk trichinæ, &c., for the analysis of which it is of interest to employ the microscope. It would be interesting to publish such photographs so that they might serve as types for the very numerous amateurs who, owning a microscope, would like to ascertain the purity of the food products that they are using. They would thus have before their eyes the exact *portrait* of the different substances free from any adulteration, and would be in a position to assure themselves (by means of easily made comparison) of the quality of the food products consumed in their house.

SCIENTIFIC RESULTS OF THE ECLIPSE.

Before the Eclipse Expedition left England, Dr. Siemens had proposed a theory of the solar atmosphere which postulated exactly such conditions as appeared to be revealed in years of least solar activity. The coincidence between hypothesis and fact was, to say the least, extremely curious, and there is no doubt that the fact that when the sun is most active the correspondence seems to vanish will have to be carefully considered. But we have learnt more touching the outer atmosphere than its changes. There has been a chemical touch added. When in 1869 its chemical nature was first investigated by means of the spectroscope, it seemed to be built up almost entirely of a substance of which we knew nothing here—a substance revealed by a line in the green part of the spectrum, at 1474 of the scale employed by Kirchhoff for his maps, which were then generally in use. In 1870 hydrogen was added to this unknown substance, if we are to interpret spectroscopic phenomena in the usual manner; and now again, with the same proviso, calcium has been added—that is to say, some lines seen in the spectrum of calcium have now been detected in the spectrum of the sun's outer atmosphere. It is now some years since the strange behaviour of calcium, when observed in the spectroscope, was noticed, and it was the first substance used to point the moral that the spectra of terrestrial substances are sometimes strangely transformed when their lines are examined among those visible in the ordinary spectrum of the sun. Thus the widest lines of all in that spectrum—the lines lettered H and K for purposes of reference—are seen in the spectrum of calcium when high temperatures are employed, though they are absent at low temperatures, when, however, a line in the blue, which is but feebly represented among the solar lines, is thick and brilliant. The observations of the eclipse in Siam in 1875 strongly suggested that the so-called calcium was really an important constituent of the lower layers, while it is now known that it plays an important part in every spot and prominence; indeed, in the spectra of sun-spots photographed by Mr. Lockyer, at South Kensington, the H and K lines behave differently from all the other lines photographed. But the point of this year's work is that this calcium has been carried very high into the solar atmosphere, where it exists in such tremendous quantity that the eclipse colouring in all its weirdness can be traced to it; and the proof that this violet light is lighting up our atmosphere more powerfully than any other is found in the fact that, in one of the photographs taken on Abney's plates, the air between us and the dark moon is shown to be of this colour. This is photographic proof certain and sure, and will remind those learned in these matters of an observation made by Captain Maclear during the eclipse of 1870. It will be seen, then, that this year's work has left its mark, both on the physics and chemistry of the outer atmosphere. We must now descend a little into the lower regions of the solar incandescent air.

Here we approach a very interesting part of the subject, but one on which it is difficult to say anything without going somewhat into detail. Up till a few years ago the idea that our terrestrial elements, such as iron, hydrogen, and the like, were anything but elements, never entered the heads of astronomers as they were daily recording solar phenomena. It was obvious that the sun was very hot—so hot that it may be said that the vapour of iron plays the same part there as the vapour of water plays here; but the possible result of the high temperature remained practically unconsidered, and our notions of the structure of the solar atmosphere were influenced by terrestrial chemistry. Hence, when it was found that the upper atmosphere consisted mainly of hydrogen, all the lines of the solar spectrum except those due to hydrogen were supposed to owe their origin to absorption of the solar light at very low levels, and close to the sun there was supposed to be a thin stratum, the work of which was so efficient in this direction that it was called the "reversing layer." But after a time, as facts were accumulated, the question whether our elements really could and did stand the temperature of the sun without breaking up into something more elementary still was fairly asked; and, as in other cases, the question had to be discussed in a scientific manner—that is, cases had to be taken in which the question could be put to the facts in such a way that, if the observations were of one kind, one view would be strengthened; if of another kind, then the other explanation would be more likely the correct one. It was pointed out some time ago that there are two very definite kinds of observations which can be made during eclipses, by which much information might be gained bearing directly upon this question of dissociation—that is to say, the question whether our "elements," as we know them, are or are not capable of existing at solar temperatures. These observations had to do, one with the "reversing layer," the other with the outer atmosphere. The challenge was of the most direct kind touching the reversing layer. It went so far as to say that the former observations had been erroneously interpreted. This, however, must not be held to cast doubt upon former observers. The contention was that the former work, dating from 1870, had been of too general a nature, and that when a small part of the field of observation was studied with minute accuracy it would be found that the general statement would be untenable, that general statement favouring the view that the elements are still truly elementary at solar temperatures. It will be seen that the issue raised then could not be complained of as lacking crispness and definiteness. What then are the facts? The facts have been exactly as they were predicted on the rival hypothesis—the hypothesis, namely, that the elements are not elementary; and in future we are not likely to hear much more of the "reversing layer." The solar spectrum, indeed, appears now to be the result of the absorptive work of an innumerable number of strata, one over the other, from top to bottom of the solar atmosphere. If we could see the work of any one of these layers by itself, it would be impossible for us, with our mere terrestrial laboratory experience, to recognise it; whereas, we do recognise the sum total, because we get, and can only get as a rule, a sum total in our laboratory experiments. Should this result be generally accepted as one of the results of this year's work a great step will have been gained. Whether accepted or not, it is quite clear that such observations as those to which attention has been directed will demand much attention when next the sun is eclipsed. Nor is this all. It is not too much to hope now that M. Thollon has so admirably succeeded in furnishing astronomers with a spectroscope which combines the maximum of dispersion and light that observations suggested by the new view may be made on the uneclipsed sun, and bring their tribute of precious facts every day the sun shines. Such work, indeed, was actually started at Sohag, and the test then afforded gave out no uncertain sound; but on this point it is not necessary to enlarge upon the present occasion, as both MM. Thollon and Trépied are pledged to use the beautiful climates of Nice and Algiers in carrying on this new survey at the earliest possible moment, and the world of science will doubtless soon hear something of the result of this new attack.

There is little doubt that, on the occasion of future eclipses, attention will be much more concentrated on the spectrum of the corona, and more specially-constructed instruments will be brought to bear on it than has been the case hitherto. We may already take for granted that the blue lines photographically recorded—in addition to H and K in the violet—will have their position determined with the greatest accuracy, and their coincidence or not with marked Fraunhofer lines will have an importance bearing upon the questions to which attention has been directed in the present letter. The work, too, has shown that the new plates are so sensitive, that it will be quite easy at the next eclipse, by means of a circular rotating plate, or some such contrivance, to record all spectroscopic phenomena, however evanescent they may be at the moment of disappearance or reappearance of the sun. Such a method will not only give us a complete history of what goes on, but will furnish us with a scale of exact reference. So science advances. Each effort, and especially the one most wisely planned, instead of exhausting the supply of new phenomena, brings still newer efforts and richer harvests in its train.—*Daily News.*

Correspondence.

A MONUMENT TO POITEVIN.

Sir,—The enclosed circular will acquaint you with the fact that a subscription has been organized by the French Photographic Society, and the Chambre Syndicale of Photo graphy in Paris, for the purpose of erecting a monument to the memory of Poitevin.

We hope that you will be good enough to co-operate, to the best of your power, as a corresponding member of the committee in England, with the work we have undertaken, and of which you, more than others, can appreciate the favourable opportunity. The committee forward you a printed form upon which to enter subscriptions, and will be glad if you will bring it to the notice of those who have taken an interest in Poitevin's admirable work.

We thank you in advance for the kindly help which we are sure you will not fail to render us.—Veuillez, Monsieur, &c.,

Davanne, President of the Executive Committee of the French Photographic Society.
Levy, J., President of the Chambre Syndicale.
Londe, Albert.
Vidal, Leon.
Audruin.
Berthaud, Michel.
Guillemot.
Stebbing.
Thouroude.
De Villechole.

MR. PLENER'S SENSITOMETRICAL INVESTIGATIONS.

Sir,—I beg to correct an error which has crept into my paper of May 26. I applied the conclusions deduced from the equation expressing the relation between the sensitiveness and the number of gradations in a sensitometer having equal differences between the transmitted light by two contiguous shades, to the sensitometer whose shades stand in constant relation λ. Nevertheless, it does not affect in the least the final conclusion I arrived at. With your permission I will shortly return to the subject.—Yours very truly, J. Plener.

Proceedings of Societies.

Thursday Evenings for Photographers.

At the meeting held on the 15th inst., the chair was occupied by Mr. J. Traill Taylor.

Mr. Cowan exhibited a negative that was intensified on the 4th of August last by Dr. Monckhoven's formula, and had been left for days exposed to the sun under a mask; there was no apparent change in the character or tone of the negative. Some of the gentlemen present had not found the result by this formula so permanent as it appeared to be in Mr. Cowan's hands.

Mr. Goodwin exhibited a dark-slide for the studio, the carrier being constructed to carry two plates side by side. This he considered a great improvement upon the old plan of taking two pictures on one plate, as it allowed them to be developed separately.

Mr. Henderson—on behalf of Mr. Atkinson, of Liverpool—passed round a "Kirkby" shutter for inspection. It was very quick working by means of a spiral spring, and opening from and closing to the centre of the aperture.

Mr. Debenham then exhibited the results of some experiments with auxiliary exposures on gelatine plates, suggested by the recently published experiences of Mr. W. K. Burton. He showed a plate that had been exposed under his multiple sensitometer, which consisted of several sensitometers arranged together for giving simultaneous exposures; the plate had on the portion covered by one sensitometer been pre-exposed to a given light for five seconds, on another portion for ten seconds, and so on; one portion was not pre-exposed at all. It was seen that the pre-exposure had made the sensitometer register higher numbers to the extent of representing a sensitiveness of twelve or more times greater rapidity. Camera exposures on a sitter did not show a greater gain than about half of the exposure, and this with some loss of quality in cases where plates had received any appreciable light during preparation; the indications of the sensitometer could not therefore be trusted as a guide for camera exposure, that is if the highest readable number were taken as the guide; but as in these pre-exposed plates several high numbers on the sensitometer came up very weak and nearly alike, it would be safer when this was observed to take the point at which the squares begin to noticeably increase in density.

Mr. W. K. Burton said that he was glad to find his conclusions verified by Mr. Debenham's results. He certainly was against the use of auxiliary exposure, and thought that the high apparent sensitiveness it conferred had misled many experimenters who thought that they had succeeded in preparing emulsions of extraordinary rapidity, whereas they had really been insufficiently guarded from light.

The Chairman, in the course of a few remarks on lenses, said that Professor Steinheil had sent him a print from a negative taken from an elevated position of a body of men marching with flags waving; the details being very sharp, and showing the extreme rapidity of the lens, which was constructed on a new principle not hitherto applied. He further stated that there was only one of these lenses at present in London, but that he hoped shortly to be able to examine it, and would then give further particulars.

Mr. Henderson found that in wet plate photography there was a gain in speed by using an auxiliary exposure only when the chemicals and bath work slow and hard, but that when the bath is in its best state there is no appreciable gain.

Mr. Mackie showed a negative that had been left without being washed after removal from the hyposulphite, and which in a few days had completely disappeared.

Mr. Henderson showed a bitumen picture taken about sixteen years ago, by the following process; *i.e.*, rub Brunswick black and bichromate of potash well together in a mortar, coat on mica, expose through the mica, and develop with turpentine; the picture had not apparently faded.

Mr. Collins said that some years ago a patent was taken out for producing pictures with Brunswick black alone, using turpentine to develop.

Mr. Brown passed round a piece of ready sensitized paper, preserved since January 1881 by being kept rolled tight and enclosed in a tin tube.

Edinburgh Photographic Society.

The eighth ordinary meeting of this Society was held in 5, St. Andrew Square, on Wednesday evening, 7th inst., Mr. John Lessels, president, in the chair.

The minutes of the previous meeting having been approved, the following gentlemen were duly elected ordinary members:—Messrs. J. H. Edwards, John Middlemas, John Donald, James H. Hamilton, Thomas Hobday, Henry Woore, and Alexander Ballantyne, M.D. Dr. Siemens was unanimously elected an honorary member of the Society.

Thursday, 6th July, was fixed for the annual picnic, the place selected being Dirlton.

A paper by Mr. Wm. Dougall was read by Mr. Henderson, "On Photography as a Hand-maid to Medical, Surgical, and Other Sciences, and as a Pleasant Recreation for a Cultivated Mind" (see page 359).

After a short discussion, in which Mr. Bremner said that photography performed an important part in the educational work of the Edinburgh Royal Infirmary, a paper was read by Mr. John M'Kean, entitled, "The Modern Photographer, His Power and Appliances" (see page 357), illustrated by practical demonstrations.

Dr. Hunter exhibited an immense number of calotype photographs taken in Burmah thirty years ago. They exhibited the marvellous details of the architectural remains in a most graphic manner.

One hundred carbon prints from negatives by the late Dr. Dougall, and presented by Mr. Wm. Dougall, were distributed by ballot to the members present.

Hearty votes of thanks to Mr. Dougall, Mr. M'Kean, Dr. Hunter, and the Chairman, terminated the proceedings.

Talk in the Studio.

Photographic Society of Great Britain.—The next Technical meeting of this Society will take place on Tuesday next, June 27th, at the Gallery, 5a, Pall Mall East, at 8 p.m.

The Royal Observatory, Greenwich.—We are glad to hear that the Astronomer-Royal has resolved to adopt the Morgan Argentic-gelatino-bromide paper in the Observatory, for recording observations of magnet, thermometer, and electrometer. It is certainly a wise step of Mr. Christie.

Balloon Photographs.—At the meeting of the Balloon Society, held at the Lecture Room, Royal Aquarium, on Friday last, Mr. Shadbolt, of Chislehurst, exhibited a photograph taken from a balloon during an ascent on Whit Monday from the Alexandra Palace. The photograph bore a very favourable comparison with the one previously exhibited by the President of the Balloon Society, of the river Seine, near Roueu. The photographs showed the district near Stamford Hill, taken from an altitude of about 2,000 feet. The exposure was made with an ordinary flap shutter, and the lens used was a Ross 8 by 5 rapid symmetrical.

The University Observatory, Oxford.—The Savilian Professor of Astronomy, Director of the University Observatory, has issued his annual report, which was preseuted to the Board of Visitors on the 1st inst. It is mentioned that a somewhat elaborate memoir is now printed in the *Transactions* of the Royal Astronomical Society on the applicatiou of photography to delicate celestial measurement. The inquiry into the relative motions of some forty stars in the Pleiades has been brought to a successful conclusion, the results agreeing generally with those recently deduced by M. Wolf, of the Observatory at Paris, who employed a very different instrumeut and method. A complete survey of the relative brightness or magnitudes of all the stars in the northern hemisphere reputed to be visible to the naked eye has been commeuced, aud it is hoped that before the date of the next report, all the stars brighter than the fifth magnitude, some five huudred in number, will have been measured. The report touches also upon the discordauces between the observed degree of brightness of Comet 1882 *a*, with the results deduced from theory. The expenditure for the purposes of the Observatory has, it is stated, been under the amount provided by Convocation; a sum of £600 per annum is available for three years from December last, and this the Savilian Professor considers will probably suffice for the future efficieut maintenauce of the Observatory, the only difficulty that might arise relatiug to uecessary repairs, &c., of the preseut instruments, or the addition of new oues that may be needed.—*Nature.*

A Phosphorescent Mineral.—At a meeting of the Sau Francisco Microscopic Society, H. G. Hanks, State Mineralogist, read the followiug interesting paper: "Some time since D. B. Huntley, of the Geological Corps of the Tenth Census of the United States, brought to the State Mining Bureau a mineral, with the statement that it had shown certaiu peculiarities which led the miuers to call it by the rather startling name of 'Hell Fire Rock.' The property known to mineralogists as phosphorescence is uot confined to one mineral species, nor is it very uncommou. But in this specimen it is so strongly marked that there is some excuse for the refusal on the part of some of the miners to work in the mine. When striking their picks iuto this formation, flashes of light were seeu, which they regarded with superstitious alarm. The locality in detail is the Shenandoah Mine, Snake Creek District, Wasatch Co., U. T. A chemical examination shows this mineral to be au impure dolomite. It is interesting not only from its remarkable phosphorescence when rubbed with any hard substance in the dark, but from its beautiful crystalline appearance uuder the microscope, and the ease with which it can be reduced to a crystalline powder, even by crushiug it between the fingers. In Cleveland's Mineralogy we fiud it stated that some varieties of dolomite are phosphorescent in the dark, either by friction or when thrown on a shovel which had been allowed to cool just before the point of redness. The lights being turned down, Mr. Hanks produced the phosphoresenee beautifully by scratching the specimen with a knife-blade. It was of bright reddish yellow or orange colour; and it was clearly seeu how a miner could be agitated by striking such infernal material in his subterranean walks.—*Detroit Free Press.*

The Telelogue.—The name of the wiuner of the Grand Prix de Paris was made kuown to a number of persons assembled in the Tuileries Gardens, within four minutes of the runniug of the race at Longchamps, by means of the telelogue, a new invention of Captain Gaumet. This is not unlike the old-fashioned system of couveying intelligence by means of semaphores, specimens of which still exist in different parts of this country. The name of the winner was spelt out in large silver letters upon squares of black taffetas placed in an apparatus above the persidential tribune. The word thus spelt was read by the aid of powerful field glasses by persons stationed at the Trocadéro, and was transmitted by them in the same manner to the centre of Paris. We described the telelogue some months ago in "Notes."

The Alexandra Park Photographs.—The *Referee* says:—"The Whit Monday photographs were very successful—too successful in the opinion of certain married gentlemen, who weut to Muswell Hill to visit a sick friend, after the manner of Mr. Tubbs in 'Pink Dominos,' and who were spotted in the groups by their too curious wives. Instantaneous photography is all very well, but if it is to bring about trouble in this way the sooner it is put down by Act of Parliament the better."

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, *"Photographic News" Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed "Union Bank, Photographic News Co. Account."*

*** We cannot undertake to return rejected communications.

*** By a mistake on the part of our engraver an error was made in one of the sketches illustrating our article on lenses in last week's issue. An air space was shown between the two glasses forming the front combination of the globe lens. These should have been shown as cemented together.

Mr. Spink's Shutter.—Mr. Spink writes as follows in answer to the letter inserted in the News on this matter:—"Mr. Volk does not assert that he would have made that or any other shutter had I not called on him and described what I required; his letter concedes all I claim, viz., the opening and closing from and to the centre behind the lens, and the fans moving parallel to the front of the camera. Of the utility of these points photographers will be the best judges. The mechanical arrangement for opening aud closing are means to an end, and could have been devised in various ways; as it now stands it has undergone certain modifications since leaving the hands of Mr. Volk, and it is capable of further improvement. As to the last part of the letter, it is unusual for those engaged in trade to execute work entrusted to them 'without fee or reward,' and it was not so in this case; payment was tendered to Mr. Volk, and declined by him—and with good reason."

A. A.—The sulpho-pyrogallol sold by the Platinotype Company.

Captain Turton.—It is quite right as it stands.

Gelatinous.—Captain Abney's new book on "Emulsions in Photography" is most suitable for your purposes; our publishers will send it iu return for 3s. 3d. in stamps.

W. E. D. Jones.—Thank you for the little print; it is certainly expressive of "joy." Your experience of "sulphite of soda" in development is one more in its favour; Mr. Berkeley's sulpho-pyrogallol (Plantinotyye Co.) we have also used with considerable success.

P. H. Davies.—See Mr. Wilkinson's article on page 298 of the present volume.

Alpha.—1. It is difficult to account for your objections to use a reflector; but if you can overcome your prejudice so far as to employ a large folding towel-horse covered with white paper, your difficulties will disappear. 2. Your suggestion may be of some value, and shall be considered.

A. S. S.—1. Yes, but it is better to use it fresh, and not make the addition. About one-sixth of its weight. 2. Do not attempt to make a saturated solution, as the commercial preparation is extremely variable; and, moreover, the solution rapidly undergoes change.

A Bisset Thom.—Thank you for the suggestion.

W. Weston.—You should obtain Abney's "Instruction," and Eder's "Dry Plates," both of which are published at our office.

H. Spink.—It is probablo that the addition in question would somewhat retard the action of the developer, but we would advise you to make the experiment.

J. Lucas.—1. Use about four times as much as you would have employed in the case of ammonia. 2. Rather longer. 3. Yes.

J. W.—1. Individual taste steps so much into the case as to render any advice on our part of little value, and the mere following in the footsteps of others will certainly not lead to any results of considerable value. 2. No such book exists. 3. In almost every case there is some such point.

J. P. S.—The glass plates should be uniformly ground on one face, the fine emery, known as "flour emery," being used. 2. A very convenient method is to make up a moderately strong solution, say 30 grains to the ounce, and add it as required. 3. Another name for sulphuric acid. 4. Not just at present.

J. Upholme.—1. It is one of the most useful methods at present known; but unless you intend to thoroughly enter into the matter, and are prepared for many failures during the early stages of your work, you had better not make a change.

Vol. XXVI. No. 1243.—*June* 30, 1882.

CONTENTS.

TRANSFERRING THE COLLOTYPIC IMAGE TO WOOD, AS A GUIDE FOR ENGRAVER.

The fatty image obtained by the collotypic method, or other similar proceeding, has long been recognized as fulfilling in the most satisfactory manner the requirements of the wood engraver. When the fatty image is transferred to artists' canvas, a basis for painting on is obtained which is far preferable to a silver image or any picture of a film-like nature, as, for example, a carbon print. We have already given directions for the preparation of fatty pictures on paper which are suited for direct transference to the wood; but when work of the highest class is desired, it is better to prepare a collotypic plate, and, after a few prints have been obtained, to transfer the most suitable of these to the wood or the canvas.

Gemoser, of Munich, has recently given directions for carrying out this kind of work, and those of our readers who have occasion either to make photographic pictures on engravers' blocks or on artists' canvas will do well to give the method a trial.

As regards the preparation of the collotypic plate, our readers will find full particulars in the News, the Year-Books, and the "Studios of Europe": or the simple directions for Major Waterhouse's photo-collotype process, as detailed in Abney's "Instruction in Photography," may be followed with success by any careful manipulator.

The wood block is first prepared with a mixture of fresh white of egg and fine zinc oxide, this pigment being sold in London under the name of "satin white." These materials are rubbed together so as to form a uniform cream, a very small proportion of mucilage of gum-arabic is added, and the preparation is well rubbed over the surface of the block, either with the finger or a small cork rubber; the most convenient way being to describe a series of small circles over the face of the block with rubbing the mixture. When the surface of the block is well saturated with the albuminous preparation, a long-haired camel's hair brush, or a badger softener, is used to give uniformity to the layer of pigment; and the thinner and more uniform the coating, so much the better will the ultimate result be.

The collotype plate is inked up with the ordinary lithographic colour, and the impression is taken on a sheet of the usual coated india transfer paper, as sold at the lithographic material stores; but the transfer paper should have been previously damped by being allowed to remain for about ten minutes between slightly moist sheets of blotting-paper. The impression having been now obtained, should be laid between sheets of damp blotting-paper, care being taken that these lie quite smoothly and without folds; and in ordinary cases, it is well to allow at least half-an-hour in order that the coating of the transfer paper, which consists mainly of flour paste, may become thoroughly softened.

The well-dried wood-block is now rubbed on the face with a tuft of cotton-wool, and the damp transfer is placed, face downwards, in position; after which the whole is passed two or three times through the press. Should the paper adhere so tightly as to make it difficult to strip it off the block, the back should be slightly damped with a sponge.

When the image is to be transferred to canvas as sold ready prepared for the use of artists, the process is simpler, as the canvas requires no further treatment, and the fatty image adheres even more readily to the painted canvas than to the wood block coated with a mixture of zinc oxide and albumen as described.

It is quite easy, by following out a similar method, to transfer collotypic pictures to finely-ground plain or opal glass, unprepared wood, marble, celluloid, or other similar surfaces, and very pleasing effects may be attained by mounting such pictures as panels in various articles of furniture.

By-the-Bye.

ON PHOTOGRAPHIC SOCIETIES.

Whatever may be said on the subject of photographic societies, it is certain that the progress of our art science is not delayed for the want of them. Indeed, the number of bodies that take photography under their wing is without parallel in any other calling. At the present moment, no doubt, there is unusual activity displayed, as has been the case for two years past, by reason of the revolution, as it has been termed, consequent upon the general adoption of gelatine plates; but apart from this, the disposition of photographers to meet together and to aid one another has always been most marked. Some societies have come and gone and again made their appearance, while there is hardly an instance of a body disappearing entirely, unless to strengthen some other more important association. If the North London Society, to take an instance, has vanished, those of its members who are still alive and well, and continue to practise the art, are yet found supporting other bodies with unabated vigour; while it is not so long ago that the appeal was made in these columns to resuscitate the old institution once more.

In the metropolis at the present moment there is no lack of opportunity for the exchange of ideas among photographers. Not only is the Parent Society, or Photographic Society of Great Britain, as it has been called of recent years, still in the full vigour of life and health, but it has of late added something to its importance by the holding of supplementary gatherings, termed Technical Meetings, where the conversation has been more general, and the reading of formal papers dispensed with; so that during the season there is a fortnightly meeting here, at which members and their friends are welcome either to take part in discussion, or listen to the experiences brought forward. The South London Photographic Society—South London only in name, as most of our readers know—is again another energetic body, holding its meetings once a month, where the technical aspects of photography are usually more in favour than the theoretical, and, as a consequence, highly esteemed by practical photographers. Next, there is the Photographic Club, where, once a week, both theoretical and technical questions are vigorously discussed, and where, as in the South London Society, demonstrations and lantern displays are not infrequent; and finally there are the so-called "Thursday Evenings" at Ashley's Hotel, partaking also of the nature of discussions and demonstrations.

The above do not even exhaust the associations in London for fostering the progress of photography. There is the Amateur Photographic Association, over which His Royal Highness the Prince of Wales presides, in which photography as an art is more especially considered, while pure science in photography, as a matter of course, receives attention both by the Chemical and Physical Societies, and by the Royal Society. In our large cities throughout the kingdom photographic associations are found on every hand. That of Edinburgh boasts, we believe, the largest number of members, not only of any society in Great Britain, but in the whole world. Glasgow owns a busy society, and there is one still further north at Dundee, of whose energy we have recently had good proof. The steady work of the Manchester Photographic Society is continually before us in the shape of valuable papers, and the same may be said of the Liverpool Society, which has of late distinguished itself by several important contributions to photographic science. The Bristol Society takes high rank, if it were only by reason of the magnificent exhibition brought together under its auspices in the West of England some months ago; while of the other associations in Sheffield, in Newcastle, in Bolton, in Cheltenham, in Yorkshire, and in Oldham, signs of vigorous activity are decidedly apparent. Cambridge University has of late started a Society that bids fair to do good work. The Photographic Society of Ireland, which has been re-established—for there existed already in 1854 a society in Ireland—has lost no time in making amends for its suspended animation, and under the presidency of Dr. Emerson Reynolds has become one of the prominent societies of the kingdom.

Thus there are at this moment a full score of societies or associations occupying themselves in this country with photography—a number which far exceeds that in any other land. France musters but five or six all told, notwithstanding the fact that her population so greatly exceeds our own; and Germany, though it puts a better face on the matter, numbers no more than thirteen, with a population twice as large as the United Kingdom; Austria is represented by one society—a large one, it must be confessed—at Vienna; Belgium has two societies; Holland, Russia, and Switzerland one apiece.

The reason of this is not far to seek. In this country there is a large number of amateurs—both ladies and gentlemen—who do not merely dabble in photography, but take up a prominent position therein; indeed, in our exhibitions, the medals or awards are given indiscriminately to professional and amateur exhibitors, without raising the least remark. It has become a matter of course for all to compete in the same class and upon the same footing, and it is, we repeat, nothing unusual to see as many high-class awards go to the amateur as to the professional. Such a thing would be regarded as very exceptional on the Continent, and hence we may take it that, in this country, photography is practised much more widely as a pastime than among our neighbours on the other side of the Channel. There is no jealousy here, for the simple reason that no dispute is likely to arise about the intrinsic value of amateur and professional work; indeed, in selecting a jury of awards in this country, the matter never comes under discussion. Men are proposed because of their position in this respect or that; but the circumstance whether they are amateurs or professionals never seems to enter into the question of selection. In a word, with us, amateur photographers, notwithstanding their number, have taken very seriously to their pastime; they not only follow it as an art, but they study it as a science.

To this is due in a great measure the flourishing condition of our societies. Some of the bodies to which we have referred are denominated "Amateur" Associations, but whether they be so or not, it is the assistance given throughout the country by amateurs that has contributed greatly to the success of our associations at home. The gelatine process, as also the many dry plate processes that preceded it, were with but few exceptions brought forward by amateur photographers, who elaborated the methods so well because to them it was a labour of love. Of course their experimental work has been supplemented by the invaluable aid which experience gives, but the professional photographer has rarely the time, even when he possesses the ability, to develop new ideas and carry out plausible theories. With us the amateur—often, as we have seen, an accomplished artist and a subtle chemist—joins hands with the professional worker, and, labouring intimately together, they bring forth good fruit. But it is usually the former who takes the initiative, and to whom we owe, therefore, much we have learned not only recently, but in the early days of collodion and collodion dry plates.

It is the manufacturer, possibly, who could tell us most accurately the number of amateur photographers in this country; but the lists of members in the various societies are sufficient for our purpose in pointing out the source of energy that characterises most of the photographic associations. The president is almost invariably an energetic amateur, whose whole exertions are devoted to the progress of photography. The honorary secretary, the other executive officer, is also a non-professional photographer as a rule, so there is here another guarantee that the art and science aspects of photography are the primary consideration. We are far from deprecating the discussion of commercial photography, but, on the contrary, believe that meetings held by professional photographers with this object would be productive of good, in the same way as the Syndicate at Paris considers the commercial aspect of the question; but the two objects are distinct, and for the present we have merely the matter of photographic progress in view. In considering this we ought always to remember that to the amateur photographer of Great Britain the progress of our art is in a great measure due, and fortunate indeed is it for us that in this country photography should be cultivated by so numerous and wealthy a class.

The "At Home" next week will be "Picture-making with Mr. H. P. Robinson at Gwysaney Hall, North Wales"; the following "By-the-Bye" will be "With the Camera in the Tyrol."

ON ETCHING FLUIDS.—No. III.

BY MAJOR J. WATERHOUSE, B.S.C.,
Assistant Surveyor-General of India.

Mordants for Zinc.

The comparative cheapness of zinc would give it an advantage over copper or steel for engraving and etching with the graver or point, but it does not seem to be recommended for these purposes. It is hard to cut with the graver, and, though it bites easily, it is not suitable for fine work. Another defect is that it will not stand a long impression; but this may be overcome by surfacing the plate with copper. The principal uses of this metal for printing purposes are for surface printing or zincography in the same manner as lithography, and for the process of biting in relief, and zincotypography or Gillotage, now so largely employed as a substitute for wood blocks. It can also be engraved very delicately in the same style as engraving is done on stone through a coating of gum.

The etching fluids for zinc are of two entirely different kinds: first, mixtures of gum and weak acids used for preparing plates for zincographic printing in the lithographic press, or for the preliminary inking preparatory to being bitten in relief by the Gillotage process; and secondly, mineral acids, more or less dilute, used for biting in relief and ordinary etching.

Zincographic Etching.—This kind of etching is more a preparation of the plate for printing than engraving or biting, the object being merely to fill up the pores of the metal with gum, and prevent it receiving printers' ink from the roller elsewhere than on the lines of the drawing.

The solution most commonly employed for this purpose is the mixture of gum and decoction of galls, in use at the Ordance Survey Office, Southampton, and given by Sir Henry James in his work on *Photozincography.* It is prepared as follows:—4 ounces of Aleppo galls are bruised and steeped in 3 quarts of cold water for twenty-four hours; the water and galls are then boiled up together, and the decoction strained. The gum-water should be about the consistency of cream. One quart of the decoction of galls is added to 3 quarts of the gum-water, and to the mixture is added about 3 ounces of phosphoric acid, which is prepared by placing sticks of phosphorus in a loosely-corked bottle of water, so that the ends of the sticks may be uncovered. The oxidation of the phosphorus produces phosphoric acid, which dissolves as fast as it is formed.

The etching solution should only just mark a piece of plain zinc.

In Richmond's *Grammar of Lithography* the following modifications of this formula are given:—

Decoction of nutgalls	$\frac{3}{4}$ pint
Gum water as thick as cream ...	$\frac{1}{4}$,,
Phosphoric acid solution	3 drachms

Boil $1\frac{1}{4}$ ounces of bruised nut-galls in $1\frac{1}{4}$ pounds of water till reduced to one-third, strain, and add 2 drachms of nitric and 4 drops of acetic acid.

Richmond recommends, however, the use of simple decoction of galls without acid, and gumming-in after etching.

Knecht, in Roret's *Manuel de l'Imprimeur Lithographe,* gives the following containing copper, but this I find gives an unpleasant dark tone to the zinc:—

Gallic acid	1 centigramme
Water	1 litre
Gum arabic...	4 grammes
Nitric acid	2 milligrammes
Sulphate of copper ...	4 ,,

Sulphate of copper	50 parts
Rock alum	40 ,,
Sulphuric acid	20 ,,
Gum arabic	60 ,,
Water	1000 ,,

Husnik gives the following, also used by Hannot at the Depôt de la Guerre, Brussels:—

Gum arabic	40 parts
Sulphate of copper	2 ,,
Gallic acid	5 ,,
Nitric acid	$\frac{1}{2}$ part
Water	1000 parts

Motteroz uses gum-water acidulated with a few drops of muriatic acid, so that it will not visibly bite the plate—or better, decoction of nutgalls.

Moock gives:—

Water	100 grammes
Gum arabic	15 ,,
Nitric acid	2 drops
or muriatic acid ...	4 to 5 ,,
Solution of nutgalls	10 grammes

Scamoni has the following, by Garnier:—Boil about $1\frac{1}{4}$ ounces of bruised gall-nuts in a pint of water, till reduced to $\frac{1}{3}$, filter, and add 2 drops of nitric acid, and 3 to 4 drops of muriatic acid. For very fine work this may be weakened with water. It is applied for about a minute, then washed off, and the plate gummed.

Zincotypographic Etching.—In biting zinc plates in relief, the acid generally used is nitric, of different degrees of strength according to the nature and state of the work.

After the transfer is made, the plate is etched with one of the foregoing preparations, then inked-in and dusted with finely-powdered resin, which adheres only to the lines. This procedure is followed after every biting, the plate being warmed to melt the resin and inky coating, so that it may run down between the lines and protect them from the undercutting action of the acid.

Kruger, in his *Die Zinkogravure,* recommends, for the first relief etching, nitric acid 30 to 40 drops to 100 grammes of water, applied for five minutes. For each subsequent etching 8 to 10 drops of acid are added for each 100 grammes of water, and the time is increased, by degrees, from five to fifteen minutes. For the final etching of the broad lights he uses:—

Muriatic acid	4 parts
Nitric acid	1 part
Water	16 parts

To soften down the ridges between the lines the plate is inked and dusted as before, and etched with dilute nitric acid at 5 per cent. applied for about a minute, and the inking, dusting, and etching repeated as often as may be necessary.

According to Husnik, the first two bitings are given with 1 part of nitric acid to 40 of water, the first biting lasting two minutes, the second four to five minutes. For the third biting the acid is used double the strength, and applied for five minutes. The acid is made stronger for each successive biting.

Moock (*Impression Photographique aux Encres Grasses*) gives a first biting with nitric acid at 2 per cent. for two or three minutes, adding about the same quantity of acid for five successive bitings, gradually increasing the time. After the first five bitings, the plate is thoroughly cleaned, strongly heated, well inked again with a harder ink, and re-bitten with acid as strong as the last used; the operation is repeated for four more bitings, using less heat, and biting less and less each time. These last bitings are for smoothing off the edges of the lines.

In his "Instruction in Photography," Captain Abney gives the following process:—

Having made the transfer in the usual way, and dusted it with resin, flood the surface of the zinc plate with a 10-grain solution of sulphate of copper, which precipitates copper on the uncovered parts, and forms a copper-zinc couple. It can then be etched with very dilute acid.

Hydrochloric acid	1 part
Water...	500 to 750 parts

This is contained in a rocking trough kept constantly in motion. The first etching takes about twenty minutes. The plate is then washed and inked, dusted and coppered again, and then etched with acid twice as strong, the operation being repeated as often as may be necessary.

The following method is somewhat similar, though, in this case, the acid bites the parts not covered by the copper.

A zinc plate, coverd with varnish, and etched with a point, is treated with a neutral solution of copper, which deposits copper on the lines. The varnish is then removed, and the plate etched with muriatic acid, which bites the zinc, leaving the copper untouched. As soon as a perceptible relief is obtained, the plate should be inked and bitten in the ordinary way.

A very excellent method of biting zinc in relief is by galvanism. Roret's Manual—before quoted—gives two methods by Dumont and Devinceuzi.

In Dumont's Method the plate, having been inked in, and dusted with resin, has a copper conducting wire attached to it, and is then placed in a wooden frame parallel to a copper plate of the same size, at a distance of about twelve inches, and the whole is plunged into a bath of sulphate of zinc. The zinc plate is connected with the carbon pole of a Bunsen battery, and the copper plate to the zinc pole. A weak current is allowed to act, and the sufficiently-bitten parts are stopped out from time to time.

M. Devinceuzi's process is similar to the above, and, from trial, I know works very well.

The plate, having been rolled up with a strongly-resinous ink, is slightly etched with very dilute sulphuric acid, to clean the surface, and is then plunged into a solution of sulphate of copper at 15° Baumé (about 70 grains to the ounce), in connection with a plate of copper of the same size, placed about one-fifth of an inch away from it. The plate is taken out every minute or so, to remove the copper, and at the end of from four to five minutes is sufficiently bitten to yield good impressions from a chalk original. A drawing with a pen may require seven to ten minutes.

Before leaving this part of the subject, it may be mentioned that, in the processes for biting with nitric acid, it is essential to keep the acid in constant motion, and in some establishments the strength of the acid is maintained during the biting by allowing nitric acid to fall drop by drop from a bottle or other vessel placed above the trough.

Deep Etching.—For simple etching on zinc, Seymour Haden recommends one part nitric acid to three of water; or

Hydrochloric acid	10 parts
Chlorate of potash	2 „
Water	88 „

Dissolve the chlorate of potash in half the water—boiling—and mix the hydrochloric acid with the remainder. The two solutions are added together for use.

Kochler (*Lalanne's Etching*) says one part of nitric acid to eight parts of water is equal in effect to equal parts of acid and water used with copper for the same length of time.

A. Martin uses one part nitric acid to two of water.

Kruger (*Die Zinkogravure*) gives:—

Sulphate of copper	2 parts
Chloride of copper	3 „
Water	64 „
Muriatic acid	8 „
also	
Nitric acid	1 part
Water	40 parts

M. Gourdon has proposed a curious process of photo-engraving on zinc, founded on M. Merget's discovery that if zinc be covered by precipitation with certain metals, it is only bitten by nitric acid in the parts left uncovered, whilst, on the contrary, dilute sulphuric, muriatic, acetic, and other acids will bite it only in the parts covered by the other metal. Thus if zinc is covered in parts, as by writing, with a thin coat of powdery platinum, the parts covered with the platinum may be etched with sulphuric acid diluted with 7,000 parts of water. If gold be substituted for platinum, sulphuric acid diluted with 5,000 parts water will etch it. Silver requires 3,500 parts water; tin, 1,500; antimony, 700; bismuth, 500; lead, 400.

M. Gourdon takes an ordinary silver print, fixed, but not toned, and well washed, and transfers it, face downwards, on a plate of zinc. It is moistened on the back, first with ammonia, and then with a solution of cyanide of potassium, pure, or mixed with carbonate of soda. After a while the silver image will be regularly transferred to the zinc, and can be etched with very dilute sulphuric acid to form an engraved plate.

Boivin plates a zinc plate with silver, treats it in the dark-room with an alcoholic solution of iodine, washes it, and passes over it a solution of tannin or pyrogallic acid, and dries.

The plate is exposed to light for a few minutes under a cliché, and then plunged in the dark into an electro-gilding bath attached to the negative pole of the battery.

Those parts of the plate where the light has acted on the iodide will take a coating of gold, while the other parts will refuse it. The iodide of silver is dissolved with cyanide of potassium, and the plate is then bitten, the gold parts forming a reserve.

Moock etches zinc with one or two Daniel's cells, the plate to be etched being in a separate trough containing dilute nitric acid at 3° B., and attached to the copper pole of the battery, while the conducting wire from the other pole dips about an inch into the acid. The etching takes an hour or two, according to the subject, and, if necessary, parts can be stopped out when sufficiently bitten.

According to Scamoni, sulphuric, nitric, muriatic, and pyroligneous acids all etch zinc, but must be well diluted with 20 to 30 parts of water.

Mordants for Brass and Bronze.—Niether brass nor bronze seems to be much used for book-work engraving. According to Kruger, the mordants for brass are much the same as for copper.

For surface printing on brass in the lithographic manner, Roret's Manual gives—

Gum arabic	8 parts
Nutgalls	2 „
Nitric acid	1 part
Phosphoric acid	4 parts
Water...	30 „

For etching bronze, the following is given in Roret's *Manuel du Graveur*—

Pure nitric acid at 40°	100 parts
Muriatic acid at 20°	5 „

Notices.

The Photographic Studios of Europe. By H. Baden Pritchard. (London, Piper and Carter.) 2s.

We subjoin the introduction to this work:—

The practical worker is very seldom a writer. He not only lacks time and opportunity to record his experiences, but generally underrates their value, and does not think them worth recording. This fact comes home very forcibly to those connected with photographic journalism, and to it is due the contents of this volume. Having found again and again the practice of photographers so different to the teachings of text-books and periodicals, we resolved upon a house-to-house visitation among the principal studios of Europe, determined to write down great things and small alike, as they came under our observation, and so produce a record of practice. At first we feared that friends on whom we called might possibly resent our visit, and for this reason we made it a rule to intimate straightway that "if you have anything you desire to keep secret, do not mention it, and it will not get into print;" but we may say at once that the caution was never taken seriously, and we did not once fail to get a straightforward answer to any of our questions.

Our object in compiling this book has been two-fold: to produce a readable volume, and at the same time to afford practical information. It is not for an author to say how his book shall be read, but if we might offer a suggestion, it is that our "Studios" may be perused as they stand, first of all; and it is with this view that we have adopted a lighter and more colloquial style than that usually to be found in handbooks. The reader will thus obtain a general view of the contents, and when he desires afterwards to refer to the practice of different men in different operations, the information is readily found by reference to this introductory chapter. As he will perceive, we have tabulated the information under nine headings, to wit, the Reception Room, the Studio, the Dark Room, Apparatus, Processes, the Negative, Mountants, Residues, and Miscellaneous; and we have further placed the name of the photographer against the number of the page, so that our reader can refer to the practice of one authority or the other as he pleases.

Let us suppose the reader desires to learn something of collotype or Lichtdruck printing. Under the heading of Processes, and *Printing, Collotype*, he will find the names of the authorities given, together with the pages where the information is to be found. Here are not only all the formulæ and the manipulations involved, but they are the formulæ and manipulations actually made use of by the chief authorites, and which have been found by experience to be the best. The whole practice, as we have personally viewed it in the studios of such men as Obernetter, Albert, and Löwy, is put before the reader as plainly and concisely as it is in our power to do. Or, take a more simple subject, that of mounting. In five minutes the reader may refer to the practice of half a dozen of the chief ateliers in Europe, and adopt either one or other of the modes of working as pleases him best.

We are well aware that our work is incomplete. The alternative was before us of postponing the publication of this volume until the series of representative studios was more perfect, or publishing forthwith such information as we had gathered together during the past two years. We decided upon the latter course, for the reason that our writings already fill one goodly volume, and that some little time may elapse before we have an opportunity of visiting Russia and Southern Italy, where several studios of note are to be found. In our next edition of the "Studios of Europe" we hope to include a description of these and several others; but as it is, we do not think our readers will complain of lack of enterprise. Where a studio of special interest was to be found, we have permitted no difficulties to stand in the way of seeing it. Whether the establishment was within the span of a London cab-drive, or beyond the reach of railways, we have visited it, if it were worth visiting, and the fact that a distance of something like fifteen hundred miles lies between Messrs. Valentine's studio at Dundee, and that of Herr Koller in Pesth, is proof sufficient that our information was not obtained without some labour and fatigue.

We have pointed out that it was with a view to watch photographers at work that we undertook these practical essays; but we are in hope the professional photographer will be able to make use of our volume, beyond learning of the formulæ and manipulations of successful men. The arrangements of the reception-room, the rules and regulations in vogue with sitters, the prices charged for portraits, the sending out of proofs, and matters that concern the business of the photographer generally, have received particular attention, and we cannot but think that many will derive useful hints from the information thus brought together. As to the construction of the studio and dark-room, we have noted points from which many cannot fail to profit, and those engaged in building a new studio, or in re-arranging an old one, should derive benefit from our notes on the subject. The good work of the photographers we speak of in these pages will be known to our readers, and, no doubt, the latter will be able to perceive in our account, now and again, certain indications as to the manner in which this good work is obtained. All must, perforce, learn something; every one who reads of an improvement on his own mode of working will be gratified, no less than those who, cognisant already of what these pages tell them, will be confirmed in the proud knowledge that there is nothing other photographers can teach them.

MUYBRIDGE ON THE ATTITUDES OF ANIMALS IN MOTION.*

I think you will agree with me, that it will be unadvisable to detain you by a long lecture on animal mechanism. I think you will prefer seeing the result of my investigations to hearing a discourse on anatomy and physiology.

The attempts to depict the attitudes of animals in motion probably originated with art itself, if, indeed, it was not the origin of art; and upon the walls of the ancient temples of Egypt we still find pictures of, perhaps, the very earliest attempts to illustrate animal motion. But artists of all ages seem to have followed peculiar grooves in this matter, and to have adopted uniform notions as to the movement of animals. How inaccurate these notions have been, I shall endeavour to demonstrate to you this evening. I will commence, however, by showing you the apparatus by which the photographs were made; you will then better understand the pictures themselves. Here is the apparatus, consisting of an ordinary camera, in front of which is a strong framework, inclosing a couple of panels, each with an opening in the centre, sliding, one up and one down. In connection with it is an electro-magnet, which, on completion of a circuit of electricity, causes a hammer to strike and release a catch which holds the shutters in position; the back shutter is then drawn upwards by a strong india-rubber spring, and the front shutter is simultaneously drawn downwards. Here is a photograph of three shutters in position, one showing the panels before exposure, one during exposure, and a third after exposure. The next picture shows the arrangement in front of the cameras. Here are a series of strong threads stretched across the track, each of which being pressed forward, causes two metal springs to touch, and thereby completes the electric circuit. These threads are arranged at a distance of 12 inches from each other, and as the horse passes along he thrusts the strings, one after the other, completes an electric circuit, which operates the shutter of the particular camera which he is passing at the moment.

Twenty-four cameras are arranged parallel with the direction of the animal. The next picture shows the entire photographic arrangements. The track is covered with india-rubber, to prevent dust flying from the horse's hoofs; and there are here five cameras arranged in a semicircle, the object of which I will explain presently. The result is this:—A horse, in its progress over the track, comes in contact with these threads successively, and is photographed in the position in which he happens to be when he strikes the thread; then he moves 12 inches, and of course assumes another position, and is so photographed, then another 12 inches, and so on; in this way we have several positions assumed by an animal during an entire stride. The time of exposure, I may say, is the $\frac{1}{5000}$ of a second.

Here is a scale I have drawn out, but which it would take me nearly an hour to explain, illustrating the position of a horse's feet during the various strides, the walk, the trot, the gallop, and the pace; if anyone feels sufficient interest in the subject to inquire more thoroughly into it by-and-bye, it will afford me a great deal of pleasure to explain it.

Now, as I have spoken of the faults of artists, I must show you what those faults are. Here are some pictures of horses walking, from different sources, with some of which you are no doubt familiar. One is from Egypt, where they seem to have had two modes only of illustrating the motion of an animal, one the walk, the other the gallop. Here is one walking, with all four feet on the ground at once. As a general rule, indeed almost always, they are going from left to right. You will notice that the lateral legs are represented as moving synchronously, both left legs touch the ground at the same time, and both right legs. Here are other examples of Assyrian and Greek art; a Roman of the 1st century and one of the 8th century, also a Norman horse from the Bayeux tapestry, a German horse, and one by Flaxman, which is the only correct one of the series. I would particularly call your attention to a representation from the column of Theodosius, where you see two mules, in one of which the hind legs are precisely in the same position as those of the mule in the next illustration, whilst the fore legs are totally different. Now a mule or a horse always walks in the same way, so that if one is right the other must be wrong.

Here are photographs of a horse in the act of walking. A horse, while walking, is alternately supported on three feet and on two, and the two are alternately diagonals and laterals. Some very eminent authorities have asserted that a horse, while walking, has never more than two feet on the ground at the same time; but he has always two—that is the characteristic of the walk—and invariably three, four times during each stride, two hind legs and a fore leg, alternately with two fore legs and a hind leg. This horse, you observe, is standing on the right laterals. The most common fault of artists in representing the walk is to mistake the laterals for the diagonals; it arises, I am satisfied, from carelessness and lack of observation. Whenever a horse or any other animal has two suspended feet between two supporting legs, those two suspended feet are laterals, never diagonals. You find them in pictures, engravings, and even in sculpture, quite as frequently represented one way as the other; but they are invariably laterals—that is, when they are suspended *between* two supporting legs. When supported on diagonals, suspended feet are outside the supporting legs. Here is a horse walking, photographed simultaneously from five different points

* Read before the Society of Arts.

of view, according to the arrangement of the cameras I referred to just now. Next, we have a photograph showing the regular series of positions taken by a horse while walking. Of course, in every thousandth part of an inch, a horse really gets into a different position, but these are all the positions of a stride which are worth illustrating.

Next we have the amble; and first I show you some specimens of Egyptian, Assyrian, Etruscan, and Modern Italian art. They are none quite correct, but they approach more nearly to the gait which is ordinarily called the amble than any others I have found. I do not know whether this gait is properly understood or appreciated in this country, because horses are not trained to it, but Spanish horses are invariably taught it. It is faster than a walk, but not quite so fast as a trot, and is an easy, sliding motion, alternately on one foot and on two feet. In this, as in the walk, the horse is never entirely off the ground; in all other gaits the weight is off the ground entirely during a portion of the stride, but in these two he is never clear of the ground. He is alternately on one hind foot, then on two laterals, then upon one fore foot, then on the diagonals, then on a hind foot again. The succession is very curious: first on one foot, then on two; the two feet being alternately diagonals and laterals.

When these photographs were first made, some experts had doubts as to their accuracy. We have here a little instrument called the zoöpraxiscope, with which we can throw the various positions in rapid succession on the same spot on the screen, and thus produce apparently the real motion; and you will readily understand that if any of the positions were incorrect, it would upset the experiment altogether.

Next we come to the trot, and, as before, I first show you some examples of ancient and modern art. There is Marcus Aurelius on horseback; but that is not a real trot, because in a trot the motion of the diagonals is more synchronous than is here represented. The best example of a trot I have been able to discover of mediæval times is from a stained glass window in the Cathedral of Chartres. There are two from the Louvre, representing Louis XIV. and Louis XV. None of them are quite correct, but none have such glaring faults as one by a very celebrated artist, Rosa Bonheur. She is, perhaps, one of the greatest artist of modern times; grand in colouring, splendid in drawing, a great observer of nature; but, unfortunately, she did not pay sufficiently strict attention to the positions of animals in motion. This is a very celebrated picture, and the horse is supposed to be trotting pretty fast. Now, one fore leg is extended backwards, really beyond the centre of gravity of the horse. It would be utterly impossible for him to bring it forward in time, at the rate he is going, to support his body, and he would be obliged to fall down—he could not help it.

Here are a series of photographs of a horse trotting at about ten miles an hour, showing all the various positions at the different periods of the stride. Now, to me it seems almost incomprehensible; but, until these experiments were made, it was a question with some very experienced horse-drivers whether a horse was entirely clear of the ground during a trot. Some imagined that he always had one foot on the ground, though I cannot see how it was possible for them to come to that conclusion. Even at a moderate rate, in trotting, the weight of the body is entirely unsupported by the feet, though they may drag along the ground at a certain portion of the stride, no matter how slow the pace. This being about ten miles an hour, the horse is entirely clear. Here, again, is a horse trotting at the rate of a mile in two minutes twenty seconds. One thing I would call attention to is this, that, when a horse's foot strikes the ground, the leg is always straight; it is never in a bent position. Though you find some eminent artists illustrate a horse striking the ground with his leg bent, it simply is not possible. Another thing is, that he always strikes the ground with his heel first; never with his toe. Here is another horse performing a moderately-fast trot, about eight miles an hour, and making a stride of six feet six inches. Here is another trotting very fast—one mile in two minutes eighteen seconds, the fastest time ever accomplished being a mile in two minutes ten seconds. There is also a peculiarity observable with regard to the position of the pastern. When striking the ground it is vertical, but it immediately sinks so as to become almost horizontal. Now, we will try the trot with the zoöpraxiscope, and you will find the motion is perfectly produced. Next we come to the canter, which is rather a peculiar gait. It differs from the gallop in many respects, and notably in this, that whereas in the gallop the horse will leave the ground with the fore feet, as also he does in the canter; in landing in the gallop he lands first on one hind foot, and then brings down the other hind foot, so that he will be on two hind feet at the same time, and throwing his fore feet forward; in a canter he will land on one hind foot, and the next foot to touch the ground will be a fore foot; then he will bring down the other hind foot, and then the next fore foot. That is the invariable order of succession in the canter; but the hind foot will follow the fore foot so rapidly that it is utterly impossible for the eye to follow the succession of movements. Here we have a series illustrating the canter. You see he leaves the ground on the fore foot, as is invariably the case with either the canter or the gallop. That is another singular fact that artists have not noticed, and they have been led into the very egregious error of imagining that a horse, while galloping, left the ground with the hind foot, and landed on the fore feet. A horse, while galloping, is always in the air for a certain portion of time; but it was always supposed that, in galloping, he would leave the ground with the hind feet, and land with the fore feet; whereas the reverse is always the case.

We now come to the fastest of all gaits—the gallop. Here is the Egyptian representation, which, with very slight variations, is the way in which Egyptian horses galloping are always represented; the hind feet are down, and the fore feet in the air. The Assyrian is not much better, but the Greeks evidently understood the motion of a horse better than a great many of the moderns; and this is very nearly the position in which a horse would be, having just landed after a flight through the air. He has struck the ground with his hind feet, one hind foot being behind the other. Here is another from the column Theodosius; here is a Norman example from the Bayeux tapestry, and here is one by some Italian artist of the 4th century, in which we find a position of the gallop exactly reproduced. Here is one by Albert Durer; this is the conventional gallop; and, with all due deference to the artists who have palmed it off on the public as being a representation of a galloping horse, I must say it is really absurd, because it is utterly impossible for a horse to get into that position. Here are some ancient pictures, one from the ruins of Angar Wat, in Cochin China; a Japanese, which is tolerably correct; and a very curious one, copied from a painting on the rocks on the banks of the Yenisi by the Tartars. This shows how artists of different ages and different countries have all agreed in representing nearly the same conventional position of the gallop.

While on the question of the absurdity of this position, I may remark that where there are ten horses it is a concentrated absurdity—it is ten times as absurd—because if it were possible even for one horse to get into that position, it would be certainly the height of improbability for ten horses at the same instant of time, all to be in the very same position; yet here is a picture by a distinguished artist, Mr. Herring, a very celebrated painter of horses. He has painted ten horses all fully extended in that conventional position. The public may have demanded that, and he painted that picture in that way. It is necessary that the public and the artist be educated together. Here we see a photograph of a free gallop, with a horse just about alighting on the ground still in the air. When the horse is in the air it is not with his feet stretched out as far forward as they will go, and the two hindmost in the same way, but they are curled up invariably in the way you see them in this photograph. That horse is now in the air, about to alight on the hind foot. In another one, you see him alighting on the hind feet, and of course, there are intermediary positions between these; and this where he is about to leave the ground with one forward foot. Those connected with the turf are well aware that, when horses break down, they always break down with the fore feet, and never with the hind feet, or very rarely. It was a mystery why that should be so, but here is the key to it; the immense amount of work that a race-horse has to perform with his fore legs is fully equal, in my judgment, to that with the hind legs. Here are all the important positions which a galloping horse will assume in making a complete stride. In its particular features each stride really differs from another. If you take one of the swiftest race horses, and measure his stride, you sometimes find one inch, sometimes two, and sometimes half-an-inch variation in the length of the stride; it depends on various little things, but this is a representative stride. Here is another, with a little longer stride—19 ft. 9 in.—in a stride of 25 or 26 feet. We might have information different to that we have obtained.

Now we come to the leap. This is the horse rising preparatory to clearing the hurdle. The hind feet are on the ground for the last time before making the spring, and you notice that one is much in advance of the other—a few inches; sometimes it is more than that. They are hardly ever at precisely equal distances from the hurdle, and on coming down, you find a greater variation. I may say that these pictures are entirely untouched; they are exactly as they were made in the camera; there is no interpolation by any artist, or any imagination. Here the horse is coming down; one fore leg you see is nearly straight, the other is somewhat curved, because he has not had time to bring it out, probably; it will be perfectly straight when he touches the ground. Here he is landed, and you notice that one pastern is almost horizontal. That is the position in which a horse invariably strikes the ground. Here we have an entire consecutive series taken from a distance of about twenty feet in front of the hurdle. There is more variation in the leap of the horse than in almost any other movement. Sometimes he will leave the ground at a distance of twelve feet from a hurdle 3 feet 6 inches high; at other times he may probably not leave the ground until 3, 4, or 5 feet of the hurdle. It depends a great deal on the disposition of the horse. Here is a series illustrating his position after he has cleared the hurdle, showing the method by which he picks up his feet, and regains the gallop, after having made the jump. This is a complete stride, and we can follow the horse here from the time he leaves the ground with his feet until he lands on his fore feet. I will now illustrate this movement with the zoöpraxiscope. Here are some photographs of the dog. In fact, some people might mistake that for a horse, because the position is somewhat like the conventional horse gallop. The motion of the dog is very peculiar. Here he has alighted on one foot, changed it to the next fore foot, and then he leaves the ground with the fore feet. In the next you find him entirely in the air, his feet all doubled up under him; he then comes down on his hind feet. Then he brings the next hind foot down, and leaves the ground again, so that he is in the air twice during a single stride—once with his body curled up, and the other when perfectly extended. I do not think that fact has ever been commented on by a writer on natural history. Here is a photograph of two dogs running a race; they were photographed together; one was a faster dog than the other, and you see how he gradually overtakes his competitor.

Next we have the ox; here are two oxen from the column of Theodosius, and they are both correct. There is one peculiar feature in the walk, of which I should like to tell you. Artists ought really to be close observers of animal movements, but it is rare to find an artist who can tell you the manner in which an animal will walk. There are two artists here, and they have not been able to tell me. There is one invariable rule with regard to the walk, so far as my observation has extended, and that is that the succession of footfallings are with any animal precisely the same; whether a dog, a horse, a monkey, or the giraffe, they are all the same. Assuming you commence your observation with the left hind foot, the next foot to touch the ground would be the left fore foot, followed by the right hind foot, and that again by the right fore foot. That order, so far as I am aware, is universal. I would not be positive so far as all animals are concerned—the hippopotamus, for instance—but, so far as I have had an opportunity of judging—certainly, so far as I have photogsaphed—it is do. You may think it a very easy thing to watch an animal, and see how it walks, but it is very difficult. There is as much difficulty in watching the massive movements of an elephant as the more light and rapid movements of the horse. I am not quite satisfied in my own mind yet whether an elephant is upon diagonals during a walk or not; I know he is on laterals, but during half-an-hour's observation I could not really positively say whether he was supported by the diagonals alone or not. With the hippopotamus I know that to be the case, but I almost question really whether an elephant in walking is supported entirely by diagonals. Here again we have a picture of an ox, by Rosa Bonheur. This is a very celebrated picture in the Luxembourg. Those two oxen are represented in a manner that no oxen would ever think of getting into. You might get a cord, and pull their feet into that position, but it would be strongly against their will. There is another one here by the same artist which is more nearly correct, but not quite.

Next we have a series of photographs of an ox walking, and the same principle holds good. The succession is the same. The trot of the ox is pretty much the same as that of the horse. The next is a wild bull; he was really wild enough for a Spanish bull fight; we had to build a long lane in order to get him to run straight, and we had three or four men ready to catch him in case he should make for the cameras. The bull gallops pretty much like a horse. Next we have a set of photographs of the pig. I thought I would attempt the pig, not that I hoped to gather much information from his movements. The principal event of our experiment was the difficulty we had in inducing him to go forward; of course we followed the old principle of drawing him backwards.

Next I have a set of photographs of the deer. Some writers on animal movements have compared the gallop of a horse to that of the deer, but there is a considerable difference. We see that the deer takes somewhat the conventional style of the horse in galloping. The gallop of the deer is hardly a gallop, it is almost a series of bounds. The deer does leave the ground with the hind foot, and lands on the fore foot, which the horse does not.

Now, we come to the movements of mankind. This man is walking pretty fast, a seven foot stride. With regard to the walker, we all know that he lands on the heel; but in taking a run, if you ask any athlete in what manner he runs, I think he would tell you that he would not alight on the heel, that he would alight on the ball of the foot. They are generally very confident that in running they never come down on the heel. That is the opinion of the runner himself, I think, in nine times out of ten, and it was with very great difficulty after this man had run, and had seen these pictures, that he could convince himself of the fact that in running he always came down in this manner. It is the same with the man as with all other animals—as far as I am aware, they always come down on the heel. Here is a photograph of a long jump of 16 feet, without any particular attempt to jump high. Here is one of a man clearing a hurdle four feet high. You would think that clearing a hurdle of that height, if it were possible for him to come down on his toes, and so break the force of the concussion by springing, that he would do so. But you see here where that man's toes are. He comes right down on the heel, and that is the only way in which he could come down. The man finds his springs in his knees when jumping; the horse finds them in his pasterns. [The various movements in running and jumping were then exhibited in the zoöpraxiscope.]

In the next photograph we see men performing athletic feats, particularly feats of strength. They are on too small a scale to show the play of the muscles. But I have a series on a larger scale of men wrestling, in which the action of the muscles is very well shown. This series of exposures was made in a slightly different way. Of course, the men in wrestling were pretty much in a small circle, and, therefore, different means had to be adopted for regulating the successive exposures. The cameras were all concentrated on one point, and an apparatus was constructed to cause them to receive the exposure at stated intervals of time, instead of distance. Here are photographs of a twisting somersault; next a flip-flap, the movement which is made preparatory to making a back somersault; and here is a back somersault. I will show these in the zoöpraxiscope. Of course, the construction of this instrument requires the movements to be effected more rapidly than a man in performing the same result would naturally do. The horse on which he is standing, instead of making two strides, would probably make three or four before he turned the second somersault. But in order to show that, it would require a disc of 10 feet circumference.

At the request of my friend, Professor Marey, of Paris, I gave some attention to illustrating the position of birds, but I cannot say I was very successful. The movements of the wing are so extremely rapid, and it is a small object any way, so that the information we have obtained from the movements of birds I cannot congratulate myself upon; however, here are a few of the results. There are only two nations, that I am aware of, in which the artists have ever thought of illustrating birds with their wings downwards; of course artists must know that birds' wings go down, but I suppose that they imagine it is inartistic to draw them in that way. The ancient Egyptians would frequently illustrate their birds with the wings downwards, and the other nation is the modern Japanese. You frequently find, in Japanese books, birds illustrated with their wings downwards. I show you these few photographs of birds, but perhaps they are of more value for art than for science.

I have now some illustrations of groups of horses galloping. These really are more difficult to make, because they were made in the open fields without any of the apparatus which I have described. There are also a few picture subjects, showing groups of horses, which are, perhaps, more interesting to the artist. Lastly, I will show with the zoöpraxiscope a picture, which we may call Rotten-row. (This was a picture of a number of horses, dogs, and men, showing the various motions of running and trotting.)

Notes.

Mr. Mendelssohn, of Newcastle, has opened a studio in South Kensington.

Mr. B. J. Edwards has been awarded the gold medal for instantaneous photography at the Alexandra Palace, and Mr. F. G. Williams, whose wonderful picture of "Ramsgate Sands" will still be remembered, has received the silver medal.

We are compelled to postpone until next week our "Concluding Remarks" to "Twelve Lessons in Elementary Dry-Plate Photography." When this final chapter has appeared, we shall commence the "Twelve Lessons in Elementary Photographic Chemistry" for our younger readers.

A certain number of the Palais Royal shopkeepers have agreed together to employ incandescent electric lamps on their premises, sharing the expense of an engine and Gramme machine between them. This, we take it, is a start towards household illumination by electricity—the beginning of the end. If the inhabitants of a square or terrace make up their minds to it, they can have electric lighting as cheaply as gas.

Lord Rosse's reported statement that faint detail cannot well be copied by photography is scarcely likely to have been uttered, since his lordship is both a scientific and practical photographer. We had an example of how much better the camera can appreciate faint detail than the eye, only the other day. A carte-de-visite received in a letter was photographed, with the result that the copy showed across its face very distinctly certain handwriting, which had been pressed in contact during the transit of the picture in the letter; and yet on the original the writing marks were so faint as only to be seen on close examination.

At a recent meeting of the Vienna Photographic Society Dr. Trapp gave some advice as to the preparation of durable sensitized paper. He recommended the use of a silver bath of 1:15 strength, to which a few drops of a concentrated solution of nitrate of ammonia are added. The ammonia is put in gradually; a precipitate is formed, but this soon dissolves again, and nitrate of ammonia is added until the precipitate refuses to disappear. This bath remains white for a very long time, and sensitized paper three weeks old shows scarcely any signs of discolouration.

It is a singular circumstance that while in London pyrogallic development is in high favour at the principal studios, in Paris, oxalate development is almost invariably used in the chief ateliers. A Parisian to whom we pointed out the circumstance lightly remarked that it might be but a question of taste, like the flavour of a *sauçisson*, some preferring it seasoned with garlic, and some without; still we cannot help thinking there must be another reason.

"British painters frequently carry with them a hand-mirror or toilet glass in which to reflect the composition they are painting, as an aid to their work, while French landscape painters affect the Claude glass—a slightly concave mirror—which is brought into requisition more particularly when choosing a subject. The landscape in miniature is studied in the Claude glass, and if the composition pleases in these circumstances, it is chosen." So writes a correspondent, who adds: "Do you not think the Claude glass might occasionally be used by the landscape photographer with advantage?"

With the approach of the holiday season we propose to write a series of "By-the-Bye" articles on Continental rambles with the camera. Switzerland we shall leave out of the question, since it is a well-known play-ground, and confine our attention to "The Tyrol," "Norway," "The Pyrenees," "The Italian Lakes," and "Thuringia." Since we have personally visited these spots—many of our readers will remember the holiday sketches we exhibited at the Photographic Society in 1877—we are sanguine about making the articles in question of practical use to the tourist-photographer.

A German photographer advertises the preparation of photographs on glass for etching with sand-blast; it may be well to point out, therefore, that thin carbon photographs upon glass resist the action of sand blast very well. If you desire to produce an image or design upon a ground of matt glass, the design in carbon has simply to be transferred to a glass plate, and this, sent to a sand-blaster, will be returned to you with the ground-work roughened. A jet of sand has been projected against the glass, and the sand particles have cut the glass surface all over, except where protected by the carbon print.

An ingenious patent, by the way, has just been taken out in America for making use of sand-blast in connection with the recovery of gold from sand and tailings of mines. Mercury and gold quickly make an amalgam, as everybody knows, and, in consequence, it is generally the aim of gold-miners to bring mercury into contact with gold-bearing minerals. The last suggestion on this score is to blow the sand particles containing gold against a wall of mercury, maintained in position by centrifugal force. Every atom of gold is thus attached by the mercury, and a ton of sand may in this way, it is said, be freed from gold in twenty minutes.

"No sketching permitted near the Fortifications," is familiar enough to the readers of Murray, and if a sketch-book is regarded with suspicion, we may be quite sure our Continental friends would not allow a camera in the vicinity. This is our reply to "Gelatino Amateur," who is contemplating a tour in Germany with dry plates.

It is not so long ago that Mr. William England was arrested on the Rhine, and marched off between two spiked helmets with all the pomp and circumstance of a spy.

But this was at the beginning of the Franco-German war; and no doubt if "Gelatine-Amateur" takes care to keep out of sight of the fortifications of Metz, Strasburg, Ehrenbreitstein, and the like, he will not be molested by German officials.

We heard the other day of a fashionable photographer whose clientèle was so extremely exclusive that it numbered only a very few of the highest families in the land; indeed, so exceptionally high-class was his business growing year by year through the exclusion of the less august, that he bade fair to end triumphantly by getting rid even of his most select sitters, and taking no portraits at all.

There is in Paris a company for providing horses and carriages and servants either for sale or hire at the shortest notice. A visitor arriving in the gay capital who desires an equipage complete has but to pay a visit to the office, make his choice from a number of photographs, and in a couple of days the original of the photograph is at his disposal. Here is a Victoria, with a showy horse, handsome harness, and smart coachman to be purchased as it stands for 4,000 francs (£160), and here a barouche and pair, with coachman and footman already on the box and fit to start at any moment, for 11,000 francs (£440). You may even purchase a sledge for the winter, for here is a swan-shaped conveyance elegantly mounted, which looks the perfection of a snow equipage in the photograph, that may be purchased for a handful or two of Napoleons.

Dr. Schnauss is busy translating "The Photographic Studios of Europe" into German, and the edition will be published very shortly; the French edition, of which the well-known Paris firm, Gauthier-Villars, will be the publisher, is also in active preparation; while the New York edition appeared this week under the auspices of Messrs Anthony and Company.

In the sculptor libel case, Mr. Belt mentioned last week the great assistance photography rendered in the work of modelling. As our readers are aware, the late M. Claudet took out a patent for a process of photo-sculpture, while Mr. Woodbury was very clever at producing bas-reliefs in plaster of Paris by his photo-relief process some years ago. The sculptor should look at his photographs either through a monocle, or make them into transparencies, if he wishes to see them to the best advantage for his work; and he should, moreover, secure as many portraits in profile as he can.

Those who adopt the recently-revived suggestion to use solid paraffin for rendering paper negatives or pictures transparent, will thoroughly appreciate the fact that the paraffined sheets are not liable to become brown with age; but the greatest care should be taken to select a sample of paraffin which is hard and quite free from the semi-fluid constituents so often present.

"From yesterday's debates in London and Paris, to the latest enquiries into the habits of earthworms, or the last photograph taken of the sun," was the Duke of Albany's summary of the contents of our newspapers in his speech at the Press Fund dinner on Saturday; from which we may infer that the latest work of Charles Darwin and the recent photographic observations of the sun in Egypt have had particular interest for Prince Leopold. The latter, indeed, though he presided at a literary banquet, is well-known to be an adept in science; he is a member of the Royal Institution and of the British Association, and is thoroughly conversant with chemistry and photography.

American photographers are already in treaty with Mrs. Langtry for sittings during her visit to the States. She is to appear on the New York stage in November next, and Mr. Abbey, who has secured her services, gives her rather higher terms than he gave Madame Sarah Bernhardt. Hence we may expect that the Jersey Lily will demand more for her photographic rights than did Madame Bernhardt, to whom Sarony, it is said, paid several thousand dollars for sitting exclusively to him.

There will be no need for any reconnoitring on the part of our sailors, should war unfortunately break out in Egypt. Photographs of the Port of Alexandria, of the mouth of the Canal, and indeed of much of its banks, are already in existence, and at the service of Sir Beauchamp Seymour, who commands our fleet; and photographs obviously, from their accuracy and exactness, are peculiarly useful as military sketches; nothing escapes the keen eye of the camera, let the observation be taken ever so hastily.

ON THE COMPARATIVE RESTRAINING POWER OF POTASSIUM AND AMMONIUM BROMIDES.

BY ARNOLD SPILLER AND BROUGHAM YOUNG.

In giving formulæ for developers, it is usual for most photographers to prescribe a definite quantity of soluble bromide, taking for granted that ammonium and potassium bromides are equally powerful restrainers. Wishing to determine whether any difference really existed between the two, we instituted a series of experiments. Our first object was to make up an exaggerated developer—that is to say, one that contained a large amount of ammonia with plenty of soluble bromide; the following solutions were, therefore, prepared:—

A.—	Ammonia ·88...	1 drachm
	Potassium bromide	60 grains
	Water...	1 ounce
B.—	Ammonia ·88...	1 drachm
	Ammonium bromide	60 grains
	Water...	1 ounce
C.—	Pyrogallic acid	16 grains
	Citric acid	8 ,,
	Water...	1 ounce

Two developers were made up—the one containing half a drachm of A, one drachm of C, and one ounce of water; and the other containing half a drachm of B, one drachm of C, and one ounce of water. Two gelatino-bromide films were exposed under a sensitometer, and developed—one with the solution containing potassium bromide, and the other with the developer containing ammonium bromide. On taking the films from the developing solutions, we found that which had been developed in the presence of potassium bromide showed No. 25, while the other, which had been restrained by the ammonium bromide, showed from 13 to 15 on the sensitometer; thus proving that the difference of the restraining power of the two bromides is considerable.

Having thus found that a difference actually existed between the two restrainers, we set about to determine the comparative restraining power of these two alkaline bromides, and, with that object, made up the following solutions:—

D.—Ammonia ·88	...	$\frac{1}{2}$ drachm
Water	...	1 ounce
E.—Potassium bromide	...	15 grains
Water	...	1 ounce
F.—Ammonium bromide	...	15 grains
Water	...	1 ounce

The following three developers were made up:—

No. 1.—D	...	30 minims
C	...	1 drachm
Water	...	1 ounce
No. 2.—D	...	30 minims
E	...	30 ,,
C	...	1 drachm
Water	...	1 ounce
No. 3.—D	...	30 minims
F	...	30 ,,
C	...	1 drachm
Water	...	1 ounce

We then exposed three films behind the sensitometer, and developed them with solutions Nos. 1, 2, and 3 respectively, and, on examining them, the film treated with No. 1 showed 15; No. 2, 5; No. 3, 3; therefore, we concluded that potassium bromide possesses only three-fifths the restraining power of the corresponding ammonium salt.

To verify our result, we made up two other solutions—one being similar to No. 3, but the other contained fifty minims of the solution of potassium bromide, instead of thirty, as in the former case. Two films were exposed behind the sensitometer, as before, and treated with these two solutions, when fig. 3 showed itself on both films simultaneously.

We have also experimented with the ferrous-oxalate developer; but, as might be expected, there was only a slight difference apparent with the two bromides, it being in the same ratio as the different percentage of bromine in the two salts, viz., 7 : 8; although, for some unaccountable reason, the image appeared first in the oxalate developer, restrained by ammonium bromide; but the other soon overtook it.

In summing up, we have come to the following conclusions:—

1. That there is a wide difference between the restraining power of ammonium bromide and potassium bromide with pyrogallic-acid developers.

2. That potassium bromide has only three-fifths the restraining power of ammonium bromide with the aforesaid developer.

3. That with ferrous-oxalate developer the difference is practically *nil*.

STRAY NOTES ON DRY PLATES.

BY J. PLENER.

On a former occasion, while examining the relation between the sensitiveness and the number of gradations in a plate exposed under a sensitometer with constant difference between the transmitted light by two contiguous shades, we found that they stand in inverse ratio to each other. Besides, it can be easily otherwise demonstrated that the number of gradations changes with sensitiveness. Let us take two good plates of different sensitiveness and expose them under a sensitometer. Suppose the first plate gave N°m for the densest, and $m+n$ for the faintest tint, so that n will be the number of gradations. The corresponding numbers for another plate we designate by m_1 and m_1+n_1. The corresponding deposits in good plates being equal, we have two equations:

$$\alpha stim=\alpha s_1tim_1, \text{ and } \alpha sti(m+n)=\alpha s_1ti(m_1+n_1),$$

hence

$$\frac{m+n}{m}=\frac{m_1+n_1}{m_1}, \text{ or } \frac{m_1}{m}=\frac{m_1+n_1}{m+n}$$

From this we see that n_1 cannot be equal to n, or that the number of gradations is different in two plates of different sensitiveness. The above conclusion applies to the case when we gradually uncover a plate to the action of the standard light, as M. Janssen did; or to the sensitometer of Mr. Mucklow and Spurge, constructed on the principle $n-n_1=C$, where n and n_1 represent the light received by two divisions, and C is a constant. But we had no right to apply it to the sensitometer in which the transmitted light by two contiguous shades stand in relation λ. We can prove it thus. Let us take again two good plates and repeat with them all the same as above, then we receive

$$\alpha sti\lambda^{m}=\alpha s_1ti\lambda^{m_1} \text{ and } \alpha sti\lambda^{m+n}\alpha s_1ti\lambda^{m_1+n_1}$$

hence we have—

$$\lambda^{n}=\lambda^{n_1}$$

This shows that n is equal to n_1, or that with the sensitiveness the number of gradations has not changed. It can be easily seen that if we had changed at the same time the light i, the number of gradations would remain the same. Consequently for a given λ the number of gradations does not change, as we supposed, but remains always constant for the good plates. It is only in the bad plates, the quickest as they exist now, and the slow ones, that the scale of gradations is lengthened or shortened through the disappearance of close proportion between the deposit on one side, and the light and sensitiveness on the other. Therefore, from the number of gradations we can judge of the quality of the plate, provided we know the number a good plate ought to have. To obtain the last we must expose and develop a good plate, and count the number of gradations in it. But at the outset we must have means to choose a good plate. This subject we have treated on a former occasion; now we wish to add that it is unnecessary to construct all the scale of perceptible gradations. If we take only four shades, viz., white, and next to it, black, and next to it, which is a very easy matter to provide, and photograph these four shades, then the plate which would reproduce them would have reproduced, of course, all other shades had they existed. It follows from all the above that when we have constructed the tablet of a sensitometer, the definition of the quality of plate will present no difficulty at all. The same cannot be said as regards the sensitiveness, because the fine λ would require much experimenting and calculation. We wish to mention here some theoretical considerations concerning the matter.

In the construction of sensitometers, all the difficulties centre in determining for one, and no matter of what type, sensitometer the rigorously true value of λ, and the number of gradations n. We think that this is by far the easier to do for a sensitometer of the type of Mr. Mucklow's. If, instead of drilling the holes, some slits of equal and due breadth were cut in the top of each division, and their total lengths were made such as to stand in two contiguous divisions in a constant relation λ, then λ being known, and n found by exposing a good plate, we would have had all that is wanted. Thus all the difficulties would be thrown off the shoulders of the photographer, and we do not doubt that the errors of engineering would be smaller than those of any photographic observation. Suppose, even, that in verifying we had discovered an error, then nothing would be easier than to correct it by lengthening or shortening the slits. It is evident that in such a sensitometer λ and n will remain constant, no matter what may be the character of incident light. Suppose that, while exposing, we covered this sensitometer with a coloured glass, which cuts off some of the rays, so that, instead of the original light used for verifying λ and n, we have now for incident light $L\lambda$, it comes to the same as if we had changed the source of light. The transmitted lights by two divisions will be respectively $L\lambda_1\lambda^n$ and $L\lambda_1\lambda^{n+1}$, but its relation will remain always equal to λ. Therefore, with this sensitometer, which we will call No. 1, we can use any standard light, as the obtained relative sensitiveness will be the same with any light.

Now let us examine sensitometers à cliché, which we will call No. 2. It is immaterial for our purpose to know of what material the tablet is made, whether of sulphur, tinted gelatine, or paper. It will have only a bearing on the question of durability, and we do not intend to investigate this question. We suppose we have the tablet already constructed, and only want to find λ, and calculate the numbers of relative sensitiveness. We proceed thus: take a good plate, expose it under the tablet to the light we wish to use as a standard, and count the number of gradations n. To calculate λ, we make use of the formula—

$$n\log\lambda = n_1\log\lambda_1, \text{ or } \log\lambda_1 = \frac{n}{n_1}\log\lambda$$

Where n and λ belong to the sensitometer No. 1.

While examining the sensitometer No. 1, we asked ourselves what will become of λ if the standard light be changed? We must consider such a case for the sensitometer No. 2. From the experiments of Becquerel it follows that λ varies not only with the transmitting medium, but also with the source of light. Consequently, for each source of light taken as a standard we may receive different series of numbers for calculating the relative sensitiveness. But will the relative sensitiveness of any two plates be the same in each case when calculated from different series of numbers corresponding to the different standard lights? Should such be the case, we might take any light as a standard, and, no matter what kind of light we might use in the studio, we could always rely upon the time calculated for exposure.

Let us see. Suppose we have exposed two different plates under the tablet to a certain kind of light, and got the numbers which indicate the lights received $\lambda^{1n}{}_1$ and $\lambda_1^{n_2}$. The relation of these two lights we designate by $\lambda_1^{r_1}$. The same two plates when exposed under the sensitometer No. 1 would have for relation of lights received λ_r, and we know it will be equal to $\lambda_1^{r_1}$. Now if we designate by $\lambda_2^{r_2}$ the relation of lights received when the plates are exposed under the tablet to a different kind of light, we again know that $\lambda_2^{r_2}$ will be equal to λ^r, consequently $\lambda_2^{r_2}=\lambda_1^{r_1}$. What is true for any two kinds of light is true for all; therefore, any kind of light may be used as a standard, and the relative sensitiveness, as indicated by sensitometer, will be always the same. But if we have the numbers calculated for a certain kind of light, we must of course use the same light as the standard.

Till now we considered only one kind of good plates, viz., the plates upon which the spectre of a given light produces always an impression whose different shades stand in a constant relation. We had in view only the changes in the standard light; but suppose the relation between the shades of spectre's impression has changed?

At first we remark that by the interposition of two differently coloured glasses between any two plates we can establish between the shades any proportion we desire. On the other hand, we know that such an interposition does not change λ in the sensitometer No. 1, therefore we can use the latter for the above plates with safety.

To see whether for these plates λ will change in the tablet, we cannot interpose the coloured glasses between the sensitomer and the source of light, because it might be tantamount to the change of the latter, therefore we put the glasses between the tablet and the plates. It is evident that in such cases λ will not be changed, and the identical proportion of shades established. Consequently the tablet may be used, too, for the plates having different proportions between the shades of the spectral impression.

To sum up the above, we say that in the construction of sensitometers the principal difficulty centres in determination of the rigorously true value of λ and n for first sensitometer, and then the λ and n for all other sensitometers will be most easy to calculate. These first λ and n will be the standard λ and the standard n, and once determined they will be imperishable. Every one who possesses a sensitometer of the type λ might calculate for it the numbers of sensitiveness from the standard λ and n, and from the number of gradations his sensitometer gives. To spare the trouble of calculation, tables might be printed, giving the numbers of relative sensitiveness corresponding to each number of gradations.

Besides this, we have seen that the sensitometer of Mr. Mucklow will have the same numbers of relative sensitiveness for all standard lights and for each kind of plates, while the sensitometer à cliché might have different numbers for each standard light; but the numbers of the latter do not depend upon the character of the silver compound in the plates, and do not change with it for different kinds of plates.

As all our calculations are based upon the number of gradations, it is very important to know how the densest tint is to be found. If we divided each division of the tablet into three parts, and gave to each part different thickness, so that the divison (say) 15 would have in the middle 16 thicknesses, and two other parts respectively 14 and 16, in this case we should have two divisions for the observation of the difference between two shades, thereby the chance of a mistake would be lessened.

For the same purpose M. Janssen's method may be good. It consists in the superposition of two plates in reverse order of their numbers, in such a way that all numbers should have equal transparency. It is evident that the number of gradations will be the number of shades overlapped in both plates + 1.

ON THE SENSITIVENESS OF THE SILVER HALOID TO THE SOLAR SPECTRUM.

BY DR. H. W. VOGEL.*

ABOUT a twelvemonth ago I published a paper on the sensitiveness to light of silver bromide, in which I showed, as the result of experiments, that finely-divided silver bromide in collodion is affected by different rays of the spectrum than those to which the same substance in gelatine, or in a mixture of collodion and gelatine, is sensitive. From this I came to the conclusion that the medium in which the silver bromide is suspended exerts a material effect on its behaviour under the solar rays.

More recently Captain Abney has taken a number of photographs of the spectrum on the bromide, chloride, and iodide of silver, and also mixtures of these salts; and he concludes that the substance in which these haloids are emulsified has no effect on the sensitiveness, since the maximum of sensitiveness with the same salt lies at the same point of the spectrum, no matter what substance is used as the medium in which it is suspended.

Apparently, Captain Abney was not aware of my own investigations—at all events, he does not refer to them; but he maintains that the results obtained by other observers which do not bear out his own views are due to imperfect instruments (direct-vision prisms, he calls them) which absorb a large portion of the violet and ultra-violet portion of the spectrum, so that the maximum action lying in these regions does not appear. Now, this explanation, though it may be true in certain cases, cannot apply

* *Photographische Mittheilungen.*

in every instance. In my own case, most of my experiments are carried out with a perfectly colourless prism of flint glass, the same that I employ in photographing the ultra-violet rays of the hydrogen spectrum.

Abney has also overlooked the variations in the action of particular parts of the solar spectrum, the existence of which I had proved, and which I had shown to be due to the varying transparency of the atmosphere for the different colours; these variations produce very remarkable differences in the action of the spectrum, under what are apparently precisely the same circumstances.

Facts like these must, of course, be taken into consideration when comparative experiments are made as to the action of the solar spectrum on different sensitive substances. Such experiments ought to be, if possible, simultaneous, or at least so close together in point of time that variations in the position of the maximum may not be able to produce any effect. Variations of this kind are most noticeable in the case of the violet and ultra-violet rays, and are less often observed in the case of the less refrangible rays, although even there they are not wanting.

Now, as regards the sensitiveness of a substance with respect to any particular coloured rays, its power of absorption plays a very important part. Only those rays act chemically on a substance which are absorbed by that substance. From photographic observations of the spectrum, it is known that the absorbing power of a body is much influenced by the nature of the substance in which it is dissolved, or with which it is incorporated; for instance, carmine and purpurine dissolved in water have a quite different index of absorption to that which they have when dissolved in alcohol. Now, with this change in absorbing power, there is a corresponding change in sensitiveness, so that it is by no means indifferent whether sensitive substances are incorporated with gelatine or with collodion. It is true there are some dye-stuffs whose absorbing power is independent of the solvent (indigotin and methyl-violet dissolved in water or in alcohol are cases in point); but such substances do not form the rule. How great may be, under certain circumstances (not always), the influence of a substance on the sensitive body with which it is mixed, is shown most strongly by my observation that silver chloride and bromide, when stained with certain dyes which absorb red, and also yellow and green light, are sensitive to those otherwise not very actinic rays.

My reasons, therefore, for doubting the correctness of Abney's observation, according to which the maximum of sensitiveness of the chloride, bromide, and iodide of silver does not depend on the medium in which they are suspended, do not appear to be without foundation. Naturally, differences like those which exist between Abney and myself cannot be settled by theory, but only by experiment; I therefore did not hesitate to repeat my former experiments, although I had by me the plates taken during my previous researches.

Equally, of course, in the examination of these plates there is room for differences of opinion. The intensity of a plate generally increases gradually towards the maximum, so that there may be doubt as to its exact position, since the intensity for a certain distance appears to be much the same. In order to obtain certainty on this point, I adopted the plan of exposing spectra for different lengths of time, beginning with an instantaneous exposure. It is also possible under favourable circumstances to obtain only one imprint of the light near the maximum point; besides which I observed the behaviour of the plate during development, since the maximum point comes out first; I also carefully examined finished plates, and among them those which had been over-exposed, in which the maximum point first manifests itself by so-called solarization. Under any circumstances, the position of the maximum point must be determined with great care. Sometimes plates exposed for a shorter time, sometimes those exposed for a longer time, are best fitted for the determination of the maximum point, a circumstance which may be explained by the fact that at the commencement the action remains the same over a tolerably broad strip of the spectrum, and the position of the maximum is only shown by the circumstance that the action near it proceeds more rapidly than in the other parts.*

The following are the preparations with which I carried on my experiments:—

1. *Silver Bromide in Collodion.*—This compound I prepared either by sensitizing in a pure silver bath, collodion plates containing bromide of cadmium or bromide of ammonium, or by adding directly the silver salt to the collodion, thus obtaining an emulsion by the ordinary method, either with an excess of silver, or of soluble bromide salt. The table below shows the results obtained with different durations ef exposure:—

Image Bearer.	Preparation.	Extent of the spectrum.	Maximum.
Alcohol and Ether Collodion	AgBr produced in the silver bath, then washed and dried	438—407	410—434
	Do. do.	443—397	
,,	AgBr emulsion with excess of $AgNO_3$	452—393	410—438
		420—438	420—438
,,	Do. do. of AmBr ...	446—397	408—438
,,	Do. do. of $AmBr+NH_3$	400—452	407—438
Alcohol and glacial acetic acid collodion	Emulsion with excess of Br	446—404	410—430
	Do. do.	455—393	410—430
	Emulsion with precipitated NH_3AgNO_3 16 hours ...	450—397	410—438
	Do. do., ripened	667—390	407—438
,,	Do. do., fresh	446—403	410—438

In order to discover whether the addition of gelatine dissolved in glacial acetic acid, which mixes readily with collodion, produced any effect, I made the experiment, the result being as follows:—

Extent of spectrum ... ... 446—400
Maximum ... ... 410—430

From these results it appears that, in all cases, the maximum action lies between the lines *h* and G, and occasionally a little beyond G; that the action between these two extremes is in general tolerably equal, but perhaps a little stronger than at G; and that the nature of the details as to preparation—that is to say as regards excess of the silver salt or of the alkaline iodide, or employment of different kinds of collodion, or mixing with gelatine—produces no effect on the spectroscopic result; in fact, the image of the spectrum taken on bromide of silver emulsified with collodion is well marked by its own special characteristics.

(To be continued.)

PHOTOGRAPHS MOUNTED ON GLASS.

BY GEORGE BRADFORDE.

There is always something that can be done in a photographic studio during the dullest of times. After the turn of the day, when the air is sharp and the wind keen, when the wayfarer seems to creep further into his clothes,

* I may observe that I had not failed to bring my results to the notice of Captain Abney before I published them. Our correspondence led to an approximation of our views, in that he maintains the position of the maximum in the case of AgBr (nearer to F than to G), only for the direct chemical action without development, and that he draws attention in his drawings (Nos. 30 and 32) to the difference of the position of the maximum on "grey" and on "white" bromide. An exchange of plates between us showed that Abney had in the majority of cases only used two exposures on the same plate, while I had generally taken six or seven spectra on one plate with different durations of exposure in order to arrive correctly at the position of the maximum. Abney's gelatino-bromide and collodio-bromide plates agree with mine, and so do his gelatino-chloride plates; but his collodio-chloride plates differ very considerably.

showing nothing of his physiognomy but a pair of watery eyes and a blue nose, despite the great glare of the spring sun, when the furniture of the studio shows frightfully seedy, then commences the dull season. The curtains and shutters have to be looked to, the show-cases and specimens want changing, the negatives require storing and catalogueing; or, as I have sometimes found it, the dull time will fall upon us like a blessing, thereby giving us time to overtake our negatives after a busy spell, and get them prepared for the printer, uninterupted save by the moist and woe-begone sitter that generally does make his appearence on such unpropitious occasions, thus leading our yahoos to suggest the possibility of their being next of kin to a born idiot.

Still I have found a prolonged dullness come in the spring, when the most industrious photographer, with all his ingenuity, could find no improvement to be made in the studio, and no sitters to improve his finances. It is at such a time that thoughts of reducing the charges take serious hold of one, especially when Jones, in the next street, declares that he was never so busy; that, in fact, if it continued, he must have extra assistance. If you are credulous enough to believe Jones, and foolish enough to reduce your prices, I may safely say, you are next door to ruined, and have played into Jones's hand to a nicety. "Poor Smith!" Jones exclaims to his customers, "doing nothing—forced to reduce his prices—thought it would come to that." And his customers go and tell their friends that they thought so likewise, and Smith, through not being wise as a serpent, finds out the truth of the old adage, "Give a dog a bad name, and hang him."

Smith's best policy, in place of reducing his prices, was to try by some legitimate plan to increase his weekly takings—in short, to raise his price instead of lowering it —to obtain 15s. per dozen in place of 10s. Had he put himself to the trouble to enamel a few specimens and make good use of a plausible tongue, I have no doubt he would have succeeded in every alternate case; and again he could have made use of paper negatives and give a variety of backgrounds, thus inducing the sitter to extend or pay more for his order.

It was such a time as I mention above with us about four years ago, when we saved the ship, so to speak, by bringing a fresh novelty under the notice of our customers; *id est*, mounted photographs upon glass, rendered transparent and coloured on a second glass fitted behind, the result being a marvellously highly-finished miniature. To the uninitiated they appeared to be as patiently worked upon as the very finest miniatures upon ivory; there was no fear of losing the likeness; you could work in any colour of background, but our general picture was a vignette with a delicate blue shading. Full length cabinets of children vignetted, and the colours carefully blended, presented a *tout ensemble* of prettiness and innocence that never failed to charm the hearts of the parents, and helped to fill our empty coffers.

The glass we used was slightly convex, some oval and some square. The ovals suit best for vignettes or single figures; the square for groups or full-length figures. It is best to look out a pair to fit before you proceed to mount your photograph—*i.e.*, see that the second glass that carries the colour fits the first glass, so that it will not lie against the photograph. This being settled, the next step in the *modus operandi* is to get a rather over-printed picture, toned and fixed in the ordinary way, and proceed to mount it upon the glass, face downwards, on the concave side. This can be done with gelatine, or very finely-strained size; but we preferred, for different reasons, a paste composed of two parts starch and one part cornflour. To ensure perfect adherence to the glass, and expel all the superfluous paste, a squeegee must be vigorously and swiftly used, first placing a pad of blotting-paper of two or three thicknesses over the picture. Having seen this important part thoroughly accomplished, you set the picture aside to dry spontaneously, prior to using the medium to render it transparent. There was, and perhaps is, an advertised medium composed of paraffin and white wax; but we could never get them clear or transparent enough by it. If the pictures were allowed the least cold while taking them out of the melted medium, the wax set hard and fast, making it necessary to have another dip. Our medium was refined castor oil. This we warmed in a pan to a little over blood heat (if too hot it will stain the pictures), and then poured it over the pictures as they lay spread out in a porcelain dish, leaving them there to soak over night.

In the morning take them out and rub them clean with a rough cloth, when, if everything has gone right, they will be found to be beautifully transparent and ready for the second glass. To facilitate the applying of the colours. stick them both together top and bottom with a piece of gummed paper, thus the second glass is kept in its place. As you have to use the brush in the same manner as the pencil in retouching by looking through the picture, I believe a retouching desk would be an admirable support while applying the colour; we only used our hands, with a piece of white paper for a reflector on our knees. The colours (oil and turpentine) having produced the desired effect, the second glass can be removed, and the eyes, lips, and hair touched up slightly on the transparent print. I would advise as little as possible of this work, as the oil is apt to make the colour run; still, a little, if carefully done, brightens and sharpens the picture. The next thing to be done is to carefully run strips of gold-beater's skin round the edges of the two glasses, back up with a piece of white cardboard, and they are ready for the case or frame.

With the greatest of ease a smart hand can turn out four cabinet pictures in a day, and about six C.D.V.'s. For the cabinets we received £1 11s. 6d., and for the C.D.Vs. 15s. One word of caution *in re* the applying of the colours. Do not lay them on heavily; the more delicately they are blended the better the result. It is merely a matter of taste whether it is a success or vulgar failure. For the shaded backgrounds of vignettes use your finger in a circular motion, and mix the blue with white so as to give a sunny brightness to the picture, and at the same time help to relieve the image.

OPERATORS' SPECIMENS.

BY "CLIFF."

The question of operators' specimens has been creating no small stir in the photographic world of late. The subject is a vexed one, and well worthy of ventilation. On the one side it is urged that an operator, being paid for his services, has no right to expect prints, as specimens, from the negatives taken by him for his employer. On the contrary, it is stated that very few photographers will engage an operator without previously seeing at least one or two samples of what he can do. One gentleman states that he should have no objection to *lend* prints to his operator; and the question then arises as to what is the liability of the operator in the event of the lent specimens being lost in the post, or dishonestly retained by the person to whom they are sent.

I am personally of opinion that specimens are practically valueless; a little consideration will show what I mean. An advertisement appears in the columns of this journal for a first-class operator, and possibly some twenty or thirty gentlemen out of engagements apply for the vacancy. Now, each of these gentlemen may be used to first-class work, and able to turn out really good pictures; yet their specimens are not approved. Why is this? It is, I take it, owing to the varied idea as to what is, or is not, really first-class work. A picture may be a perfect art gem, and yet the photographer to whom it is sent as a specimen often rejects it, owing to some peculiarity of style, or of lighting, incidental to all the photographs turned out from the studio at which the sender is then operating. The receiver is used to a certain kind of work, possibly equally good as the rejected sample, and yet of a totally different character. In such a case, how much better would it be simply to ask a reference as to abilities, and to give a trial. The chances are ten to one that the applicant, had a trial been afforded, could at once have fallen into the style of work required, instead of receiving one of those politely-worded notes with which we are all so familiar, and which inspire us with much the same feelings as must animate the breast of the would-be poet who receives back his verses marked with the touching legend, "Declined with thanks."

Then, again, as "there are black sheep in every fold," so are there unscrupulous photographic assistants, who do not for an instant hesitate to use specimens with the production of which they personally have had no connection whatever, and, in many cases, gain situations over the heads of far more skilful workmen, who have been honest enough to submit their own work. The head of a well-known firm of portraitists once informed me that he always asked for specimens previous to engaging an operator; but stated, at the same time, that he did not look upon them as samples of the applicant's work, but rather as criterions of his taste in selection; he therefore expected every specimen shown him to be really first class, as he simply judged them as samples of work by various operators, the lighting, posing, and *toute ensemble* of which were considered by the persons showing them to be really first class.

I am firmly of the opinion that the sending of specimens should be given up, and that a reference be given instead, and such being the case, no really efficient operator would object to a trial of his abilities, for once having seen the class and style of work required of him, he is much more likely to give satisfaction. This would compel every man to stand on his own merits. If specimens are sent, they should be accompanied by a written guarantee that they are the applicant's own work, his own posing, his own lighting, &c.

If specimens are asked for, I do not think any employers would object to allowing their operator to have, say, half a dozen prints from negatives taken by him in different styles, or, supposing they did object to give them, surely he might pay for them. Six specimens are, I take it, quite sufficient to submit in any case, and the cost of that number—say two promenades, two cabinets, and two cartes—would not be sufficient to ruin an operator in receipt of any salary worth mentioning. In opposition to this it may be alleged that an operator out of berth does not content himself with answering a single advertisement, and that, therefore, a single set of specimens is not sufficient for him. I think, however, that this is quite a mistake; granted that he answers three or four advertisements, it would be useless sending specimens with the first application. Let him write first and see if the salary he requires is likely to meet with the views of the advertiser, and if he is otherwise suitable for the berth; then, all things being right, let him forward his specimens, with a request that they be returned speedily. Of course there are some persons (as I have pointed out in a previous article) who never think of returning specimens sent them. To quote from a well known play, "I have personally suffered from the depredations of these sharks," and I do not disguise the fact that it is partly owing to this that I so object to the sending of specimens at all.

I have been trying to think of a remedy for this state of things, and the only one I can think of is, after writing and asking for the return of the pictures, if they do not come to hand, the operator might insert an advertisement in the NEWS, something in this style: "Mr. Bromide will feel extremely obliged if Messrs. Nitrate and Chloride will kindly return at once the specimens of his work forwarded to them on the 14th inst." This would be pretty sure to bring back the pictures, and the fear of exposure would prevent others from keeping back photographs to which they have no right.

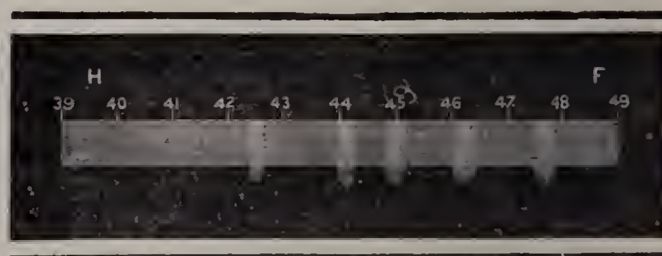
ON THE PHOTOGRAPHIC SPECTRUM OF COMET (WELLS) I., 1882.

BY DR. WILLIAM HUGGINS.*

ON May 31 I obtained a photograph of the spectrum of this comet, with an exposure of one hour and a quarter. On the same plate I took a spectrum of *a* Ursæ majoris for comparison. The comet's spectrum on the plate consists of a strong continuous spectrum extending from about F to a little beyond H. I am not able to distinguish any of the Fraunhofer lines in this continuous spectrum. The slit was rather more open than was the case in photographing the spectrum of the comet of last year; this would make these lines less distinct, but the lines G and H are well seen in the star's spectrum taken under the same conditions. We may therefore conclude that the part of the comet's original light which gives a continuous spectrum is much stronger relatively to the reflected solar light in this comet than was the case in the comet of last year, and for this reason the Fraunhofer lines are not distinguishable.

Observations of the visible spectrum had already shown that the comet differs remarkably from the hydro-carbon type common to all the comets, some twenty, which have appeared since spectrum analysis has been applied to these bodies.

The photographic spectrum shows, as was to be expected, that this essential difference of spectrum exists also in the more refrangible region. The very strong ultra-violet group assigned to



cyanogen is not to be seen on the plate, and the bright groups between G and *h*, and between *h* and H, do not appear to be present.

The head of the comet was in sharp focus upon the slit, and the continuous spectrum with defined edges corresponds to the nucleus which in this comet was very distinct. In this continuous spectrum at least five separate places of greater brightness are seen, which very probably represent groups of bright lines, though they are not sufficiently distinct in the photograph to admit of resolution. That this interpretation is correct, seems probable, from the circumstance that these groups, as shown in the diagram, project beyond the strong continuous spectrum on one side. This side corresponds to where the light of the coma, on the side of the nucleus next the sun, falls upon the slit. We learn, therefore, that the light of this part of the coma consists for the most part in this part of the spectrum of these groups, as here on the plate only an exceedingly faint continuous spectrum can be seen.

It is not possible to measure with any useful accuracy the beginnings and endings of the groups, as they are too faint at these points. Measures as accurate as the circumstances would permit have been taken of the brightest parts of the groups. The wave-lengths of these brightest parts are:—

$$\left.\begin{array}{l}\lambda\ 4253\\ \lambda\ 4412\\ \lambda\ 4507\\ \lambda\ 4634\\ \lambda\ 4769\end{array}\right\}$$

In the visible spectrum the bright lines of sodium appear to have been strong, and it may be that some of the light of some of the groups may be due to this substance.

Prof. A. Herschel and Dr. von Konkoly showed long ago that the spectra of the periodic meteors are different for different swarms, and it does not seem surprising that we have now a comet, the matter of the nucleus of which under the sun's heat

* Substance of note read before the Royal Society, June 15, 1882.

shows an essential chemical difference from the long series of hydrocarbon comets which have appeared since 1864.

Mr. Hind has kindly furnished me with the distance of this comet from the sun at the time the photograph was taken. The comet was then 42,380,000 miles distant from the sun, while the comet of last year was 69,420,000 miles when I obtained the photograph of its spectrum.—*Nature.*

Correspondence.

A DRY-PLATE DEVELOPER.

Sir,—A long experience with the various developers having satisfied me that a simpler and equally satisfactory formula could be devised, after considerable thoughts on the matter, and carefully-made experiments, I have devised the following, the working of which has been pronounced perfection by many. I, however, forward it with the only desire of its being of use to the photographic community, and hope it may prove a boon to my fellow-workers.

To come to the point, the formula simply stands thus:—
In a Winchester, full of rain-water, put—

Sulphite of soda	½ ounce
Citric acid...	30 grains
Bromide of potassium	2 drachms
Liquid ammonia (*forte*)	6 ,,

To develop a quarter-plate, take one ounce of the above, in which put one grain of dry pyrogallic. The picture will develop rapidly, and with full density, at one operation.

With this developer it will be found that all the qualities conferred by the sulphite of soda, as used hitherto, are obtained without any of the drawbacks usually met with, the deep shadows bare glass; in fact, all the appearance and valuable qualities of a wet plate. G. H. Martyn.

ALBUMEN IN EMULSION.

Dear Sir,—I do not find in any directions for making bromo gelatine dry plates any mention of the use of albumen in conjunction with gelatine. Having tried a batch of plates I find it most satisfactory, as it appears to give great cleanliness, freedom from spots, and clearness to the shadows; it also appears to greatly assist the setting, and there is no sign of frilling in those I have made. I do not know if it will affect the keeping qualities, I have not had time to ascertain. If this is any use, I shall be very pleased.—I am, sir, your obedient servant, H. Spink.

PS.—I presume there is albuminate of silver formed. Do you think the sulphur would be injurious in any way?

[We can only, like Mr. Spink, leave it for time and observation to determine.—Ed. P.N.]

THE LIGHT OF THE GLOW-WORM.

Sir,— Seeing your suggestion in this week's News, of trying the effect of the light from a glow-worm upon a gelatine plate, I made the experiment last night. The worm was placed on the reverse side of the plate, in the centre, where it remained stationary for about five minutes; it then walked forwards to the left side, then back into the middle, where it remained some minutes again. I then took it off, and developed the plate, which I send to you. The marks are very distinct. You will observe where it remained stationary in the centre of the plate, and it also shows plainly where it passed over, which proves beyond doubt the action of its phosporescence upon the plate.—Trusting this may interest some, I am, your truly,

A. N. Langdale.

[The curious record of the glow-worm's march which our correspondent sends shows all gradations from the lightest shades, which evidently correspond to its quickest pace, to complete opacity. The two dense patches, which evidently correspond to the resting-places of the worm, show traces of the reversing action of light, as the central portions are not quite opaque.—Ed. P.N.]

Proceedings of Societies.

Bristol and West of England Amateur Photographic Association.

The first excursion meeting this session was held on Saturday, the 17th inst., the place selected being Castle Coombe, Wiltshire. The day opened beautifully fine, and in pleasing contrast to the style of weather which the Society had for its meeting last session.

The majority of the members taking part in the excursion met at Clifton Down Station, and proceeded by the Midland Railway to Bath, where it had been arranged for a brake to be in readiness to convey the party to Castle Coombe, a charming, old-fashioned village about twelve miles from Bath. The first part of the drive was through Somersetshire, and as the brake ascended the somewhat high hills, the beautiful panorama of the valley of the Avon was every moment increasingly laid open to view. With the well-built and clean, though quiet, city of Bath on the one hand, and the large hills (through one of which the Box Tunnel pierces), rich in verdure, on the left, with the river running between the trees, the prospect, when looking back, is very charming, and made a most agreeable commencement to a drive which throughout was thoroughly enjoyed.

At Bath two more of the party were picked up, and, after driving some distance, another member was met, and the party was nearly complete.

After driving some miles a very quaint old cromlech was passed. It was composed of four massive stones, one in each of the counties of Gloucestershire, Somersetshire, and Wiltshire, the fourth being laid on the top of and joining the three others. Although the remainder of the journey was through some fine panoramic scenery, and passed many objects of interest, such as an exceptionally grand cedar, and a very handsome grove of beeches, none of the members "unlimbered" their "traps," preferring to wait till Castle Coombe was reached. This was accomplished about twelve o'clock, and after a call on the vicar (who, like most vicars, was only too pleased to show the beauties of a most interesting old church), and another on Mr. Lowndes, the owner of the beautiful estate at the place, arrangements were made for spreading the contents of a most massive and ponderous luncheon hamper. Mother earth supplied a fit table for such a weighty meal, and the members without an exception commenced to "coat" their interiors, at the same time "cleaning the plates." During this most interesting operation, all the members seemed perfectly agreed that both the "wet" and "dry" processes were indispensable, although some (but very few) persisted in not using the "beer preservative."

Well, the broken plates having been made away with, stray pieces of paper collected and stowed away (for they were not vulgar excursionists), and the fragrant weed lighted up, cameras were "stood" (that is, put on the stands), and work earnestly commenced. The first exposure took place upon a very pleasing view of the quaint old village street, with the river Box and old bridge in the foreground. This made a very good subject, the place being quite a sample of old English villages, there being at the top of the gently inclining road a very old and picturesque cross. After this, some of the party exposed some plates upon a small bridge spanning the trout-inhabited stream. Just outside the village, another general move was made for the most beautiful and picturesque grounds of Mr. Lowndes, through whose kindness the pleasure of access thereto was afforded.

No estate and residence, either for situation, design, or laying out, could be more charming than that of Mr. Lowndes at Castle Coombe. Standing in front of a grand slope, at the top of which are Roman remains, is the finely proportioned and artistically designed mansion, a rich parish around it, with the river Box artificially widened into ornamental water, making a picture of the grounds and house on its surface; from the house to the old church is a private, secluded, and cool drive, and on a slight eminence at the side of the house, and approached by graceful steps, stand the conservatories, &c. All is so richly embedded in verdure, that nature and artifice seem to conspire to make it certainly as delightful a residence as one can easily imagine. It is needless to say that in these grounds the members made many a "shot." But time was rapidly going on, and after the old cross had been subjected to the keen eyes of "rectilinears," the return drive was commenced.

A slight digression was made, the party calling at Colne Vicarage, where the Rev. J. Strutt Bird, one of the members, had kindly prepared tea. Prior to commencing this gentleman's hospitable meal, the church was inspected, and the restoration much admired. Ascent to the belfry was also made, and, with permission, attempts made to get an insight into bell-ringing.

A pleasant half-hour was then spent with the kind host, and, after many mutual good wishes, the party drove off amidst, figuratively speaking, "blue-fire and rockets," and the first shower of the day, which, with the exception of some little wind, had been in every way most enjoyable, the arrival in Bristol taking place at about ten o'clock.

Thursday Evenings for Photographers.

At the meeting held on the 22nd instant, Mr. Shadbolt's balloon picture was exhibited, and provided subject-matter for some discussion. By taking a measurement of the distance between the railway metals, and knowing the focus of the objective used, it became possible to calculate the height of the balloon when the exposure was made, and this was found to be practically identical with the altitude as determined at the time by barometric observation.

Mr. Cowan showed his changing tent or box as arranged for gelatino-bromide work, the compactness and convenience of the arrangement being generally commented on.

Mr. Coles showed negatives which had received about three times the correct exposure, and had been restrained during development by potassium bromide and citrate of soda respectively; the result being especially satisfactory when the last mentioned salt was used.

Talk in the Studio.

On the Determination of Chlorine in presence of Bromine and Iodine.—By G. Vortmann.—MM. C. L. Müller and G. Kircher have recently published in the *Berichte der Deutchen Chemischen Gesellschaft* certain experiments on the behaviour of peroxides with chlorides, bromides, and iodides in presence of free acetic acid. On the faith of these experiments they maintain that the author's method of separating chlorine from bromine and iodine (*Berichte*, xiii., 325) is not trustworthy. A full description of the process appears in the May number of the Vienna *Monat'sheft*, and in the meantime the author seeks to explain how MM. Müller and Kircher have arrived at results differing so widely from his own. As regards the fact that on boiling potassium chloride, lead peroxide, and acetic acid a perceptible escape of chlorine, and consequently a loss of hydrochloric acid, occurs, his observations agree with those of the chemists just named, provided the concentration of the acid exceeds 5 per cent. He has observed, however, that not a trace of potassium chloride is decomposed if acetic acid of only 2 to 3 per cent is used, and the evaporation is conducted upon the water-bath, even when the evaporation is repeated five or six times; under which circumstances potassium iodide is easily decomposed, and potassium bromide less readily, but still in small quantities, completely if the evaporation is repeated two or three times. The same holds good with the action of manganese peroxide acetic acid upon potassium bromide. Whilst acetic acid at 2 or 3 per cent. decomposes potassium iodide in presence of manganese, peroxide very easily the first or second time of evaporation, the same mixture has no action upon potassium bromide, and acetic acid at 10 per cent. must be used to liberate even traces of bromine. The author promises to publish the details of analyses showing that his method is not merely accurate, but in many cases very convenient.—*Berichte der Deutchen Chemischen Gesellschaft.*

M. Charnay's Discovery.—The *World's* correspondent at Mexico reports, May 4, the arrival there of M. Désiré Charnay, bringing photographs of the newly-discovered city on the left bank of the Usamasinta River, in Chiapas, near the frontier of Guatemala. M. Charnay believes this town was built by colonists from Palenque, because the ruins of the temples and houses, the inscriptions on the monuments, the sculpture and ornamentation are identically the same with those in Palenque. The discoverer of this ancient city has named it "Lorillard," in honour of his New York patron.

Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed "Union Bank, Photographic News Co. Account."*

*** We cannot undertake to return rejected communications.

J. T.—Success is very doubtful in such a case, but a prolonged immersion in a weak solution of cyanide will occasionally prove effectual. The tendency to frill may be overcome by mixing the solution with one-fourth of its volume of methylated spirit.

W. O. Clark.—The sensitizing bath is far too weak for the sample of paper in question. Increase the strength to the extent of twenty grains, and add a few drops of carbonate of soda solution. This reagent should be added until a cloudiness is produced which does not disappear on thoroughly stirring the solution. Filter, or allow the solution to settle before using the bath.

Mealy.—The previous answer applies also to your case, as you appear to be using a paper of similar quality.

C. Banfield.—1. It is quite unfit for use at present. 2. About seven shillings per pound. 3. Not unless considerably diluted with water. 4. Any soluble chloride will answer, but the sodium compound is ordinarily used on account of its cheapness. 5. Add about six drops of liquid ammonia to each ounce of water.

Little Nemo.—The theory you suggest appears to us untenable, as there would certainly be no more likehood of sulphide of silver being formed at the points referred to. If the prints were not sufficiently agitated in the wash water, it is quite possible that the hyposulphite may have been less perfectly removed from immediately under the air-bells. Next time you notice the appearance of the air-bells, you might cut the print in two; one portion being washed by gentle displacement of the water, so as not to disturb the bubbles, and the other being thoroughly rinsed. A map of the air-bells should be made for comparison with any faded spots which may ultimately appear. In order to expedite the fading of the experimental prints, they should be placed in a damp cellar.

T. C. Bradshaw.—If you write to Mr. Philip Magnus, of the City and Guilds Institute for the Advancement of Technical Education, Gresham College, London, E.C., you will receive a syllabus giving full details.

A. B. C.—The only institution of the kind is the Photographers' Benevolent Association, 181, Aldersgate Street, London, E.C.

R. Offord.—We have forwarded the letter.

G. G.—1. Prolonged soaking in a strong solution of alum. 2. Full particulars are given on page 133 of our last volume.

A. Read.—That which you mention is quite as good as any in the market.

H. T. Hall.—The incrustation no doubt consists of metallic silver, and it can be readily removed by treating alternately with a solution of iodine in iodide of potassium and a solution of potassium cyanide.

Patience.—1. Certainly not until you set to work in a more systematic manner. 2. The nitrate is to be preferred, as it is much more soluble. 3. It is not intended that you should use a looking-glass, but merely some white surface, as a screen covered with paper.

C. Ovenden.—1. The markings arise from the use of collodion which is too thick, and if you dilute with a mixture of ether and alcohol (rather more ether than alcohol), you will no longer be troubled. 2. The bath is probably alkaline; add one drop of nitric acid to each pint, and try again. 3. It is sold in the druggists' shops under the name of grey powder, and there is every reason to believe that the greater part, if not the whole, of the mercury exists in the metallic state.

J. Mc J.—It was certainly not less than twenty years ago; we will, however, ascertain particulars, and write to you.

John Clement Smith.—Your failure doubtless arises from the carelessness with which you have preserved the solution. When made up it should be completely protected from the air.

S. J. R.—You may regard one part dissolved in eighteen parts of water as a saturated solution.

Charles Bellman.—An article on the subject will probably appear next week.

Simpleton.—Your customer will certainly act very unwisely if he signs such an agreement, as you would then have the power to continually draw him into expensive litigation if he were not in a position to comply with the unreasonable provisions of Clause 6.

Iberian.—1. It is merely a solution of bitumen or mineral pitch in light coal oil, but a small proportion of india-rubber is often added in order to give it toughness. 2. Merely dissolve it in strong alcohol. 3. About sixty grains to each ounce.

Sulphur.—1. Yes; but not just at present. 2. Extremely improbable.

ELECTRIC LIGHTING FROM A PHOTOGRAPHIC POINT OF VIEW.

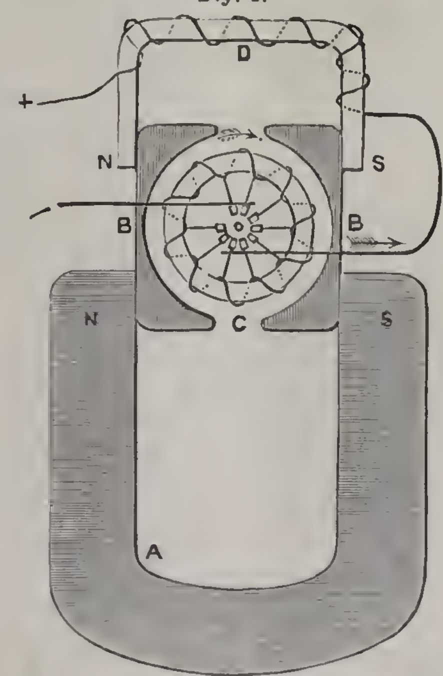
We have, from time to time, laid before our readers particulars of progress in electric lighting as bearing directly or indirectly on the work of the photographer, and nearly a year ago we referred to the Pacinotti machine as having been mainly instrumental in bringing about the present condition of electrical activity. Not only did Professor Pacinotti anticipate, by the construction of his now celebrated machine, the so-called dynamo or regenerative principle, as enunciated seven years afterwards by Siemens and Wheatstone, but he gave to the world the first magneto electric armature in which the magnetic changes are progressive rather than sudden, a condition of affairs which not only enables us to obtain a current of absolute equality and constancy, but also much of the heating which ordinarily results from the quick reversal of magnetism in soft iron is obviated. For these reasons, and more especially on account of the diminished heating of the rotating armature, the Pacinotti machine has been found to be by far more effective than the older machines constructed with the ⊢⊣ armature of Siemens. Although the *Nuovo Cimento*, which contained a description and drawing of the Pacinotti machine, found a place in several of the public libraries of Great Britain, and fell into the hands of most scientific men, it appears that very few appreciated the importance of the invention, and probably not half a dozen models of it were made in this country until M. Gramme constructed the Pacinotti machine on a much larger scale than had been attempted by the original inventor, and called prominent attention to its industrial value. It may interest our readers to know that about fifteen years ago M. Gramme assisted Mr. Woodbury in the arrangement of a magneto apparatus and Lenoir gas engine, used in the production of the electric light for photographic purposes at his premises in Brompton, and after this M. Gramme remained for some time helping Mr. Woodbury in the manufacture of his gelatine reliefs. This was, however, before the commercial advent of the Pacinotti machine.

Gramme, after having devised several new commutators, so far modified the commutator or collector of the Pacinotti machine as to replace the alternately placed strips by parallel conducting rods mounted somewhat like the staves of a barrel or tub; but the experience of more recent times seems to show that Pacinotti's original method of so alternating the strips as to ensure the contact of each brush with two successive studs or strips is preferable, and calculated to reduce sparkling at the commutator. We see a return to Pacinotti's original commutator in the Brush machine, while the Weston machines are made with slightly bent strips, and a similar end is attained by the use of two brushes on each side of the commutator, as exemplified by the Hefner Altneck machines.

In October last we detailed some particulars as to the use of the Swan incandescent lamp for photographic portraiture, and described a number of experiments in which an ordinary or full-sized Swan lamp was used in conjunction with thirty cells of Grove's battery. We mentioned at the time that the lamp could not be satisfactorily worked by a small hand gramme (Pacinotti) machine, with which we tried it. Since the time referred to the smaller, or five-candle, Swan lamps have been introduced into the market, and it was found that the hand-machine in question would work from three to five of these when arranged in parallel circuit; in fact, this was shown not long ago at a meeting of the Society of Arts; while on the occasion of one of Mr. W. H. Preece's juvenile lectures at this institution the same hand-machine was used to generate a current by which more than 500 buttons were electro-plated with silver in a few minutes.

In order to render the machine in question more effectual as an electric generator, we determined to try the effect of a small electro magnet so placed as to form consequent

Fig. 1.



A, compound permanent magnet; B, B, jaw pieces; C, five-inch Pacinotti ring; D, electro magnet. (One of the commutator strips, with its conducting wire, has been omitted from the diagram).

poles with the permanent magnets of the machine, and the result proved so satisfactory that it became possible to produce a sufficiently actinic light for ordinary portraiture by the current produced when the motive power is no more than can be generated by easy turning with one hand.

The diagram (fig. 1) represents, in a manner which will be sufficiently intelligible to any one familiar with electrical matters, the machine with the additional magnet; and the machine in this form may be regarded as standing between a magneto machine and a dynamo machine. Non-electrical readers must understand that the representation of the wire is intended only to indicate the manner of coiling, not the amount used.

The advantages of the arrangement in question will be understood if we point out the way in which a current arises in a dynamo machine. When the armature is turned, a weak current is generated owing to the residual magnetism of the field magnets, and this current circulates round the field magnets in such a direction as to tend to increase their activity. If, however, the resistance in the exterior circuit is very great, it may happen that the intensity of this current is below that minimum which should suffice to induce an amount of magnetism corresponding to the residual magnetism of the soft iron field magnets. In this case the dynamo is practically inactive, as the cumulative principle does not set in. If, however, the speed of the armature is so far accelerated as to bring the intensity of the current above the before-mentioned minimum, the cumulative action will set in; or the machine may be put into full action by temporarily reducing the external resistance. It follows, from the above considerations, that there is a certain external resistance, which will serve to prevent any given dynamo machine from starting into full action for each rate of speed, and this limiting resistance will be higher as the coercive force of the metal of the field-magnets is greater; but, as the coercive force of the field magnets is raised, the machine approximates more and more nearly to a magneto machine, and is so much less serviceable as a pure dynamo or regenerative machine. The apparatus figured above unites in itself the principal advantages of a magneto machine and dynamo machine. When the armature is made to rotate, and the external circuit is left open, a considerable difference of potential arises between the poles, although this is, of course, not so great as would have been the case if the soft iron of the electro-magnet were not so placed as to form a keeper to the permanent magnet; and this initial potential is sufficient to ensure the efficient action of the machine even when a very high resistance is included in the circuit. When a five-candle Swan lamp is placed in circuit, and the machine is turned with the full force of one hand, the lamp is almost immediately destroyed, the thread breaking, and volatilized carbon being deposited on the inside of the bulb; but, by working the machine at a lower rate of speed, any required temperature, from a low red heat, upwards can be readily maintained.

By keeping the carbon thread at a temperature somewhat short of that required for its rapid destruction, a highly actinic and intense light is produced, and this is so effectual as a photographic illuminant, that when the lamp was placed at a distance of four feet from the sitter, a bust portrait was readily obtained with an exposure of from two to three seconds, a 1B lens being employed. Here we have an advance of nearly twenty times, as regards rapidity, on our previous experiments; and instead of thirty cells of Grove's battery, a machine which can be easily turned with one hand is used. Several determinations gave us from 200 to 300 as the candle power of the lamp during the experiment. It will be understood that under these circumstances the incandescent lamp will not remain effective for a very long time; but several experiments indicate that on an average from fifteen to twenty portraits may be made with each five-candle lamp as at present sold. Considering, however, that in most cases the rupture of the thread took place at a weak point, and long before the whole of the filament had become considerably attenuated by the volatilization of carbon, there is every reason to hope that as the manufacture of the lamps is improved, two or three times as many exposures may be reckoned on from each lamp.

At the present time, it is evident, from various estimates which have been made, that the cost of incandescent electric lighting is approximately equal to that of gas lighting; or that the difference is, at any rate, not very great. If it could be made practicable to work incandescent lamps at a high temperature, as in the case of our experiments, the cost of incandescent lighting would immediately fall to about one-fortieth that of gas, as the high incandescence does not require a correspondingly increased comsumption of electric energy. It is, however, difficult to conjecture as to what body, considerably more refractory than carbon, and yet a sufficiently good conductor, we may hope to make available; but problems seemingly more difficult than this have been solved by modern research.

Assuming that the incandescent lamps are finally sold at fifteen pence each, each exposure will cost rather under one penny; but if, at the same time, the durability of the lamp is increased, the cost will be notably lessened.

It must be remembered that the experiments we have described were performed with the small, or five-candle, Swan lamp; but, by using the larger lamp, and a proportionately powerful current, there can be little doubt that still more satisfactory results might be obtained.

Mr. Peter Mawdsley—who was with us when some of our experiments were carried out—suggested that in many cases it might be advantageous to employ a powerful gas light to lower the intensity of the shadows cast by the electric light.

It appears to us that the incandescent lamp, actuated by such a hand Pacinotti machine as we now describe, would form a very suitable arrangement for optical lantern work.

The subjoined cut represents an arrangement which we

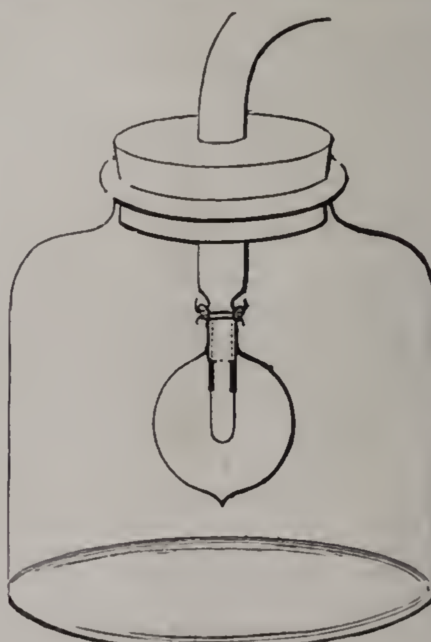


Fig 2.

found convenient for mounting Swan lamps, the conducting wires passing through the cork of a wide mouth bottle. The bottle forms a protection against fragments of glass, should the lamp fly on the powerful current being suddenly passed through it.

The same arrangement would probably be a most convenient one for the non-actinic incandescent lantern, a ruby or orange bottle being employed.

We hope, before long, to be in a position to give our readers some useful information regarding the use of the Planté secondary battery as a means of producing a light for photographic purposes.

SILVER BROMIDE IN GELATINE AND COLLODION EMULSIONS.

Every photographer longs for the day when he can purchase a fluid emulsion as sensitive as our present dry plates, and as convenient to handle as our old friend collodion. It is a problem on which many of our photo-chemists have worked hard and patiently, and none more so than Dr. Vogel, of Berlin. Few, indeed, outside our photo-chemists, appreciate fully the difficulty that lies in the way of securing this panacea. It is a double difficulty, according to our Berlin colleague, and anyone who reads his last researches on the subject, which we here append, will at at once understand its gravity. The blue-sensitive bromide of silver, the form we desire to produce in our plates, can, Dr. Vogel assures us, only be formed in an aqueous solution--not, therefore, in collodion; while, if we proceed to prepare it separately, and then add it to collodion, we are little better off, for gelatine itself enhances the sensitiveness of bromide of silver, as Eder and Vogel have already shown.

But to come to Dr. Vogel's own remarks, which appear in the *Mittheilungen.* He says:—In May last I published an account of various kinds of bromide of silver I had produced. My experiments led me to state that the bromide of silver in gelatine emulsion, which hitherto has been termed green (Abney tells us it is grey by transmitted light), should, by reason of its behaviour under the influence of the spectrum, be called blue-sensitive bromide, because it is most highly sensitive to blue rays. This blue-sensitive bromide of silver, so far as we know at present, is only produced by its precipitation in aqueous solutions in the presence of an excess of an alkaline bromine salt.

Precipitation in a collodion emulsion never produces this particular form of bromide, even after lengthened heating, or adding of ammonia.

Bromide of silver, produced in collodion emulsion by the precipitation of a soluble bromine salt with a silver salt, is of a different character; it is most sensitive to the violet rays, and is thus markedly different from the blue-sensitive bromide of gelatine emulsion.

Whether the violet-sensitive form of bromide can be transformed into the blue-sensitive bromide without the presence of gelatine, I am doubtful; my experiments so far do not seem to point to this conclusion, and for this reason it is that I think the attempts to produce a collodion emulsion as sensitive as a gelatine emulsion will be fruitless. More likely does it appear that the solution of the problem will be brought about by separating the blue-sensitive bromide of silver from gelatine emulsion, and mixing it with collodion. I have already made experiments in this direction, with the view more especially of studying the properties of blue-sensitive bromide of silver apart from gelatine. The separation I effected after the manner that has been described by Dr. Lohse.

The results of my researches have been that I found on adding silver to an emulsion that the most sensitive form of bromide can be formed in the presence of a very minute quantity of gelatine. I took twelve grammes of ammonium bromide and one gramme of gelatine, dissolved these in one hundred grammes of water, and effected the precipitation when warm (temperature 155° Fahr.) with twenty grammes of silver. The resulting bromide of silver emulsion was, after boiling for one-and-a-half hours, divided into two portions; to one half of it was added three grammes of gelatine, and then plates were coated with it, which on development were found to equal the best English plates in sensitiveness. The other half, very poor in gelatine, was treated with ten cubic centimetres of glacial acetic acid, and permitted to stand in a warm locality. In twenty-four hours the bromide of silver was precipitated. In the same fashion, it was treated afterwards with three changes of water to wash it, and finally rinsed with alcohol to remove the last trace of dissolved bromide. The resulting finely-divided silver bromide was of a greenish colour, and closely adherent. To compare it with the ordinary bromide of silver formed in collodion emulsion, some of it was shaken up in a collodion composed of pyroxylin, glacial acetic acid, and alcohol (similar to the collodion in Vogel's emulsion), and in this way a homogeneous emulsion was produced, with which plates were coated. In these films the bromide of silver had preserved all its original character; that is, it was most sensitive to blue rays (wave-lengths about 450). The plates, moreover, were in daylight much more sensitive than ordinary collodion emulsion plates, although they were rather inferior to the gelatine plates prepared with the first half of the emulsion—another proof of the sensitizing action of gelatine itself, which I have before referred to.

The bromide of silver in question separates itself faster from the liquid than the violet-sensitive bromide of ordinary collodion emulsion, a proof of the higher specific gravity of the former.

The difficulty of reducing the bromide in presence of a chemical developer, which I showed to exist in collodio-gelatine emulsion, was also apparent in the collodion mixture. The tendency of the silver bromide particles to adhere together and to form a compact mass was also very marked, and great difficulty was experienced in shaking up the mixture. Moreover, in fixing, a much longer time was necessary to dissolve the bromide in the hyposulphite solution, an operation that lasted half an-hour.

At Home.

PICTURE-MAKING WITH MR. H. P. ROBINSON, AT GWYSANEY HALL, NORTH WALES.

The smock-frock and flapping sun-bonnet, so indicative of English village life, are rapidly disappearing before the advances of railway and school-board, and artists will soon despair of meeting with homely-clad models to give life and light to the sweet scenes of woodland and pasturage that abound in our island. Already the painter has to search deeply for forgotten nooks, where outlying hamlets have not yet been contaminated altogether by the innovations of town life; and he deems himself fortunate indeed if the knee-breeches and cotton night-cap of past generations are still found in possession of "the oldest inhabitant," and examples of female attire are seen free from vulgar frippery and the suspicion of "town-cut." If the "eye" of a picture is to be a figure, or group of figures, it is necessary to have suitable models, and this holds good, whether the picture-maker is painter or photographer.

Mr. H. P. Robinson's photographs are known to all of us, and they are known, too, as earnest attempts to compete with the painter in making pictures. Compete, perhaps, is scarcely the word, for Mr. Robinson is not so foolish as to suppose he can vie with the accomplished landscape painter; but he strives to produce a picture, by the aid of the camera, which shall please by reason of its art merits, while possessing photographic qualities of value to boot. If he does not produce works in colour, he gives us pictures full of charm, full of meaning, and full of life and beauty. He does not merely search the woods and fields for views, directing his camera at them with what taste and judgment he possesses—he does something more. His aim always is, like that of a painter, to carry out some idea that tells its own story, and how he proceeds to do this we shall try to tell in this brief article.

Mr. Robinson carries a pocket sketch-book. In this is roughly limned any pose he may see, or that may be suggested to him in general observation. Whether it is in the streets, in a room, in the fields, he notes the points of any agreeable pose. The position he observes may not be quite satisfactory, but by altering a few lines in his sketch he can make it so. The figure he sees may be too old or too plain. It matters not; when he selects his model, he can alter this. What he desires is an idea for a picture, and as soon as he perceives one it is noted down.

But he can do more than make rough preliminary sketches of figures in this way; being a photographer, he can pose a model in his studio, and thus proceed further with his study. He arranges his model according to his note-book sketch, and by altering the lighting, changing position and expression, make half-a-dozen different "suggestions" for a picture. The chosen "suggestions" in the form of little silver prints are then put away in the sketch book, and here they remain until the time and opportunity arise for making a picture.

To put the matter quite clear before the reader we have taken one of Mr. Robinson's outline "suggestions" from his pocket sketch book. Here it is.

It is the sketch of a picture to be called "Goodbye." When Mr. Robinson has chosen a spot to his mind, he will pose his models suitably, and realise his picture. Another outline sketch is "A Merry Tale," showing simply half-a-dozen girls sitting down in a woodland path, one narrating, and the others enjoying the narrative. Our readers may soon have an opportunity, in all probability, of seeing how far Mr. Robinson has been successful in the fulfilment of his work in this case. This third sketch, again, is to be executed in a park-like landscape, the picturesque group of figures here shown gathering ferns to be posed in the foreground.

This sketch-book, full of suggestions, is in Mr. Robinson's pocket when we accompany him with a few chosen painter friends to Gwysaney. Gwysaney Hall is a shooting-box of a near relative, Mr. F. H. Gossage, J. P., of Liverpool, and although there is no shooting at this time of the year, there is still plenty to attract, and plenty to enjoy. An old-fashioned stone-built mansion, with queer latticed windows and rough walls tinted red and green with lichens, stands at the top of a green hill, as if on a pedestal. On three sides the solid old mansion is fringed around with the green and black foliage of oak and fir, with blooming rhododendrons, red and pink, with clustering rose bushes, and sweet-scented briars; while on the fourth face you enjoy a clear unbounded view of pasture, lake, and woodland. At your feet stretches a smooth green slope of parkland, across which silver-furred rabbits furtively scamper; stately trees dot the verdant sward here and there, while further contrast is afforded by dense patches of foliage that deck most of the hill-tops with luxuriant greenery. To the right, deep in a shadowed dell, is a silvery pool, haunted by teal and wild duck, while afar in the distance on the left the shining Dee is seen, a broad band of light that can be followed almost to its mouth. The blue Welsh mountains rise far round to the right of the picture across the wooded valleys, while the quaint town of Mold, with its square church tower, is seen through a niche in the brown hills.

Not less attractive is the interior. Wainscoting of shining brown oak is in every room, and quaintly-carved presses and furniture that have lived through centuries. Here, on the first floor, in this oak four-poster—so black and shining, it looks like burnished ebony—the Lord Protector once slept; while tradition says Charles II., whose portrait hangs below, also occupied the same chamber. That there are ancestors frowning from the dark walls need scarcely be stated, any more than the fact that one of the big, dimly-lighted dormitories is invested with mystery, and supposed to be haunted.

Most of the pictures Mr. Robinson exhibited last year at Pall Mall were completed at Gwysaney. "Her Ancestor" was taken in this very room of dark brown panels, where Mr. Robinson has now set up his camera again to get a picture in the Angelica Kaufmann style. Here is both a sketch of his model and a photograph of his model in his pocket-book, and here, too, is the model herself ready dressed for the part she is to play. The picture has been thought out from beginning to end, and in ten minutes from this, it will be taken. Our friend has simply to place the model in its surroundings, to see that his idea is carried out as he projected, and the thing is done.

The room is admirably adapted to his purpose—that is why he has chosen it. At the back of his camera is a big bay window of clear glass, fifteen feet across, that lights the room admirably, while a second smaller window which comes into the picture supplies supplementary light, and adds much to the pictorial effect. The walls are five feet thick where this little window is, so that Mr. Robinson can show you the strongly-lighted embrasure of the casement, without showing the light itself.

He gives an exposure of twenty-five seconds, using, of course, a gelatine plate. It is a 15 by 12 picture, and he employs Dallmeyer's rapid rectilinear. With a quick eye he notes certain shining points in the room, and either removes them or covers them up. "One matter is particularly important," says Mr. Robinson, "in these interiors; you must always see that your base-board is perfectly level."

We note two other points in Mr. Robinson's manipulation. One is that his dark cloth never slips off the camera. Near one edge of the cloth, sewn on to the binding, is a piece of elastic webbing, making a loop through which the lens is slipped when the cloth is thrown over the camera. The cloth is then always in its place. But the elastic band does not alone do this; it fulfils a yet more important function. The employment of very sensitive plates has caused photographers to be very careful of their apparatus, and Mr. Robinson has found that the Waterhouse diaphragms he is using admit light sometimes sufficient to fog his pictures. For this reason he takes care that his dark cloth during exposure shall always cover the slit in the lens above the diaphragm, and this is done effectually by means of the rubber webbing we have alluded to. In response to Mr. Robinson's invitation, we examined his camera when capped, with and without the cloth clasping the lens, and the admission of light was to be remarked at once. We cannot, therefore, too strongly advise photographers to follow Mr. Robinson's example in respect to his dark cloth arrangement.

The other point we noticed was in connection with the withdrawal of the slide when it comes to exposing the plate. Mr. Robinson uses the modern arrangement, whereby the slide is withdrawn bodily, but to be quite sure there shall be no entry of light during the operation, he makes use of a broad velvet sleeve, through which he pulls the slide. By adopting these two precautions he always secures clear and bright negatives with the most sensitive emulsion.

You ought to know so well what you want, and what you mean to do, that when you set up your camera indoors or out-of-doors, there shall be no delay in taking the picture. So thinks Mr. Robinson; and for this reason he goes to work without a camera in the first place. Having certain "suggestions" for pictures in his sketch-book, he looks about him for subjects to help him carry them out. A rustic bridge, a brook, a tangled thicket, a corner in the wood, whatever may be the subject that strikes him, he notes it as a suitable scene or background for a picture. He makes up his mind, in a word, how to carry out the various ideas he may have, and so it comes about that when he takes his camera in hand, he can, accompanied by his attendant models, secure half a dozen good pictures in the course of a still and sunny morning.

Every painter possesses a model wardrobe—not theatrical frippery, but worn garments of unconventional character—and the photographer who would make pictures must needs have the same. The best costumes are those purchased direct from country people "off their backs," so to speak, and there is no artist who has not at some time or other been compelled to bargain for a garment. As we have said, the peasantry in England unfortunately are now-a-days rarely seen in their old-fashioned costumes, and hence, if you desire to compose a picture, whether you are painter or photographer, you must be in the possession of suitable costumes wherewith to clothe your models when you have found them. Mr. Robinson makes use of coffee (an ordinary decoction of it) for tinting many of his white costumes, and rendering them more amenable to photography.

Making photographic pictures is pleasant work, so far as we can judge. The merry models—a troupe of laughing girls in picturesque costumes—run helter-skelter across the park, full of gaiety and fun, now scaling fences, now jumping ditches. Fortunately Mr. Robinson has a liking for lightsome pictures, and if his "merry tale" is not a success, we undertake never to pass another opinion. If there is genuine fun reflected in it—and we believe every spectator will say so—it is because the conception of the picture is not less good than the carrying of it out. There is laughter in all degrees depicted in the picture; it runs right up the scale in the girls' faces, from a smile to a scream.

"Come and see my dark-room," says Mr. Robinson. To change half a dozen 15 by 12 plates at a time, obviously requires some care; but Mr. Robinson does it without the least misgivings in the extemporised laboratory he has here provided. It is a room containing a single table, and having a door that opens into a passage, lighted from end to end, and not with a cross light. There is a double casement in the room, but half of it has been blocked up with thick brown paper, of which Mr. Robinson carries a plentiful supply. The other half of the window, measuring twenty-four inches by eighteen inches, is covered by two thicknesses of ruby fabric. This affords protection enough if the sun is not shining directly on it; in that case another ruby sheet, together with a sheet of yellow paper, are added. "There is nothing like darkness," says Mr. Robinson; "you can then take your time over these big plates, and need not hurry." But it is under the door that the most injurious light is apt to enter, and, to prevent this, our friend makes use of brown paper again. On the threshold he simply lays a piece of this pliant material, so folded that an upright edge one inch in height runs the whole breadth of the doorway. The door shuts against this ridge, and stray daylight is effectually shut out. A strip of brown paper may also be fastened against the door-post, should the precaution be necessary. "Brown paper is one of the most useful articles a travelling photographer can carry," sums up Mr. Robinson.

Working pictures of large dimensions necessarily involves much heavy baggage, and we note as one item that the five dozen plates with which Mr. Robinson has provided himself are contained in a case the weight of which is marked on the outside—1 cwt. 1 qr. 5 lb.

The "By-the-Bye" next week will be "A Tour in the Tyrol with a Camera."

SEASON PHOTOGRAPHY.

BY ALEXANDER BULEY.

It is a remote, out-of-the-way lace indeed, that is not represented by or known to photography; and let the place be ever so much out of the way, although circumstances will not permit of a resident photographer, he is nevertheless a known character, for what place is there having a name that does not know the itinerant photographer?

There is the fashionable watering-place, in which are several establishments fitted up regardless of expense, and where the inhabitants alone ensure a business, leaving out the visitors altogether. Such places are, no doubt, season places, but it is not of such that I intend writing. I have in my mind's eye a place that is very beautiful indeed, and a place that I wish I could do justice to descriptively. It is away from the haunts of men, and, comparatively speaking, is to the general tourist unknown. But out-of-the-way places like this are gradually unearthed, and, what with the railroad and the press, they get more and more known in time. Unlike the fashionable watering place, here you depend entirely upon the visitors for custom, and they are not here to-day and gone to-morrow; it is a little worse—they are here to-day and gone to-day. I have had some experience of the class who get photographed at these places, and it is curious to remark how they treat you as though you and all your belongings were liable to leave the place perhaps an hour after they have driven off. Hence, they say in a very significant manner, "Upon receipt of the photographs I will send you P.O.O." I used to think I ought certainly to have the money first; that I was the stationary party, and they were the fleeting folks, who came from goodness knows where, their addresses being some lodging house at the nearest watering place. As a rule, I have always let them have their own way, and I am glad to say I have lost very little by so doing; my losses being traceable to quite another source.

When I started photography in my quiet season place, I did it with the idea of supplementing my income; so after building a studio, furnishing it, and procuring the necessary apparatus, the next thing to do was to engage an efficient operator, having other work to do myself. How devoutly I wish that all operators were proprietors, and all proprietors able to do their own work!

My first operator I took as a partner, share and share alike. The result was not satisfactory—at all events, not to one of the partners. The hotel, with its beautiful grounds, in which we photographed our groups, pic-nics, &c., was too near, far too near, for the health of my next operator. Then, after two or three years of much worry and little profit, I at last got one who was able, quiet, intelligent, gentlemanly, and a teetotaller: he left me for something much better than photographing. Then I determined to do without one, and take my chance of doing what I could in between whiles. It was here that I realized to the full the benefit and luxury of gelatine dry plates—always ready, never hurrying for fear the plate would spoil, and always knowing that the chances of the group moving were reduced to a minimum through the rapid exposure I could give. The most difficult folks to photograph are those ladies who are everything that art and dress can do to make superb, but who are never less than a certain age. To such the camera is a most uncomfortable detective; it is like the strong-minded party who considers it a duty to speak the truth, the whole truth, and nothing but the truth, in season and out of season. She complains that the photograph makes her look stouter than she is, and goes on to say that up till then she certainly thought she had a neck as well as head and shoulders. What are you to do? You know perfectly well that the photograph is a good one—a good likeness and in good position—and had she been twenty years younger, and with the twenty years of accumulated fat removed, she would have been charmed with it. But you can't tell her so.

Fortunately, all the customers at a season-place are not stout old ladies; there are bevies of beautiful girls, full of fun and frolic, with their attendant swains. And how well they know how to pose themselves. One would almost think that they knew they were beautiful, and had really studied how they looked best. They are a picture now; but will they keep still? Oh, gelatine, I have much to thank thee for! Not that stop, the next size larger, and two out of every three are unconscious that the work is accomplished.

Another group I like to have is the parson and his choir. That group is made up of men and boys, with a few friends thrown in. One reason why I like them so much is because, photographically speaking, they are always so well under control; another is because they always seem to me to enjoy themselves so thoroughly. They are not quite so easy to pose as the pretty girls before mentioned; but that done, they make a happy group. The jolly parson runs and jumps and tumbles with the youngsters, and takes his real pleasure out of the pleasure he gives to them. He has his pet, too. In that curly-headed little chap, posed somewhere between the parson's knees, you recognise him. He was playing leap-frog just now on the green, and making huge efforts to leap over the parson's back, but never succeeding. He, of course, is looking at the camera, his face all wonder and pleasure. There is generally another picture to take of the friends, with the boys left out, so that I look upon the parson and his choir with especial favour. There is not much actual studio work in this season-place, always excepting the servant-girl, who thinks as much of the property chair and the curtain being in the picture as she does of her portrait; and the gentleman who tells you in strict confidence that he will "come up some *night* after milking's over, and have one done something like this here." It is practically all out-door work, mostly done in this romantic garden, with its leafy bowers, its grottoes, its shady walks and sparkling fountains, through all of which a stream meanders, cooling the air around.

There is, however, one other source of work and profit to the season photographer, which is the photographing of drags, tandems, &c. This, of course, has to be done just as they are about to start, and the driver is on his box, whip in hand. This kind of photography is not always of the easiest. In the first place, it cannot be done—as I have said—till they are about to start, when the light is nearly gone. Again, horses just about to *return*, feeling the coachman is on his seat, are impatient to be off, and you must be careful what you are about. Once more, and for the last time, let me praise thee, O gelatine! for my more than friend, those prancing, anxious steeds succumb to thy marvellous power.

SOME NOTES ON THE DEVELOPMENT OF DRY PLATES.

There has been a singular difference of practice between French and English photographers in their treatment and development of dry plates. In the manufacture itself England was certainly first in the field, and dry plates had come into extensive use here long before the Continental photographers had grasped the conveniences and the extraordinary merits of well-prepared gelatino-bromide emulsion.

The photographic profession seems to be singularly prone to a "follow-my-leader" style in conducting their business, and this is illustrated by the manner in which they have, as a body, gone in the groove originally ploughed out, by sticking most pertinaciously to the development of gelatine plates with pyrogallic—pyrogallic in many forms and with many modifications, but still the original, all-powerful pyrogallic. At one time almost all the dry plates used in France were exported by English makers, and it was only the absolute and total failure of our English makers to supply their French clients, as well as their home ones, that threw the French trade, not into the hands of a Frenchman, but into those of an energetic and clever Belgian—to wit, Dr. Von Monckhoven. He, as a sound chemist and thoroughly practical man, soon saw that his account lay in making the development of his dry plates easy to the Frenchman—not only easy, but pleasant. He knew that a French operator does not like staining his fingers, trying his eyes by measuring minute doses of bromide or of liquor ammonia, so in his instructions he boldly threw pyrogallic over altogether, and insisted upon ferrous oxalate, which had just at that time come into vogue in England.

Dr. Von Monckhoven put his French clients into the ferrous oxalate groove, just as our first English makers put their clients into the pyrogallic groove, and both nations have, as a rule, stuck to their respective grooves, the only difference being, that whereas the Frenchman has a process which is simple, easy, and cleanly, the Englishman has adopted one which is neither simple, easy, nor cleanly.

But it may be said, and is said: "Oh, but you have not the power over the negative with ferrous oxalate that you have with pyrogallic; you cannot possibly produce such fine results!" Well, the sayer of these things has probably not seen the splendid work of Walery, of Van Bosch, of Reutlinger, and of hosts of other first-rate photographers, not only in Paris, but in the provinces, and who none of them ever touch pyrogallic.

Everybody knows that the majority of the dry-plate negatives taken up to this time in England are stained. Is the stain an advantage? Does it add anything to the quality of the resulting print? By no means; it is as ugly to look at as it is prejudicial to the progress of business. See how it retards the printing; how much more time and labour—which means money—does it take to get the work out of hand! Why, then, is it used? Simply because we are accustomed to use it, that is all. But English photographers don't like a stained negative, after all, and so the pyrogallic must be tinkered up with something to prevent it staining. Mr. Berkeley finds that sulphite of soda will enable a plate to be developed without stain; so the pyrogallic is still kept on, and sulphite of soda comes in to play its part in the comedy. Many try it, and the diversity of opinion about its merits is not a little remarkable; but it does one thing—it prevents staining; but that does not seem to be certain, as one gentleman found it gave green fog; but, as there seemed to be a concurrence of opinion that the fog was somewhere else, this idea may be put aside. So sulphite of soda is a remedy for yellow stain. But has anybody tried what else it will do? Has anybody pointed out how it slows the development? Let anybody put a plate into his camera, or expose it in his sensitometer, if he has one, and then cut it in two, and remark that, if he develops one-half with the pyro-sulphite formula, and the other half with ferrous oxalate, he will promptly discover that he would be able to develop three plates with the latter whilst he was coaxing up one with the former, and that, in all probability, he would get more detail and good quality with the ferrous oxalate than with the pyrogallic, with a total absence of stain, and have in every way a better result.

"But," we are told, "you have no power over the ferrous oxalate developer." That is entirely a mistake; if your picture is supposed to be over-exposed, a trace of bromide will retard the action of the developer to any extent that may be desired, and give golden opportunities for coaxing a faulty plate into decent printing quality. Still, pyrogallic has its uses; in the competition to supply the market with cheap plates, some makes are very low in price—so low, in fact, that to give good glass, a sufficiently thick coating of bromide of silver, and pay sufficient wages to secure skilful and trained labour, is impossible—that is to say, impossible with any notions of a profit hanging to the transactions. Now as nobody works without some hope of reward in the shape of pounds, shillings, and pence—at least, commercial dry-plate makers do not—there must come some profit from somewhere, and it comes from the difference in cost between cheap and inferior glass, and good glass; it comes out of the saving made by a thin, stinted coating, as against a good and sufficient one; it comes out of the wretched payment made for plates prepared anyhow, and plates prepared by careful hands earning good wages. For cheap plates pyrogallic has its advantages; by its means a thin plate may be coaxed up into something that will pass muster, and if it takes three times as long to print, why it is all in the day's work.

But is the ferrous oxalate development as easy as it is stated to be? A description of the best way to go to work will show that it is simplicity itself. Procure two large common jugs, over the tops put two pieces of common coarse muslin, or strainer, so that they hag into the jug; now put a quantity of neutral potassium oxalate into the one, and a quantity of protosulphate of iron into the other, fill the jugs up with warm water, leave them to get quite cold, and the two are ready for use—take care to have always some undissolved crystals left in the bags. Before commencing to develop, mix a sufficient quantity for the day's work, in the proportion of one part of the iron solution, stirred into four parts of the oxalate.

To develop, simply put the plate into a shallow tray, and send the developer over it at once; the details will soon begin to appear, the plate gradually grow up to density; when sufficient, take it out, raising it with a quill pen pushed under the edge, or a piece of wood cut to an edge, and rinse well under the tap. Then—throw the developer away and commence afresh? By no means! Put another plate into the same developer; it will take a shade longer, because it is impossible to eat one's cake and have it; and equally impossible to use a developer and not take something out of it; but a second and a third plate can be developed in the same solution just as well as only one.

But, to do the thing properly, get a vertical dipping-bath, fill it with ferrous-oxalate developer, and simply put the plates in, one after another. A couple of people, with half-a-dozen baths, could develop about a gross of plates in an hour, and never have a failure. Surely nothing can be more simple and easy than this.

There is one advantage, however, which pyrogallic has over ferrous oxalate, and that is, pyrogallic exercises a tanning influence upon the film, and therefore a film is less likely to frill with pyrogallic than with the oxalate; but this is remedied at once by putting the plate for a minute in Mr. Cowell's solution of—

Alum	2 parts
Citric acid	1 part
Water	10 parts

This will make the film perfectly safe, and eliminate the only possible objection that can be made to this cleanly, easy, and simple method of developing dry plates with the ferrous-oxalate developer.

One other advantage has been nearly overlooked, and that is, that plates developed in this way take the pencil for retouch much more kindly than those developed with pyrogallic; there is a delicate tooth upon them which makes working very easy and pleasant.—*Autotype Notes.*

AN EXHIBITION OF PHOTOGRAPHS IN NEW ZEALAND.

In speaking of the Exhibition at Christchurch, New Zealand, the *Otago Daily Times* thus criticises the photograpic section:—

In this branch of art the exhibits, although not very numerous, comprise a fairly representative collection from different parts of the Colony, and an opportunity is afforded of comparison with the work of two leading Melbourne photographers. Several specimens are also shown from English studios, but these can scarcely be placed on the level of equal criticism with the Colonial productions, seeing that they have for the most part been executed for commercial purposes, and have not received the same amount of finish as has been been bestowed upon the latter class. We allude more particularly to the exhibits of the London Stereoscopic Company, which, although good, are by no means fair average specimens of Home work. It is to be regretted that in so large a building the management has not thought it advisable to set aside a space exclusively for the photographic exhibits, which would in that case be easily available for inspection and comparison. As it is, the idea that has been followed appears rather to be to utilise the various frames for the purpose of decorating any blank space there may be, entirely irrespective of classification. The visitor, in consequence, stumbles unexpectedly upon photographs in the course of his peregrinations, and has probably forgotten whose they were, and what they were like, before the next collection meets his eye in some out-of-the-way corner. It was originally intended to set aside one of the octagons in the New Zealand portion of the building for the reception of photographs; but this idea has not been carried out, only two exhibitors having placed their frames there.

Among the English productions most worthy of attention is an exhaustive series of views by Messrs. F. Frith and Co., of Reigate, Surrey. These are not confined to any particular locality, but include a long list of places and objects of special interest throughout England and the European Continent, and are, as works of art, far and away better than what can be found in nine out of ten of the studios of English landscape photographers. The interiors of many of the most celebrated cathedrals throughout Europe have been reproduced with specially good effect, the arrangement of light in almost every instance being extremely striking. One view, in which Messrs. Frith have been more than ordinarily successful, is the celebrated "Salon d'Apollo in the Louvre," an apartment the gigantic dimensions and elabourate decoration of which will be remembered by many Continental travellers. This, among some hundred specimens of the same class of work, may be singled out as a fair sample of Messrs. Frith at their best.

Amongst the English exhibits may also be mentioned some portraits shown by Mr. H. Chatteris, of Christchurch, from the studio of J. E. Mayall, London and Brighton. These photographs possess the novelty of having been taken by electric light, and are interesting as an example of the utility of this for photographic purposes. It is safe to say that no ordinary spectator would recognize in them any deviation from the usual process. They are soft—perhaps remarkably so—and as distinct as could well be desired. Mr. Chatteris has also specimens of instantaneous photography.

To turn to Colonial productions, we have from Messrs. Lindt and Co., and Tuttle and Co., of Melbourne, excellent collections; the latter sending enough frames to fill an entire bay which has been allotted to them. These consist principally of photographs (boudoir size) of celebrities on the dramatic and operatic stage, and leave very little to be desired in any direction. It is difficult, indeed, comparing their work with that of Messrs. Lindt (which, by the way, is placed in a totally different part of the building), to arrive at any decisive opinion as to their relative merits. The latter show, perhaps, on the whole, greater nicety of finish, and include, moreover, specialities—such as enamelled portraits and specimens of instantaneous photography.

On turning to New Zealand, however, it is but fair to say, without the slightest partiality, that it suffers in no way by comparison with older countries in this particular branch. There is no reason, on reflection, why it should, as the light during a great portion of the year is such as to satisfy the most fastidious artist. For portraits, Messrs. Morris and Frost, of Dunedin; Hemus and Hanna, of Auckland; and P. Schourup, of Christchurch, are the principal exhibitors. Mr. Schourup fills a large case and frame with work that really invites a very lengthy inspection, but where he chiefly commands admiration is in specialities—such as permanent carbon photographs on opal, and in the artistic display of colouring that is made. His are almost the only specimens of coloured photography in the building, but it is safe to say that no one would in any case have succeeded in wresting the palm from him in this respect, had an attempt been made. A careful comparison of the other three exhibitors leaves not much margin for choice, the work of all being excellent. The two frames shown by Mr. Morris, however (which are hung on either side of the entrance arch), have, on the whole, taken precedence in public favour—and deservedly, we think. They show not only softness and depth of tone, but an elaborate finish that is not surpassed, if indeed it is equalled, by any exhibitor in the building. Those sent by Mr. Frost, which are found some distance away in the Auckland octagon, save in this latter item, are by no means unworthy of comparison. They represent the best work that we have seen from his studio, and are certain to meet with favourable attention. A novelty is also on view here in the shape of several portraits enlarged by a new process, in which, considering that this is its first introduction into the Colony, Mr. Frost has been singularly successful. The process, which we cannot profess to have entirely mastered, has the effect of producing an enlargement the exact counterpart of the original, but resembling at the first glance a lithograph rather than a photographic picture.

In the way of landscape photography, a series of good views of the Lake country are sent by Messrs. Hart, Campbell, and Co., of Invercargill; whilst Mr. Burton, whose proficiency is well recognised, has hung in the concert-hall a collection of photographs of the Purakanui cliffs, showing the line of railway completed and when in progress. These, we believe, were executed for the Government, and have received all the skill and attention that always mark Mr. Burton's work.

Notes.

An International Exhibition at Berlin is talked about.

A company of Royal Engineers at Chatham has received orders to hold itself in readiness for service. The men include proficients in photography, telegraphy, lithography, printing, and other technical arts.

The Berlin Photographic Society has followed the example of the Society of Great Britain as regards extra meetings; a series of social Thursday evening assemblies being announced for the Autumn recess.

Mr. Jones, of Plaistow, finds that a very simple method of preventing halation is to rub the back of the plate with glycerine, and then to lay on a piece of black velvet rather smaller than the plate. If this method is as effectual as that of Dr. Fol, there is a decided gain as regards simplicity.

A strange revelation was made in court last week touching a prisoner brought up for sentence. The chief warder of Wandsworth prison stated that the delinquent in question had "refused to allow himself to be photographed, and had been flogged in consequence, in accordance with the prison regulations." If the prison rule now insists upon the photographing of prisoners immediately after conviction in their ordinary attire, it is a very wise one, for such portrait is far more valuable as a record than the regulation picture of a convict in his grey suit, with cropped head and shaven jaw.

There is rarely any difficulty about photographing the prisoner at the end of his punishment. Practically, no man or woman serves full time, but in some cases is permitted freedom many months before the expiration of the sentence. But this indulgence is only granted if the prisoners obey the regulations, and one of these is to the effect that they shall be photographed shortly before release.

That wonderful phenomenon, known as the mirage, is a sort of sea-serpent in the world of science. It appears year after year, and is described with vivid exactness by all who witness it, and yet one never seems to get at the rights of it. Sir David Brewster has described the why and wherefore of the phenomenon; he ascribes it to refraction due to unequal temperature of different atmospheric layers; but it is a thing that must be taken a good deal upon trust. According to *Nature*, Sweden sees more of the phenomenon than we do, whole landscapes, cities, and castles, with moving objects, being sometimes reflected on the sky for hours.

Only last month a mirage of this kind was observed over the lake of Orva. In the heavens were reflected "a number of large and small steamers, as if plying on the lake, and from whose funnels even the smoke could be observed to rise. Later on the scene changed to a landscape, the vessels now taking the form of islands in the lake, covered with more or less vegetation, and at last the mirage dissolved itself in a haze. The phenomenon, which lasted from four to seven o'clock p.m., is said to have furnished a most magnificent spectacle." When somebody has been able to secure a few photographs of the "magnificent spectacle," there will be less incredulity felt on the subject of the mirage.

Speaking of literary *ré-unions* in Paris, the *Daily News* the other day gave some examples of the gossip that goes on, and it is interesting to know that *litterateurs* are looking anxiously towards photography as a ready means of illustrating their works. "You hear," says our contemporary, "the company exchange a lively cross-fire, in which such words as 'Helio-gravure,' 'Photo-gravure,' 'Gillotage,' and 'Woodburytype,' are the smallest projectiles thrown. It is a burning question, for we are to have a charming little pastoral scene of Moreau done for the next annual, and by what process is it to be done?"

When referring to Mr. Grant's Arctic voyage, we mentioned the fact that a circle of Polar observing stations were in course of establishment by various European nations. The arrangements for these are now complete. A few weeks hence a complete ring, consisting of twelve scientific stations, will be formed around the North Pole, and they are to be in operation from August 1st of this year to September 1st of next. The British station is to be established at Fort Rae, on the Great Slave Lake, in British North America, Captain Dawson, R.A., being in command of it.

The observations, which will be strictly carried out through all the dark and perishing cold of a Polar winter, include Arctic meteorology, magnetism, and astronomy. They will begin simultaneously at all stations, and be carried out on a system agreed upon by all nations taking part in the arduous work. America has stations in Discovery Harbour, where Sir G. Nares wintered in 1875-6, and at the most northern point of Alaska. Russia has established herself in the extreme north of Siberia, where the ill-fated *Jeannette* expedition was found; Austria goes to the north-east of Iceland; Denmark to Greenland; Holland to North West Siberia; Sweden to Spitzbergen; Norway to North Cape; and Germany to Davis' Straits.

It is pleasant at a moment like this, when many of us are preparing camera and dry plates for a tour on the Continent, to learn that in Belgium, at least, travelling Britons enjoy a better character than formerly. Englishmen used to be so wrapped up in their country that they could do nothing but breathe England, think England, and talk England. Our contemporary, the *Bulletin de l'Association Belge*, seems to bear testimony to the contrary; they never do it now

But then, it is only fair to say, he is delighted with all the world, and has an idea that a Belgian may well pass for a Frenchman, since the former does not think and talk Belgium on his travels. In a word, he would have us believe there are no such beings as Cockneys now-a-days beneath or beyond Bow Bells.

It is suggested that photographers should utilize their old hyposulphite baths for cleaning tarnished silver or plated articles; mere immersion and friction with a cloth being required, while the old bath is made richer in silver at the same time. The use of an old cyanide bath for a similar purpose is objectionable on account of its poisonous qualities.

Mr. Charles Watkins, whose portraits of theatrical celebrities especially, have made his name a household world for a score of years past, died on Monday in last week after a two months' illness. Mr. Watkin's work was always well done, and it is not so long ago that a negative of the Prince of Wales in Masonic costume, he had taken, was sold to Messrs. Marion and Co. for £180, and this, too, after a large number of impressions had been taken from it. Mr. Charles Watkins was more known in the theatrical world than among photographers; but he was "good company" everywhere, and won troops of friends by his amiable, light-hearted bearing.

Magnetical observations will soon be resumed at the Paris Observatory in subterranean chambers which have been, says *Nature*, excavated in the newly-annexed grounds. These observations will be self-registering by photography, in conformity with the instruments established by M. Mascart at the Collège de France. Direct observations will also be conducted with the old instruments which were used by Arago, which were famous for his prognostications of Auroræ, at a period when, the electric telegraph not having been invented, many days elapsed before the arrival in Paris of news from the northern parts of Europe.

Opinions are rapidly changing on the subject of photographing paintings. Mr. Bingham, who was one of the cleverest men in this most difficult branch of photography, was compelled to migrate to Paris some years ago for the simple reason that there was no work for him to do in this country. Fifteen years ago an exhibitor at the Royal Academy would not permit his picture to be photographed under any circumstances; now there is scarcely a painting on the walls that is not reproduced by photography. According to *Truth*, the principal pictures in the gallery at Buckingham Palace (where there is one of the choicest collections of Dutch paintings in the world) are about to be photographed by the representatives of a Berlin firm, who have obtained permission from the Queen through the good offices of the German Crown Princess.

There is a project for attaching to each of our Coastguard stations and light-ships a few carrier pigeons, or rather homing pigeons—for the so-called carrier is an impostor, and could not fly a dozen miles to save its life—for the purpose of conveying intelligence in times of danger. In France, homing pigeons have been a Government institution ever since the siege of Paris, when they carried the micro-photographic despatches out of the capital so successfully. Indeed, if "pigeon conveyance" is to be established by Government in this country, it would be well for our Post Office to learn something about the preparation of these micro-photographic despatches as well; knowledge might prove useful one of these days.

Photographs upou porcelain! Sleeve-links eight shillings a pair; pipe-bowls, five shillings; serviette rings, five shillings; tombstone plates with suitable inscription and initials in black and gold, by agreement; beer glass tops, five shillings; ash-trays, five shillings; card baskets, five shillings; letter-weights, nine shillings, &c., &c. Thus, in the price-list of an energetic firm in Frankfort which seems to provide photographers with everything, from lessons in the art of retouching, to Mr. Woodbury's luminous photographs.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

Conclusion.

In conclusion we have but little to say. We have endeavoured in our "lessons" to give as clear and as practical instructions in the various manipulations connected with negative making and printing as possible. It must be understood, however, that few rules or instructions appertaining to photography are absolute; they are all varied by circumstances. All that can be done by written instructions is to guide the intelligence of the beginner. When he ceases to be a beginner, he should depend on his own intelligence and faculty of observation more than on any instructions.

Let the beginner not be discouraged by failure. Failures he is certain to have. Even the most experienced fail occasionally, the majority more ofteu than they are willing to allow; and if they do not always succeed, it is unreasonable for the tyro to expect to do so. Nevertheless, he should aim at perfection, and should not be satisfied till he reach it. Let him remember that at least in landscape work no amateur need despair of reaching the highest degree of perfection. Amateurs and professionals compete continually against each other, and the former as often as not carry off the palm.

The young photographer should, from the first, exercise his faculty of observation, and note the most minute departure from received rules. There are few departments of science in which there is so wide a field for investigation as in that of photography, and even the veriest tyro, if he observe closely, may add his mite to the mass of knowledge, which has been built up, for the most part, of such mites of observation freely given to "the brotherhood" by those who have made them. Frequently, a fact noticed by one comparatively inexperienced in photography may give the hint to a more experienced investigator, who may make good use of it.

Another thing to be impressed on photographers is that they should not fear to give others the benefit of their observations merely because it is possible that similar observations have been made before. It is sufficient that a fact is not generally known or appreciated to justify its publication, and the oftener it is published until it is appreciated, the better.

We have before remarked that, if the beginner can get the help of a photographic friend, he will find his first labours much lightened. We would now urge upon him that, whenever he has begun to feel his way, he should, if possible, join one of the numerous photographic societies which there are in the country. Let him not suppose that he will meet with ridicule or contempt on account of his comparative ignorance. We were for some time ourselves deterred from joining a photographic society for such a reason; but, on attending the first meeting, all our fears were dissipated. The terrible "professional" whom we had dreaded to meet we found to be a most kindly individual, willing—nay, apparently anxious—to give what aid he could to anyone who asked advice or assistance from him. In this respect we believe photographers are different and superior to most other professional men. An amateur architect, or engineer, or doctor would by no means meet with the same kindly reception from professionals at the gatherings of their societies that the amateur photographer does at the gatherings of societies composed chiefly of professional photographers.

Finally, we repeat our advice, that the reader, while he is still unfamiliar with the various manipulations, follow to the letter our instructions; but that when he begins to feel his way, he trust to his own intelligence as his great guide. If he do so, we are sure that from the time the first succeeds in producing by development *something* on his plate, till the time when he has arrived at such perfection that he need not hesitate to hang his pictures on the walls at photographic exhibitions side by side with those of the first photographers of the day, he will feel that every step in advance which he makes is a triumph, and will find his work—or play, as he likes to consider it—a more absorbing and delightful one than almost any other that he could have taken up.

Let him bear in mind that every operation is but a means to an end (the end being the picture), and that *any* means that conduces to the end is permissible.

We would fain carry him on to more advanced branches of the art-science; we would with pleasure instruct him in the various methods of producing permanent prints, and in the delicate manipulation of vignetting and combination printing from two or more negatives; in the mysteries of enlarging, and in the thousand and one various manners in which the end—a picture—may be produced from the photographic beginning—a negative; but such is without our limits, and we recommend those who wish to go deeply into the matter to read diligently any of the several excellent and complete manuals or text-books on photography which exist.

We believe that we have filled a little gap in photographic literature—that we have produced the first set of instructions for working modern dry plates which presupposed no knowledge of any other photographic process.

ODD JOBS.

BY THE AUTHOR OF "LOOKING BACK."

No. 10.—A Grave Subject.

What is it that has not been photographed? From a lamp-post to a love-letter; from a spirit fresh from the unknown world to the great sea serpent; from a housemaid's broom to a three-masted ship—all have had their turn before the camera. Lions and horses on the rampage; trains going like greased lightning; obstreperous convicts; "found drowned" and corpses in private life by the thousand. The latter is the craze that astonishes me. It shows as deep a morbid hankering, in my estimation, as those who travel miles to look at a house where a murder has been committed, and go away happy if they can secure a bit of plaster or a chip of brick off the ill-fated house. How the relatives can bear to look upon these photographs I cannot understand, unless they have a peculiar love for the horrible. For my part I cannot see the necessity of photographing the dead at all. If the departed were truly beloved, nothing that may happen in this world can ever efface the dear features from the mind's eye: it needs not a cold, crude photograph representing the last dreary stage of humanity to recal those lineaments. Indeed, I should imagine it would in time lead to the forgetting of the pleasant smile or the lightsome laugh, and supply, in place, a ghoul-like resemblance of anything but a pleasant nature. Then look what cold blankets these photographs prove! If a pleasant party is assembled and the family album produced, just observe how the fun collapses when one of those buried subjects turns up! Do what you like, the rest of the evening has a shadow on it. Perhaps they serve the same purpose now as the mummy did at the Egyptian feasts, but——yes! we would rather not, thank you!

There is one kind of photograph in connection with the dead that the most fastidious can find no fault with, and that is, photographing the memorials in God's Acre. That there is something sad even in a tombstone, no one can deny; yet a tasteful design, a touching epitaph, the green sward, the flowers planted by those loving hands, rob the picture of the ghastliness that accrues to the corpse, let it be ever so pleasant, as the Mrs. Gamps and Harrises always declare them to be. Along with other things, I have had my share of work in grave-yards. It is a strange sort of work. I never met with the party yet that did not strongly object to having any of the surrounding tombstones introduced into the picture—no, not a particle of another. They must have it by itself, and show a space around, as if it were a select tomb in the world.

I remember the first tombstone I went to photograph. It had something to do with a family squabble over the tenantry of a farm. What was fun to me might have been death to them; but the spring morning, with its cheering, bracing air, the fresh buds peeping from the hawthorne hedges, and the birds carolling around, made that "grave subject" a holiday for me.

Not long ago I was in Sussex, and received orders to get our dark tent ready, and a dozen 8 by 10 dry plates, and start for the country to photograph the new tomb memorial erected over the remains of the second wife of one of the richest wine merchants in London. Everything being ready, I started alone, as I considered that I could manage such a steady "subject" easily without help. When I was shown the "token of love" placed by the bereaved over the ashes of the dear defunct, I was a little more than astonished. It was of colossal proportions, and all of pure Parian marble. Six angels supported the leaf of the tablet, whereon were inscribed in sorrowful terms the names, births, deaths, and marriages, of his departed spouses, intermingled with quotations from Scripture. Above this tablet rose a splendid draped figure of a female, her left hand hanging by her side, and grasping a scroll with the warning words inlaid in gold, "*Tempus fugit!*" while with her right hand she pointed to Heaven.

There was no doubt this wine merchant had put up a splendid advertisement. On one side was a dark cypress; behind was one of those blood-red weeping willows. I saw that I could make nothing worthy of it until the sun had two hours passed the meridian, so I thought I would have a look through the churchyard.

It is a curious place to find fun in; yet, in a queer corner, I found a dark grey stone in wonderful preservation, that made me at once turn back for my camera. In the corner where this stone was, the grass grew over a foot in length. I had to go and stamp it down so as to get all the inscription. I had to pick off the moss and the green fungi. I exposed a dry plate two seconds, and, singular to say, some of the words I could not make out upon the stone, I was able to make out distinctly on the plate: the plate is thin, and unless very carefully printed, gives a hideously black print. I have often remarked how much detail a dry plate will show when held against tissue paper, looking for all the world as if it would make a print that nothing could equal, and when put to the test, the fine detail disappears, and the deceptive thing gives you a black and white result that is really most galling. This grey stone was in memory of a "John Stone, aged 70," and the epitaph ran as follows :—

"My sledge and hammer lie reclined ;
My bellows, too, have lost their wind,
My fire extinct, my forge decayed,
And in the dust my vice is laid.
My coals are spent, my iron gone,
My nails are driven, my work is done."

Not bad for a village blacksmith !

By-and-bye I returned to study the light on the "job" I had come upon. I sometimes take a pipe when I am at out-door work, and, feeling so inclined, I thought I could not do better than to light up ; so, seating myself upon a flat tombstone, I puffed and stared at the dazzling monument, until I was fain to wheel myself round to ease my eyes. When I did so, I found that I was facing a part laid off for children. The nearest of these little mounds to me had a small dome-shaped black board, with white letters upon it. For some time I could not make out the letters, the glancing of the sun upon the £1,000 worth of marble having dazzled my eyes. At last I made out the two simple words—"Little Johnnie." I involuntarily glanced back at the marble that marked the spot where the wealthy man's wives lay, and then at the little board under which "Little Johnnie" lay, and asked myself what difference it would make to me whether I lay under a canopy of marble, erected through the pride that springs from a full purse, or a board like "Little Johnnie's," placed there through the love that springs from a full heart. Yes, a great difference, and, foolish-like, I chose the latter.

I exposed three plates upon the grand sarcophagus three seconds, six seconds, and eight seconds. The first plate brought forth the details in the tombstone, the feathers in the angels' wings, the inscription on the tablature, and the light and shade on the great figure, splendidly ; but the surroundings were a blank. The next was better as regarded the foliage, and worse as regarded the marble. The third was the one printed from, and, like almost every other subject we may have with a great contrast, it had to be dodged in the printing.

I may mention that I had a row with the wine merchant over his wives' grave ; he very unceremoniously gave me a box on the ear for not dusting the base stone before commencing operations. Mr. Editor, you have never seen me in the flesh to my knowledge, but you have sundry pictures of me that may lead you to suppose that I would not even take a Xmas box without giving one in return, so you will not be astonished to hear that the wine merchant in a very short time regretted his hastiness. He never mentioned the circumstance, and gave a good order. So much for my "grave subject."

HISTORICAL NOTICE OF THE ORIGIN AND PROGRESS OF THE COLLODIO-BROMIDE PROCESS.

BY B. J. SAYCE.*

Some months ago our Hon. Secretary suggested that an exhibition of early work in collodio-bromide might be of interest to those who have only within recent years joined the ranks of amateur photographers. Circumstances then prevented my complying with his request ; but I trust this evening to place before you what will show the progressive stages of the now-called "emulsion process" with collodion, but for which, to convey an idea of its principles, I coined the word "collodio-bromide" in my first description of the process. Before going directly to the subject indicated in the notice convening this meeting, let me briefly trace back to nearly thirty years ago—when I, as a boy, made my first essay in photography.

There were in 1853 amateurs who, notwithstanding the introduction of collodion by Archer, were actually working the slow waxed process, and others who showed the best results, and excellent they were (for especially may be mentioned Mr. Carr's fine collection of Roman views), who employed the albumen process, which, though slow and troublesome to work, is, nevertheless, very hard to beat for gradation of effect, but will scarcely comply with our present demand that photographs shall show life and atmosphere. In producing these it is, or ought to be, our endeavour that they shall not be artificial ; but in this respect our old friend albumen signally failed, for the skies were represented by white paper, the negatives at that point being painted over, and cloud negatives had not come into fashion to furnish effects which might, perchance, belong to lands other than that in which the picture was taken. We have most of us seen photographic prints in which skies, utterly foreign to the subject, have made an imposing show, but have been untrue to nature.

Professional photographers in 1853 were still working the Daguerreotype process, at a charge from one guinea and upwards per impression ; but among amateurs there are those who are ever to the front of the march of improvement, and these began to take an interest in Archer's discovery. Good work was done in the production of collodion negatives a generation ago, but beginners, as a rule, were satisfied with what were then, and perhaps are now, called "positives," but which were really only weak negatives backed up with black varnish.

Before dismissing this topic I will ask you to notice a print from a waxed-paper negative taken earlier than 1853 by Mr. George Thomas, and a print from a collodion negative of the year 1853, now on the table. I well remember that in the spring of that year (stocked with a quarter-plate sliding-box camera, a portrait lens, and a single slide) my first plate was sensitized. Mark well, that prior to collodion, all sensitized surfaces were *dry*, namely Daguerrotype, calotype, and albumen. After collodion appeared we had plates covered with preservative to keep a short time, but yet to be used *moist*—for example, the "honey process," which, if my memory does not play me false, was the method by which Mr. Maxwell Lyte took an impression of a moving figure somewhere about 1853.

We had soon a gallant band of amateurs who produced rapid and excellent results on dry plates prepared with collodion containing a grain or so of resin to the ounce—a very simple and reliable formula requiring no preservative. Those who were members of the Liverpool Photographic Society, from which we are an offshoot, made a reputation in this branch in days when the manufacture of everything but the paper and the glass was compulsory, and the work of him who would follow photography. Let me mention the names of Mr. Jones and Mr. Dutton (of Birkenhead), Mr. J. A. Forrest, Mr. John Glover, Dr. Cauty, Mr. Berry and Mr. Corey (of Liverpool), as belonging to that little regiment of our pioneers in dry-plate collodion photography, and then arrive at my subject proper.

My first hand-book informed me that the sensitive surface was iodide of silver. Now, I happen to know that this substance could be produced *without* the intervention of an iodised collodion and a nitrate of silver bath, and it appeared to me, when I sensitized my first plate in this manner, that the means of arriving at the sensitive surface were more troublesome and dirty than need be, and that the result necessary ought to be more simply accomplished. I mentioned my ideas to a friend (a chemist of experience), and he said :—"You can't do it ; the iodide cannot be held by the collodion sufficiently long to coat a plate evenly." I accepted his verdict as that of a senior, and worked through those troubles with a bath under which many have broken down, until I had come to regard it as a good friend, if managed rightly, but as one of a peculiar disposition which required constant humouring.

So attached was I to it that the first paper read before this Society, in this room, was one by myself on the subject of "The Nitrate of Silver Bath," and I praised it as capable of doing its duty—"like a Briton." But we little know what changes are in store for us, and from working with a forty-grain bath and bromo-iodised collodion for dry plates I advanced to sixty grains and *entirely-bromised* collodion.

In this direction, but unknown to each other, were experimenting also Major Russell and the late Mr. John Glover, the first Secretary of this Association. When comparing notes with the latter at our introduction he mentioned that he had got good results with the bromide alone, and that Major Russell and he had been in correspondence on the same subject. We agreed that it was rapid and admirably adapted for foliage. Mr. Glover,

* Read before the Liverpool Amateur Photographic Association.

however, did not pursue it very closely, but Major Russell followed it up and produced his valuable "Appendix" to his work on "The Tannin Process," in which bromised collodion and a strong bath were brought to a workable process.

I place before you a negative of the Channel Fleet in the Mersey, taken in September, 1863, on a bromised collodion dry plate, instantaneous exposure with a Grubb's D single lens, six inches focus and a quarter-inch stop, as showing of what that process was capable.

Perhaps you may have considered that I have been rambling from my text, but such has really not been the case; for it was this very working with bromised collodion which led me to construct the formula by which the first collodio-bromide negative was produced, the print from which is now exhibited.

The idea of making a sensitive collodion cropped up in August, 1864, in a conversation which has been alluded to in an article on "The Origin of Collodio-Bromide," and it suddenly flashed across my mind that, when working with bromide of potassium as a wash to retard development of bromide plates, I had noticed that bromide of silver was much more flocculent and lighter than the iodide, and it occurred to me that it was capable of being suspended in collodion. Suspension of the iodide had been attempted some time previously, and for this I believe a patent had actually been applied for, but was abandoned as impracticable.

Referring to the tables for the combining equivalents of bromides of cadmium and ammonium with nitrate of silver, I wrote out the formula by which the first negative was taken. This you will find in my note-book as :—

Ether and alcohol, each	½ ounce
Pyroxyline	2 grains
Bromide	3 ,,
Nitrate of silver	4 ,,

I had been using a collodion containing six grains of pyroxyline for my sixty-grain bath, but I thought it would be necessary to reduce this to facilitate the flowing of the emulsion, and you will see that, compared with my later formulæ, the quantity of bromide of silver was also kept low, and for the same reason.

The first negative was taken on Saturday, September 3, 1864, with emulsion prepared August 31, 1864. The press copy letter book (which I exhibit), contains the impression of the letter addressed by me, on September 6, 1864, to Mr. J. Traill Taylor, on handing him the first print in illustration of my article on "Photography Without a Nitrate of Silver Bath," signed by B. J. Sayce and W. B. Bolton.

The second formula was published with my signature only, on September 16, 1864. I show the negative and print alluded to; the negative is marked No. 2. This emulsion contained eight grains of bromide and eight grains of nitrate of silver. It worked cleanly, but was slow. Increasing the bromide and silver I made many experiments, but still worked with little pyroxyline.

The third formula was—

Bromides	6 grains
Silver	8 ,,
Pyroxyline	2 ,,

and the negative and print of the inn and "stocks" at Walton show how it answered.

I finally settled upon an emulsion composed of—

Bromides	8 grains
Nitrate of silver	11 ,,
Pyroxyline	6 ,,

The negatives of Grasmere Church were so produced, and I have been informed that these (which I exposed in the early summer of 1865) gave the stimulus for the first trial of the infant process to members of this Society, which was the cradle of collodio-bromide, and still contains names of those who were its nursing fathers.

The large photographs by our friend, Mr. Osmond R. Green (one of which, the view from Pont-y-pair, Bettws-y-Coed, is now before you), were by the formula of the Grasmere Church negatives.

I will just invite your attention to a 10 by 8 negative taken in July, 1865, during an excursion of this Association to Corwen, on the invitation of its then President, the Rev T. B. Banner; also to a print of the runic cross in Gosforth Churchyard, which was taken on 1st August, 1865. At this period an attack of illness closed my association with collodio-bromide, and separated me, not only from further pursuit of my hobby, but also from meeting in this room with those friends who were always ready to welcome my early efforts with hearty encouragement, which I now most gratefully acknowledge.

Colonel Stuart Wortley soon accelerated the exposure. I venture, with his permission, to show two instantaneous photographs taken on collodio-bromide films. My only approach to the rapidity of wet collodion in this emulsion process was when it was used *wet without preservative* and with *iron development*. I will now show a negative, taken in ten seconds, in June, 1865, under conditions which would have required the same time from a wet plate prepared with the bath.

This ends my connection with emulsion photography, and, with restored health, I welcome the gelatine process, and recognise how great have been the strides since the days when I was more eager to try what *could* be done than to obtain pictures.

INSTANTANEOUS SHUTTERS.

BY CHARLES R. PANCOAST.*

With the introduction of photographic plates having a high degree of sensitiveness, and the consequent desire for rapid exposures, comes the possibility of making pictures of moving objects in such a small space of time as to depict them, as it were, stationary. To do this requires a mechanical contrivance by which the light admitted to the camera through the lens can be controlled.

Having always had a predilection for instantaneous photographs, and having experimented largely with wet collodion with only passable results, I was among the first to employ gelatine plates for this purpose. My first experiments with these were made some two years ago, but not having the proper appliances, were far from satisfactory. They demonstrated to me, conclusively, that in gelatine the instantaneous worker had found a boon. Since then, I have devoted considerable time to the subject, and will give a description of some of the apparatus necessary.

Regarding lenses, I might say that any lens giving good definition and moderate depth of focus, and having stops as large as $f7$ or $f8$ will answer perfectly. My experience has been that for marine views a stop of $f10$ is sufficiently large, while for animal and landscape studies stops of $f7$ and $f8$ are better suited, the ratio between the stops $f7$, $f8$, and $f10$ being as 49, 64, and 100.

Without entering into a discussion as to the proper position in which an instantaneous shutter should be placed, I consider that the best effect will always be obtained where the shutter is situated directly in front of the plate, as then, during the brief time in which the light is acting, the lens can do its full work. Such an arrangement would require an especially constructed camera, and be at once cumbersome and inconvenient.

Of the shutters which are attached directly to the lens, I will make three classes, namely, drop, flap, and rotary.

The simplest of the drop shutters consists in having a slot cut through the lens mounting, directly in front of the stop, in which a piece of sheet metal having the proper shaped opening can pass entirely through. This is open to the objection that, aside from mutilating the lens mounting, there is no way of controlling the exposure. I have constructed a form of drop shutter, which is attached to the front of the lens, and in which I have endeavoured to overcome nearly all the faults inherent to shutters of this class.

This shutter is constructed on the drop principle of Col. Stuart Wortley, and consists of a wooden frame, having at the edges two rabbeted strips, these with the frame forming a groove, in which a hard rubber slide fits neatly, yet sufficiently loose to move with perfect freedom. At one end of the frame is a circular aperture, equal in diameter to that of the lens. A wooden block attached to this frame, and fitted with a set screw, clamps the shutter to the lens.

At one side of the frame is a lever, one end of which being pivoted to it, the other engages on a pin in the slide. Near its fixed end is attached a spiral spring which, acting through the lever, gives the slide the requisite impetus, depending on the tension of the spring.

At the bottom of the frame are two springs, one of which takes up the jar of the slide, and the other automatically locks it, to prevent any rebound.

To afford a quick and certain method of releasing the shutter, a pneumatic trigger is provided, consisting of a brass case, in which is a flexible rubber diaphragm. A small rubber tube connects this case with a rubber ball; this, on being compressed, forces the diaphragm against a lever, which frees the sliding shutter.

* Read before the Photographic Society of Philadelphia.

This pneumatic arrangement is made in a careful manner, and so very sensitive that the slightest pressure suffices to make the exposure.

From the description of this shutter it will be seen that it is adapted to work equally well in either direction, horizontally, or at any angle; the maximum rapidity, however, being attained when it is placed vertically.

In all drop shutters operated by gravity alone, the slide in falling will have a constantly accelerated motion, hence the foreground receives less exposure than the sky. This can be avoided, in a measure, by using a spring to operate the slide, which will gradually lessen in strength as the slide moves. In many cases it is desirable to shield the sky, especially when cloud effects are wanted. This may be done by an auxiliary sky shade, or having a shutter like the one I have just described, in which the slide has a triangular-shaped opening, and is caused to move horizontally. An ingenious form of shutter described in an English contemporary accomplishes this end in a novel manner, but which has a serious defect in construction which will undoubtedly give rise to a jar at the moment when the lens is wholly uncovered. This apparatus consists of a disk pivoted at one side and connected by a toggle joint to a weight or spring in such a way that the pull of the weight or spring will raise the disk and immediately lower it. The sudden reversal of motion when the disk has attained its maximum height must certainly tend to shake the instrument.

For small lenses, the double-flap shutter designed by Mr. Partridge is one of the most convenient, and in some respects superior to the drop. For stereoscopic work it is without a superior, as both lenses are exposed alike.

Rotary shutters must necessarily be made large and cumbersome, and have, I think, few good qualities in comparison with those before described, although many good results have been obtained with them.

One fact I have noticed which, I think, has an important bearing in making photographs of rapidly moving objects. It is, that where the shutter moves in the same direction as the object, a much sharper picture will be obtained than if it moves at right angles to the line of motion. For this reason a shutter capable of working in any direction is preferable to a simple drop.

The rapidity of an instantaneous exposure is largely dependent on the rate at which the object is moving. This can readily be approximated after a little practice, and enables one to form a better idea of what exposure will be required. As a rule, it will be found that so-called instantaneous exposures will range from $\frac{1}{10}$ to $\frac{1}{60}$ of a second.

For example, the image of a vessel moving at the rate of 10 miles per hour, at a distance of 500 feet from the camera, would, in the $\frac{1}{40}$ part of a second, have moved about $\frac{1}{200}$ of an inch on the ground glass (supposing the lens to have a focal length of 8 inches). This would be sharp enough for all practical purposes. If this same vessel was moving at the rate of only 5 miles per hour, then the movement of the image would be $\frac{1}{400}$ of an inch.

As it is very desirable to measure the rapidity of an instantaneous shutter, I have devised a piece of apparatus which will answer the purpose, and give practically correct results. It consists of a revolving disk of white card-board, having a broad black line drawn from the centre to the circumference. Surrounding this disk, but stationary, is a scale graduated in feet and inches. The whole apparatus being placed in a strong light, the disk is made to revolve at a known rate, and a photograph made of it with the shutter whose rapidity is desired. The exact amount of movement will be shown by the line on the disk, which will be blurred for the distance it has travelled during the exposure. For example, a disk having a circumference of 10 feet, being caused to revolve once in a second, would give a point on the periphery a movement of 10 feet per second. If the exposure was $\frac{1}{40}$ part of a second, the black line referred to would be blurred for 3 inches, as shown by the scale.—*Philadelphia Photographer.*

Correspondence.

MORE ABOUT BURETTES.

SIR,—In reading "By-the-Bye" for June 16th, I saw you advocated among other things the use of test-tubes, beakers, burettes, &c. I should like to know that such things could be found in every photographer's chemical room, but I find they are generally more conspicuous by their absence. However, what I more particularly wish to say has reference to the burette as a ready and certain means of ascertaining the amount of silver in any given solutions containing that metal.

Those who have used the "argentometer" for the last quarter of a century will not, I am afraid, be converted to the better and more accurate method you have suggested; but from those who have a less experience there is reason to hope for the adoption of the burette.

I need scarcely point out the advantages of studying applied chemistry, but I would remark that the better acquaintance we have with the chemistry of photography, the less vexation we shall endure; our status (that, we sometimes hear a good deal of) and our work will be much improved.

In describing the method of Gay-Lussac, it should be mentioned that although it is as accurate as any other, if not the most accurate, there are certain precautions necessary, and great care must be exercised in the determination, owing to the heavy character of the precipitate which falls in large clots taking unacted upon silver nitrate within its recesses; also the supernatant liquor will be found to contain both silver nitrate and sodium chloride in suspension.* To obviate these sources of failure the vessel containing the precipitate must be frequently shaken. When no further precipitate is formed upon adding sodium chloride, one drop of the silver nitrate should be added, and the operation repeated until the supernatant liquid is quite clear, and not until then is it safe to take the reading of the burette (see "Thorpe's Quantitative Analysis," page 281).

In Sutton's work on "Volumetrical Analysis," page 190, a method is described as used in photography, thus:—Dissolve 43 grains of pure sodic chloride in 10,000 grains of distilled water. Each decem (=10 grains) of this solution will precipitate 0·125 (*i.e.* $\frac{1}{8}$ grain) of pure silver nitrate; therefore if 1 fluid drachm of any silver solution be taken for examination, the number of decems (or 10 grains) of salt solution required to precipitate all the silver will be the number of grains of silver nitrate in each ounce of the solution. (*Note.*—Sutton proposed using the term decem as an equivalent to the decimal cubic centimetre, 10,000 grains or 1,000 decems being equal to 1 litre or 1,000 cubic centimeters.)

Another method is described by Sutton under the same heading, which in the hands of persons not expert in analysis is more likely to give satisfactory results, viz., the use of the indicator, potassic chromate. It is necessary to have a standard silver solution of the same chemical power as the salt solution; this is made by dissolving 125 grains of neutral silver nitrate in 10,000 grains of distilled water; both solutions will then be equal, volume for volume.

It should be noted that by this method the silver solution to be tested must be previously neutralized with sodic carbonate.

Example:—To 1 drachm of silver solution to be tested, 100 decems (= 1,000 grains) is added, 3 or 4 drops of potassic chromate solution put in, and the silver solution delivered from the burette, until the blood-red colour of silver chromate is just visible. Suppose 25·5 decems have been added, let that number be deducted from the 100 decems of salt solution, 74·5 or 74½ per ounce will be the result.

Perhaps the most suitable method for photographers would be the determination by means of ammonium thiocyanate, using ammonia ferric alum as the indicator. The greatest degree of accuracy may be obtained by this method, using acid solutions, which are more frequently met with in practice than neutral or alkaline.

Instead of using one burette, it will be found more convenient to attach two on a suitable stand. An upright pillar, with a cross-beam, is generally used for the purpose.

* [Our correspondent doubtless alludes to the remarkable circumstance that a stage is sometimes arrived at when either a soluble chloride or silver nitrate will cause turbidity.—ED.]

One burette should be marked "Silver," the other "Thio," to prevent mistakes. Two standard solutions should be made, as recommended by Sutton. The silver solution should be made by dissolving 1·7 grammes of silver nitrate in 100 cubic centimetres of distilled water, the object being to standardize the ammonia thiocyanate solution. There being some difficulty in getting this salt dry, it will be found better in practice to make a larger quantity, and I would suggest that 19·8 grammes be dissolved in 1 litre of distilled water; both solutions will then be decinormal strength. Fill the burette marked "Thio" with the latter solution; run off 10 c.c. silver solution into a clean beaker or other vessel, add 5 drops of dilute nitric acid (1·5), a simliar quantity of a 10 per cent. solution of ammonia ferric alum, then cautiously 10 c.c. from "Thio" burette. If the above solutions are correctly prepared a perfect reaction should have taken place, and upon finally shaking the beaker, there should be a pale pink colour retained. If more or less than 10 cub. cents. have been added, the correction must be made by adding either more of the salt or distilled water. The amount is easily determined by figures. After correction (if necessary), the silver (standard) solution should be run off for future use, and the burette re-charged with the silver solution to be tested, when the operation before mentioned is to be repeated; this time a less quantity may be used, say 5 cub. cents. of silver solution. It will be seen that in standardising the "Thio" solution, each cub. cent. is equal to ·0017 grammes of silver nitrate; therefore, if 5 cub. cents. of solution to be tested require 20 cub. cents. of "Thio," each cub. cent. of silver solution contains ·0068 grammes of silver nitrate, or 6·8 grammes per 100 cub. cents. of solution.

The metric system given here may easily be converted into English weights, if desirable, so the standard solutions may be made in grains, instead of grammes. After Sutton's plan—as given above—I have used this method for negative and positive printing baths with great success, and never found the reading of the argentometer to agree with it. The more work the baths have had, the more startling is the difference; and upon repeating the test on fresh portions of the same solution, I found no variation. In one case, lately, in testing a positive bath, the argentometer indicated 46 grains strength; but the "Thio" test proved $31\frac{33}{100}$ only, or (say) $31\frac{1}{3}$ grains per fluid ounce. In another case the negative bath registered 33 grains per ounce; but, on applying the "Thio" test, it was found to contain very little over 22 grains per fluid ounce of silver nitrate. If any one doubts my assertion, let him procure a pair of burettes, and try the experiment for himself.

W. M. Ashman.

OPERATORS' SPECIMENS.

Dear Sir,—I should most sincerely like to see the matter of operators' specimens settled in some satisfactory manner. At any rate, I think if a few of the operators were permitted to tell their grievances through your paper they would perhaps be better dealt with. I have suffered very sorely from having my specimens kept. I am in one of the first houses of the day, so you can guess my specimens would be good. Twelve months ago I wrote in answer to an advertisment, sent six C.D.V.'s, and photograph of self. My letter was answered asking if I could do out-door work. I sent eight cabinets of groups, &c. (out-door), but never heard any more. I threatened the man, and received no reply. Four times the same year I was served thus, so you can guess how I was fixed—no specimens of work left. The same dealing applies to some of the employers. I have found that unless you get pictures by underhand means, you never can get a specimen to show. Fancy a photographer without a specimen of his own work to look at—no views to put on his own walls. I am willing to pay even full money, but no; an operator must not have such a thing as a photograph. Like the greengrocer, he is supposed to get tired of the fruit by continually stuffing. Once I went out on a holiday, borrowed my employer's camera and stand, bought my own plates, and developed under my employer's nose, using his chemicals, then gave him the negatives, and could not afterwards, for love or money, obtain a print from one out of thirteen negatives cabinet size. Is this not infamous? I have taken negatives I would pay ten shillings to get a print of. Besides, does it not cultivate the mind to see good photographs? How much might a retoucher gain by studying a well-lighted and artistically worked-up head! I have paid two shillings many a time for a London celebrity, when I could have got one of my own equally as good.—Yours truly, W. E.

Proceedings of Societies.

South London Photographic Society.

On Saturday last the first outdoor meeting of the season took place, and was followed by a tea at the "Bull and Bush," Hampstead Heath; nearly two dozen members being present. As is usual on such occasions, but few cameras were brought into the field, it being generally preferred to devote the afternoon to an unencumbered ramble and conversation.

After tea some of the members took a ramble over the Heath, and they found the numerous notices and cautions issued by the Metropolitan Board of Works to constitute by far the most prominent objects; no less than ten of these ugly-looking notice boards being simultaneously visible from one point of sight. Other members joined in such amusements as were provided in the grounds of the "Bull and Bush," quoits and bowls being foremost.

It should be mentioned that Mr. F. A. Bridge, who is now acting as honorary secretary, occupied the chair at the tea, and Mr. Mawdsley occupied the vice chair. Great satisfaction was expressed with respect to the arrangements made by the landlord.

Thursday Evenings for Photographers.

At the meeting held on the 29th ult., Mr. A. Haddon in the chair,

Mr. W. M. Ayres exhibited some very fine enlargements from negatives of the moon, taken by Dr. Common, of Ealing, with Eden's telescope.

Mr. Brown exhibited a quantity of pyrogallic in solution (strength, 1 oz. to 109 ozs. of water), to which citric acid had been added, but without apparently adding to its keeping qualities, as it was much discoloured; he had since added sulphite of soda, but without any apparent effect. He also showed another bottle containing a much more concentrated solution, and to which the sulphite of soda was added when first made; this was not nearly so much discoloured.

Mr. Henderson found that the more concentrated the solution, the better were its keeping properties.

Mr. Brown exhibited the results of a series of experimental trials with various intensifiers; he had tested Dr. Eder's new formula in all three stages, and also Dr. Monckhoven's cyanide of silver formula. The plates had been cut in halves, and one half of each kept from the light, the other halves being exposed to the sun for about three weeks. With Dr. Eder's formula in the first two stages the plates had *darkened*, but in the third or brown stage there was very little change, the exposed portion being very slightly *bleached*. That treated with Dr. Monckhoven's formula had changed, most of it being much darkened.

Mr. Mackie said he had found it very useful, after removing a negative from the developing solution, to slightly rinse and then immerse it in a weak solution of hydrochloric acid, which dissolved out the pyrogallic stain previous to placing it in an alkaline solution of hyposulphite; he had never found plates subjected to this treatment frill, and the hyposulphite solution was kept colourless.

Mr. Debenham said that recently, in moving a plate over a splash of emulsion on the slab while coating, he had noticed a distinct phosphorescent flash caused apparently by the friction.

Mr. Henderson said that Mr. Cobb had called his attention to a number of sparks in an eartheuware jar when stirring emulsion contained therein with a glass rod, and on repeating the experiment in a dark place he had noticed that a large number of the sparks, quite enough to effect an emulsion, were emitted, which he attributed to frictional electricity.

The Chairman thought that the sparks were not caused by electricity, but by the conversion of mechanical energy into heat.

The discussion adjourned from last meeting on varnishes was then resumed.

Mr. Coles said he had washed seed lac till the water was highly coloured, then dissolved separately some of the washed and unwashed lac, and in the resulting varnish could detect very little difference in colour.

Mr. Barker said that if a quart bottle was about half filled with the rough lac, a piece of gum thuss about an inch square being added, and the bottle filled up with alcohol, and the whole allowed to stand for fourteen days, then well shaken up, the soft spongy portion would fall to the bottom, and the varnish might be poured off bright and clear.

This being the last of the Thursday evening meetings (the next being the first of the new association) the Chairman then, on behalf of those who had attended them, presented Mr. Henderson with a chemical balance, as a small token of their esteem, and a souvenir of the many pleasant evenings spent in that room through his hospitality. In a short speech he alluded to the gratifying manner in which photographers had answered to Mr. Henderson's invitations. He might, he said, compare the minds of a certain portion of the photographic fraternity to a super-saturated solution of a salt ready to give up on the introduction of a suitable nucleus the excess over what it ought to contain; Mr. Henderson had in a sense represented that nucleus, and the results had been seen every Thursday evening. He concluded by expressing the hope that the London and Provincial Photographic Association, which was the outcome of these meetings, might prosper and eventually become, as its promoters desired, the most popular photographic society in London.

Mr. Henderson having briefly thanked the subscribers for their kind expressions, the meeting adjourned.

Liverpool Amateur Photographic Association.

The monthly meeting was held at the Free Library, on Thursday, the 29th ult., Mr E. Roberts (President) in the chair.

The minutes of the May meeting having been read and confirmed,

Mr. B. J. Sayce read a paper entitled, "Historical Notice of the Origin and Progress of the Colodio-Bromide Process (see page 395).

Mr. J. A. Forrest, as the oldest photographer in the room, expressed his pleasure in listening to Mr. Sayce's interesting paper, and alluded at some length to Mr. Berry's discoveries with regard to bromide of silver, and to Mr. W. B. Bolton's labours, in conjunction with Mr. Sayce, in the discovery of collodio-bromide emulsion.

Mr. W. H. Wilson, who had been a member of the oldest Liverpool Photographic Society, did not think that Mr. Sayce had ignored the labours of Mr. Berry, in claiming to have inaugurated the use of bromide of silver in emulsions, and said that it should not be forgotten that the merit of the invention of emulsion processes belonged to the Liverpool Amateur Photographic Association.

Mr. H. A. Wharmby remarked that, in 1865, he had procured bromized collodion from Mr. Berry, but had understood from him at the time that it could not be used photographically.

Mr. Forrest said that he had in his possession photographs produced by Mr. Berry with his bromized collodion.

Mr. Wilson thought that iodide was combined with the bromide in the collodion in question.

Mr. Sayce having made some remarks in reply to the criticisms on his paper,

The Hon. Secretary proposed a vote of thanks to Mr. Sayce, for his very valuable and interesting communication to the Society, which was seconded by Dr. Kenyon, and carried unanimously.

The Rev. H. Palmer proposed that the summer meeting on the last Thursday in July should be held at his house at Wallasey, and be preceded by an excursion on the river, with the view of a comparative testing of the usefulness of the various instantaneous exposers in use among the members.

The proposal was carried.

The Hon. Secretary exhibited some negatives, and prints from them, sent by Messrs. Morgan and Co., to show the usefulness of their new adaptation of gelatino-bromide paper to negative purposes. One of the negatives handed round had been waxed; but it was noticed that prints from this did not seem to have the advantage of those from unwaxed negatives. All seemed to be equally good and of the highest excellence.

Mr. J. H. T. Ellerbeck asked if the paper exhibited was the ordinary gelatine emulsion paper supplied by Messrs. Morgan and Co., or some specially prepared for negatives. He (Mr. Ellerbeck) remarked that the idea of transferring the film from the paper to glass for printing purposes had been suggested by him to Messrs. Morgan and Co. many months back, and he hoped that it would eventually be successfully carried out.

Tho Rev. H. J. Palmer said that, unfortunately, Messrs. Morgan and Co. had forwarded no particulars whatever as to their mode of exposure, development, &c., and that, therefore, he could not give any information on these points.

The Hon. Secretary gave a demonstration of the comparative value of various remedies for blistering of gelatine films. A plate coated with decomposed gelatino-bromide emulsion was cut into several portions. One of these was heated to a considerable extent; a second was plunged into a saturated solution of sulphate of magnesia; and a third into a saturated solution of alum. They were then exposed together to the action of the developer for some time. The portion which had been placed in the Epsom salts remained entirely free from frilling; the heated film blistered very slightly in one corner; but the alum-treated portion of the plate seemed to be affected by the evil most of all. A remarkable result was noticeable in the portion of the plate which had been treated with Epsom salts; whereas the other plates speedily discoloured under the action of the developer, this film remained white.

The Hon. Secretary stated that the baking might be used before or after exposure without affecting the sensitiveness of the plate, and that the Epsom salts might be applied with perfect safety between exposure and development.

Dr. Kenyon said that he had tried the saturated solution of Epsom salts with invariable success.

A voto of thanks to the Hon. Secretary was proposed and carried for his invitation to the members to his house for the next summer meeting, and also for his useful demonstration.

Mr. Phillips exhibited a new and very ingenious instantaneous exposer on the ball-and-socket principle, and also a beautifully-made instantaneous shutter for two stereoscopic lenses, slightly different from that exhibited at the last meeting.

Mr. H. Greenwood passed round a print from a negative taken by Mr. Cecil V. Shadbolt from the car of a balloon. This created much interest, as the first successful photograph produced under such circumstances.

Mr. E. Phipps exhibited a fine enlargement on Morgan's paper, and afterwards worked upon it artistically in black and white.

Mr. Sayce furnished a most interesting historical exhibition of negatives and prints in illustration of his paper. Among the most noticeable of his exhibits were the first negative taken by an emulsion process; a magnificent collodio-bromide print, 20 by 15, of the firs at Bettws-y-Coed, taken direct by Mr. O. R. Green; and some instantaneous sea views, taken on collodio-bromide plates years ago, by Colonel Stuart Wortley.

Dr. Kenyon and the Rev. H. J. Palmer showed some fine prints taken at the last excursion to Port Llewyd falls.

The meeting, which was largely attended, then separated.

West Riding of Yorkshire Photographic Society.

The above Society held its first outdoor meeting of the season on the 7th ult., at Ripon, for Fountains Abbey. There was a good muster of members and their lady friends, and a number of cameras, varying in size from quarter-plate to 12 by 10, presented a business-like appearance. Pending the preparation of breakfast at the Unicorn Hotel, several gentlemen exposed plates at the Cathedral from various points of view.

Having partaken of breakfast, conveyances were in waiting to drive to the Abbey. A slight shower of rain falling sufficed to lay the dust and render the drive particularly delightful and exhilarating.

On reaching the Abbey grounds the members at once dispersed, like Dr. Syntax, in "Search of the Picturesque," which fortunately lay all around them. Over a dozen cameras were at once at work, making it a difficult matter to go about without coming in the range of somebody's lens or tumbling over their tripod legs.

The sun shone brightly, the grounds and woods were at their gayest; indeed, a more delightful day it was impossible to imagine. About 130 plates were exposed by the various operators, after which they all met at the lodge, where a group of the whole party was taken, and were driven back to the "Unicorn" for a knife-and-fork tea. After taa an hour or two was passed in looking round the city, and then the party assembled for the return journey.

The excursion was one of the most successful the Society has held, and it was decided to have another in August. A special meeting was arranged for exhibiting the day's work.

BOLTON PHOTOGRAPHIC SOCIETY.

AN out-door meeting was held at Whalley, on Saturday, the 24th June. The first place visited was the Church, where, as soon as the members had got their cameras in position, an individual demanded who had ordered them to photograph that church, and further intimated that "if they did not depart, they might be made to." He, however, finding the party were not very greatly impressed by his authority, finally drawled out the customary whine "to remember the clerk and sexton," and confidentially informed them he was agent for an artist, and had some pictures of the church to sell. It is almost needless to remark they "did not remember either the clerk or sexton." The Abbey was also visited, and afterwards Stronghurst, where Mr. Taylor photographed the members. After a substantial tea at the Aspinall Arms, the party returned by the 8 p.m. train.

Talk in the Studio.

SENSITIZED PAPER.—Mr. Valentine Blanchard has favoured us with a few sheets of his sensitized albumen paper. We employed a lime toning bath for it, which we believe Mr. Blanchard recommends, and were gratified to find the printing was everything that could be desired.

DEATH OF MR. CHARLES WATKINS.—Our readers will be sorry to hear that Mr. Charles Watkins, who attained a deservedly high reputation as a portraitist, died on the 26th ult., at his residence in Camden Town, after a painful illness which extended over a period of more than eight weeks.

THE ELECTRIC LIGHT AT STAFFORD HOUSE.—The Duke of Sutherland has set a good example in adopting the electric light for the illumination of his residence in St. James's. Incandescent lamps on the Lane-Fox system have been installed in the grand staircase, banqueting-hall, and picture gallery, with very fine effect. The lamps have been fitted to the existing brackets and candelabra as far as possible, but additional lustres have been added, especially in the picture gallery. There are some 250 lamps in all, fed by six B Gramme machines, which are excited by the current from one E Gramme machine. The field magnets of the B machines are fed in series; but the revolving rings are coupled in multiple arc. The resistance of the external circuit, plus the lamps, is only 0·6 ohm, the lamps being connected in parallel arc, and leads having a strand conductor equivalent to a solid rod of copper ⅝-in. in diameter being employed. The speed of the machines is about 1,000 turns per minute, and they are driven by a Marshall engine of 20-horse power nominal. All the generating apparatus is located in a shed placed in the garden to the west of the house, and skirting the Green Park. The lamps displace some 8,000 candles, and cannot be injurious to either gilding or statuary. This fact, together with the undoubted sanitary advantages of the incandescent light, cannot fail to hasten its introduction into mansions where valuable works of art are treasured and large assemblages are held. The Duke of Sutherland's example will doubtless soon befollowed.—*Engineering.*

THE OXIDATION OF FERROUS SULPHATE.—E Johanson, writing in the *Analytische Zeitschrift*, points out that ferrous sulphate becomes oxidized all the more readily when the external air is carefully excluded. This phenomenon he explains by assuming that the ferrous sulphate exercises an ozonizing action upon the oxygen of the air, which then reacts so much the more strongly upon the ferrous sulphate the less it is diluted.

THE DETECTION OF FUSEL OIL IN ALCOHOL.—A. Jorissen adds 10 drops of colourless aniline oil and 2 to 3 drops of hydrochloric acid to 10 cub. cents. of the alcohol to be tested, when a red colouration is indicative of the presence of fusel oil.

A SIMPLE INCANDESCENT LAMP.—"La lampe soleil," or the sun lamp, as it is called, from the likeness of its rays to solar light, was successfully tried on Saturday last in the vaults of the Royal Exchange. This lamp is the invention of MM. Clerc and Bureau, of Brussels, and is so simple in its action as to require no regulating mechanism. It consists of a square block of marble or dry limestone, having two holes pierced into it from above. The holes slant together until they nearly meet just within the base of the block. Into these holes are inserted the two carbon rods forming the poles of the arc, and the current traversing the partition of calcareous stone between their points heats it to incandescence, and thus a soft white light is emitted from the bottom of the block. This light is remarkably steady, and is very suitable for picture galleries. It was used to light the picture gallery in the recent Paris Electrical Exhibition, and is now employed in the foyer of the Grand Opera House, Paris. The limestone is calcined by the current, and the carbons feed themselves by gravity as they are consumed. The ugly shape of the lamp is certainly against its use, unless it be sufficiently well screened from view, but its simplicity is decidedly in its favour.—*Nature.*

To Correspondents.

STUDIOS.—The "Photographic Studios of Europe" will be published in German by Ed. Liesegang, of Düsseldorf.

BRIGHTON.—We are very glad to hear you say so.

B. B.—Take the stains out with a little iodine solution, dissolving a few flakes of iodine in a solution of iodide of potassium. After applying this to the fabric, rub with hyposulphite of soda solution, and the spots will disappear.

PINCHBEC.—Abney's new work on Emulsions includes everything you are likely to want.

ALPHA.—1. We cannot answer. 2. The sulpho-pyrogallol sold by the Platinotype Company.

TRIPPER.—Next week. We shall commence with the Tyrol, and then proceed with the others.

H. W. F.—There is a retouching school in Leipsic, and one is forming in Berlin, but we know of none in France. If either of the former would suit, we can send you particulars. Three months' tuition should be ample if you have previous knowledge.

HOPEFUL.—We have no doubt that the patches arise from the local presence of hyposulphite, either arising from contact with dirty fingers or other contaminated objects.

J. BRICKSON.—You might write to Messrs. Johnson and Matthey, of Hatton Garden.

J. W. BARRY.—When ice can be obtained, it is by far the cheapest and most convenient refrigerating agent; but when ice cannot be obtained, the following may be used:—*Powder No.* 1.—1 part powdered sal. ammoniac, 2 parts powdered nitre. *Powder No.* 2.—Ordinary crystallized washing soda reduced to a coarse powder. No. 2 powder should be kept in a well closed tin, and when a freezing mixture is required, equal bulks of the powders are mixed and dissolved in a volume of water about equal to the bulk of the powders.

CONSTANT READER.—The details have not been published.

GROSVENOR.—Exposure for a few hours to the temperature referred will do no mischief, provided that no great amount of moisture is present; but our experience does not extend so far as to say what would be the result if the action of heat were continued for a prolonged period.

H. ORTON.—1. The glass plates should be ground by working two of them together with fine emery and water between. 2. No; use tin foil. 3. An ordinary camel's-hair brush. 4. Without, by all means. 5. You can get it made at any large India-rubber works.

JOE.—Use a stronger bath, or less iodizer in the collodion.

W. BRADNEE.—Such pictures copy better than one would expect, and experience has shown that it is best not to attempt to revive the image.

J. C. J.—Although we know of several who practise it as a business, we cannot say with certainty that there is anyone prepared to give instruction. We post you some notices which may help you in finding what you require.

W. E. D. JONES.—1. No. 2. Very slightly damp. 3. So much depends on the condition of the coating that it is impossible to fix any definite period, but one corner might be cautiously lifted from time to time. 4. About one part in ten parts of water. 5. Yes, you should make use of a tolerably vigourous print. 6. Thanks.

W. C. S.—1. The third on your list will be most suitable for all round out-door work; but if you can make up your mind to have two objectives, you had better obtain No. 1 and No. 5. 2. It is not an inherent defect, but is due to careless workmanship.

T. Y. SINCOX.—Certainly one of the worst samples we have met with, the coating being not only uneven and full of thin places, but also in an advanced state of decomposition.

A READER.—It is due to the presence of common salt, and your best course will be to soak in water for some hours, and then dry.

POSITIVE.—1. Not unless the water is slightly acidified. 2. Yes.

Vol. XXVI. No. 1245.—*July* 14, 1882.

CONTENTS.

SULPHITE OF SODA IN THE ALKALINE DEVELOPER.

Sulphite of soda as an adjunct to the alkaline developer may be said to have passed its time of probation, and its use is now an established custom with numbers of photographers.

It need not surprise us on this account to know that with many it is still a matter of doubt whether or not the innovation is altogether for good, and to hear the most contrary opinions expressed in the matter; to hear one loud in its praise, whilst another has nothing but evil to say for it; to hear one say it causes, another that it prevents, green fog; to hear one state that a stock solution mixed with it is practically everlasting, whilst another will have it that it deteriorates in a few days. In the case of far more old-established customs than that of the use of sulphite in the developer, we find the same difference of opinion. The reason is not far to seek. It is to be found in the tendency, far too common, to generalize from individual cases. A man, for example, finds a certain modification of developer suited for the particular make of plates which he is in the habit of using. He straightway proclaims to the world that this one developer is *the* developer for all plates under all circumstances. We have been in the habit of using sulphite in our general work for the past month or two, and with decided advantage. We have, however, besides this, made a set of experiments to determine whether the advantage which we find with some plates is to be found with all. We used various commercial plates, and also plates made by ourselves by different formulæ.

We have used the sulpho-pyrogallol made by the Platinotype Company, and have also mixed solutions with a commercial sample of sulphite.

Before giving the result of our experiments, we may state, for the benefit of any who have managed to keep their ears and eyes closed to all the talking and writing which Mr. Herbert Berkeley's discovery has brought about, that the object of the use of sulphite in the developer is to prevent the brown stain which is so common in gelatine negatives developed by the alkaline method, and that it is recommended that four grains of sulphite of soda should be used to each grain of pyrogallic.

We may also state that the following objections have been urged against its use. It has been said that it produced chemical fog; it has been said that it produced green and red fog; that it greatly increased the time taken for development; and that it was the cause of thin and weak printing negatives.

We found that in all cases the use of the sulphite resulted in improvement of colour; that is to say, that negatives developed with the sulphite did not show the yellow tint which those developed without did when the alum bath was not used. At the same time, we must say that by the use of the acid alum bath we were able to get, in the case of many plates, quite as good a colour without the sulphite as with. This was not so in all cases, however; some plates show a very obstinate tendency to yellow stain which is not to be cured by alum and citric acid, whether used before or after fixing.

As regards the objections urged against the use of Mr. Berkeley's developer, we may say that we have found all of them to hold good to a certain extent *with some plates*.

In the case of one batch of plates of our own make, which gave perfect negatives with the ordinary developer, there was dense chemical fog when using the sulphite. These plates contained chloride, and this may have something to do with the matter. The most noticeable drawback to the new developer is certainly the tendency to produce colour fog. With plates which have no inclination to green fog, sulphite will not produce it; but when there is an inclination, it will greatly aggravate it, and will even produce red fog, when green fog only would make its appearance with the ordinary developer. It must always be borne in mind, however, that colour fog, so long as it is confined to the green variety, has little influence on the printing qualities of a negative; whereas the yellow stain, which is prevented, has.

That there is any great increase in the time taken for development when sulphite is used we have not found, nor that there is any difficulty in gaining density; but in connection with this last it must be borne in mind that in a sulphite developed negative there is not that density which shows in the print whilst it is invisible to the eye which is the peculiarity of ordinary pyrogallic developed negatives, and which often enables us to get passable results from negatives which at first appear hopelessly thin.

The conclusion which we have arrived at with regard to the use of sulphite is, that it certainly is a new power in the hands of the photographer, and that with the majority of plates good is to be gained by the use of it. We can, at least, commend it highly to those who have difficulty in getting negatives of good colour without it.

It has been said that a pyrogallic solution mixed with sulphite of soda loses its power as a developer after a time. We have not found it so, nor can we see any reason why it should be so; but, should it turn out that there is any truth in the statement, we should recommend that the following method of using the salt, which we have found in every way satisfactory, should be adopted. We are in the habit of using a 10 per cent. solution of each of the three principal ingredients of the developer, and of mixing the final solutions from them. We now suggest that these be mixed as follows:—

A.—Pyrogallol	1 ounce
Citric acid	1 drachm
Water	up to 10 ounces
B.—Bromide of ammonia	1 ounce
Water	up to 10 ounces
C.—Strong ammonia	1 ounce
Sulphite of soda	$2\frac{3}{4}$ ounces
Water	up to 10 ounces

Here we have the pyrogallol preserved by citric acid, as in Mr. Cowan's formula, and we have quite enough acid to neutralize the alkalinity of the so-called "neutral" sulphite. In the ammonia solution we have enough sulphite of soda to make just about Mr. Berkeley's proportion in the final developer when an average amount of ammonia is used. At the same time, we do not have the sulphite in contact with the pyrogallic till when the mixture is about to be poured on to the plate. A minor advantage is to be found in the fact that a less near approach to a saturated solution of sulphite of soda is necessary. In one case, on making up an ounce of sulpho-pyrogallol to ten ounces with water, we found that, on leaving the bottle in a very cold place, a considerable quantity of the sulphite of soda crystallized at the bottom.

SOME INFLUENCES OF MOISTURE ON PHOTOGRAPHIC WORK.

FEW agencies work so much mischief to the belongings of the photographer as dampness, his apparatus, materials, and finished work suffering in turn; and although in certain cases the injurious effects of moisture make themselves more felt during the cold weather, there are frequent instances in which the mischief caused by the accidental presence of moisture is considerably exaggerated by the warmth of the weather—as, for example, when fungoid or other growths result from the dampness of bodies of organic origin.

With respect to mischief caused to apparatus, damage to cabinet work stands foremost, and there are few photographers who have not had occasion to mourn over dark-slides and cameras which have become disjointed, swelled, and been rendered almost useless, as the result of being stored in a damp place. When any piece of cabinet work has become swelled by the action of damp, it is most important not to dry it too rapidly, and to take care that the drying shall proceed as equally as possible from all sides. A good coating of French polish is a remarkable protection against damp, and any piece of apparatus which has not been French-polished may be rendered much less subject to absorb moisture by treatment with a mixture of beeswax and oil of turpentine. Lenses often become considerably deteriorated by prolonged exposure to a moist atmosphere, the surface of the glass becoming disintegrated, and partially losing its polish; but some samples of glass are much more liable to become acted on than others. Cupboards or boxes lined with extremely thin sheet lead are very well adapted for the conservation of photographic apparatus; but it must not be forgotten that the same precautions which serve to exclude external moisture also prevent the escape of internal moisture; hence it is most necessary to make sure that articles are dry when stored away. Unless albumenised paper is kept in a thoroughly dry place, a slow decomposition of the animal matter is tolerably certain to take place, resulting in the formation of certain sulphur compounds, which exert a very prejudicial influence on the work of the printer, and in all probability render the prints far less permanent than might otherwise have been the case. Albumenised paper, after having been thoroughly dried, should be preserved in cylindrical tin boxes provided with lightly-fitting lids. Carbon tissue is even more liable than albumenised paper to deterioration by damp, and the greatest care should be taken that it is thoroughly dry before it is stored away in the usual cylindrical tin cases. In some instances, damp causes the tissue to become generally insoluble, this being more especially the case when earthy substances and metallic oxides have been employed in pigmenting the gelatine; while in other cases insolubility sets in locally; the result of this being that small clots of insoluble gelatine are found distributed over the finished picture. In this latter case, the insolubility arises from a fungoid growth, which can easily be detected on the surface of the unsensitized tissue. The influence of moisture on sensitized carbon tissue is now well known, the tissue becoming increasingly sensitive up to a certain point, after which a fatal insolubility sets in. The impression of light on exposed carbon tissue, if kept in a damp place before development, becomes so far intensified that, by availing himself of this continuating action, the carbon printer may obtain satisfactory results with less than one-fourth of the exposure which would be required if development immediately followed exposure; but the results are not so certain when the continuating system is adopted. Many saline bodies which are not deliquescent under ordinary circumstances—as, for example, potassium bromide or sodium chloride—absorb a variable amount of water from the atmosphere if they are carelessly kept, and the work of the photographer is thus often stultified and upset without his having any idea as to the real cause of the error.

Dampness undoubtedly exercises a remarkable influence on the fading of prints on albumenized paper; and moisture accompanied by warmth will still more accelerate the fading of prints; hence the advantage of enamelling or waxing the silver print on the surface.

Many apparently contradictory experiences of photographic workers may be explained, and become easily comprehensible, when the disturbing influence of moisture is taken into account.

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

A TOUR IN THE TYROL.

ALBERT SMITH was wont to sing the praises of the *Continental Bradshaw* very sweetly, but many things have altered since the days of Albert Smith. Unfortunately Bradshaw, like Murray, has altered very little, and hence it is that they have been left far behind in the race for popularity.

Baedeker replaces Murray now-a-days in the case of nine travellers out of ten, and if *Bradshaw's Continental* edition is not eclipsed by *Hendschel's Telegraph*, this is only because the latter is published in the German language, and its advantages are not yet fully appreciated. One example will suffice to show how thoroughly Hendschel caters for the traveller. At the end of the volume he gives a series of circular tours in Mid-Europe; the towns or spots through which the traveller may pass are mentioned, and the price of the circular ticket, so that an intending tourist sees at once whether a tour will suit him or not. But it is not a question of a dozen tours to choose from, or even a dozen dozens; there are something like five hundred different tours set down in Hendschel, in which every combination of places of interest is included. The plan, indeed, seems to have been drawn up by a mathematician, it is so exhaustive. You have simply to make up your mind what places you desire to visit in your journey out and home, and then a little study of Hendschel will show that if you secure, say, No. 44 ticket, series D, this will take you the whole round without trouble, and at a fare about one-third less than that ordinarily demanded.

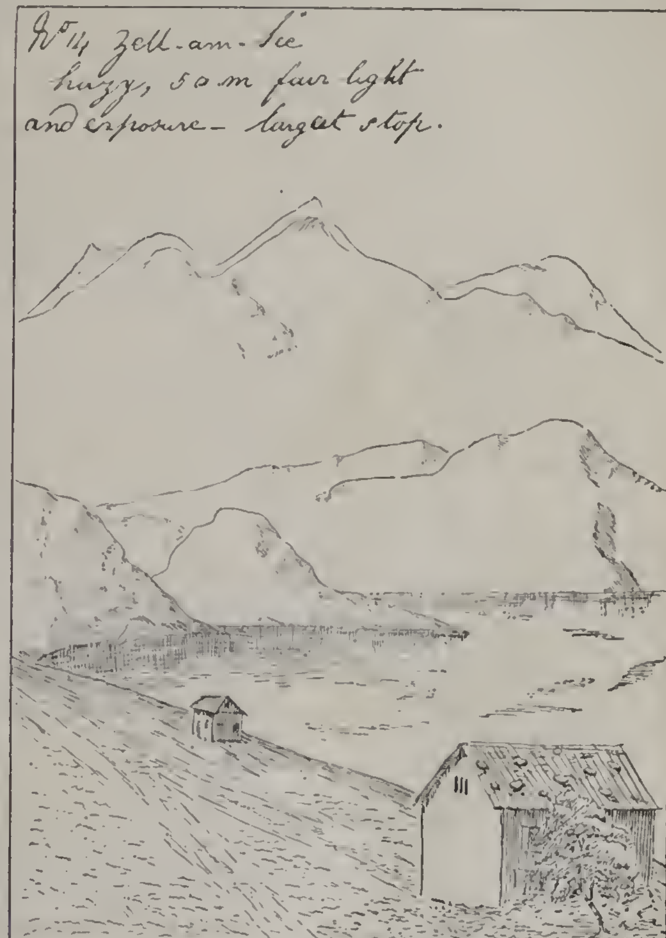
We are bound for the Tyrol at this moment, and a glance at a railway map will show that the most direct route is via Cologne and Munich. Cologne is reached in half a dozen ways—one of the best now-a-days is that by way of Flushing—and, once there, we advise the purchase of a circular tour ticket to Munich. From early morning to late at night is required for the journey from Cologne to Munich, even by express, so two days at least have to be sacrificed for travelling. The Custom officials are not troublesome at Cologne, and you will not be worried with them again until you arrrive at the Austrian frontier in the Tyrol itself.

From Munich—we must get quickly over the ground now, or our space will be wasted in preliminaries—we have still a short railway journey to perform south; we take tickets for Zembach, a station one hour this side of Innsbruck, the capital of the Tyrol, and are set down at the mouth of the valley of the Ziller, or Zillerthal, whence we can proceed on foot, or in a trap, without difficulty, to begin our journey.

With dry plates, a light half-plate camera, and two or three in the party, there is no reason why the photographic apparatus should not be carried personally in addition to a light knapsack; for a long country road is easily got over by a lift in a trap, while in mountain climbing the guide naturally takes the greater part of the burden upon himself. We ourselves have always adopted this plan, and only in the case of the professional photographer, who moves with much apparatus and a large supply of plates, is a special conveyance necessary. On the subject of packing plates, changing, &c., we have already spoken in a previous "By-the-Bye;" so merely premising that we carry in a pouch ready to hand our double-dark slides (two or three as the case may be) ready filled for the day's work, we make a start forthwith. Six plates in a tourist journey is ample for a day's work, and sometimes four suffice very well, for it will be found, practically, that half an hour is taken up on an average at each exposure, and as you have, moreover, your distance to walk in the day, two to three hours is the utmost you can devote to photography.

Leaving Zembach—the little white village resting in a broad green plain at the junction of many valleys—we direct our footsteps due south. A quaint old monastery, enclosing a big, grass-grown quadrangle, stands at the head of the Ziller valley, the road leading right through it. It is a charming pastoral scene around—soft pasturage and green hill-sides on every hand. Dotted over the plain, here and there, are clustering villages, their tapering green spires rising sharply above grey cottage roofs and clumps of trees. The same soft charm prevails as we enter the valley—a pleasant contrast to the grander and wilder nature of much of the Tyrolese scenery. The village streets are of the quaintest. The wooden architecture of the cottages—their boarded roofs weighted with immense stones, for security's sake—is wrought in a most elaborate style, and the balconies under the over-hanging roofs are often masterpieces of wood-carving. Crowning each farmhouse is a conical belfry, sometimes fashioned in a most ornamental style, and enhancing the general appearance of the structure; in fact, the châlets here are more Swiss than those in Switzerland, if one may say so, while the villagers, especially if you see them in their Sunday best, are delightfully picturesque; in fact, they seem to have assumed *opéra-comique* costumes, they are so smart and gay. The tall sugar-loaf hat and knee-breeches are before you, the gaudy red braces and coloured stockings of the well-known Tyrolese type; while the women, with their short skirts and neatly-braided hair, add further to the theatrical nature of the picture.

At Schlitters, the first picture is taken. We select the picturesque village street, taking the view diagonally, which permits us to include a quaint wooden belfry, and also allows us to get under an overshadowing roof, which screens the lens admirably. There is a little too much exaggeration of the road and of the side of the building under which the camera stands; but this may be corrected when it comes to trimming the print. While we compose our picture and focus, a friend roughly sketches an outline in his pocket-book, so that we have something to remember the scene by when it comes to development. This is very convenient, for, after a month's interval, you frequently forget the nature of your subject altogether; and, before you know what you are doing, a delicate horizon may be spoilt by pushing development too far; or details in the shadows of a village picture lost through not permitting sufficient action. To the sketch is added a remark as to sufficiency of exposure, the time, and any other memoranda that may be deemed desirable. Here is an example of what we mean, which has been copied from our note-book by the phototype process. It is a sketch of Zell-um-See, to which we shall come presently. A helping com-



panion is invaluable to the tourist-photographer in many ways, as the latter soon discovers when he first begins to work in a foreign land; he not only saves one's time, but one's temper as well. However, in the Tyrol, and particularly in the Zillerthal, the tourist will find the simple village people exceedingly pleasant and companionable.

The first day's walk may be to Zell, where there is a capital inn, the "Post," this village being the principal one in the valley. A fine view of the rushing stream, half river, half torrent, with Zell among the trees lying beyond, just when the village is first sighted, is likely to make the photographer halt a second time, unless he has not exposed a second plate already upon one of the road-side skittle-grounds, without which no hostelry is complete in this part of the country. Sometimes the playthings are of the most primitive kind, a slender fir trunk cut into lengths furnishing the skittles, while the first best round stone from the mountain side serves for a ball.

Except at Innsbruck, there are no grand hotels in the Tyrol, and in this, it presents a marked difference from Switzerland. The inns are for the most part post-houses, with a room for humble guests on the left ("Gast-stube"), and another on the right of more pretensions, usually called the "Speise-saal." These Tyrol inns are very comfortable, and are, moreover, right reasonable in their charges; only, of course, there are not the conveniences nor the advantages (and disadvantages) that the modern hotel affords. The Zillerthalers are very proud of their musical capacity, and you cannot stay an evening in the villages without hearing their plaintive zither melodies, or some of their mountain jodels. The waiter is an unknown personage in the Tyrol; but a trim waitress in laced boddice and short skirt, with a courier bag hanging to her girdle to receive the money, takes his place. The waitress is usually a performer on the zither, and during the intervals of waiting will sing you "die Berge von Tirol," if you behave yourself, accompanying herself on the zither. We have a picture of Julie of the "Post," playing the zither in a balcony overlooking the rushing Zembach; it is a very bad photograph, but we value it highly, for all that.

Still ascending the valley, we reach Mayrhofen. One of the picturesque châlets surrounded by orchard land is here chosen as a fit subject for the camera, and while our friend keeps the landlady talking in the doorway, we manage to secure her portrait into the bargain. It now becomes steep climbing, but as we have left all heavy baggage behind at Zell, and only carry our photographic kit, we get on as well as ever. There is no road beside the foaming white stream, only a tortuous footpath, that winds in and out among gigantic boulders, now passing under threatening masses of overhanging rock shaped like monster grottoes, now leading under trees through shady recesses, full of luxuriant undergrowth, the most beautiful fern gardens that can be imagined. There is not a breath of air to stir the delicate stems, so we take a picture of the green paradise then and there, a photograph that turns out one of the most successful of our tour.

In two hours the Carlssteg is reached, almost the head of the valley, a rough covered bridge thrown across the foaming Zembach, as it rushes through the rocky mountain gorge. The scenery is grand and wild in the extreme; tremendous masses of detatched rock fight with the cascade at every turn, and sheer precipices on either side constitute the upper part of the valley a dark-shadowed defile of magnificent proportions, through which are seen the lofty white peaks of some of the Tyrol giants.

Of course, we obtain a view of the Carlsteg, although it is some time before we can get a safe place for the tripod on the brink of the stream. There is a rush of cold air—a blast it might almost be termed—that is a considerable source of danger to our zephyr apparatus, but by carefully loading the same with heavy bits of granite, picked up at the edge of the torrent, it is at last secured with tolerable safety.

One matter in the day's journey is always a little worrying to the photographer. His day's supply of plates, let it be four or six, he naturally desires to make the best use of; now he may be too chary in the morning in making exposures, or, again, he may be too improvident. When evening arrives, and he is at his journey's end, with one or two unexposed films in his pouch, he thinks how well he would have done to photograph that cascade or wonderful mountain gorge he passed in the morning. On the other hand, if he has lavished all his plates early in the day, the chances are he meets with some tempting subjects in the afternoon when his wallet is empty of virgin films. Now of these two evils we hold it best not to save up one's plates. In the first place, the morning light is usually the best of all lights for photography, and if you meet with subjects that appear good, if you expose your plates, you have the satisfaction, at any rate, that you have wasted none of them. You have had your own way, and that is something.

We return to Zell, and start early across the Plattenkogl Pass to Krimml, where the finest waterfalls in Germany are to be found. The pass is not a high one—between 6,000 and 7,000 feet—but we take a guide to the top to help us with our packs, and make quite sure of the way. A Sennerhütte, or shepherd's hut, up here serves to make a capital little photograph, which forms a pleasant souvenir as well, for we are entertained by its owner with brown bread, cream cheese, and cool milk *ad libitum*, in right Royal fashion, hospitality that comes very grateful after a hot and laborious climb.

More useful than an unlimited supply of dry plates to the tourist-photographer, he should remember, is a never-failing stock of good humour. Travellers, and pedestrians especially, should always bear this is mind, especially towards the end of the day, when they are weary, or when matters go "contrariwise," as Mrs. Gummidge would say. Keep your own counsel, travel steadily, take little with you, start off in good time, and leave your cares at home, is the advice of an old traveller, Philauder Von Sittewald; or, as it runs in the original German:—

Wer reisen will,
Der schweig fein still,
Geh steten Schritt,
Nehm nicht viel mit,
Tret an am frühen Morgen,
Und lasse heim die Sorgen.

(*To be continued.*)

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

A Photographic Assistants' Association—Photography and Electricity—The Chevalier von Hesse's Photographs—Tobacco-Smoke Photographs.

A Photographic Assistants' Association.—Remembering the number of photographic associations which already exist, we hesitate about suggesting another. And yet there is decidedly room for such an association as we have in our mind's eye. We refer to the necessity there appears to be for a Society of Photographers' Assistants. It is obvious that none of the present societies exactly meet the wants of the assistants. While the objects of such a Society would be essentially progress in photographic science, there are yet many fruitful topics in professional practice which only those engaged in photography as a means of livelihood could adequately discuss. The admission of amateurs, therefore, would be scarcely admissible. Such a society need not, in the least degree, partake of the nature of a trades-union. The practice of the present day compels the principal of a photographic studio to devote himself more and more to the artistic details of the picture; the mechanical manipulation must be left to the assistant. Hence it is to the assistants that one must, to a great extent, look for points of practical experience, which, after all, are the most important stepping-stones to reliability. In Berlin there is a Photographic Assistants' Association, and if Berlin finds an association of this kind necessary, surely London and the provinces ought. Of course the exact form of such an organization can only be settled after reflection and discussion We merely throw out the idea in the hope that some one may be able to shadow forth something that will not only be practical, but practicable.

Photography and Electricity.—It should be gratifying to the photographic profession that two of its members, Mr. Swan and Mr. W. Crookes, should have taken so high a position in regard to investigations as to lighting by electricity. The world has seen what Mr. Swan can do; Mr. W. Crookes has yet to exhibit the capabilities of the lamp which bears his name. We notice there has been a little difference of opinion between Mr. Crookes and the Board of the Electric Light and Power Generator Company, to which Mr. Crookes was consulting electrician. It would seem that Mr. Crookes had offered his lamp to this Company, who, the Chairman stated at a recent meeting, were advised not to purchase it until they had opportunities for testing its powers of endurance; and these opportunities were not afforded. Without knowing Mr. Crookes' side of the question, we presume that after being appointed consulting electrician, and feeling sure of the qualities of his lamp, he looked upon this "advice" as implying a want of confidence; and if this should be so, it is not surprising to find that he offered his lamp to another company of which he has become director. At the meeting referred to, it was stated that Mr. Crookes was receiving from the Generator Company a salary of £600 a-year, and had been engaged for two years. In the course of a discussion, Mr. Crookes justified the sale of his lamp to the other company, and intimated his readiness to resign his position as consulting electrician. We have referred to this matter because the fact of Mr. Crookes and Mr. Swan being both practical photographers should encourage the profession to hope that at some future time they might be led to devise a special lamp for photographic purposes.

The Chevalier von Hesse's Photographs.—We have this week had an opportunity of inspecting the photographs, now exhibiting in the map room of the Royal Geographical Society, of the Chevalier E. von Herse Wartegg, who has just returned from a scientific journey in Mexico, New Mexico, and Arizona. The majority of the photographs have been taken on 15 by 12 plates, and, apart from their interest geographically and topographically, are excellent specimens of photography. The figure subjects are of necessity more entertaining than the landscapes to the general observer; but there are many points in the latter which make them notable. The puebla of Zuni is the city to which the Chevalier has paid most attention, and, from the photographs one gets a very good idea of the habitations of the natives. Zuni is literally a city of the plains; all is arid and bare, and not so much as a stunted bush is to be seen. At first sight the city appears to be in a half-finished condition—in fact, simply a collection of scaffold poles and square hovels. On closer inspection, however, the scaffold poles turn out to be rudimentary ladders, which are highly necessary, as the houses are built one on the top of the other. Besides single figure subjects, such as a woman polishing pottery, Moki rabbit hunters, native weavers at work, and others, there are a couple of photographs of dances, in which the performers are all women. Here, unfortunately, owing to the size of the plate, and presumably to the fact that wet plates were used, one fails to get an idea of the dance. An instantaneous process could alone do justice to such a subject, and gelatine plates the Chevalier appears not to have had. To the student of ethnology these photographs should be of the greatest possible interest. In this particular study a great future is open to photography. It is only by comparison that the scientific man can deduce theories, and as it is perfectly impossible for him to visit every part of the globe, the photographer performs a valuable service in collecting specimens on whose truth there cannot be any doubt thrown.

Tobacco-Smoke Photographs.—A photographic toy—not very novel, by-the-bye—has made its appearance in the cigar shops of the Continent. With a cigarette mouth-piece you also purchase a number of photographic papers about the size of a postage stamp. Taking one of these stamps, you place it over a lateral orifice in the mouth-piece, and a sliding piece is drawn over it. You then indulge in a whiff, take out the piece of paper, and, presto! it has an image upon it. The process is thus explained by *La Nature*. A small photograph, prepared on chloride of silver paper, as usual, but without toning or fixing, is put in a solution of bichloride of mercury, when it fades and disappears. The bichloride of mercury changes the photograph partly into white chloride of silver, and partly into proto-chloride of mercury, also white, making the image invisible. The image may be brought back by action of hyposulphite of soda or of ammoniacal vapours, and tobacco-smoke, as containing the latter, does very well. Easy enough when you know how.

RECENT ADVANCES IN PHOTOGRAPHY.

BY CAPTAIN W. DE W. ABNEY, R.E. F.R.S.*

IN beginning this course of Cantor Lectures, I make this presumption—that amongst my audience I have those who have commenced photography but recently; also, those who commenced photography about the time I did, say twenty years ago; and that there are very few now who practise those old processes which our forefathers, if I may use the expression, were accustomed to manipulate. I may also say, that I have reason to believe that amongst my audience there are some who know very little of photography at all. I must try and do the best I can to address myself to all. It is a difficult thing; but I hope those to whom I am not exactly fitting my remarks at the time, will remember that I am addressing others, who I also have to consider. I thought, perhaps, it might be useful to go over the very oldest processes with which photography started; and when you recollect that photography is not very old—in fact, is a chicken compared with some of the sciences—and yet that there are very few who can remember its discovery, I think it may be of interest if you see worked out practically before you these very early processes to which I refer.

The first germ of photography was when Scheele investigated the action of light on silver chloride, and found that it discoloured it. It was subsequently found that this discolouration of the chloride was due to a liberation of chlorine from the chloride of silver. In 1802, eighty years ago, Wedgwood read a paper before the Royal Institution, in which he described a method of taking profiles, and also copying painted pictures, by means of what we should now call photography. These profiles were taken on paper washed over with silver nitrate. In other words, the profile of the person to be portrayed was thrown against sensitized paper, in a strong light, and the outline was photographed or made visible by the strong light acting outside the profile. Of course it produced a white profile on a black background. About the same time that Wedgwood read this paper, Sir Humphrey Davy was practising this process, and he found that silver chloride was preferable to silver nitrate. He also found that if he used white kid as a basis of what I will call the photograph, he got a stronger impression than if he used simply paper. In 1814, twelve years later, Niépce devoted himself to studying the action of light upon asphaltum, and he worked out a process which up to this day is still used, and which I shall not refer to more particularly now, as I shall hope to do so in a subsequent lecture. He developed the process which was then called heliography, which consisted in the production of a picture in bitumen on a metal plate, the light causing the oxidation of the bitumen or asphaltum, and rendering insoluble or less soluble those parts which had been acted upon.

In 1827, Niépce came to England, and endeavoured to introduce the results which he had obtained, to the notice of the Royal Society; but, owing to the process being a secret one, the communication was not received.

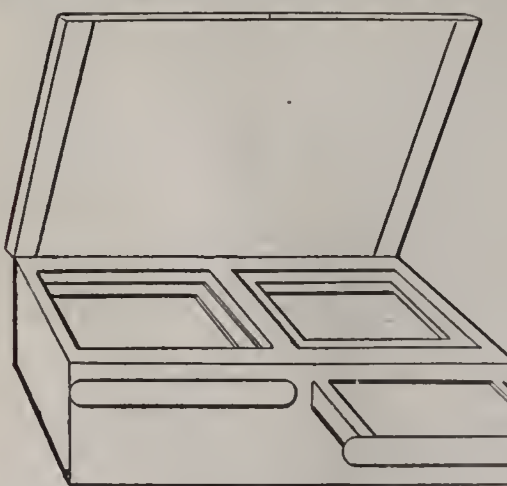
In 1824, Daguerre, a name to be remembered, a French painter, began similar experiments in the same direction, and, in 1829, he and Niépce entered into partnership to work out that which eventually received the name of photography. Now, Niépce has left it on record, that in his bitumen pictures he had one considerable trouble; he found that, instead of the lines of an engraving being represented by black stains on the white metal, the lines were represented by white metal on black bitumen. In order to overcome this difficulty, after coating the silver plate with his bitumen, and developing it by dissolving away the unaltered parts, he treated the metallic silver plate beneath with any ingredient which he might choose, and amongst others, he has left on record that he treated it with iodine, and then rubbed off the bitumen. This, in the case of an engraving, would of course give dark lines on a white background. Here we have the first introduction of iodine and silver together.

Now, we cannot suppose that two such shrewd observers as Niépce and Daguerre could have used this combination of iodine and silver without noticing that it was altered by light; and I may say that there are a number of grave grounds for considering that this was really the origin of the Daguerreotype process, which consists, as you know, in the treatment of a silver plate primarily with iodine, and subsequently with other substances, to cause sensitiveness. Daguerre and Niépce must have noticed the alteration by light in the silver iodide which they had formed on the silver plate, but up to that time of which I am talking, they had not discovered the secret of what we now call deve-

* Delivered before the Society of Arts.

lopment; and when we come to consider the early history of photography, it is a most remarkable fact, that the two first modes of development were discovered, if I may say so, by flukes. The discovery of the development of the Daguerrean image was as follows:—He, Daguerre, had been trying to reduce the exposure of iodide of silver, in order to get an image in a reasonable time. Instead of exposing his plate for a quarter of a hour or an hour, he wished to obtain an image in one or two minutes, which, to him, would have been very quick. Many months were passed in these apparently fruitless researches, until one day he placed one of his iodised plates, which he had exposed to light for some short time, in his chemical cupboard. Now, in that chemical cupboard were a variety of bottles of all descriptions. He had worked hard, and as chemists know perfectly well, when a man is working at research, there is usually a collection of all sorts of chemicals. He placed his Daguerreotype plate in the cupboard over night, and, to his astonishment, next morning, when he opened the cupboard, he found that he had a fully-developed Daguerrean image. This was a discovery which he immediately turned to account. He exposed other plates, shifting first one bottle, then another, and by this process of elimination, at last he was able to find that it was an open bottle of mercury which had caused the development of the image. This was really, I believe, the true history of the Daguerreotype process, so far as the mercurial development was concerned. It was considered a very short exposure in those days if you sat five or ten minutes in the sunlight to have four portraits taken. We have changed all that now, and I dare say before this course of lectures is over, not only five or ten minutes will be considered a long exposure, but perhaps $\frac{2}{100}$ of a second will not be considered short.

I have the pleasure to-night of introducing to your notice an old worker of the Daguerreotype process, Mr. England. He has kindly consented to show the whole manipulation of the process from beginning to end, thinking it might interest what I may call a juvenile audience, for juvenile I suppose most of you are, as regards photography. Mr. England has left me to do the talking, and therefore I must do the best I can to explain the operations which will be gone through. We have a little box,



Daguerreotype developing box.

divided into two parts, in one of which is placed iodine, and in the other is placed what is called bromide of lime, that is to say, caustic lime impregnated with bromine. You will find that, first of all, having polished it, he will place the plate over one of these apertures—over the iodine; the iodine vapour will be allowed to play upon it a certain time, and then he will shift the plate over to the bromine, and thus he bromises the silver. He will finally give it another touch of iodine vapour, and the plate will be ready for exposure. Mr. England has taken the trouble to polish these plates beforehand, since their polishing is one of the chief difficulties of the Daguerreotype process. The fact is, the plate requires the most elaborate polish, such as even a silversmith can scarcely give them. One of these plates he will now place over the iodine, and for two minutes allow the iodine to rise and attack the silver. (Mr. England here explained that the first process is to bring the plate to a deep yellow colour, by means of the iodine, and then to place it over the bromine.) In the first place, it is necessary to be able to see the colour, so that a reflector is placed on the one side of the sensitizing box, the other being open. By this artifice, the plates may be viewed, and the colour of the Daguerreotype plate can be watched, till it has attained a deep yellow colour. It is passed on, to be acted on by the bromine, and that is continued until it attains a rose colour. It is a little difficult, by artificial light, to see the exact colour; this process was seldom worked by artificial light, and, therefore, one may be misled by false colour.

We propose, between us, to take a Daguerreotype picture. Now, the operation of sensitizing is very nearly finished. It has been treated with iodine, and then with bromine, and now it is having a final submission to iodine. The plate Mr. England prepared has now been exposed one minute; Mr. England is rather doubtful about the sensitiveness of the plate, but I am afraid, myself, it is rather over-exposed. Mr. England is now going to develop the picture, and he will do so by the use of mercury. He has here the original mercury box with which he was accustomed to manipulate. He will hang it against the wall, and light a small spirit lamp under a bowl of mercury beneath it. The mercury fumes will rise through an orifice into the box, and so on to a plate; he will watch it from time to time, until it is developed, when we will show it to you. [A copy of an engraving was here taken whilst illuminated by the electric light.]

I should like you to understand exactly what takes place in the Daguerreotype plate when it is exposed and developed. On the surface of the plate we have a mixture of silver iodide and bromide, but, for simplicity's sake, I will suppose that there is simple silver iodide on it. When light acts on such a compound, the action is to split up the silver into a salt, which we call silver sub-iodide, and the iodine is liberated, $Ag_2 I_2 = Ag_2 I + I$. The iodine is taken up by the silver plate at the back of the sensitive film. To develop the picture, mercury vapour is caused to condense on the sub-iodide, and leave the iodide intact. Amongst some pictures which Mr. England has kindly brought, we have an instantaneous view of New York Harbour, taken about twenty-five years ago; and I doubt very much whether there are any wet plate instantaneous pictures equal to that; from age it has become a little bit tarnished, but otherwise it is a most perfect picture—the size is about 5 by 4 inches. I have a transparency taken from this, and one from a negative, also in the possession of Mr. England. This last is a portrait of Daguerre, taken by himself. This is interesting as showing one of the very earliest Daguerreotypes known.

The next process is the Talbotype process. In Talbot's original process, chloride of silver formed the basis, and from that sprung our silver-printing process of the present day. But the great improvement he made was by the introduction of iodide of silver. I may mention that he introduced this in January of the same year in which Daguerre introduced the Daguerreotype process in France—namely, in 1839. The outline of the Talbotype process is as follows:—First of all, he gave a wash of nitrate of silver to plain paper (some papers answered better than others); this he dried, and then washed over it the iodide of potassium, so forming iodide of silver; then dried the paper, and again washed over it the nitrate of silver. Such a paper was found sensitive enough to take camera pictures. But how about the development? Curiously enough, the development of the Talbotype picture was discovered in an independent way by the Rev. J. B. Reade. He was practising with the solar microscope, and copying certain objects. One afternoon, having given his paper, which he had washed over with gallic acid, a short exposure, he was obliged to leave it for the night. Next morning he found that his image was fully developed. That gave him the idea of the development of what was called the latent image. Talbot introduced this mode of development into the calotype process. This calotype process was the subject of litigation, and the claims of the Rev. J. B. Reade to be the discoverer of the gallic-acid development was disputed. I do not wish to enter into the legal question as to who was the discoverer; my own opinion is that Mr. Reade should have the credit which belongs to the discovery. From the negative pictures so produced an unlimited number of portraits would be made by what we call the ordinary silver-printing process. A Daguerreotype, on the other hand, could be only reproduced by electrotype, and Mr. England has kindly lent me such a reproduction, which can be examined afterwards. I propose, however, to show you how Talbot was able to make a picture on paper. I intended to have taken a camera picture by the process, with the aid of the electric light; but I find it will take up too much time. I have here a negative with some Talbotype paper upon it, prepared as described. I will expose this to the light from a bit of magnesium wire, and then will develop it in the way in which that development was practised in the old time. I have a solution of gallic acid, which I place in a little dish, and with it will mix a solution of nitrate of silver and acetic acid. The acetic acid is meant to retard the action of the gallic acid, to prevent the reduction of the silver before the development takes place. I should say the usual method of using the paper was as follows:—A final wash of gallic acid and silver nitrate was given it, and it was then exposed while damp in the camera. This is what I intended to do, but the minutes steal on us so very rapidly, that I have been obliged to leave out the wash of gallic acid and silver, and to give it a rather longer exposure behind a negative, and thus I shall produce a positive on development. The undeveloped picture is now placed on this piece of glass, and now I proceed to develop it. The glass is placed on a stand, and the light from the lantern, after passing through orange glass, is allowed to

Stand for developing paper pictures.

illuminate it. The lines begin gradually to appear, and they must now be visible to you all. I continue brushing over the picture the solution of gallic acid and nitrate of silver with acetic acid, and it becomes still more visible. A paper process is a most fascinating process, because you can dabble about, and do exactly what you like; it is not like the gelatine plates of the present day, which you have to leave to come out mechanically. With paper, if you want to bring it out a little better detail in one place there you can dab it out; and if you want to keep it back you can put a little water over the place. There is no process like the paper process to please an artist; not that I profess to be an artist, but, belonging to the Science and Art Department, I have a sort of art instinct, I suppose. I think you can see that the image is very fairly out now. In the old days, I dare say it would be considered passable for a beginner, not that I am a beginner, because I practised it in India; but it is a long time ago since I did so. So much, then, for the Talbotype process. Now, what is the meaning, I would ask you, of that development. It is a curious thing that a small exposure to light should cause an image to appear. I will ask Mr. Woods to throw on the screen something which perhaps will illustrate how development arises. This morning I was in my laboratory, and I saw lying on the bench a feeble negative which I had badly developed, and which I had fixed with hyposulphite of soda. On taking it up, I found the salt had crystallised over the surface in a most beautiful manner, and I do not think I could point out to you anything which would give you a better idea of what development is than those crystals whose images you see on the screen. When you have silver precipitated from a solution by any means whatever, you have it always in a crystalline form, and as all crystals possess polarity, so crystals of silver possess polarity; and where one silver particle is deposited, there another silver particle will deposit, exactly in the same way as those crystals of hypo-sulphite of soda follow one another in regular course in those beautiful feathers. Thus, then, I looked upon it as a physical development; we have a crystalline action going on during development, and nothing else. The iodide of silver is altered into sub-iodide, and this, like the pole of a magnet, attracts the precipitating silver, and from that time, where the silver is deposited, other crystals of silver are deposited. That is what I call physical development.

(*To be continued.*)

PHOTOGRAPHING IN THE CAVERNS OF LURAY.

One of the most interesting and entirely successful series of photographs which we have seen for a long time has been made by Mr. C. H. James, in the interior of the caverns of Luray near the town of the same name in Virginia.

The pictures will undoubtedly do much towards creating a widespread interest in this wonderful natural curiosity, which is just beginning to be known, but which offers, according to the unanimous opinion of those who have visited it, a richness and variety of the stalactite and stalagmite formation unsurpassed in this country, besides other features peculiar to itself alone.

In the course of a long and interesting conversation with Mr. James, we expressed the desire of sharing what we heard with our readers; to which he very readily and kindly assented.

The outfit was of a solid and practical character, though not a very extensive one, and comprised a 7 by 9 box with an 8-inch Ross portable symmetrical lens, and a 5 by 8 stereo box with two sets of lenses, the most useful being a pair of Dallmeyer's quick-acting 4½-inch single view lenses; the shorter focus doublets being found to give rather too much angle, and to work too slowly. A notable point here is the fact that almost all the exposures were made with the smallest stops of both the lenses; this was necessary from the long reaches comprising both near and distant objects, both of which had to to be in a sharp focus, and were undoubtedly more trying to the lenses than an ordinary open view or architectural subject.

Focussing was no easy matter, and was accomplished by means of a lighted candle set upon some spot carefully chosen; the focus being drawn upon the flame itself.

The illumination under which the exposures were made was furnished by the powerful Thomas-Houston electric lights, with which all the more frequented parts of the cave are supplied, and which are accompanied by a telephone wire communicating with the engineer in his room at the distance of nearly a mile from the cave's mouth. The power of each light was estimated at three thousand candles, and in all cases where the character of the subject required more than one of the lamps, the greatest care was taken in the management of the secondary illumination; the principal or strongest light being supplied with a screen or partial reflector of white paper immediately behind it, so that the light was somewhat broken up and modified in character, and devoid of the extreme harshness so often seen. Mr. James attributes much of his success, particularly the delicate half-tone in which his negatives abound, to this simple plan. The secondary lamps, after being brought to bear upon very dark spots, were allowed their full power, so as to give all the detail possible. Mr. James spoke of the deceptive appearance of the electric light, and he estimates its actinic power to be fully three times its visual, for in many cases where little or nothing could be seen on the ground glass when focussing, a comparatively short exposure gave negatives full of softness and gradation, even in spots where the prevailing colours were yellowish-brown and red.

The damp atmosphere of the cave proved rather trying to the woodwork of the cameras, and at first the lenses showed a tendency to sweat; but this was got rid of by wrapping them up in a thick cloth while above ground, and after descending letting them rest for fully half an hour before undoing the parcel.

It is hardly necessary to say that gelatine dry plates were used exclusively. Two well-known makes were taken, and a pyrogallic acid development was depended upon throughout to the exclusion of ferrous oxalate. The sensitiveness was estimated from six to ten times wet collodion, and, owing to the feeble light, after-intensification was resorted to in nearly all cases.

Mr. James spoke in high terms of Mr. Carbutt's formula for developer here given:—

No. 1.

Pyrogallic acid	1 ounce
Bromide of ammonium	1 „
Citric acid...	60 grains

Dissolved in 10 ounces of water.

No. 2.

Aqua ammonia	½ ounce
Water	2 ounces

These are stock solutions.

To develop, take six ounces of water, and add half a fluid drachm of each of the above stock solutions, and if more density is required, add from four to five grains additional dry pyrogallic. The citric acid is of great value in any stock solution of pyrogallic in preserving it clear and free from discolouration. The plates were strengthened by the ordinary formula of bichloride of mercury followed by ammonia, but Mr. James insists upon the necessity of laying the plates in an alum and citric acid bath before applying the mercury, otherwise stains and unevenness are sure to arise. This is conclusive proof of the value of alum as a hypo-eliminator.

The choice of subject and arrangement of light were of course the main difficulties to be surmounted, the chemical operations offering nothing remarkable. And that they have been most successfully overcome, all will agree who have the opportunity of looking over this beautiful collection of nearly forty stereos and thirty 7 by 9 views, which were brought home by Mr. James as the fruits of two months' labour in the bowels of the earth.—*Philadelphia Photographer.*

Notes.

Mr. J. T. Taylor sails next week for America; he will take part in the convention of photographers which meets in Indianopolis about the middle of August.

Lieutenant S. M. Maycock, R.E., succeeds Lieutenant Darwin in charge of the Military Photographic School at Chatham.

Mr. Maxwell Lyte will continue the duties of honorary secretary to the Photographic Society of Great Britain, which he took up at the last meeting of the Society, on the sudden departure of Lieut. Darwin for the Colonies.

Another electric light exhibition is to be held in November, this time at the Westminster Aquarium, the whole of the building being devoted to the purpose. The exhibition is to demonstrate "practical electric development," and will include, therefore, many interesting improvements that have been made of late.

Good studios fetch good prices in Germany. That of Herr Weisbrod, in Frankfort-on-Main, was sold on the first of this month to Hanfstaengl, of Stuttgart, for 60,000 marks (£3,000). It is not every photographer who has £3,000 to pay away, but then Herr Erwin Hanfstaengl, it appears, has a clever wife, who is engaged at the Frankfort Opera House at a salary of £1,250 per annum.

It is a pity the navy does not recognise photography officially. The earthworks, chiefly of sand, at Alexandria, seem to have resisted the heavy artillery wonderfully well, and our sailors are said to be very disappointed at being able to make so little impression. Photographs, therefore, of these land batteries after the firing would be exceedingly valuable and instructive, for we know very little just now about defending ourselves from modern artillery. The pictures would show what measures are effective, and what ineffective, in keeping out the big thunderbolts hurled from our heavy cannon.

Fortunately, many naval officers are apt photographers, and there are doubtless several cameras in the fleet at this moment. At the Royal Naval College at Greenwich some attention is paid, it is true, to photographic chemistry, but officers desiring to become practically efficient must look after themselves. The torpedo explosion pictures exhibited last year at Pall Mall by Lieut. White, R.N., of the *Polyphemus*, afford ample proof that there are good photographers in our navy.

A party of gentlemen, numbering exactly a score, dined at the Manchester Hotel on Tuesday, for the purpose of welcoming Mr. J. T. Taylor, who is in this country on a brief visit. The chairman, Mr. Stuart, in a kindly speech, bore testimony to the esteem in which Mr. Taylor was held in this country, and expressed a hope that in his new home in America he would be not less highly appreciated.

We mentioned last week a statement in *Truth*, that the principal pictures in the gallery at Buckingham Palace were to be photographed by the representatives of a Berlin firm. The work is being done by the well-known house of Braun et Cie., Dornach, who have also received permission to avail themselves of the Royal Art Treasures at Windsor Castle, Balmoral, and Osborne. The reproductions will be printed in carbon, and it is this fact, indeed, which largely influenced the Queen to afford the necessary facilities.

The Autotype Company, we are glad to hear, have made arrangements with Messrs. Braun et Cie. for the sale in Great Britain of the copies of these pictures in the Royal collections. The selection from the pictures in Buckingham Palace is likely to be a popular issue from the conspicuous merit of the paintings of the Dutch school, and the fact that no copies of these master works have been hitherto attainable.

Mr. P. A. Taylor asked for an explanation last week in the House about the flogging of a prisoner in Wandsworth Gaol who refused to be photographed, and the hon. gentleman was told, amid much laughter, that the penalty incurred by a convict for not submitting himself quietly to the camera was ten strokes with a birch rod, and this punishment had been inflicted. Mr. Taylor evidently had a professional beauty in his mind, and did not quite realise the situation.

The Paris correspondent of the *Daily Telegraph* praises very highly an equestrian album of M. J. Delton, who has taken pains to obtain portraits of the more fashionable riders in the Bois de Boulogne. He calls his album the "Tour du Bois." We have not seen M. Delton's pictures, but it is only a few months ago that we called our readers' attention once more to the attractive nature of equestrian pictures, when describing the Atelier Adèle in Vienna. There are ten times as many cavaliers and lady riders to be seen in the Row every season than are met with in the Bois or the Prater, and yet we permit Paris and Vienna to go far ahead of us in the matter of equestrian photography.

Herr Perlmutter, indeed, of the Adèle studio, threatens to come over here to do such portraits himself if we cannot make up our minds to them. A lady or gentleman possessing a valuable horse is much more anxious to have a photograph of it than of herself or himself, and if equestrian portraits are more difficult of execution, the results are usually more pleasing. There is the making of a picture in a horse and his rider, but you cannot say this of a rider alone, very often. In any case, it is a subject well worth the serious attention of London portraitists, and yet, since the days of Disderi, it has been woefully neglected.

Since M. Nadar is said to have spent the sum of 30,000 francs (£1,200) in obtaining his balloon photographs of Paris, the £40 which the Municipal Council of Paris have placed at the disposal of the æreonauts of that city for going on with the work does not seem a very large amount. The further attempts at balloon photography are to be made from captive balloons.

M. Nadar's balloon pictures, which won the admiration of Wheatstone, were secured upon three-inch plates, with the briefest exposure. The most successful was obtained at a height of 1,000 feet. The enlargements, measuring something like twenty inches, we have seen, and although the pictures are hazy from the flood of light entering the camera, the main buildings of Paris and heights around are rendered with much distinctness. M. Nadar told us that the principal difficulty to be overcome in the work was the gyrations of the balloon.

The French chemist, Dessan, has made a discovery in respect to the action of light that is likely to prove very important. He has found that oxygen may be converted into ozone by the action of light rays. In making his experiment, Dessan employed very pure oxygen; it was contained in a glass globe, which, together with the other apparatus, was carefully covered with black paper to prevent the admission of light. In these circumstances the oxygen did not betray the presence of ozone, but, after the rays from a Drummond oxy-hydrogen lamp had shone upon the oxygen for twenty-five minutes, ozone was distinctly shown to be present on testing with iodide of starch.

According to military journals, it is the men in the first army corps who are nominated for active service in Egypt, and, thanks to stricter regulations of late with regard to men and *matériel*, an army corps is soon put on a war footing. The guns and transport for such a body, which should muster 36,000 men, are not only in store, but maintained in efficiency down to the smallest detail. Thus, besides the proper number of baggage, ammunition, and ambulance waggons, the equipment includes telegraph waggons and telegraph wire for immediate use, surveying apparatus, printing and lithographic waggons, together with a waggon devoted solely to photography in the field.

The telegraph waggons, printing waggons, and photographic waggons are convenient little offices on wheels, drawn by two or four horses as the case may be. The staff of field photographers usually consists of a serjeant-photographer and half-a-dozen non-commissioned officers and Sappers who have gone through a course of instruction at Chatham. The work of the field photographer consists chiefly in the taking of reconnaissance photographs and reproducing plans and drawings; and so well supplied is the photographic waggon with everything, from camera to clips, and from pyroxilin to pyro., that a Sapper may step out of the Chatham laboratory into the field waggon without suffering the loss of a single requisite.

The Technical Photographic School at Salzburg has issued its yearly report. The school can afford space only for thirty students in its laboratory and work-rooms, and not only were these fully occupied, but twenty applicants for admission were refused for want of room. Photography, retouching, photo-lithography, zinc-etching, Lichtdruck or collotype, and photo-enamelling are the subjects taught, both theoretically and practically. The institution appears to be a great success in all respects.

"Toggenburg," a German novel by Paul Lindau, deals with a practice—to be found only in the pages of a novel, we suspect—sitters have of appropriating any portraits that take their fancy in a photographer's reception room. The action in the novel is to this effect: A gentleman has his portrait taken for the sole purpose of entering a certain studio and enquiring the name of a certain young lady whose picture hangs in the show-case. During the posing he asks the name of the lady, and, having learnt it, thus proceeds.

"You must lend me her portrait for twenty-four hours; I'll do nothing wrong with it."

"I can't do that under any circumstances. At least, I dare not lend you a hand in the matter; but, of course, many photographs about here do happen to get lost somehow or another. . . . ."

"All right, then, lend me a pair of scissors, and just make an entry that I want three dozen of my portrait, do you hear; I will manage the rest."

The photographer handed a large pair of scissors, and then busied himself deeply at his desk. Gustav availed himself of the opportunity, cut the picture neatly out of the book, and, coolly pocketing it, went his way.

TWELVE ELEMENTARY LESSONS IN PHOTOGRAPHIC CHEMISTRY.

Introduction.

Before entering upon these lessons, we propose giving, in the first place, an outline of what they will comprehend, and our reasons for taking up the consideration of the subject. We have often had enquiries addressed to us as to the best means of obtaining a knowledge of practical chemistry sufficient to thoroughly understand the science of photography. In advising on this head, we have generally recommended the student to consult one or other of the various manuals of chemistry. It has, however, long been felt that in the different works at one's disposal there is a lot of matter quite unnecessary for the average photographer to charge his memory with, and it is with this view that we have undertaken to select the information and supply the deficiency by bringing before our readers a series of articles on practical chemistry as applied to photography. In doing so we shall explain everything in as simple language as possible, and always define technical terms before applying them. Although the lessons will be mainly devoted to practical chemistry, the theory of the reactions will be also explained so far as space will permit. The following are the subjects that will be treated of :—

Apparatus; photographic chemicals and re-agents—their properties, impurities, and mode of manufacture; qualitative analysis of such chemicals as are likely to be found in a photographic laboratory.

Preparation of pyrogallic acid, hydrokinone, gold, silver, and platinum salts, gelatine, pyroxyline, and collodion.

Estimation of silver nitrate, gold chloride, pyrogallic acid, bromides, chlorides, and iodides, ammonia and hyposulphite of soda.

Treatment of gold, silver, platinum, and oxalate residues.

In the valuation of chemicals, the processes known as the "volumetric" will be described, as they require a less delicate balance, and are generally quicker performed, and give more accurate results.

The principle of these volumetric methods depends on the gradual addition of a solution containing a known weight of a substance that will re-act on the chemical to be tested, using an indicator to show when the necessary action is completed. Take, for example, the determination of commercial silver nitrate: one gramme of the sample is dissolved in water, and a trace of potassium chromate is added, sufficient to give a blood-red colour (this is the indicator). Now add, drop by drop, from a suitable measure, a solution of sodium chloride (one cubic centimetre of which contains ·00585 gramme of the salt) till the red colour has disappeared, showing that all the silver present has been converted into chloride of silver. On reverting to the measure glass, it is found that fifty-eight cubic centimetres of the solution of sodium chloride have been used; therefore—

$$58 \times \cdot 00585 = \cdot 3408.$$

But one gramme of absolutely pure silver nitrate will decompose ·344 gramme of sodium chloride; thus—

$$\cdot 344 : \cdot 3408 :: 100 : x = 99 \cdot 07.$$

Consequently, the sample contains 99·07 per cent. of the pure salt. Of course, it must be understood that further details of the method will be described in a future article, the object being to illustrate the principle on which volumetric processes depend. It will be noticed that in the description we have used the terms "gramme" and "cubic centimetre," our intention being to adopt the Continental mode of weights and measures known as the "metric system" in calculating quantitative analyses, as it is now used almost entirely by scientific men throughout Europe, and we think it would be a great advantage if English photographers adopted the same system, thus effecting a great saving of time in troublesome calculations, and understanding at a glance the formulæ given by the Continental photographers.

We will explain shortly the metric system. The unit of all measurements is the mètre (29·37 inches), which is said to be the ten-millionth part of the meridian between pole and equator; this measure is divided into decimètres, centimètres, and millimètres, or millimeters, as they are called in this country.

The unit of weight is the gramme (=15·43 grains), which is the weight of a cube of pure water at 39° F., whose sides measure exactly one centimeter; thus a cubic centimeter, or c.c. of water equals a gramme. The chief measure for liquids is the volume occupied by a thousand c.c., and is termed a litre.

We hope that the above remarks, and their fuller application as we proceed, will go far to induce photographers to replace the old-fashioned grain weight and fluid ounces by the more convenient and scientific system now in course of general adoption.

FRENCH CORRESPONDENCE.

Bolagny's Method of Removing Gelatine Films—M. Fourier's Gelatino-Photography—French Edition of Mr. Baden Pritchard's "Studios."

New Studies by M. Marey.—M. Marey, whose remarkable works on the study of the movements of birds on the wing are known to our readers, has just communicated to the Photographic Society of France the results of new experiments made on living objects in motion. While acknowledging the great work accomplished by Mr. Muybridge through the application of photography to the study of animal movements, it seemed to him possible to arrive at more scientific results, and more easily to be compared, by taking on one plate a successive series of the same subject at rapidly-succeeding intervals (say at one-tenth of a second). In Muybridge's case the animal to be studied was run in front of a white wall divided into equal spaces by black lines. Cameras were placed at equal distances from each other, and the exposure was regulated by instantaneous shutters worked electrically. The animal put in motion, by straining a thread across its path, caused the exposure to take place, and, consequently, the plates bear each a different position of the animal in a different place. Of course, the motion of the animal may be accelerated or slackened in speed between the two tensions of thread, in which case the successive impressions do not give an absolutely correct result. M. Marey prefers to use but one camera and one sensitive plate. To be able to fulfil these conditions, a kind of awning is erected, lined with black, having only a side opening, in front of which the object is led; and as from the black no actinic ray can be reflected on to the plate, the object—whether bird, horse, or dog—comes out light. The lens is covered by an instantaneous shutter having a continuous motion, allowing at each tenth of a second a little crack to open; in front of this is a drop shutter having a pneumatic handle. The observer gives the signal, and the moment the animal in motion arrives within the field of vision of the lens, the drop-shutter is opened, and not shut till the subject has reached the other extremity of the field of vision. By this means the plate, once developed, shows a series of images taken at one-tenth of a second interval, and easily to be compared with one another with the view of analysing the pheuemenon of motion. M. Marey has shown me a series of different views thus executed, and by the help of which he will with greater precision than ever be able to determine the laws of motion of the different animals in creation, commencing with man.

Phototypography.—We have always looked forward to the time when photocollotypes would reach the perfection of photo-engravings. M. Rousselou, who, we have seen, obtained such splendid results in photo-engraving in intaglio at Asnières, told me at a conference held several months ago, when we spoke of the possibility of arriving at greater perfection in typographic negatives, that he had almost attained that perfection; and, in fact, we have just received specimens of phototypography from him which surpass in delicacy of modelling anything we have ever seen of this kind. Of course, to be able to print from such negatives, it is necessary to use hot-pressed paper, and good rollers and ink; good results cannot be expected from coarse-grained paper, rollers dented and uneven, and bad ink. We are none the less happy to be the first to have seen and pointed out this new and remarkable progress in the graphic arts. M. Laporta, a Spanish lithographer, has made signal progress in work of the same kind, but less complete. A film of bichromated gelatine is spread over a plate, which is exposed under a negative, and treated with hot water to obtain pronounced reticulations. A coarse image results, which is transferred to zinc; it is then bitten, and a phototypographic negative is obtained, but of too coarse a texture for small subjects. We are convinced that the collotype process would form an excellent base of operations for leading up to the formation of typographic negatives. This idea has been realised by M. Sylvestre some days ago, in a Parisian illustrated journal, *Le Contemporain*, on the first page. We have bought the number in question, but a closer inspection shows that it must have been produced from two processes, typography and phototype. M. Sylvestre has called this glyptography, or *impression by engraving*; but until more ample information is given, we believe it to be simple phototype.

Shutters of Dr. Candize, MM. Trompette, and Bournier.—The course of rapid shutters is still uninterrupted, and Dr. Candize has one in which the cap is placed between the two lenses. It consists of a revolving cylinder in which certain segments are wanting. When the complete portions are in front of the objective, it forms a shutter; when only the skeleton segments, light is admitted. It is complicated, and is surpassed by many others. Still, Dr. Caudize is said to have photographed with it while travelling by rail at full speed. MM. Trompette and Beurnier have produced a shutter which is nothing but a movable diaphragm between the two lenses of the objective moved by pneumatic action. The objection to it consists in the necessity of having a lens specially constructed to receive it.

M. Montagna's Calcography.—M. Montagna, editor of the *Reivista Fotografica* at Brindisi, has thought of a process named by him calcography, somewhat resembling that of Mr. Charles Petit. A sheet of granulated tin is placed upon a glass plate, under a pellicle in relief, similar to that required for Woodburytype, and pressed. The tin reproduces the impression in relief, and forms a sort of typographic negative. Mr. Charles Petit used paper which was embossed in relief by the gelatine mould.

M. Bolagny's Method of Removing Gelatine Films.—M. Bolagny always strips his gelatine films off the glass. The plate is first covered with French chalk before receiving the film, then, after development and fixing, it is covered with glycerined gelatine, and allowed to dry; by cutting the edges, the negative is taken off readily.

M. Fourier's Gelatine Photography.—M. Fourier points out a process which we have ourselves indicated for transferring photographs to sheets covered with gelatine by the powder process. He dusts on a fine powder capable of tanning the gelatine, and then it is possible to print off from portions of the surface thus acted on. It resembles M. Otto's black auto-copyist method from photographic prints. The powder employed is a mixture of alum and nitrate of uranium reduced to almost impalpable powder, coloured black with lampblack.

French Edition of Mr. Baden Pritchard's "Studios."—Our esteemed Editor, we are glad to see, has just published his interesting collection of the "Studios of Europe." It gives us great satisfaction to be able to announce that our special publisher of photographic works, M. Gauthier-Villars, has prepared the French edition, which is to appear directly. Such complete detail as Mr. Baden Pritchard has given on the studios of the principal towns of Europe cannot fail to interest the photographic world. LEON VIDAL.

NOTES ON LEVELS.

BY DR. STOLZE,*

SINCE the advent of gelatine emulsion into the every-day work of photography, the general practitioner has had occasion to make frequent use of the level; hence some information regarding it may be of use.

The level depends on the general principle that an air-bubble, when in a closed vessel otherwise full of a fluid, will always take the highest place. Whether we deal with the circular level, the glass top of which is slightly arched or domed, or the ordinary tube level, the same principle of greater sensitiveness in proportion as the inner curvature is less, holds good. When, therefore, the radius of a level is spoken of, the radius of a circle corresponding to the inner curvature of the tube or dome is understood, and it is interesting to trace the relation between the radius of a level and its sensitiveness. For ordinary gelatino-bromide work it suffices to use a level having a radius as short as 1·146 metres, while those levels used for astronomical work must be much longer as regards radial length; an instrument which indicates six seconds requiring a radius of 68·755 meters, and one indicating two seconds must have a radius of no less 206·265 meters. Shallow curves like these are difficult to grind, and such levels are necessarily expensive.

The circular level is in some respects a convenient instrument, as it is easy to verify it by slowly rotating it over any even surface, and noting if the bubble always remains in the same position in relation to the centre. Should it not be true, the under surface of the brass casing must be ground down by friction on a sheet of emery cloth or other abrading surface until the adjustment is perfect. One notable defect of the circular level is the continual tendency of the included alcohol to evaporate, a condition of things which appears to be unavoidable, as glass and brass expand by heat at unequal rates. Hence the bubble constantly increases in size until the instrument becomes valueless, unless it is re-filled. In order to do this, the screw which closes the instrument is taken out, and the instrument is filled with alcohol by means of a fine pipette, after which the whole is slightly warmed either by means of a spirit lamp, or by partial immersion in hot water. The aperture is then tightly closed, and as the level cools, and the spirit contracts, a small bubble, which should theoretically contain only alcohol vapour, becomes visible inside; but in actual practice some air is always present.

Good tube levels are more accurate than circular levels, and they may therefore be used when large plates are to be coated with thin films, and the best contain ether rather than alcohol. In almost every case adjustment screws are provided, so that the instrument may be exactly set to truth when required for use. In general it is, however, more convenient for the photographer to employ good circular levels than tube levels, as these latter are liable to be temporarily thrown out of adjustment by unequal heating.

* Abstracted from the *Wochenblatt*.

THE BIRTH OF THE PHOTOGRAPHIC LENS.

BY DR. J. M. EDER.

IT is a well-known fact, observed over three hundred years ago, that in a darkened chamber or box into which light is admitted through a small opening there is pictured upon a white screen a representation of objects outside the aperture. The farther the intervening object, the

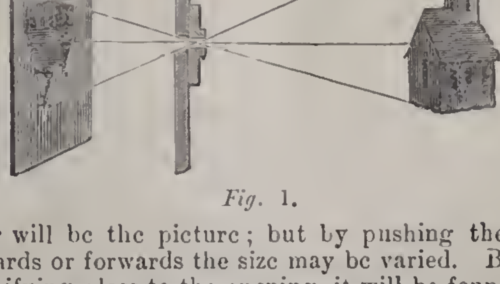


Fig. 1.

smaller will be the picture; but by pushing the screen backwards or forwards the size may be varied. By fitting a magnifying-glass to the opening, it will be found that at a certain distance it will be more sharply defined, and by changing the position of the screen the effect blurred.

The result obtained by enlarging the hole is indistinct in outline.

In fig. 2 the diagram shows how the enlarged aperture gives a hazy definition.

Fig. 2.

In the camera without a lens, no matter how far the the objects are from the opening (A A′, B B′ C C′, fig. 3), they always appear distinct upon the screen, at whatever distance it is placed. Unlike a lens, therefore, there is no focussing point for varying distances. In 1855 Berry is

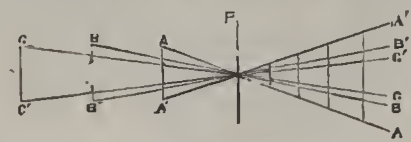

Fig. 3.

reported to have taken a landscape with an aperture of $\frac{1}{30}$ of an inch, and in America a portrait is said to have been taken by this means.

According to Emerson, a picture taken with the commonest glass lens is far superior to any using the simple aperture; as for the latter, with the most sensitive wet collodion plates, from three to seven minutes' exposure are necessary. To obtain clear definition, ·0001 inch opening is requisite. It is certainly possible to produce sharp pictures with a camera having, instead of a lens, a small round hole, the diameter of which is only $\frac{1}{5556}$ of the focal length, if such a term may be used. Nevertheless, Spiller's latest experiments show that the application of a camera without lens to photography is not practicable. For instance, a house in full sunshine being the object in front of a camera with 1.4 mm. aperture and 26 c.m. distance between it and a gelatine plate, gave, after eight minutes' exposure, a very blurred picture; with 0·5 mm. the definition was sharper, but the exposure was lengthened to one hour.

Lenses may be divided into two distinct kinds, viz., convex lenses, which are thicker in the centre than at the edge; and concave, having the centre thinnest. Fig. 4 shows sections of various forms of lenses employed in the construction of optical instruments, including portrait objectives. 1 is a double convex; 2, a plano-convex; 3, a concavo-convex, or converging meniscus; 4, double concave; 5, a plano-concave; and 6, a diverging concavo-

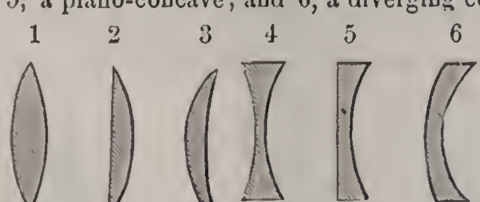

Fig. 4.

convex, or meniscus lens. In most lenses the focal length of the outer rays is less than that of the central rays, These differences of focal length, acting upon pictures. make them indistinct, as the rays do not converge to one point, but spread over the disc. Again, in these simple lenses, another cause of indistinctness results from the varying degrees of refrangibility of different colours. The violet rays are more refracted than the red. By taking a distance less than the focal length of rays of medium refrangibility, a picture is formed of a white disc having a red border; while, by reckoning a greater distance, a blue-violet band encircles the white. Observations on these appearances have been made by the Abbot Franciscus Mourolykus, 1575; Keppler, 1604; and Dollond, in 1758. Achromatism is prevented by employing crown and flint glass, heavy and light flint glass, or heavy and light crown glass.

In the sixteenth century Johann Baptist Porta used a plano-convex lens as objective, the convex side of which was fixed outwards towards the view, and it was behind a screen having an opening equal to from $\frac{1}{20}$ to $\frac{1}{30}$ of the focal length (fig. 5). A sharp picture resulted, equal to $\frac{1}{5}$ of the focal length in size. The diaphragm being moved

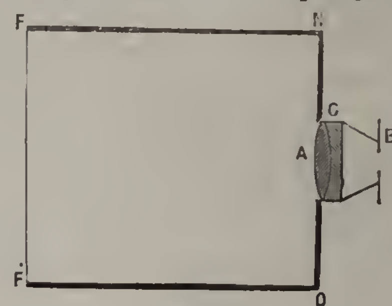

Fig. 5.

in front of the lens, the picture was larger, but the outer edges gave distorted forms, as shown in fig. 6.

B (fig. 6) is a plano-convex lens, with flat side turned towards the object, the diaphragm C being placed in front. The flat-receiving surface at O′ shows the outer lines more curved as they approach the edge. By reversing the position of diaphragm C (as in fig. 7), the outer lines of the square appear to be curved outwards.

Fig. 6.

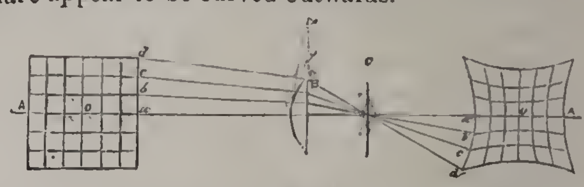

Fig. 7.

Wollaston altered the form of the lens. He used a concavo-convex meniscus having the concave surface exposed towards the object. The focal length varied from twenty to thirty inches, and altogether the meniscus gave a much larger and sharper picture plane. This kind of lens used with a diaphragm of $\frac{f}{30}$ was employed at the time of the discovery of the Daguerreotype in 1839. The objection to this single view lens consisted in the difference existing between the chemical and optical foci; that which appeared sharp on the focussing glass gave an indistinct impression on the plate.

In 1840, the French optician Chevalier constructed an achromatic photographic objective by cementing a double convex crown glass lens to a plano-concave flint glass lens. Professor Steinheil and Kobell in 1839 cemented telescope objectives for photographic purposes. The old view lenses all partake of this form, the outer plano-concave flint glass being turned towards the object, and the crown glass convex towards the focussing glass. The picture is equal to about one-third the focal length. The diaphragm was usually placed before the lens as shown in fig. 6. The tube B contains lens A close to the flange; at C the tube is narrowed, and the smaller one, E, is inserted having the diaphragm at F; D is the cover. Daguerre used a simple achromatic lens of three inches diameter, and in 1839 required an exposure of twenty minutes. Townson made larger lenses, and made more accurate corrections in the foci, so that Draper, in New York, took the first portrait in 1840. As the exposure was from ten to twenty

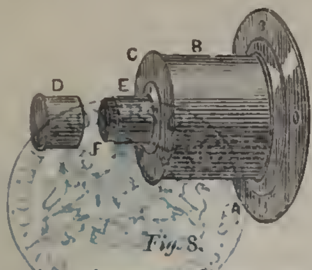

Fig. 8.

minutes in duration, hazy outlines resulted, as no one could remain in a free and unconstrained position so long.

At that time, according to the proposal of the French optician, Baron, a lens was wanted, the focal length of which was to be twice the size of the plate, the diameter of the diaphragm to be $\frac{1}{7}$ of the focal length.

At the present time a simple lens is required to produce a larger picture, and is further stopped down in proportion; but as light must be sacrificed, they are almost entirely used for landscape, and otherwise they are greatly excelled by doubled objectives.

The achromatic concavo-convex meniscus allows the use of larger diaphragms, and gives the pictures more brilliancy and relief on account of greater lighting power. In the Grubb lenses, as the spherical variation is not corrected, the opening must be altered. This form of lens consists of a crown glass meniscus, concave surface outwards, fixed to a diverging flint glass. It has the same expansion of view, but shorter focal length than the preceding. Grubb patented it in 1857, but the patent expired in 1860. These single view lenses are still largely used for landscape work in England, Germany, and France. Those known as Waterbury lenses are single view lenses having a permanent diaphragm of $\frac{1}{5}$ the diameter, and nickel-plated mountings. Their name is derived from the town Waterbury, Connecticut, where the factories of their manufacturers, the Scovill Company, are situated.

In 1857 Burnett endeavoured to change the simple lens into the form of band lenses. A strip from $\frac{1}{3}$ to $\frac{2}{3}$ of an inch in width was cut out in order to avoid the distortion by the admission of nearer objects, also at both ends of the strip a stereoscopic action took place by two pictures of an object coming together.

With the intention of reducing distortion to the slightest possible amount, and to give the lens the widest angle, Dallmeyer gave the simple lens a more pronounced meniscus form, and brought the diaphragm closer to the lens. Had he retained the early system of objectives, his aim would have been attained at the expense of sharpness of definition at the edge; it was therefore necessary to adopt a new optical construction. To the two lenses, one of crown glass and the other flint, Dallmeyer added a third, made of crown glass, the refractive index of which was somewhat different to the first. These cemented together form a single objective, the concave side being turned to the object to be reproduced. The rotating diaphragm is placed in front of the lens at a distance equal to its diameter, the smallest opening being $\frac{f}{30}$. The chief advantages derived from Dallmeyer's single view lenses are that with an aperture of $\frac{f}{20}$ a circular focal plane of 72° is perfectly sharp; while with $\frac{f}{30}$ the angle of vision is increased from 85° to 90°. The picture plane of the objective is very large for the longer side of the picture, which is always rectangular, is greater than the focal length of the objective, while with all lenses of earlier construction it was at most two-thirds the distance. This is a great advantage in landscape photography, as not only is the foreground well defined, but also the distance is rendered in practically correct perspective, although when used for architectural purposes the outer lines appear slightly curved.

The picture plane is more even than in the preceding lenses, and therefore the result is more brilliant in effect, owing to the chemical focus reducing slightly the angles of the rays converging to the axis.

Much unnecessary work is done by the wide-angle double objective, as some aplanatic lenses are superior in every way. In order to obviate the difficulty arising from having different lenses with various-sized tubes, a great number are made of the same diameter.

In 1881, W. K. Burton made use of single-view lenses reversed (that is, having the flat side towards the focussing glass for portraits, working with gelatine plates), and found them answer admirably when extreme rapidity of exposure was not necessary. These must not be compared with a portrait objective of equal focus, the largest field covered being equal to half the focal length; neither are they so clear as the aplanatic, but give softness, which is so desirable. Portrait lenses give detail in dark drapery with brilliancy and clearness, which is to be expected from six reflecting surfaces instead of two. Under favourable conditions, a picture—on gelatine plates—may be produced in a room in ten seconds, and in a studio in from two to five seconds, with a single-view lens.

A landscape, having rather a large angle of vision (40° to 45°) requires a portrait lens to be more stopped down, to give the necessary detail, than a single-view lens of shorter focal length and greater rapidity.

REGNARD'S INCANDESCENT LAMP.

THERE has for a long time been sought a process for obtaining a bright light which should permit of projections being easily made. In places where electric lights exist the thing is very simple; and it is also easy in places where there is gas, but then oxygen being necessary the apparatus became quite difficult to arrange and move about. But in all localities where even gas does not exist it becomes absolutely necessary to dispense with a method of teaching which, it is generally agreed, is an excellent one.

Quite recently the Minister of Public Instruction requested a special commission to design for him an apparatus that might be readily used in primary schools for making projections. The result of this commission's examination is that even if simple apparatus for projecting be not wanting, we are very far from having luminous foci sufficiently intense for obtaining somewhat enlarged images.

Dr. Regnard has conceived the idea of obtaining a very brilliant light by burning a mixture of air and vapour of petroleum on a platinum gauze. There results from this an intense heat, which raises the platinum wires to a white heat, and thus produces a light about half as bright as that of the oxyhydrogen light. The apparatus is very simple, consisting of an ordinary Bunsen burner terminating in a litttle cage of platinum wire. Instead of supplying this burner with gas, there is forced into it a mixture of air and petroleum vapour, according to a process known for a long time, and utilized recently by the numerous inventors of thermo-cauters. A simple kitchen bellows or a syringe bulb is quite sufficient to set up the necessary current of air. In order to throw all the light in one direction the Bunsen burner may be covered with a tube having a flaring orifice, like the bell of a trumpet, covered very accurately with a net-work of platinum wire. In order to obtain an extremely brilliant light whenever the blowing is done, it is only necessary to regulate the flow of the gaseous mixture by the ring of the burner. If, instead of using a bellows, the current of air be forced by a pneumatic machine or tromp, quite a number of lamps may be supplied and made to give a light having the aspect and power of incandescent electric lamps for rooms, factories, &c., in places where no gas exists.

Dr. Regnard's lamp is based on the Bourbouze burner, but is superior to that in not requiring the use of illuminating gas. It has another very great advantage, and that is that it costs almost nothing, and even when operating at a maximum the expense is only a few cents. per hour. It will prove of service to physicians for making laryngoscopic and otoscopic examinations.

If it be desired to give the apparatus greater constancy and make it serviceable for regular lighting, we suppose it would be necessary to go to a little more expense and increase the size of the carburetter in order that the impoverishment of the petroleum may not make itself too quickly felt. This may be accomplished by causing the air to bubble through one of those large flasks found in all drug stores, and into which there will be put nine or ten pints of the liquid. Such a flask may be placed under the table holding the apparatus, or even further off.

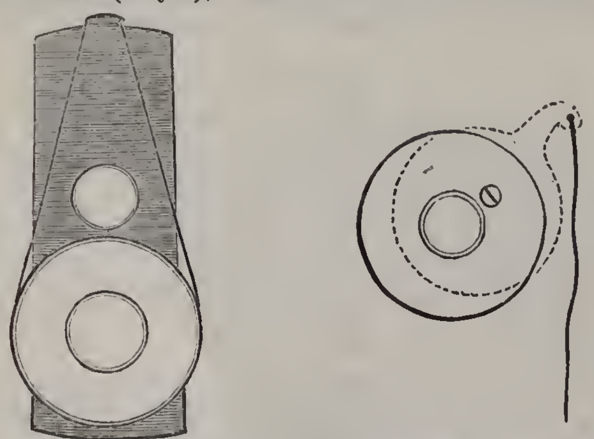
If it be not desirable to perform the blowing with the hands, there may be disposed under the table a large blowing apparatus that anyone can construct by loading with a weight a bag filled with air. If the bag is tolerably large the lamp will be enabled to operate for several hours without any attention being paid to it. The petroleum product to be put into the carburetter is the ordinary benzine of commerce.—*La Nature.*

Correspondence.

SIMPLE INSTANTANEOUS SHUTTERS.

Dear Sir,—I enclose rough prints of photographs taken on the open sea by two forms of instantaneous shutter which might be handy for some of your readers.

The picture of ship in full sail was taken between South America and the Cape of Good Hope by a Ross' rapid symmetrical (8 by 5), in which I had cut a slit opposite



Rapid Symmetrical. Portable Symmetrical.

the diaphragm or stop slit. A piece of brass about 5 in. by 1 in. passes thus right between the lenses, this strip being provided with a hole in the centre; an india-rubber band round the lens completes the apparatus.

The other shutter was made by substituting a disc of brass with a hole in it for the rotating stop, and a string fastened on to a small projection can be pulled nearly as fast as the quickest plates require; or, if wanted, a slip of blackened paper with a hole in can be used to stop it down.—Yours, Herbert Green.

[The first described arrangement recalls Mr. York's idea of using a drop shutter between the lenses of a portrait combination.—Ed. P. N.]

THE FERROUS OXALATE DEVELOPER.

Dear Sir,—I notice in your last number an article taken from "Autotype Notes," advocating the ferrous oxalate developer in preference to pyrogallic acid, and giving an easy method for the preparation of the same.

Allow me to second the writer of that article.

For the last two or three months I have developed all my plates with ferrous oxalate, and I am so pleased with the ease and certainty with which it can be worked that I fully intend to continue to do so.

My method of working differs but slightly from that given in the article referred to, with the perhaps rather important exception that I almost invariably commence developing with a small quantity of potassium bromide in the developer, and that I find the addition of a few drops of a very weak solution of sodium hyposulphite, as recommended by Captain Abney, has a very marked effect in restoring the energy of a worn-out developer, or in bringing out detail in an under-exposed plate.

By this means I have often developed six or more half-plates with between two and three ounces of developer. The negatives develop quickly and evenly, and ample intensity is readily obtained.

Perhaps the only thing to guard against is an alkaline sample of the potassium oxalate, which should invariably be tested, and, if necessary, be neutralized with oxalic acid.

When I find a plate to have been over-exposed, I stop the developer as soon as the details are out, fix, and then intensify with mercury and ammonia.

Hoping that the few details above may induce others, who have not yet given this mode of development a trial, to compare its merits with those of pyrogallic acid,—I remain, yours truly, Alex. Campbell Swinton.

[Our correspondent sends us half-a-dozen admirable out-door studies as an illustration. They are fully detailed in the shaded parts, yet well gradated and vigorous.—Ed. P.N.]

Proceedings of Societies.

Sheffield Photographic Society.

The ordinary meeting of this Society was held at the Freemasons' Hall, July 4th, Thos. H. Morton, M.D., President, in the chair.

The minutes of last meeting were confirmed.

A letter from Mr. Cecil V. Shadbolt was read, giving an account of his recent balloon ascent, and a photograph taken on that occasion was submitted to the members; it excited much interest and some discussion.

The Chairman proposed, and Mr. Hatfield seconded, that a vote of thanks be given to Mr. Shadbolt for his communication, and congratulated him on his success.

Circulars relating to the forthcoming Cornwall Polytechnic Society's Exhibition were placed upon the table.

Mr. Dakin exhibited negatives developed by ferrous oxalate, showing well the remarkable clearness in the shadows and freedom from fog secured by this process, even when development was prolonged.

Dr. Morton made some suggestions on packing negatives; although apparently a trifling subject, care was needed in handling and storing. With exposed plates, when travelling he thought it a good plan to take the plates from the double slides and place them in pairs facing each other with a fold of clean white blotting-paper between the upper and lower edges, then slip them into paper bags which were numbered, or could have description written with pencil on the back, and afterwards replace in the original card-packing box. The envelopes he made were of thin but tough wrapping paper.

Mr. Millward brought several good pictures, the result of recent excursion to North Wales.

Mr. Hatfield moved that the question of the Society's exhibition be considered at next meeting.

Messrs. T. Firth and G. V. Yates were deputed to make arrangements for an out-door excursion to "Rivaulk Abbey", on the 12th inst.

The meeting then adjourned.

Edinburgh Photographic Society.

The Edinburgh Photographic Society held their annual picnic at Dirleton, one of the most lovely spots in Scotland, on Thursday, the 6th of July. The party, numbering nearly seventy ladies and gentlemen, representatives being present from Glasgow, Hardwick, Liverpool, &c., after luncheon supplied in a spacious building kindly granted by Mr. Guild, of Castlemains farm, visited the gardens and grounds of Dirleton Castle, where five operators set to work and took views of the various points of interest, as well as groups of the whole party, which were accomplished under favourable conditions. Dinner was served by Mr. John Pillans, of Edinburgh, Mr. J. Lessels presiding.

After the usual loyal toasts, Mr. Lessels proposed "Prosperity to the Edinburgh Photographic Society," which was duly honoured. Mr. Tunny proposed "The Health of the President and Executive Committee," commending them for the very satisfactory arrangements made for the comfort of the company. Mr. William Dougall proposed "The Ladies," which was replied to by Mr. Louden. Mr. J. M. Turnbull proposed a vote of thanks to Mr. Guild for his kindness in giving such ample accommodation for luncheon, dinner, tea, and dancing. Mr. Guild suitably replied, and expressed the pleasure it gave him to add to their comfort, as the weather was so uncertain.

After dinner the company assembled in one of the parks, and a number of suitable prizes for races and walking matches were competed for. A blindfold barrow race afforded much amusement to all present.

After tea the party joined the train at Dirleton Station at 7 p.m., having spent a very enjoyable day of varied amusements. The arrangements were under the superintendence of Messrs. W. Dougall, J. M. Turnbull, John Simpson, J. Crighton, W. Hume, T. Wardale, jun., and the Secretary.

London and Provincial Photographic Association.

The first ordinary meeting of this Association was held at Ashley's Hotel, Covent Garden, on Thursday, the 6th inst., Mr. W. M. Ashman occupying the chair.

Mr. Henderson exhibited two experimental negatives by Mr. Phillips, of Fareham. They were taken under exactly the same conditions—one being developed with the ordinary pyrogallic and ammonia solution, and the other with the same strength of pyrogallic and ammonia, and the addition of sulphite, the latter being badly green fogged.

Mr. W. K. Burton was of opinion that the sulphite caused green fog.

Messrs. Debenham and Brown found its use slow the development.

Mr. Coles found that plates which, when developed with the sulphite formula, were green fogged, were often not so when the sulphite was not used.

Mr. Burton enquired if any one present could corroborate Mr. Brooks' assertion, that a stock solution of pyrogallic and sulphite will not keep, but, after a few days, loses its density-giving powers?

Messrs. Mackie and Rieman had found it undeteriorated after some considerable length of time.

Mr. Brown said it had been stated that the substitution of common washing soda for ammonia in the developing solution was a cure for green fog; and he produced two plates, one developed with the ordinary pyrogallic and ammonia solutions, the other with the soda formula; he found that although there was no green fog, its place was taken by a yellow one.

Mr. Henderson preferred the use of caustic soda or caustic potash.

Mr. Cowan produced four plates, illustrating the restraining action of citrate of potash; the first three were exposed alike (six seconds), No. 1 being developed with a normal pyrogallic developer; No. 2 with the same developer, 2 drachms of a 60-grain solution of citrate potash being added; No. 3 with only 1 drachm of the citrate solution added. No. 4 was exposed thirty-six seconds, or six times as long as No. 1, and developed with the same formula as No. 3, the result being no perceptible difference between it and No. 1. He also exhibited a piece of mosquito netting, such as he used for straining emulsions; it was a very fine mesh, and cost 2s. 9d. per yard square.

Mr. Henderson said he had recently handed two plates prepared according to his formulæ to a large maker who had tested them against the most rapid commercial plates in the market, and stated that with $\frac{1}{8}$ of the exposure necessary for the commercial plates Mr. Henderson's was over-exposed.

Mr. Collins passed round a sample of seed lac varnish; he said there was a large sediment, and consequently great waste in preparing it.

Mr. Henderson thought that if the varnish was forced through wash-leather, it would be found to filter very fine and clear.

Photographers' Benevolent Association.

The Board of Management of this Association held its monthly meeting on the 5th inst., at 181, Aldersgate Street.

The minutes of the previous meeting having been read and confirmed,

The Secretary submitted his half-yearly statement, which showed that the improvement made last year in the Association was being continued this year, the subscription from ordinary and honorary members being in excess of those of previous years.

Messrs. B. Moil (Kimberley, South Africa) and E. Wyse (London) were elected as ordinary members of the Association.

A cheque for one guinea was also received from W. T. F. M. Ingall, as a subscription to the funds.

The Board, after dealing with other business, adjourned.

Dundee and East of Scotland Photographic Association.

The annual holiday and out-door meeting was held on the 7th ult., when a party of upwards of one hundred and fifty ladies and gentleman drove in open carriages from Dundee to the beautiful Den o' Airlie, passing *en route* through seme twenty-two miles of delightful country; a most pleasant day was spent, an occasional shower or two varying the proceedings. Numerous cameras were at work at landscapes and groups. Substantial dinner and tea were well provided and duly discussed, and the party returned in the evening well pleased with the day's outing.

An extra meeting of the above Society was held on Thursday, July 7th, in Lamb's Hotel, the President, Mr. J. C. Cox, being in the chair.

After the Hon. Secretary had read the minutes of the last meeting, which were duly approved, Mr. James Sturrock and Mr. W. B. Davidson were unanimously admitted members.

The President read a letter from Glasgow anent proposed exhibition, and several communications were read by the Secretary.

Some excellent photographs, the results of the out-door meeting at the Den of Airlie, were shown by Mr. J. Geddes, Mr. J. Robertson, and Mr. A. C. Lamb. A most satisfactory list of contributors of papers for the winter session was made out, including the President, Vice-President, Treasurer, and others, and the winter session is expected to be both agreeable and profitable. The usual vote of thanks to the chair closed the meeting.

Talk in the Studio.

The Recent Alexandra Palace Award.—One of Mr. B. J. Edwards' two pictures, for which the gold medal was awarded, having been found to have been taken before the appointed day, the gold medal has been given to Mr. G. F. Williams; Mr. T. G. Horsey taking the silver medal, and Mr. W. T. Wilson the bronze medal. Mr. Edwards wishes us to state that one of the two pictures which were selected by the judges as the best was not intended for competition, but was simply inserted to fill up a space in the frame, which space would otherwise have been vacant owing to an accident to one of the negatives taken on Whit Monday.

The Bristol Review.—We have received, through the kindness of a Bristol friend, the second number of this readable periodical. It is a shilling quarterly, printed in good type and neatly bound. The present number contains ten different papers, some of them of considerable interest.

Electricity at the Crystal Palace.—It is proposed to hold a second electrical exhibition at the Palace during the coming autumn and winter, the exhibits to consist principally of arrangements to be used in connection with electric lighting; but in order that gas lighting may be compared with electric illumination, modern appliances for utilising coal gas will be included.

French Equestrian Portraits.—Mr. J. Delton, who has devoted so many years to bringing to a rare perfection the art of photographing equestrian subjects by his instantaneous process, has just achieved a marked success in his charming album of the "Tour du Bois," in which many of the best-known riders, military and civil, not to mention many fair horsewomen, with their steeds, are depicted in the pleasant alleys of the Bois de Boulogne with a fidelity which nothing can surpass. This is simply the first instalment of a series of work of a similar character that will make up a collection which will be prized by the fashionable world, whose morning rides in the shady avenues of the famous wood form by no means the least agreeable incident in the round of the Parisian day.—*Daily Telegraph.*

Pirating Photographs.—The persons who have recently been pirating photographs are being vigorously prosecuted and punished. The great celebrity portraits of Oscar Wilde, Sarah Bernhardt, and Patti, for which large sums were paid to secure the exclusive right of sittings in this country, have been copied photographically and lithographically in immense quantities, one firm having sold about 600,000 lithographic copies of Oscar Wilde alone, which very naturally lessened the sale of the originals, and consequently resulted in great loss to the enterprising photographer. Several cases have already been settled, and an important test case now is in the courts. Some of the pirates actually had the audacity to print the word "copyright" on their publicatious. A great service is being rendered the fraternity by Mr. Sarony in prosecuting these people, for nearly every photographer of any noto has suffered more or less from the same cause.—*Anthony's Bulletin.*

Physiological Action of Light.—Recent investigations by Tissoni and Fileti appear to thoroughly prove that the proportion of hæmoglobin contained in the blood of animals diminishes notably when they remain for a considerable time in the dark; but full exposure to the light causes the proportiou of hæmoglobin to rapidly increase.

Vitrified Typographic Printing on Glass or Porcelain.—J. B. Miller uses an india-rubber stamp charged with a mixture of fat oil (oil of turpentine, resinified by exposure to the air) and French oil of turpentine. The impression is then dusted with a finely-powdered vitrifiable pigment, and fired iu the usual manner. This method would doubtless be available for phototypic work on glass or porcelain. The (so-called) over-glaze colours should be used.

Summer and Winter.—Mr. J. Vaughan, of New Wandsworth, forwards us a neat little album containing a series of views elegantly mounted upon loose cards. Some of them—the wintry scenes more particularly—are executed with much taste and judgment.

Mansion's Colours.—Mr. J. Solomon has been good enough to send us some pretty pictures coloured by means of "Mansion's colours," for which he is agent. The pigments are said to be particularly suitable for photographic colouring, by reason of their transparency.

An Artificial Moon.—Mr. A. Stewart Harrison writes, in *Knowledge*:—"Take a soup plate and slightly grease the surface with lard or oil; distribute irregularly iu varying thicknesses about a tablespoonful of so-called granulated citrate of magnesia. Take a basin, pour in enough water to fill the soup plate; shake into the water about two-thirds the quantity of fine freshly-burnt plaster of Paris, which will sink at once; pour off nearly all the superfluous water; stir two or three times with a stick or spoon, so as to mix irregularly the paste; then pour it on the powder in the soup plate. The water in the plaster will cause an immediate disengagement of carbonic acid gas, which will rise in bubbles of various sizes through it in irregular patches; the plaster almost immediately setting, the shape of the outline of the bubbles and the walls of them become fixed, and, as a result, a most startling resemblance to the cratered surface of the moon is produced. If a photograph of this be taken with a strong light, the resemblance becomes so perfect as to deceive almost all who are not professional astronomers. I believe that a little sugar, or syrup, or gum in the water would produce larger craters, but I have not tried this." To this the Editor appends the following:—"As we have for several years used illustrations of the moon's surface formed by Mr. Harrison in the way described above, we can vouch for the accuracy of his statements."

To Correspondents.

*** We cannot undertake to return rejected communications.

T. W. H.—The best and quickest way to Berlin is by the Flushing route in twenty-four hours. Write to address we have given for particulars.

Bromide.—1. Our Publishers securo the registration for a fee of 1s. 6d. each picture. Neither size nor the nature of the subject affect the registration. 2. You seem to think that if you register the portrait of an individual you secure some right over any subsequent portraits which may be taken of him. This is not the case, as you have only property in your own photograph. 3. No. 4. A picture from each negative must be registered.

J. L. M. C.—Write to Mr. Spink, Western Road, Brighton.

Hector Colard.—On page 628 of our volume for 1880.

Weaste.—The material of the negative belongs to the photographer, but the copyright in the picture to the customer.

Constant Reader.—They are, as a general rule, far more permanent than ordinary silver prints; but under the circumstances you would do well to supply carbon prints.

F. Cowley.—1. About six or eight times. 2. In such a case an aperture equal to one twenty-fifth of the focus will be generally satisfactory; but experience alone will help you with respect to the second part of your query, as there is nothing like a constant ratio. Still, to give some idea, we may perhaps give you the numbers $\frac{3}{4}$, 1, and 3 as representing the relative times of exposure. 3. Probably from one and a-half to two minutes.

R. Thompson.—1. We believe they can be obtained through any wholesale dealer in photographic materials. 2. No.

Henry Spink.—1. We fear that there is no remedy, and that the stock of old collodion is practically useless, except for copying, or for cleaning plates.

L. F. Simkins.—1. Under the circumstances a much larger aperture must be used. 2. Double the quantity of pyrogallic acid.

George Davy.—We are now experimentally investigating the matter, and we hope shortly to publish full details.

Glasgow.—Almost every manufacturer makes the statement, but it is not true, for all that.

J. Johns.—1. It is quite useless, and must be replaced by new. 2. Quite safe as long as you heat in a water-bath. 3. It is extremely corrosive when in a concentrated form, but when it is largely diluted no danger is to be apprehended.

Beginner.—Considering that you have been endeavouring to fix your prints with glauber salts or sulphate of soda, it is not to be wondered at that you failed altogether. The salt you require is sodium hyposulphite, or, as it is porhaps more systematically called, sodium thiosulphate.

F. Roberts.—1. When a tough film is required, as in the case of film negatives, it is usual to mix about one part of castor oil with 200 parts of the collodion. 2. Magnesia may be used instead of lime, and your best way will be to obtain some of the nativo carbonate of magnesia, known as magnesite, and thoroughly calcine it at a red heat; after which suitable cylinders may be cut out of the compact magnesia.

T. K. J.—There are pretty clear indications that your dark slides admit light at the joints.

B. B. Wilkinson.—A quarter-plate lens, without name, can generally be purchased at a pawnbroker's for six or seven shillings; and a person who can recognise a good lens without actually trying it may often obtain a very good instrument. On the other hand, it not unfrequently happens that the bargain-hunter finds his purchase absolutely valueless. 2. It very rarely pays to have a broken glass replaced.

Gold.—There are some who hold such views, but we would not advise you to undertake experimental work in this direction.

Young Printer.—The bath not being strong enough, the albumen dissolves. Add an additional 10 grains of silver to each ounce, and try again.

C. P. Morgan.—You will find full particulars in the Year-Book.

Many answers are unavoidably crowded out.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1246.—*July* 21, 1882.

CONTENTS.

THE DRYING OF GELATINOUS FILMS.

A FEW years ago the general photographer had but little occasion to devote attention to this subject, gelatine being but seldom used in every-day work, excepting by the carbon printer, or those engaged in the various methods of photo-mechanical printing. Now all is changed, and the expeditious and convenient drying of gelatinous films is one of the most important points in connection with the photographic practice of the present time.

The drying of the freshly coated gelatine emulsion plate, and the desiccation of the finished negative, are the only operations which require special study from the general photographer's point of view; while a few points must be incidentally considered as bearing on the work of the carbon printer, or on the phototypist.

General experience points to the necessity of drying gelatino-bromide plates slowly, and at a low temperature; but these conditions can only be fulfilled in the most complete manner by employing air artificially dried by some desiccating agent, such as chloride of calcium.

Several effective drying cupboards, constructed for use with hygroscopic substances, have been described from time to time in our columns, that devised by Professor Herman Fol being very convenient, and, moreover, easy to construct. Chloride of calcium offers many advantages over sulphuric acid or quick lime as a drying agent, as it can easily be restored to an effective condition by half an hour's baking in an ordinary kitchen oven, and it is not, as quick lime, liable to give off dust-like particles, while it is free from the specially corrosive properties which characterise sulphuric acid. Chloride of calcium, when its solution is evaporated by baking in an ordinrry oven, takes the form of a sponge-like mass; this form being especially convenient, as a large surface is exposed to the air, and is consequently operative.

When a thick film of bichromatised gelatine is to be dried, as in the case of tissue intended for use in making reliefs for the Woodbury process, it is generally necessary to have recourse to chloride of calcium as an absorbent of moisture; each sheet of tissue being supported, coated side downwards, over a layer of the chloride contained in a metal tray; and in most cases several of these trays are constructed to slide into a casing, so that the whole arrangement resembles a chest of drawers in miniature. An arrangement of this kind we have found to be extremely useful when it has been a matter of importance to dry either freshly coated plates or negatives with rapidity, ten minutes being sufficient in either case, provided that care is taken to use the chloride of calcium in good condition as regards sponginess and dryness. The plate should be supported about one-fourth of an inch from the surface of the chloride of calcium, but it is scarcely necessary to remark that the chloride of calcium must never come in actual contact with the surface of the plate.

Some years ago Mr. Foxlee proposed an ingenious method of rapidly drying either freshly-coated plates or negatives, and his method is also applicable to other cases in which it is necessary to dry gelatinous films rapidly. The plate is soaked in alcohol, or, indeed, ordinary methylated spirit, for a few minutes, part of the moisture being thus removed by the alcohol, little or none of which is itself absorbed by the film. The alcohol is next blotted off by a piece of clean bibulous paper, after which the drying may be finished by the application of a gentle heat. Exposure to a moderate temperature—say 130° to 150° F.—is not injurious to an unexposed film at this stage, it being a known fact that, as the proportion of water in such a film diminishes, an increasingly high temperature may be employed without mischievous consequences. The so-called "methylated finish," which is in reality a dilute solution of certain resins in methylated spirit, must not be used instead of the pure methylated spirit.

When negatives are to be dried, there is a decided gain in removing all loosely adherent water by means of blotting paper, as recently suggested by the Rev. Mr. Bird, and the advantage of this proceeding has long been fully recognised by carbon printers and phototypists. Any person who adopts this method, and uses ordinary care, will find it to be of considerable practical value; but it is scarcely necessary to suggest that the blotting paper should not be smoothed down on the plate by the hand, as the warmth may cause adhesion; and the under, or web side of the blotting-paper should alone be brought into contact with the film, or fibres may remain behind when the paper is stripped off.

THE DEVELOPMENT OF GELATINO-CHLORIDE AND GELATINO-BROMIDE PLATES, AND ON GREEN FOG.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.

DURING my recent visit to my almost annual resort, the Riffelberg, near Zermatt, in Switzerland, I have learnt something which may, perhaps, be of benefit to your readers during the coming summer and autumn. My object in making so early a visit to a place which is usually sought during the next three months, was to make certain spectroscopic observations at a high altitude, and as near midsummer day as possible. These investigations have, however, nothing to do with my present article; suffice it to say that a residence at a height of 8,500 feet above the sea for between a fortnight and three weeks has been most delightful, surrounded as we were by pure air, with a barometer standing about twenty inches, and with the hill sides below the snow line covered with Alpine flowers of almost every hue and description.

My work necessitated the transport to this spot of several hundred plates of all descriptions, and supplies of collodion emulsions; but the plates to which I wish principally to refer were the gelatine plates which I took with me, these being pure bromide, bromo-iodide, and chloride plates, some of all sorts being taken for the spectroscopic work, and also for views. This is the first time abroad that I have developed many gelatine plates, and I only did so this time since, for the spectroscopic observations, it was necessary to know what was impressed on the plates, and then one naturally developed an occasional landscape. A very simple tent, weighing two or three pounds, was sufficient to work in comfort, in a room I secured for photographic purposes: it is something like Mr. Werge's tent, I believe. It had a large window covered with two thicknesses of ruby cloth, and the light coming through this could be dimmed by nearly closing the shutters, or by placing orange paper over the window. For ordinary gelatino-bromo-iodide plates, the unshaded window could be used with impunity, as it could with the chloride, though, of course, not for those plates which were sensitive to the very low parts of the spectrum.

Development of Chloride Plates.—I think we certainly are making an advance in the development of chloride plates. Several dozen of these were exposed and developed during my stay, being used both for spectroscopic work and also for landscape work. Up to the present time I have employed the ferrous citro-oxalate developer, which is admirable in its results; but at the Riffel it struck me that alkaline development might be more readily worked. I certainly tried this development before, and failed with it, but a slight modification renders it available for these plates. The emulsion employed was pure chloride of silver, prepared with an excess of common salt, and rendered slightly acid by hydrochloric acid, boiled for a quarter of an hour, and washed in the usual manner. (This method of preparation I have described elsewhere.) For the ultra-violet end of the spectrum these plates are slightly more rapid than rapid bromide plates when developed as follows:—

No. 1.—Pyrogallic acid (dry)

No. 2.—Potassium bromide	...	20 grains
Water	...	1 ounce
No. 3.—Ammonia ·880	...	1 part
Water	...	9 parts

To make up the normal developing solution the following were taken:—

No. 1*	...	3 grains
No. 2	...	1 drachm
No. 3	...	½ "

and made up, by the addition of water, to three ounces. This was poured over the plate at once, and development proceeded, giving images bright, dense, and perfectly free from fog of any description.

If the reader will follow out the above method of development, he will have no need to complain as to the difficulty of developing silver chloride. It may seem curious that bromide should be used as a restrainer, and for the sake of theory it may be as well to see what action it has. When the developer is applied, of course the tendency is for the sub-chloride to be reduced, but, at the same time, a minute layer of unaltered chloride is converted into bromide, which, owing to its conversion, is not readily reduced. This is what occurs at the first shock of the developer. Density is obtained, as we know, by reducing the haloid salt in contact with the first reduced silver, and this haloid has now been converted into bromide, hence the development goes on as in a bromide plate. In an interesting experiment made some time ago, and described by Dr. Eder, after exposing a chloride plate, he soaked it in potassium bromide till all the haloid silver salt was apparently converted into silver bromide, and then developed a perfect picture. I think, however, that it is probable that the sub-chloride was not converted into sub-bromide, since a theoretical difficulty arises, and my present impression is that the sub-chloride was left behind, forming the nucleus on which the development took place. If so, Dr. Eder's experiment and this latest mode of development are equivalent one to the other. Every plate developed as above gave perfect results, except in one or two instances, where the presence of green fog was most manifest. The presence of this green fog was my own fault. I found in the case of chloride plates, as I do with any other gelatine plates, that if they were *fixed in white light, green fog was sure to occur*, and that if fixed in the tent it was invariably absent. As a proof, if half a plate be fixed in the dark, and the other half in white light, green fog will show in the last half fixed, and not in the other. These experiments also showed me that chloride plates are excellent for ordinary landscape work, giving detail and density, as before stated.

* A portion of dry pyrogallic acid was taken from the bottle at the end of a strip of glass, and judged to be that weight.

Development of Bromide and Bromo-Iodide Plates.—In developing these plates, the same solutions as the above were employed. In several cases, over-exposure was known to have been given, two or three plates having more than six times too much exposure, and in one case twenty times too much exposure. The treatment adopted, and which with plates containing iodide proved uniformly successful, was as follows. The plates were developed with the same proportions as given above for the chloride, adding more bromide or ammonia as the progress of the development indicated was required. If the image began to appear in fifteen seconds, the same strength of developer was continued, adding the same proportions of bromide and ammonia till proper density was secured. On the other hand, if the image did not appear in that time, more ammonia was added, and if it began to appear almost immediately, a drachm of bromide was at once added. By this means the plates were saved. For a properly-exposed picture, the normal developer used was—

No. 1	...	3 grains
No. 2	...	1 drachm
No. 3	...	2 drachms

applied at once. The solution of No. 2 is weaker than I generally employ for gelatine plates, though it is the strength I use for collodion emulsion. I usually make it up—

Potassium bromide	...	50 grains
Water	...	1 ounce

in which case, of course, the amount added must be proportionally reduced to 25 minims.

The water used was from the small stream which runs outside the Riffel hotel, and had we such water in England the use of sulphite in the developer would be abandoned. In the measure used for developing, and after a plate has been developed, I have let the mixed solutions stand some five or six hours, and at the end of that time it has only been of a light brown colour, with no trace of blackness about it. I have, in fact, developed several plates with the same solution. The water is snow water, and does not run through limestone. It thus appears that the chalk has something to do with the horrid black mess which so often disgusts the cleanly photographer. Can it be that the sulphite of soda and the carbonate of lime form sulphite of lime and carbonate of soda? Anyhow, in no case was I obliged to trench on the stock of sulphite of soda which I had with me.

Sulphite of Soda and Green Fog.—Touching sulphite of soda and green fog, I should here like to say a word or two. I think that if photographers would read my paper on the subject of the cure for green fog, which appeared a few months back in the News, they would see that it is in reality a deposit of silver in a minute form, and that it can only occur when some substance is present in the developer in *which the silver salt is soluble.* Now the silver haloids are soluble to a notable extent in sulphite of soda, and we may therefore expect that it should aid its formation. It has been asserted that with ferrous oxalate you can get green fog. My own experience is that, with this developer (which I have employed more extensively than most photographers have done), green fog is impossible unless some substance be present with it, as I said before, in which silver bromide is soluble. Two instances were brought before me of green fog with ferrous oxalate. After close questioning, in one case I found that hyposulphite had been added to the developer, and that accounted for it; in the other, the ferrous oxalate had been made up with ammonium oxalate instead of potassium oxalate. In both cases a solvent of silver bromide was present. Fixing a plate developed in white light after moderate washing will give green fog with alkaline development, but fails to do so with ferrous oxalate.

In a subsequent article I propose to say something about exposures necessary to be given at high altitudes, which I am afraid will somewhat shatter the notions which now prevail.

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

A Tour in the Tyrol.*

The Krimml waterfalls—there are three magnificent cascades—is a difficult subject to photograph; at any rate, we found it so. If you recede far enough to get out of the way of the spray, then the stupendous mass of white water, as it comes tumbling and thundering into the big cauldron of black rock, loses all its grandeur; while you cannot expose the lens for a couple of seconds in its vicinity without the whole apparatus being bathed in vapour. Our focussing cloth was wringing wet before we could withdraw it, and the only picture of the Krimml Falls we possess is one taken from the summit of the Plattenkogl, in which the mighty fall, at a distance of five miles or more, looks like a brooklet of milk.

But the Krimml inn makes amends to the photographer, for it is the most charming specimen of architectural woodcarving in the district. The balcony is a masterpiece. The ornamental balustrades are wrought so delicately and elaborately that one hardly knows which to admire more—the skill, or the labour involved. The roof of loose boards is weighted, as usual, with huge stones instead of nails or pegs to keep it down; while another point in its picturesque nature is the heavy timber cross beams that project here and there from the structure.

It is very cold at Krimml, for the village lies at an elevation of 3,300 feet, and it is unprotected from the chill winds that seem to blow all day long. In fact, the only warm place is in bed, and one is rather glad to be off betimes in the morning down the valley to Zell-am-See (not to be confounded with Zell-im-Ziller). It is a long and monotonous road, albeit there are charming glimpses by the way of the snowy Venediger and other white peaks, and for this reason we avail ourselves of a conveyance. And here we may mention that on the Tyrol highways carriages are both reasonable and cheap. Sometimes you have a choice of three different modes of travelling—that is, if you happen to be on one of the post roads. In the first place, there is the so-called "Extra-post," which answers to our old posting. A carriage and pair of horses, with a smart postilion arrayed in shining brigand hat, orange-faced uniform, with bugle complete, costs but tenpence a mile (English), and as the carriage holds four, provided there is little luggage, this mode of journeying is as cheap as it is luxurious. You drive from one post-station to the other, and can break your journey at any one of them (it is usually an inn as well) either for ten minutes, or the night, as you wish. Next, there is the Eilwagen, that is, the mail-coach, which travels as quick as a post-chaise, charging at the rate of about threepence a mile; and finally, there is the Stellwagen, a humbler conveyance, for local people, which stops rather more than it goes on, and altogether travels without much rule or regulation. Nevertheless, a Stellwagen is comfortable travelling in its way, especially if there is no reason for hurry, and you wish to look about you; in fact, so far as we are concerned, we have nothing but good words for it. The charge is frequently not more than a penny a mile, and as you can always walk a bit now and then without delaying your companions, you have more independence than in the case of most public vehicles.

We journey to Zell-by-the-Lake in a Stellwagen, then, and so free-and-easy is our driver that he thinks nothing of deferring to our request when, coming in sight of the picturesque little village, we ask leave to dismount and to set up our camera to get a view. It is a delightful picture. As you approach, the road runs close down beside the placid water, and the white church and cottages of Zell are seen standing out, as it were, upon a promontory jutting far into the lake. On each side are dark rugged hills rising from the shore, and beyond is a rare background of silver grey cliffs of the most fantastic outline. These magnificent crags appear hollowed out, and the dainty little town seems set in a casket of silver and black.

Zell-am-See is a Rip-Van-Winkle of a place; that is, the town is animated enough, but the costumes of the people are of the quaintest and most antiquated. They gaze at you in good-humoured wonder, as they would at wax-work, and when we attempted a view of the street with a glimpse of the cemetery beyond, they crowded round so quickly as to obstruct the horizon. During the exposure, and before we were aware of it, one of the most curious patted the camera gently with his hand, and the consequence was, when we developed, there were four rows of houses instead of two, and a double cross over every little grave.

Speaking of the dead, they have a curious custom in Zell of putting up memorial boards with inscriptions in the streets outside their houses, sometimes the whole front of a shop being covered by these lugubrious inscriptions. The effect upon a stranger is depressing in the utmost, for it is not a cheerful idea to make a dwelling house do duty for a tombstone. This custom one only sees here at Zell-am-See, but the visitor to the Tyrol, and especially the pedestrian, cannot walk a mile along the road without meeting two other marked characteristics having to do with the people's religion, which is Catholic throughout. The first is the number of large painted crucifixes by the road-side, with figures of our Saviour life-size; these are not only posted in cross-ways, but in fields and plantations, by their proprietor, the erections being more or less gorgeous in point of colour and tinsel, according to the wealth of their owner. The other custom is that of putting a roughly-painted picture, about a foot square, by the roadside, representing any fatal accident that may have occurred near the spot. Now, as these paintings last fifty years and more, and accidents occur not unfrequently, the end is that they accumulate, especially where the road is dangerous. The name of this form of memorial is termed a "Votivbild" or "Maeterle," and to it is appended the request for a prayer or "Ave Maria" on behalf of the soul of the departed. The paintings, crude as they are, all possess that strange fascination which the description of anything horrible always excites. Now it is a man drowning in a rapid stream; now a waggoner crushed by his horses; now a woman perished in the snow, &c. The ambition of the village artist is to show every detail of the accident. The unfortunate victim is depicted, not merely with a serene countenance, but with one betokening absolute indifference to his perilous position; and there is painted over his head a little black cross, to show that his doom is sealed. If there are any lookers-on, they are shown in gay holiday attire, regarding the matter with much interest and satisfaction.

* Continued from page 404.

On the way to Zell, at a spot where the Stellwagen crossed the stream by a ford, we saw no less than five "Maeterle" of drowned people, while at Zell itself there is a very grand one, representing a boat accident, with a number of bodies lying on the shore, the dead being distinguishable from the quick by the circumstance that the latter have no black crosses by them.

From Zell, our way leads up the valley of the Fusch towards the monarch of the Tyrol, the Gross-Glockner. It is always well, if you include any arduous mountain travelling in your trip, to defer it for a while, until your feet and legs grow accustomed to the work; in making this little tour, there is no snow or glacier crossed for the first ten days—in fact, not until you reach the head of the Fusch valley. On your way thither, you pass the little spa of Fuschbad, where a day or two's rest is very agreeable in the midst of fine mountain scenery. A whole series of pictures may be here secured looking up the valley towards the snowy region of the Gross-Glockner, or back at the grey crags beyond Zell, mountains in the neighbourhood of the Watzmann and the Steinerne Meer.

Ferleiten, at the head of the Fusch valley—here is an outline sketch of it—is a miserable hamlet with poor

accommodation at the simple inn, but you must perforce stay the night, as you require a long day to walk over the snowy pass of the Pfandelscharte to Heiligenblut. We secure the services of a guide, who cheerfully carries most of the heavy baggage, and set out steadily on our way at four in the morning. The path grows steep at once, and after an hour's climb you have left all vegetation behind you, and can see Ferleiten at your feet, resembling a Lilliput village, the tiny white buildings set up like toy models upon a strip of grass-green carpet.

The Fusch valley ends in a sharp comb chaining together two peaks, and this comb, which is called the Pfandelscharte (some 9,000 feet English, and reached in five hours from the start), must be surmounted to get to our destination. It is now all snow as far as the eye can reach, except where rocky crags, black and green, pierce the shining white coverlet. The far-stretching plains up here seem to be cut off from the living world; there is nothing but glittering ice and smooth snow bounded by gigantic peaks, that seem to have risen up on all sides while you were climbing the slope.

We must have a picture of the order of march, so we ask the line of pedestrians to halt when half way up one of snowy inclines. It is a difficult matter, rather, because we naturally want to be taken in the line as well. A strapping young barrister we have met at the foot of the pass is put in the van, then comes the guide with his huge burden on his shoulders, then other two companions; and we arrange to take up a position in rear, as soon as we have uncapped the lens. A very small stop is used to lengthen exposure; the focussing cloth is made to shade the lens as much as possible from the glare, and then, having pulled off the cap, we rush hurriedly over the snow to take up a position. We halt behind the others, and remain immovable, counting five seconds, feeling all the time very uncomfortable, from a knowledge that the camera has all of us before it, and is in charge of itself. How we should like to glance for a moment behind, to see if it is all right, and that no one is tampering with the lens! Then we rush back again, down the snow slope, and nearly overturn the little camera in our anxiety to cap at once. It is not a bad little picture, when we come to develop it, although there is a strange look about our own ghost-like figure, which has not half the vigour of the preceding ones.

Another view is obtained on our descent of the famous Pasterzen Glacier, one of the most magnificent ice scenes in the Tyrol. The photograph is of value as a reminiscence of travel, but it conveys, unfortunately, little idea of the wonderful mass of ice crystals which sweep down the whole side, from top to bottom, of the cone-shaped Gross-Glockner. Here, from the Johannis Hütte, where we place the camera, you see the dazzling glacier in its entire length, for directly opposite rises the peerless mountain, as spotless as if made of Sicilian marble. Above the Hütte, the Pasterzen is of a pure virgin white, but below it breaks up into huge crystalline masses of translucent emerald. The glacier encircles the rocks at one's feet like frozen billows, and one feels tempted to descend, as it were, to the beach, and toy with the glacial water.

We now enter a pine-clad valley, and, still descending, come once more into the land of the living, passing through pastures fresh and green, and by tiny water mills and white cottages that deck the banks of the rushing river. The big white church—a cathedral-like pile—of Heiligenblut comes into sight, and at the twelfth hour from starting, we reach the village itself. The journey quite suffices for a day's work, but in the evening we mark a subject for the camera to be attempted in the morning. This is no other than the charnel-house beside the church—a scene of the most weird and terrible description. Old crucifixes, figures of human beings in purgatory, and other uncanny objects, were stacked in heaps in this cavern against bones and skulls innumerable, making a picture such as the Belgian artist Wiertz loved to paint. We gave our plate (collodion emulsion) an exposure of three-quarters of an hour, an artist friend, with his pipe for company, guarding the door the whole while: but nothing came of it, we are happy to say, on development.

The inn at Heiligenblut is also rather primitive (they talk of building a better one), and, therefore, a prolonged stay is scarcely to be recommended. Meat is scarce (there was none at all at Ferleiten), and the sleeping accommodation a little rough. A day's walk from the village brings you into the Puster Valley, where there is a railway; but we mean to have another look at the Gross Glockner district, and a peep at the Dolomites, before returning, and so secure a guide to take us over the Katzensteig and Kals Pass to Windich Matrei.

(To be continued.)

SULPHITE OF SODA: ITS USES AND ABUSES.

BY HERBERT B. BERKELEY.

I HAVE read with interest your remarks upon sulphite of soda in the alkaline developer, which appeared in the leading article of your last number. Perhaps I may be permitted to supplement these by commenting on the several points raised by yourselves and by others.

Taking your remarks in the order they appear in the article referred to, I may say that, while it is true that one of the objects aimed at is the prevention of the brown "pyrogallic stain," another point is secured hardly less valuable, and that is, the "wet-plate" character of the image. You state that, with *some* plates, the same effect can be secured by subsequent treatment by citric acid and alum. I much doubt whether the colour and character of the image can be altered to any very marked extent, even though the shadows may, in some cases, be easily freed from the stain. If the image is so affected, the colour being altered, the treatment will generally have made it hopelessly thin; however, in any case, prevention is better than cure.

Then we come to the four charges brought against my method, though, perhaps, some of these complaints may arise from not following my method. Firstly, it is said that it produces chemical fog. This I entirely deny, if reliable chemicals are used. I can, however, account for the appearance of fog under certain conditions. The development may be somewhat prolonged; at the same time, the developer does not deepen in colour; the consequence is, that the plate is exposed to such actinic rays as may pass from the lantern or window during a much longer time than would be the case were the ordinary alkaline developer employed. It is easy to avoid fog by screening the plate from the direct rays, or by covering up the dish.

With the second charge I am more in accord; and in the main I hold your opinion on the matter. It is certain that sulpho-pyrogallol will not initiate green fog; and I do not believe such fog will be readily and entirely avoided by omitting the sulphite; yet my observations lead me to the belief that any substance causing the necessity for the more prolonged action of the developer, further, even simple under-exposure in the camera, will favour the appearance of green fog in those plates which contain the germs of this annoying dry plate pest.

The best way to avoid green fog is to avoid the plates which are afflicted by it; and the best cure for this green fog, when we have it, is the ferric oxalate treatment of Mr. Willis.

Then we come to the third objection. In my own opinion a restraining action on the activity of the developer is a positive advantage. From the first day when I used the sulphite I noted the gradual way in which the full-detailed image appeared to be a distinct point in favour of the addition. In portraiture, perhaps, this "flashing out" of the image may be more allowable than in landscape work, for two reasons—the contrasts of light and shade are not so great in the former as in the latter case; and there is also much greater ease in obtaining the correct exposure in the studio than there is with the varying nature of landscape photography.

But, after all, there is no necessity for prolonging the development should the method of "flashing out" the image be preferred, provided the preparation used be of suitable quality. To ensure "flashing out" to heart's content, simply use a little more ammonia; but, mind, I do not advocate this method; I simply throw it as a sop to those who cannot bear to wait a few minutes longer for their negative. It may here be mentioned that in a developer containing three grains of pyrogallic to each ounce (the solution of sulpho-pyrogallol being used) there will be about sufficient acid present to convert half a minim of strong ammonia. With weakly alkaline development this fact should not be overlooked.

The cause of the remaining change arises from this system of "flashing out" the image. The whole of the detail having appeared, the plate is taken out of the developer, is fixed, and, lo! one of the main objects of the addition is defeated.

To obtain a vigorous negative with full gradation, the development must be of a gradual and steady character; the detail in the shadows must not appear until the high-lights have gained most of the strength desired; and in any case the sojourn of the plate in the developer must be one of six to twelve minutes. Though I do not wish to generalise on this point, at any rate if thin images be obtained, take means for preventing—either by less exposure, by more bromide, or by more sulpho-pyrogallol—the too rapid formation of the image, and allow plenty of time for intensity when acquired. As you remark, the degree of apparent intensity required is much greater than is the case with the ochre-coloured image so commonly obtained by the ordinary alkaline developer.

Lastly, we come to that statement the origin of which I am at a loss entirely to comprehend. We have seen it stated on several occasions that the opinion of some who have made solutions ostensibly by my formula—but, I fancy, generally somewhat diverging from it—is, that the preparation will not give good results for long together, but that it must be made freshly at intervals of a few days. I can only say that any solutions giving cause for such opinion must have been of a shadowy character from the beginning, or that they have not been suitably stored or properly treated. Amongst other things, I do not advise the dilution of the 10 per cent. solution, unless shortly before it is to be used, when, if thought convenient, it may be done. The solution I am now using was made early in October last.

With reference to your formula it has been a puzzle to me to find out—looking to the object sought to be attained—what "the difference 'twixt tweedle-dum and tweedle-dee." If the sulphite become oxidized in the pyrogallic solution, why should it not be similarly attacked in the solution of ammonia? We should get an interchange between the bases soda and ammonia; but this is probably of little moment.

However, in addition to its more important capacity, the sulphite exercises an important function in preserving the plain pyrogallic in good condition. Citric acid alone is not nearly so good a preservative of pyrogallol as is a properly-prepared solution of sodic sulphite.

It has occurred to me that, as it has been found in several instances that green fog is not liable to make its appearance when sodic carbonate is used instead of ammonia, it might be well, where the treatment of these plates is necessary, to use this alkali in combination with sulpho-pyrogallol. However, I only throw this out as a hint, having no practical experience of the combination as a developer.

IODIDE OF SILVER IN EMULSION.

BY A. L. HENDERSON.

THE experience of photographers on the above subject is so varied that it is evident that more light is required.

As a matter of fact, iodide in bromide emulsion does certainly make the plate slower, and this in proportion to the quantity added. Notwithstanding this, no one can gainsay that there are certain advantages which accrue from the double compound.

I have lately hit upon a circumstance (doubtless not entirely new, yet possessing features of interest), viz., that if a bromide and an iodide emulsion are made and washed separately, they may be mixed just before coating without greatly lowering the sensitiveness of the resulting plates. The actinic opacity of the iodide emulsion, compared with the bromide, is invaluable to the photographer, and to this is due the fact that plates containing a small quantity of iodide, from one to two per cent., generally give greater density and pluck; but if a large quantity of iodide is used, say equal parts, entirely different results are obtained—*i.e.*, a thinner image, from the fact that less bromide of silver is reduced, and this result is attained without the blurring by halation.

Strange to say, plates containing the pure bromide gave green fog in the shadows; while others containing the mixed iodide and bromide were perfectly free from this defect, both sets of plates being exposed the same time, and developed together; but no difference in detail was perceptible in either case.

To photograph subjects with great contrasts, the compound emulsion is decidedly best, because of the absence of too great density in the high-lights, and the usual concomitant—halation.

In a former communication to you, I mentioned that the Derby race photograph "did not convey the idea of motion so well as some others taken with a slower shutter in which there is a movement perceptible." In substantiation of this, I enclose some pictures taken on Whit Monday at the Alexandra Palace. The photographs were not sent in competition, as they were slightly under the determined size.

ON THE COMPARATIVE EFFICIENCY OF VARIOUS INSTANTANEOUS SHUTTERS.

BY JAMES CADETT.*

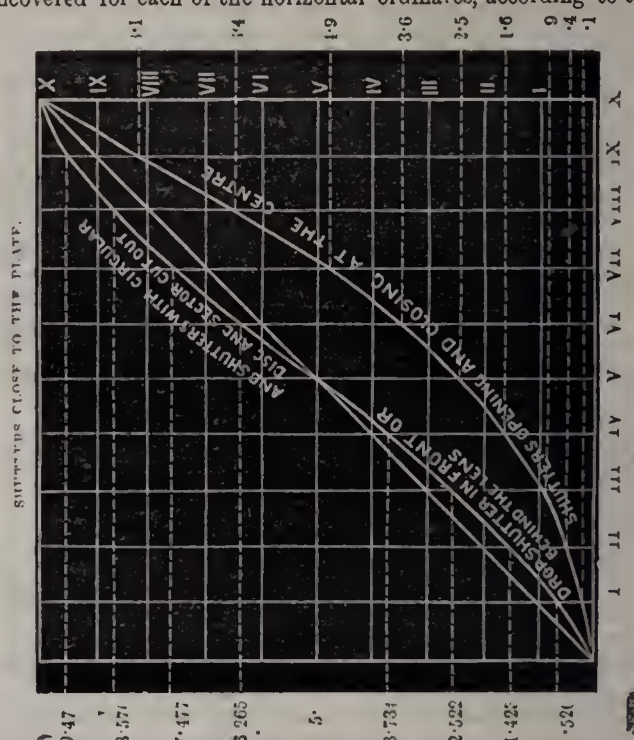
I am one of those who believe there is a great future for instantaneous photography, in spite of the ridicule which is often cast on it from an artistic point of view; in most cases, however, deservedly so. Perhaps the principal reason is, that we are obliged to cramp the capabilities of our lenses by using large apertures, the result being that we cannot get a fair angle of view without loss of marginal definition, and light and depth of focus. If my memory serves me, I once heard Mr. Dallmeyer remark, when speaking of the rapid rectilinear type of lens, that a whole-plate lens should not, for instantaneous work, be used with full aperture for a larger plate, at the outside, than the half-plate; now, under ordinary circumstances, he is right. When we consider that, with an angle of 60°, the margins of the picture only receive 55 per cent. of the amount of light received at the centre of the picture, and with an angle of 70° only 45 per cent., or less than one-half, we see one great difficulty to encounter when exposure is more likely to be under than over. This difficulty, coupled with want of marginal definition and depth of focus, has the tendency to urge the photographer to give his attention mainly to the centre of his picture, generally on some particular object, and thus the surroundings which constitute an artistic picture are, in most cases, ignored. The lens-diaphragm is, of course, an indispensable adjunct, and, unfortunately, its use is very limited in instantaneous photography as at present practised. I am aware that a few seascapes have been fairly successfully photographed with apertures as small as $\frac{f}{18}$, but this case is an exception to the rule. I think that quick exposures ought, and ultimately will, help us more with landscapes, and also tend to more artistic results. How often, when in search of the picturesque, we observe patches of sunlight rapidly travelling over the landscape, according to the movement of the clouds! and, when some particular parts become lighted, though only for a second or so, we give a sigh, and say, "Ah, if I could only get that!" I need scarcely say that we have a suitable stop in the lens, and from ten to twenty seconds are probably required. Again, there is a view in which there is a flowing stream with overhanging trees; who has not wished to catch the ripple and sparkle of the water, and yet get detail in those cool, deep, liquid shadows? Alas! it is not to be done as it ought to be. The fact is, that we want a very sensitive plate to make a new departure, and I must say that some plates made by Captain Abney, showing all the numbers on Warnerke's sensitometer—and more if the scale went far enough—with good quality, give me courage to assert that ere long some effects will be obtained which will raise instantaneous photography to a position as a source of artistic merit.

Mr. Payne Jennings is always complaining that he cannot get plates sensitive enough, and I have heard him remark that his best work has been done on the most sensitive plates he could get; still, I have known him to give twenty seconds' exposure on a bright day, with a plate showing more than 20 on the sensitometer. This shows that a plate showing 20 is not sensitive enough, as he is rather fond of small stops. We all know his work too well to question the value of his opinion. He says that the quicker a negative can be taken the better. I hope that during discussion he will kindly favour us with his reasons.

I have made these remarks to endeavour to impress the importance of what is, perhaps, the chief point with regard to instantaneous shutters—it is, that we should get the greatest possible amount of effective light during the short time of exposure; this point I put first in importance until our plates become vastly more sensitive. I will endeavour to treat of other points afterwards.

The efficiency of a shutter with regard to the maximum amount of light received by the sensitive plate is mainly influenced by the manner and proportion of time in which the lens or sensitive plate is uncovered and covered. The various kinds of shutters in general use differ comparatively very much in this respect. I intend to compare four different kinds, viz., shutters which work close to the plate, such as Mr England's original drop-shutter; the ordinary drop-shutter behind or before the lens; shutters consisting of a revolving disc, with a portion of a sector cut out of it; and shutters which open and close at the centre.

In order to make comparisons more clearly, I have drawn curves representing the efficiency of each shutter with regard to the amount of light received by the lens, presuming that they all take the same time in making exposure. The horizontal ordinates represent the distance or space taken by any shutter to completely uncover the lens, and this distance is divided into ten parts. The vertical ordinates represent the areas of the lens uncovered for each of the horizontal ordinates, according to the



shutter used, the total area being represented by 10. The shutters giving the greatest efficiency are undoubtedly those which work close to the sensitive plate, because the whole of the lens is always uncovered; immediately therefore that the plate is uncovered in any part, that part receives all the light the lens can give. These shutters have their disadvantages, which I will presently mention, but their efficiency is practically total; I will therefore call it 1. When we come to shutters which work immediately before or behind the lens, the conditions are at once greatly altered. Taking the ordinary drop-shutter, it is clear that the lens must be uncovered by degrees, and that, as the lens forms a circle, the amount of surface of the lens exposed does not increase proportionally with the distance moved by the shutter. The surfaces uncovered form increasing segments, and, until the lens is half uncovered, the movement of the shutter is proportional to the versed sine of half the angle extending from the centre of the lens to the edges of the shutter, cutting the circumference of the lens. As we have divided the whole move-

* Read before the Photographic Society of Great Britain.

ment of the shutter necessary to uncover the lens—in this case it is assumed that it is equal to the diameter of the lens—into ten parts, it is easy to calculate the efficiency by finding the areas of the segments of which these parts form the height or versed sine, and representing these areas as vertical ordinates. In this way we can show the area of lens uncovered at any part in the path of the shutter. Its efficiency is ·5 as shown in the drawing, and is one-half that of the shutters which work close to the plate. Many persons are under the impression that there is a loss of about ¾, or more correctly ·7854, of the light with a drop-shutter having the same aperture as the diameter of the lens (on account of the shutter having a square opening which travels over a circle made by the lens); but a little reflection will show that this is not the case. If lenses were square instead of round, the opening of the shutter would be smaller for a lens of the same area to be in proportion; but the efficiency would be ·5, or the same as from a round lens, the only difference being that a square lens would be uncovered more evenly, as shown by the straight-diagonal line in the drawing. It will be seen on examination of the curve that the efficiency of the drop-shutter is a little under ·5 during the time that half the lens is being uncovered, but that during the uncovering of the second half the efficiency is as much above ·5 as it was below it, thus making a total of ·5 exactly. We now come to the shutter made with a circular disc, having a sector cut out of it. It will at once be seen that its efficiency is exactly the same as the ordinary drop-shutter, viz., ·5. Next are the shutters which open and close from the centre between the lenses, or where the diaphragms are placed. Now, it is clear that the area of the opening made by the shutter is proportional to the square of the diameter of the opening, and in consequence its efficiency is only ·25; in fact, we lose ¾ of the light. A glance at the curve will show this at once. I need scarcely say that such a serious defect ought not to be tolerated, especially as it can easily be cured. The only place for these shutters is, of course, where the diaphragms are intended to be placed. It is simply ridiculous to place shutters of this kind in front or behind the lens, as it at once greatly increases the evil inherent to every lens—that of giving greater illumination to the centre of the plate than to the margins. Our lenses are quite bad enough in this respect without unnecessarily increasing the evil; besides, in this case, the evil would be still further increased if a diaphragm should be inserted. In spite of this a great many people use these shutters in this way, perhaps in sheer ignorance of what they are doing.

I will now say a few words about the disadvantages peculiar to each kind of shutter I have spoken of. The shutter which works close to the plate has the tendency to give moving objects a slanting direction; this, of course, is an objection only under some circumstances, and the larger the plate the greater the objection is likely to be. Though we can get any amount of rapidity in exposure for any particular part of the plate by making the opening narrow, different parts are exposed at different times, and at widely different times if the plate be very large. A moving object, if very large, would, of course, suffer; the exposure also would be very much shorter at the bottom of the plate than the top, the slit having to fall the whole distance of the plate; it is, however, in the right direction, as the sky would have the shortest exposure.

The drop-shutter in front or behind the lens has not, practically speaking, the objections of the shutter close to the plate; and, theoretically, the less so as the diameter of the lens is smaller. It is, however, of very great importance as to whether the shutter is in front or behind the lens. In front, simply means giving the sky considerably more exposure than the foreground. For instance, if the top part of the lens had one-tenth of a second, the bottom part would have, approximately, one twenty-third of a second. The smaller the diaphragm used, the nearer would the exposures of sky and foreground approach the above exposures relatively. Under these circumstances, a drop-shutter in front of the lens is bad practice. Of course, I am now supposing that the lens is a doublet, as the difference between the exposures of sky and foreground by a shutter in front of the diaphragm of a single landscape lens working with the ordinarily small aperture would be practically insignificant, though the sky would get a little more exposure than the foreground. The shutter with a circular disc and a sector cut out may be placed in any position with regard to the lens, as it can be adjusted to favour the foreground in any case.

Shutters opening and closing from the centre must be placed between the lenses, or in the same place as the diaphragm. This is imperative, and needs no further comment.

Taking all points into consideration, the best place for any of the above shutters (with the exception of those close to the plate) is where the diaphragm is intended to go, or between the lenses. This enables the greatest possible reduction in the size of the shutters, and, of course, size and weight are most important factors in the photographer's impedimenta.

We now come to a most important point with regard to giving efficiency to any of the above shutters (those close to the plate excepted); it is, to make the aperture of the shutter several times that of the lens or its working aperture; in this way we can get a very high efficiency, but we are, of course, limited by the size that the shutter becomes. Shutters opening and closing at the centre, of course, require to be made proportionally larger in aperture than the others to get the same efficiency. The size of aperture is easily calculated for any efficiency. Those who are unable to make the necessary calculations have only to ask Captain Abney, and I am sure that he will kindly give any required information. I do not think myself that the efficiency of any shutter should be less than ·75.

With regard to testing the rapidity of exposure with any shutter, I have no doubt that many will remember the paper by Mr. Warnerke and myself on this subject. We used a revolving stick; and though it was revolved by hand in a rather unscientific manner, still repeated trials showed that error was not greater than about five per cent. Since then Mr. Warnerke has made a disc, with a small round hole in it near the edge, to revolve by clockwork; I regret that I cannot show it to you to-night, as Mr. Warnerke has taken it with him to Russia. The hole is illuminated by reflected light from a white surface, or by the sky direct; and a photograph is taken while the disc is revolving, and rapidity measured by degrees of arc.

The rapidity of exposure by drop-shutters is easily calculated without experiment. It may be interesting to some to have simple formulæ by which to make the calculation, and this must be my apology in bringing so simple a matter before those of superior mathematical attainments. The formulæ are as follows:—

S = the space or distance fallen in inches;
t = time in seconds.

$$S = t^2 \times 193$$

$$t = \sqrt{\frac{S}{193}}$$

From these two simple equations we can calculate anything we require. Supposing we wish to know what diameter of aperture would uncover and cover a point in one-tenth of a second by falling:

$$S = (\tfrac{1}{10})^2 \times 193 = 1{\cdot}93 \text{ inch.}$$

Supposing that the lens has the same diameter as the aperture of the shutter, in this case 1·93 inch, and we wish to know the rapidity of exposure at a point at the bottom of the lens. We have one-tenth second for the top of the lens, as above; to get our answer, we have simply to subtract the time taken to uncover from the time taken to cover.

$$\text{Time taken to cover} = \sqrt{\frac{3.86}{193}} = \sqrt{\frac{2}{100}} = {\cdot}141.$$

$${\cdot}141 - {\cdot}1 = {\cdot}041 = \text{approximately } \tfrac{1}{24} \text{ second.}$$

Here 3·86 = the distance through which the covering portion of the shutter has to fall, being in this case twice the diameter of the aperture; from this we get the time, and subtract from it one-tenth second, the time taken by the uncovering portion to fall the distance of the diameter of the lens, as above. In practice, we should, of course, allow for the amount of extra cover of the lens given by the shutter before starting; this is easily measured and allowed for, according to the shutter. It must not be imagined that calculation will be practical in every case, because in some shutters there is so much friction as to upset all calculations, especially with very long drop-shutters. Captain Abney pointed this out very clearly in the Cantor Lectures, by experiments with wave lines from a tuning-fork, and he showed, in many cases, that after a certain period in the exposure there was no increase in speed.

With regard to shaking the camera during exposure, *practically speaking*, none of the above shutters, if properly made, will do so, though, theoretically, they must. Under proper conditions, I have failed with a strong magnifying lens to detect any movement in the photograph by any of the above shutters.

In conclusion, I hope that others, more experienced than myself, will give their views on this important subject.

Notes.

Mr. William England has gone to the St. Gothard, to take views on the picturesque route through which the new railway passes.

The Photographic Exhibition at Pall Mall opens this year on the 7th October. No pictures will be received after the 29th September, Michaelmas day.

The constitution of the jury for the award of medals is now definitely fixed; two painters have accepted an invitation to serve, viz., Mr. Pickersgill, R.A., and Mr. Cave Thomas.

Captain Abney has made a scientific trip to Switzerland in connection with the study of solar physics. It was his mission to secure a photograph of the spectrum of the sun, if possible, free from that absorption exercised by the lower atmosphere of aqueous vapour. To do this, it was necessary for him to carry camera and spectroscope to a considerable elevation above the ordinary level of the clouds, and this could be done, obviously, nowhere so conveniently as in Switzerland.

Mr. T. S. Davis called attention at the Photographic Society to the excellent plan of Mr. T. G. Whaite for coating paper with gelatine emulsion. The cold emulsion is applied to the paper by a stiff hog-hair brush, and the paper then drawn over a hot water reservoir of suitable shape, when the emulsion melts and spreads itself evenly. Mr. Whaite's paper recently contributed to the News explains the process more fully.

Upwards of three thousand francs have been subscribed towards the Poitevin memorial. We shall be happy to transmit to the central committee at Paris any sums our readers may entrust to us for the purpose.

Shutters worked by elastic webbing are convenient, but sometimes treacherous. A friend of ours, who was present on the occasion of Her Majesty's visit to Epping Forest, has reason to remember this. Provided with camera and plates, he secured a capital out-look on one of the grand stands, and having focussed and made ready, anxiously awaited the Royal approach to take a snap-shot. It was a long time to wait, so he set to work testing his shutter to be quite sure of its action. Horror! suddenly snap went the rubber, and the slide was motionless. There was plenty of sympathy for his misfortune—for those around had viewed the young photographer's preliminaries with deep interest—but sympathy would not mend the elastic webbing.

At last there came a suggestion from one of the bye-standers. It was a little girl who spoke, and she called out, in a loud whisper, "Mama, I've got a garter." And without more ado the brave little woman stripped off a rose-coloured circlet, and handed it blushingly to the photographer. *Honi soit qui mal y pense*; and let us add, if we had a copy of that photograph, we should value it very much indeed.

Yet another anecdote from the same source. It was a question of changing plates in the country, and our friend knocked at a cottage door to beg permission for the use of some dark corner for a few moments. A solitary old woman was within, who was too frightened by the sudden apparition and strange request to answer rationally, but she made no objection to the young fellow entering a sort of wash-house, and, in fact, carefully closed the door after him, as he bade her.

The plates were changed, and he knocked at the door for the old lady to open. No one came, so he knocked louder. The house was evidently deserted. He knocked once more. Then there came sounds of people hurrying towards the house, and presently the door was unbolted, and an angry cottager, bludgeon in hand, stood over him. Our friend had been mistaken for a burglar, and the housewife had taken considerable credit to herself for having trapped him so neatly.

A correspondent asks for a formula for collotypic ink. Here is the plan recommended by Herr Allgeyer, who for several years superintended the collotype work at Albert's establishment at Munich:—The so-called lithographic chalk-printing ink is to be slightly thinned with special boiled oil lithographic varnish; this latter being sold in London as 'middle litho varnish.' It is generally advisable to tone down the black colour by the addition of madder lake and indigo, both of which can be obtained ready ground in oil varnish at any lithographic material warehouse.

Some years ago, when the construction of our ironclads was under consideration, and the battle of guns *versus* armour was being waged *à l'outrance* at Shoeburyness, the Admiralty and War Office wisely resorted to photography as the most impartial recorder of the experiments. Photographs of the damage done to armour plates by heavy shot were secured, so that every one could see how far a shot penetrated, and what actual mischief was wrought to the structure. Now that our ironclads have experienced actual warfare at Alexandria, it would surely be well to have recourse once more to photography; pictures of a most valuable character would thus be at hand to illustrate the reports, which, we are told, every captain is to render of the first naval action in which our modern battle ships were engaged.

The "Postal Photographic Society" is the name of a new body, started with the object of interchanging photographs among ladies and gentlemen who practise with the camera. One of the principal features is what our German cousins call a "Wander Album," a sort of scrap-book to go the round of all contributors. Full information about the Society will be found in another column.

Delton's equestrian album, of which we spoke last week as containing portraits of most of the well-known riders in the Bois de Boulogne, is commanding a good sale in Paris. Its publishing price is 100 francs, and it has become quite fashionable. M. Deltou secured many of his pictures by stealth, placing cameras in ambush, and taking snap shots at cavaliers and dames as they passed.

The photographers of Germany meet in convention on the 23rd of next month, at Eisenach, in Thuringia. Foreign photographers, both professional and amateur, are invited to this beautiful district of mountain and dark pine woods, which is as full of legendary lore as the Harz mountains and the Black Forest. We shall describe a tour in Thuringia after our trip to the Tyrol.

Military maps of Egypt seem to be scarce. There is no difficulty now-a-days in multiplying a map, because it can be done readily by photo-lithography; but you must first get your map to copy, as Mrs. Glasse would remark. Of course there are maps of Egypt in plenty, of some sort or another, but none of them possess that accuracy in respect to roads and distances that military maps should have.

Germany appreciated very quickly the value of photo-mechanical printing during the Franco-German war, and maps were reproduced so rapidly and numerously that every subaltern, and well-nigh every serjeant in their army, was provided with a good road map. An "intelligence department" is now a recognised branch of every army, and it is one of the principal duties of officers attached thereto to collect plans, surveys, and maps of countries and towns in every corner of the world, so that copies of these may be furnished at a moment's notice. Our Ordnance Survey Department at Southampton, where photo-zincography is practised on a large scale, undertakes all the work in this country connected with the copying and printing of military maps.

In respect to map making itself, Austria is far ahead of any other European country. At home, we still pursue the laborious and time-taking method of engraving every line on metal, the old-fashioned plan that obtains in most map-making establishments. But in the Vienna Government office the maps are all drawn on a large scale upon white paper with Indian ink, and then, by the aid of the camera, these plans are transferred to metal and etched; the consequence is, Austria produces her Ordnance maps about ten times as fast as we do.

An interesting telephonic experiment was tried at Malta during the bombardment of Alexandria. A telephone was attached at Malta to the Alexandria cable, and it was found that the firing at Alexandria was distinctly heard, through the telephone, at Malta, a distance of more than a thousand miles. The next bombardment that happens may, therefore, be telephoned to London, and we shall be able to listen to it at the Royal Exchange, or at Charing Cross, distinguishing the heavy booms of the 80-ton guns from those of our lighter artillery; and, as Mr. Shelford Bidwell has shown us how a system of telegraphic photography may be established, who knows but one of these days we may see as well as hear something of a bombardment by wire.

Mr. Ireland, one of the Vice-Presidents of the Dundee Society, of whose capital work in Norway we had occasion to speak in high praise at the Dundee Exhibition, has again visited Scandinavia this year, and brought back with him some more delightful camera sketches from the far north.

"The Photographic Society's Standards," relating to standard flanges for lenses and screws for cameras, are likely to be adopted in America, if not also on the Continent. Sealed patterns of the "standards," and specifications relating thereto, will be in the custody of the hon. secretary of the Photographic Society of Great Britain, who will give opticians information concerning them.

Mr. W. D. Valentine sends us some charming instantaneous views, all difficult subjects, and most of them taken against the light and just off the sun. Tthere are among them steamers on the Clyde at full speed, the circling black smoke from the funnels so crisp and clear, there can be no doubt about the rapidity of exposure. They were every one of them secured, Mr. Valentine tells us, by the shutter which is sketched and described in our "Studios of Europe."

TWELVE ELEMENTARY LESSONS IN PHOTOGRAPHIC CHEMISTRY.

No. I.—Apparatus.*

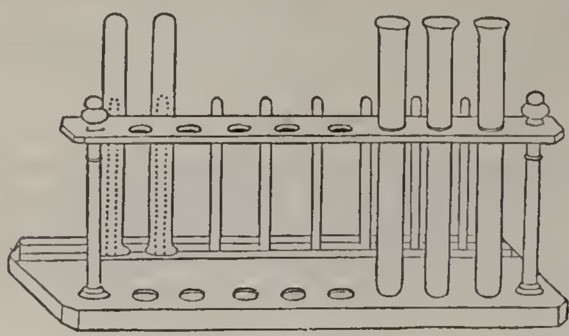
In dealing with this subject, we shall treat of it under three headings: Firstly, "apparatus required for the simple testing of photographic chemicals"; secondly, "apparatus required for the preparation of certain photographic chemicals"; and thirdly, "apparatus necessary for the estimation of photographic chemicals." In this way the student can take up any one of the three branches without buying apparatus which may be useless to him. For the first-named purpose, the following apparatus will be required:—

Test-tubes and stand.
Tube-cleaner.
Spirit lamp or Bunsen gas-burner, with rose top.
Retort staud.
Wash bottle.
Small evaporating-basin.
Funnel.
Filter paper.
Platinum wire.
Sulphuretted hydrogen generator.
Two watch glasses.
Glass rod and tubing.
Triangular file.

Test-tubes are made of thin, hard glass tubing closed at one end, and should be about five inches long by three-quarters of an inch in diameter; they are used for dissolving the substance to be tested, and for experimenting upon it in a manner to be described in a future lesson.

* The woodcuts are of apparatus supplied by Messrs. J. J. Griffin and Co., of Garrick Street, W.C.

Test-tube Stand, as the name implies, is used for holding test-tubes in a convenient position.



Test Tube Stand.

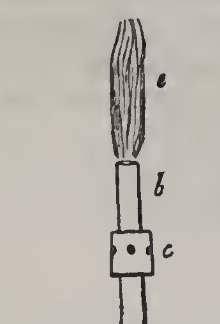
Tube cleaner consists of a piece of wire with bristles worked in at one end. To use it, soak the bristles in water and push into the test-tube, when any dirt adhering to the inside will be quickly removed.

Spirit lamp is a glass bottle with a perforated brass cap through which an ordinary wick passes. Methylated spirit

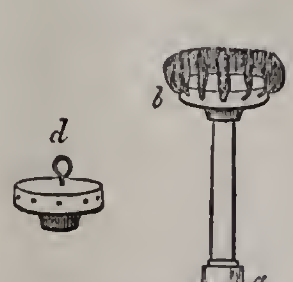
Spirit Lamp.

is placed in the bottle, and a ground glass cap is used to extinguish the flame and prevent the evaporation of the spirit when not in use.

Bunsen burner should be used in preference to a spirit lamp where gas is laid on. The burner consists of an upright brass tube about three inches high, through which the gas passes; at the bottom are situated two holes for the inlet of air. On applying a light at the top of the tube the gas burns with a colourless flame, which is incapable of smoking anything placed in it. A brass cap perforated



Bunsen Burner.

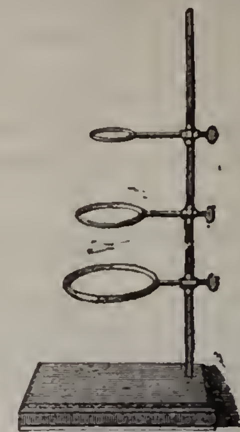


Burner with Rose.

with six or eight holes, called a "rose," is placed on the top of the burner to diffuse the flame when a gentle heat is required.

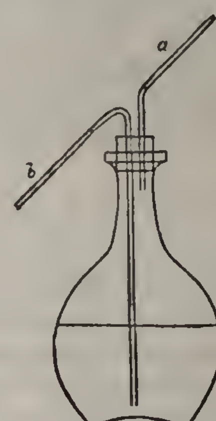
Retort stand is simply a vertical iron rod fitted with two or three rings, which can be adjusted to any convenient height above the stand. It is used for holding evaporating basins, beakers, and flasks whilst being heated, or for supporting a funnel during filtration.

Wash bottle may be used as a convenient vessel for distilled water; but its chief use is for washing precipitates on filters. This apparatus may be constructed of any bottle at hand; or, where it is desired to boil the water, a flask should be used. To the bottle is fitted an ordinary cork perforated with two holes, through which two bent



Retort Stand.

glass tubes pass, one of which should reach to the bottom of the bottle, with the outer end terminating in a fine jet. The other tube need only be long enough to pass through



Wash Bottle.

the cork, and here the mouth is applied to blow the water out of the bottle up the long tube through the jet in a fine stream on to the filter.

Evaporating basin is a shallow vessel made of thin porcelain, and for analytical purposes should be about three inches in diameter. In order to evaporate a solution, pour it into the basin supported on a ring of the retort stand; now place a spirit lamp or gas burner fitted with a rose under the apparatus, and the heat applied will soon warm the water and drive it off in the form of steam, leaving the solid residue behind.

A small *funnel* about three inches in diameter is required for filtering any liquid containing a precipitate; the apparatus requires no further description, and no photographic laboratory is complete without one.

A packet of one hundred *filter papers*, about four inches in diameter, will be required for use with the funnel.

A piece of *platinum wire* four inches long, and about the average thickness of a pin, is useful for the "colour-flame" test.

Sulphuretted hydrogen generator can be constructed of an ordinary six-ounce medicine phial by making a hole in the cork and placing it in a glass tube bent twice at right angles; one end need only be sufficiently long to go just through the cork, the other end should be about three inches in length. About an ounce of iron sulphide is placed in the phial, and, when the apparatus is required for use, about half an ounce of strong hydrochloric acid mixed with an equal volume of water is poured into it, and the tube and cork quickly placed in position, when a plentiful supply of the gas will escape from the tube. This operation should only be performed out of doors on account of the bad smell.

Watch glass is useful for holding solutions which necessitate stirring in order to prove the presence of such substances as potassium or sodium salts.

Two or three feet of *glass tubing* about three-sixteenths of an inch in diameter is required for making the wash bottle and sulphuretted hydrogen apparatus. To bend the tubing it must be placed in the upper part of the flame of an ordinary fish-tail gas burner till it is soft; it can then be bent to any required angle or drawn out to a jet; glass tube can be easily cut by scratching with a file and then breaking it.

In the second branch the following apparatus will be required:—

Four beakers.
Two flasks.
Dial glass.
Funnel.
Filter paper (a quire).
Bunsen burner.
Retort stand.
Glass rod.
Wire gauze.

Beakers are tumbler-shaped vessels made of very thin, hard glass, and will consequently hold boiling solutions without cracking; four will be required, holding, say, 20 ounces, 10 ounces, 4 ounces, and 2 ounces respectively.

Flasks are also made of thin, hard glass, and in appearance are not unlike decanters; those containing from ten to twenty ounces are of most useful size for ordinary purposes.

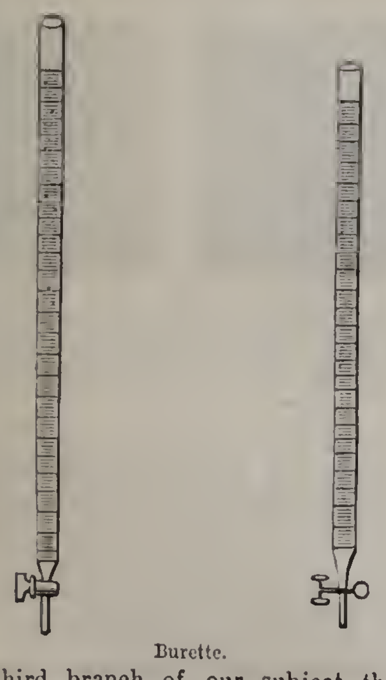
Dial glass, which is simply a large watch glass, is useful for covering a beaker to prevent evaporation, and keep out dust.

A ribbed or fluted *funnel* of about five inches in diameter is best for quick filtering.

Thick *filter paper* (bibulous) will be necessary for drying any moist solids or precipitates. A square or round piece, cut of convenient size, folded in four, and opened upon a funnel, constitutes an ordinary filter.

A few *glass rods* from eight inches to a foot long are useful for stirring solutions to facilitate dissolution.

A piece of coarse *wire gauze* about four inches square is necessary to stand beakers or flasks upon to equalise the temperature when being heated.



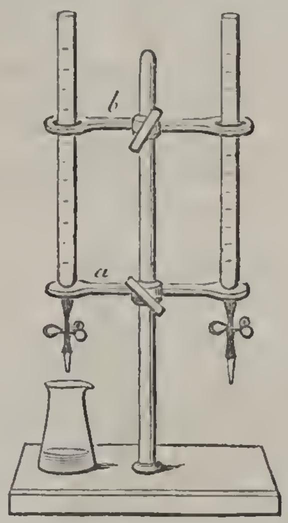
Burette.

For the third branch of our subject the following apparatus will be required:—

Burette.
Burette stand.
Pipette.
Flask.
Evaporating basin.
Balance.
Weights.
Litre flask.

Burette is a long glass tube graduated into tenths of a cubic centimeter, and fitted with a stopcock at the bottom, consisting of either a metal clip pinching a small piece of india rubber tube, or a glass stopcock. We show the two kinds of burette here, but should advise the student to use the one having a glass stopcock.

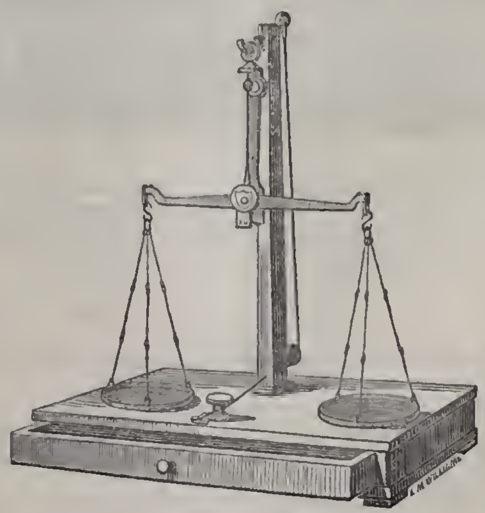
Burette stand is a necessary piece of apparatus for supporting the graduated tubes in upright position.



Burette Stand.

Pipette is a glass tube graduated into cubic centimetres, and drawn to a fine jet at both ends. It is used for delivering exact measures of standard solutions, which may easily be accomplished by inserting the lower end in the solution and applying suction at the top till the liquid has risen to the required point; now place the finger on the top instead of the tongue, and in this way the pipette and its contents may be carried to any convenient vessel, and the measured liquid delivered into it.

A chemical balance is very expensive; but one which answers all the requirements of the photographic student can be made with a good apothecary's balance (costing about seven or eight shillings at Messrs. Griffins' establishment) fitted on a stand.



Scales on Stand.

A set of weights varying from ten to one hundredth of a gramme is indispensable, and should cost about seven-and-sixpence.

APPARATUS FOR TESTING SHORT EXPOSURES.

BY G. L. ADDENBROOKE.*

I think it becomes daily clearer that, within certain limits, the shorter exposure one can manage perfectly with, without using unduly large stops or strong developers, the better; but this exposure must be just as well known and under control as longer ones, and must be subject to this reservation, which may at first appear paradoxical, that while for perfectly still objects the very minimum of exposure may be used, on moving objects this is not the case; the exposure should always be so regulated, in relation to the rate of motion of the object, as to give soft outlines. There is no artistic beauty in a sea-piece taken in the $\frac{1}{50}$th part of a second, and which, to borrow an expression from *Patience*, looks as if were "struck so." Some slight indisdinctness of outline is absolutely necessary to convey the idea of motion, though this should not go so far as blurring, which offends the eye. Turner's paintings of motion are rather leading ideas for imagination to fill in, than accurately detailed representations of particular scenes.

Perhaps, therefore, an apparatus to test short exposures is desirable, and may prove useful; and it may not be altogether unprofitable to recapitulate briefly what has been done in this direction.

As far as I am aware, the methods used up to the present have been as follows:—

To photograph a falling weight, which requires a good deal of delicacy and care to carry out in practice, and is not altogether satisfactory.

To photograph a pendulum.—This must be attached to a clock, or the arcs of vibration will not be equal, and then it hardly moves quickly enough; and there are other objections.

To photograph a hand moving round a dial.—Not a bad way; but, though I have not tried it, it seems that it would be difficult to avoid blurred images, and that it could only be used in very strong light indeed.

To cover the slide of the shutter with camphor smoke, and mark it as it falls with a vibrating tuning-fork.—This, the simplest and prettiest of all methods, is, I fear, too delicate to succeed in the hands of most men, and does not meet the case of a shutter with separate opening and closing slides.

About four months ago it occurred to me to use a similar apparatus to that designed for measuring the velocity of projectiles, which may be shortly described as follows:—A clockwork apparatus to turn a disc rapidly round in a known time, say one second. Two screens, each made of a continuous wire connected with a battery and induction coil, and placed, say 100 feet apart, in the direct line of the projectile. These screens are so connected up with a point almost touching the revolving disc, that, when the projectile breaks the screens in succession, a torrent of sparks passes during the interval between the point and the smoke-covered surface of the revolving disc. The arc thus made by the electric sparks gives the velocity of the projectile.

All that was necessary to adapt this apparatus to testing-shutters was to alter the two screens into two spring contacts of the proper form, acted on by the falling shutter. This I succeeded in doing; but, as the connections were very complicated, and it was almost impossible to avoid disagreeable shocks sometimes while operating, I determined to try and utilize the principle of the revolving disc in another way. The above method gave graphic records of the exposure, as brown lines on a sheet of paper moistened with starch and potassic iodide.

The method which I have finally succeeded with is as follows:—A small gelatine plate is placed on a revolving axis, in a light-tight box, by taking off the removable front. On this front a thin sliding plate of ebonite is fixed, having a small hole about one-tenth of an inch in diameter drilled in it. This hole is, first of all, pushed exactly to the centre of the front, so that when the plate is revolved a small black speck is formed on it, which afterwards gives accurately the centre to measure from. The hole is next drawn from the centre towards the side, and if now a shutter be put close in front of the box, and be released while the plate is kept turning, the light, falling through the shutter, and through the small hole in the front of the box, will leave a narrow black line on the plate for exactly the time the shutter took to act. By using a gelatine plate three inches square, and beginning with the hole half-an-inch from the centre of the front, and pushing it about one-tenth of an inch further after each exposure, so as

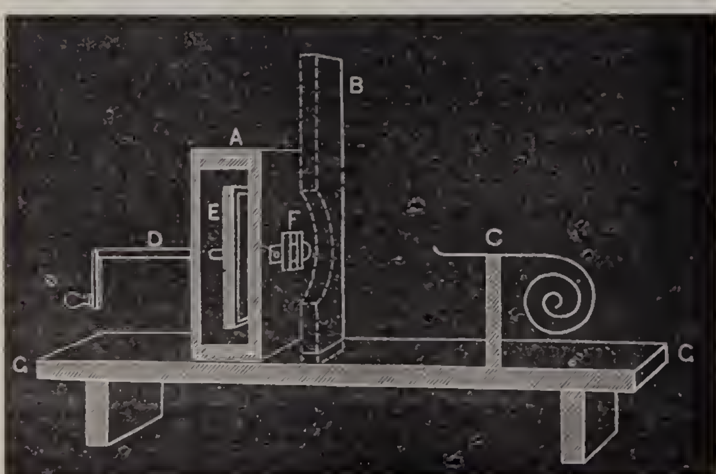


Fig. 1.

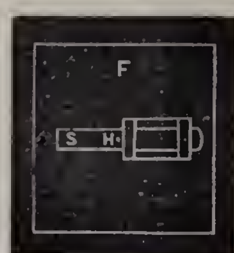

Fig. 2.

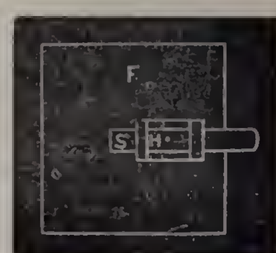

Fig. 3.

Fig. 1 shows a vertical section through the centre of the apparatus. A is a light-tight box, about 6-in. square and 1½-in. deep; B is the shutter to be tested, which is clamped to an upright, not shown; C is a piece of magnesium wire; on turning the axle D, the photographic plate, mounted on E by an elastic band stretched over opposite corners, is revolved; F is the removable front of the box. Fig. 2 is a front view of F, showing the sliding plate of ebonite fixed with the hole H in the centre. Fig. 3 gives the same view, with the slide S pushed so that the hole H is out of the centre, as ready for testing a shutter.

to keep the arcs formed distinct, as many as ten testings may be made on one plate.

The markings, after development, are plotted on a sheet of paper, and measured with the common arc.

I find about an inch of magnesium wire is all that is necessary for one testing. An ordinary candle may be used instead of the wire, but it requires a very strong developer to get the markings out on the plate afterwards.

In my own experiments I have turned the axle by hand, and, used in this way, any one could obtain results always within 20 per cent. of absolute accuracy; while the apparatus is so simple that an amateur could easily make it in a few hours.

The markings obtained on the plate are so sharp and clear, that I think any one using this will prefer it to the other methods.

By adopting proper clockwork to turn the axle, results of the most perfect accuracy would be secured, and it would be practicable to test the relative exposures given to the sky and foreground by different forms of shutters; the loss of light on the edges of the plate, by using shutters opening and closing in the centre; and, in fact, to settle nearly all questions connected with the comparative exposures given by the different forms.

There are three methods which promise success for turning the plate:—

1. A clockwork movement controlled by a fly.
2. An apparatus founded on the gravity of an escaping liquid properly regulated.

* Read before the Photographic Society of Great Britain.

3. A very simple modification of the driving-movement of an equatorial: the suggestion of a friend.

It would, however, be somewhat outside the intention of this paper to go into the comparative merits of these motors and their construction; and I must therefore conclude, venturing only to hope that in some small way it may aid in bringing about a more scientific use of the various forms of shutters.

I must beg to mention that I heard, for the first time, from Mr. Cadett's paper, that Mr. Warnerke had designed and carried out a clockwork apparatus having a revolving disc with a hole in it, through which bright light was reflected as it revolved and photographed.

REPORT OF THE "LENS COMMITTEE" TO THE COUNCIL OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

We, the Members of the Committee appointed by the Council of the Photographic Society to consider and report upon the best means of attaining uniformity in the construction of apertures in the "diaphragms of lenses," "flanges," and "camera screws," have now the honour of communicating the result of our investigations. Our aim has been, as far as possible, to combine the nearest approach to scientific accuracy with practical utility. Had either consideration exclusively engrossed our attention, modified recommendations might have resulted. Dividing our report into three divisions, the first section has reference to "lens diaphragms," the second to "flanges and adapters," and the third to "camera screws."

Lens Diaphragms.—With regard to diaphragms we recommend—1st, that the aperture of the standard-unit diaphragm should have a diameter equal to one-fourth the equivalent focus of the lens, and be marked "1," the approximate equivalent focal length of the lens itself being engraved on the mount; 2nd, that diaphragms with smaller openings should have apertures diminishing in area to the extent of one-half from the unit standard downwards, and be marked successively 2, 4, 8, 16, 32, 64, &c. These numbers would indicate to the practical photographer that if a given sensitive film requires with the unit stop an exposure of one second, the introduction of a smaller one would necessitate an exposure of as many seconds as the numbers marked on it; in other words, each stop would require double the exposure of the preceding one.

Should a lens not admit of a diaphragm with an aperture as large in diameter as one-fourth its focal length, nor exactly any one of the above-mentioned sizes, we still recommend that all the apertures be made in uniformity with the above scale, with the exception of the largest, which should be marked with the number its area requires in relation to the unit diaphragm. In the case of a lens having a working aperture exceeding in diameter one-fourth its focal length, the diaphragms should be marked in fractions (as ·5, ·25, &c.), in uniformity with the standard apertures, according to the sizes of their relative apertures. We further advise that diaphragms required to be made with apertures intermediate to the standard sizes should invariably be marked with numbers corresponding to the ratio of their area to the aperture of the unit diaphragm.

Flanges.—We advise the construction of flanges with internal and external screw threads of a standard series, for attachment to cameras having screw threads adapted for screws $1\frac{1}{2}$ in., $2\frac{1}{2}$ in., 3 in., and $3\frac{1}{2}$ in. in external diameter, and made with twenty-four threads to the inch; if larger ones are required, we recommend that they increase in size to one inch in diameter, from four inches upwards, with twelve threads to the inch. We also recommend the manufacture of a series of adapters, with inner screws made to carry any existing lenses, and with outer ones corresponding to the next or other larger size of the standard flanges above described. Hereafter, whenever practicable, the screws cut on the mounts of all newly manufactured lenses should be suited to one of the above-sized standard flanges.

Camera Screws.—With regard to camera-screw connections, we recommend that henceforth all screws fitted to cameras, either for attachment to the stand, for fixing rising fronts or for other movable parts, should be either $\frac{3}{16}$, $\frac{1}{4}$, $\frac{5}{16}$, $\frac{3}{8}$ of an inch in external diameter, and in pitch of thread and other details in accordance with the generally recognised Whitworth standards for the above-mentioned sizes.

Signed, on behalf of Committee, T. Sebastian Davis, *Chairman.*

The Council, having accepted this report, have directed that a series of standard flanges and camera-screws be constructed and kept in the custody of the Society, and be called "the Photographic Society's standards." Upon application to the Secretary, these standard flanges and screws will be shown, and printed copies of this report be given to those manufacturers of lenses or cameras who may be desirous of adopting the above standards.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The exhibition of this Society, for 1882, will be held at the Gallery of the Royal Society of Painters in Water Colours, 5a, Pall Mall East, London, S.W. It will be inaugurated by a conversazione, open to members and their friends, at 8 p.m., on Saturday evening, the 7th of October. The exhibition will remain open daily (Sundays excepted), from Monday, the 9th of October, until Thursday, 16th November. Admission (from 10 a.m. till dusk), 1s. It will also be open every Monday, Wednesday, and Saturday evening. Admission (from 7 to 10 p.m.). 6d. Members will be supplied with tickets to admit their friends. Season tickets will be issued. Single, 3s. Double, 5s.

All packing cases must be sent (carriage paid), addressed to the Photographic Society of Great Britain, care of Mr. James Bourlet, 17, Nassau Street, Middlesex Hospital, London, so as to arrive *not later* than Friday, September 29th. No packing cases can be received at the Gallery. Pictures by hand will be received at the Gallery, 5a, Pall Mall East, on Friday, September 29th, until 9 p.m.

Each exhibitor must send a letter of advice containing a description of each picture, as also a statement of process and any further detail, to be inserted in the catalogue (and it is suggested that when the work shown is taken by a special process, prepared, and made by the exhibitor, information as to particulars should be communicated), addressed to the Hon. Secretary, Photographic Society of Great Britain, 5a, Pall Mall East, London, S.W.

Each frame or picture may have the exhibitor's name and subject neatly inscribed, but no address, or anything in the shape of an advertisement will be permitted. No pictures in Oxford frames, and no pictures previously exhibited in London, will be admitted.

Photographs coloured by scientific or mechanical means will be admissible. Photographs coloured by hand will not be admitted.

Photographic apparatus and appliances may be sent for exhibition. Negatives and transparencies will be admissible.

The Hanging Committee will have the power of rejecting any pictures or apparatus forwarded.

Medals will be placed at the disposal of the judges for artistic or scientific excellence, and the judges are instructed to reserve three medals for portrait or figure subjects (if they find them worthy of awards). The judges will consist of the following gentlemen:—Two artists (painters), Frederick R. Pickersgill, R.A., W. Cave Thomas; the President of the Society, James Glaisher, F.R.S.; two members of the Council, T. Sebastian Davis, F.C.S., W. S. Bird; two members of the Society, W. Ackland, G. Shadbolt.

No charge will be made to members of the Society for exhibiting their pictures; but to non-members a charge of 1s. per square foot will be made for wall space, the minimum charge being 5s. No charge for wall space will be made to foreign exhibitors. The charge for wall space to those exhibitors who may become members of the Society at the November meeting will be remitted.

It is proposed to lay on the table a catalogue containing the price of pictures to be disposed of; those who wish to avail themselves of this proposal will please state the price of their pictures in the letter of advice.

Notice will be sent to exhibitors when to fetch away those works which are left at the Gallery by hand, and should any exhibitor not be able to send to the Gallery, he can, by giving notice to the Assistant-Secretary, and paying the cost, have his pictures packed in a case and returned by carrier. The Council do not hold themselves responsible for any damage that may happen to the pictures, or other exhibits, whilst in their custody, but they will take every precaution to insure their safety, and their prompt return to the owners at the close of the Exhibition.

Any further information respecting the Exhibition can be obtained from the Assistant-Secretary, Mr. Edwin Cocking, 57, Queen's Road, Peckham, S.E.

Proceedings of Societies.

Photographic Society of Great Britain.

The twelfth Technical Meeting was held on Tuesday, June 27th, John Spiller, F.C.S., Vice-President, in the chair.

The Chairman stated that there were three questions sent in for discussion that evening, as also some exhibits; probably it would be better for the exhibits to be taken first.

Mr. Starns then exhibited a quarter-plate camera he had designed, which was constructed to act as a changing-box, the plates being kept inside; no dark slide was necessary. The camera was prolonged behind the focussing-glass so as to admit of two chambers which contained the plates before and after exposure; at the back of the camera was attached a light-tight sleeve which, when the hand was inserted, was fastened round the wrist; the plates were then put in the place occupied by the ground glass, exposed, and put back into their proper chamber.

The Chairman inquired how many plates could be carried.

Mr. Starns replied that three dozen plates could be used; also that, the lens being of short focus with only one-quarter inch range, he had introduced a little screw-adjustment which moved the lens, and did away with the necessity for any sliding movement of the camera.

Mr. Peek said that, whilst the matter took a long time to explain, he could state from experience that it took but a little time to work.

Mr. T. S. Davis remarked that possibly a difficulty might arise in focussing, as, from the construction of the camera, the eye must be some distance from the ground glass; this would also be increased if the camera was constructed for large pictures.

A conversation then arose respecting focussing in general, and darkly lighted objects in particular.

Mr. T. M. Brownrigg then exhibited some photographs taken in a very close and dark wood, the focussing being done from a single point, seven minutes' exposure having been given.

Mr. E. Dunmore exhibited a new developing-dish made of wood, with a corrugated bottom, which would enable small plates to be easily lifted; also a lever at one end for lifting large plates; the dish was coated first with black varnish, then with shellac.

The Chairman remarked that it was a most useful apparatus. In his own practice he used pasteboard boxes coated with paraffin; when the box got wet it was dried, and became all right again.

Mr. Maxwell Lyte suggested, for coating trays, the use of lead plaister in conjunction with paraffin, which could be spread with a hot iron.

Mr. Inck said that he had made a developing-dish with a flat piece of glass, upon which four pieces of thick plate glass ½ inch wide were attached by moisture; the ends of the bars were touched with glycerine, the whole was then water-tight. The advantage was that any size could be made at once.

Mr. T. S. Davis stated that a little time since a difficulty arose to him in covering a certain batch of plates with emulsion, so that round the edge the development was more rapid; he exhibited several of the plates, and said he fancied it arose from the length of time taken in drying the plates, owing, probably, to the gelatine being too soft, and, by remaining damp in the middle of the plate, set slower.

The Chairman then read the question, "Will the borax and gold toning solution, as recommended by Mr. Cowan, keep when the solutions are mixed; or is it desirable to mix sufficient required for the number of prints, and then throw it away?"

Mr. Cowan said that it was only necessary to mix as much as was wanted at the time, and, after being used, thrown away.

Mr. Maxwall Lyte stated that some years ago he was the first person who proposed phosphate of soda, and also borate of soda, for toning purposes; but he found that the borate did not keep so long as the phosphate, as also that he did not get so many pictures toned by the former as he did with the latter, viz., phosphate. The toning action of the borate began quickly, but soon got slower, and then stopped.

Mr. Cowan said that there was no necessity to keep the borax bath, and it would be better to tone no more than one sheet of paper at a time, as also that the borax bath was very useful for the commercial sensitized paper.

The Chairman then read the question, "Upon scientific grounds, what is the difference between liquor ammonia and ordinary washing-soda when used with a pyrogallic developer?"

Mr. Cowan thought that with the soda the yellow stains did not come.

Mr. Davis stated that with the soda the development was more gradual; at the same time, the balance in the end was equal as to results.

Mr. Mawdsley said that plates liable to green fog when using ammonia, would be free from it by using the soda.

The Chairman then read the question, "Does the addition of sulphite of soda to pyrogallic acid in bulk, after a time, cause the developing action to be slow? If so, can each—viz., the pyrogallic acid. the sulphite of soda, and the citric acid—be kept in solution and mixed together at the moment of using?"

Mr. Berkeley remarked, that if the solution of pyrogallic and sulphite of soda was used as strong as he had recommended, it would keep well. Some he had mixed last October was good now. With the addition of more water, the preservative action was lessened.

The Chairmam said that the sulphite acted as an antiseptic, and prevented decomposition.

Mr. Davis stated that when pyrogallic acid was kept in alcohol, it was necessary that it should be absolute alcohol, and the solution should be kept in darkness.

A conversation took place respecting the keeping properties of the addition of sulphite of soda to the pyrogallic acid, as also its retention of developing power, when,

The Chairman said that the question seemed to be answered by the concurrent testimony in favour of Mr. Berkeley's formula.

Bristol and West of England Amateur Photographic Association.

The second excursion meeting this session took place on Wednesday, the 12th inst., the place selected being Froom Glen, Stapleton.

Mr. T. Davey (Vice-president), the Hon. Secretary, and other members, assembled at Clifton Down Railway Station and proceeded to Stapleton Road Station, thence by vehicle to Stapleton, and, alighting at the Bell Inn, apparatus was at once put in form for work.

Stapleton is a pretty country district, only a short distance from Bristol, so that very little time was occupied in reaching it. The "hunting-ground," Froom Glen, was soon reached, when all were evidently disappointed to find that the river—along the banks of which there was a large number of charming subjects—was almost covered with white flakes of foam, caused by its being very full from the recent rains, and falling over many weirs before reaching the spot visited. Although the light was very favourable for exposing plates upon many subjects, they had to be abandoned, all being spoilt by the foam.

A move was made higher up the stream to Wyckham Bridge, where the foam took a far less decided and conspicuous form, and made a view of this most picturesque and beautifully-situated bridge possible. Many of those present had taken negatives of it many times before, but it is a subject one never tires of, and can nearly always find something new in making a picture of it. The party next continued the walk still further up the river Froom, and after passing the first mill, some more very picturesque "bits" were met with; but it was utterly impossible to get pictures of them, the wind having by this time got very boisterous. At this point the quantity of surplus water in the in the river was very apparent, it having in places overflowed its banks, and rendered paths almost impassable. On arriving at the snuff mill, some brethren of the "brush" department were met; they, too, were lamenting the extreme fullness of the river, and consequent inability to find work. The members had therefore to pass this spot, where generally such pleasing and well-composed subjects could be secured, and (by permission) pass over the land of Mr. Vassal, to whom one bank of the river belongs at this spot. But from the same cause it was impossible to secure any pictures of the numerous fine parts of the river scenery, and beyond one or two shots at a group of foxgloves (really to have something to do) nothing was attempted.

The wind was now blowing with such persistency and force that a feeling of despondency became pretty general, and everyone seemed disinclined to spoil plates by exposing them under such hopeless conditions. It was therefore resolved to alter the programme, and instead of having meat tea at the inn at Hambrook, the party resolved to at once retrace their steps, and see if things generally were in a more favourable state at Wyckham Bridge, where they started from, so that until the arrival at that place "the weed" was more the order of the day than photographic apparatus.

It was, however, some little consolation, on arriving again at Stapleton, to find that there was not quite so much wind affecting that district, and that the amount of white froth in the river had considerably decreased. Plates were therefore exposed on a few of the many choice subjects in close proximity, after which it was found time to repair to the Bell to take tea.

Every member seemed at once in a brighter and more hopeful humour on entering the snug and pleasant hostelry, and over the table jokes were bandied, until the appearance of the conveyance at the door reminded all that traps must be packed up, and, unfortunately, the day written down as "unfortunate."

Every member present brought apparatus, and, as far as "the fates" would allow, worked.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Association, held at Ashley's Hotel Covent Garden, on Thursday, the 13th inst., Mr. A. J. BROWN in the chair,

Mr. COWAN exhibited some plates, the results of further experiments with citrate of potash as a restrainer. Two of the plates had been six times over-exposed, and he found that if the citrate was added to the developer and used from the first it acted so powerfully as a restrainer that the plate appeared to have received the correct exposure. If, however he treated the plate in the ordinary way for over-exposure until the image started, then added the citrate to his solution, its restraining action was apparently *nil*.

Mr. JOHN STUART (Helensborough) said he found sulphite of soda very uncertain in its working, and, if not made acid, it got very brown in two days. If sufficient citric acid is added to keep it from turning brown, he thought it had no advantage over the ordinary solution. He found the only way to work it at all satisfactorily was to keep the sulphite in solution, and add the pyrogallic as required.

Mr. HADDON had, about a month ago, prepared a stock solution of—

Pyrogallic	1 ounce
Sulphite (about)	2 ounces
Water	10 ounces

and it had gone very brown.

Mr. COLLINS exhibited one of England's bamboo camera stands to carry a 15 by 12 camera, its weight being about 3 lbs. It was very rigid and firm.

Mr. COLLINS stated that Mr England had had a similar stand in use about fifteen or sixteen years.

Mr. NORRIS demonstrated the method of estimating the amount of silver in solution, as described in the issue of the PHOTOGRAPHIC NEWS of the 7th inst.—*i.e.*, by means of the burette and ammonium thio-cyanate, using ammonia ferric alum as the indicator.

At the request of Mr. Ashman a solution containing by argentometer reading 30 grains to the ounce was tested, and gave by the burette 25·6.

Mr. NORRIS said this method had been in use for some time for estimating the quantity of silver in coinage, and was found to be most accurate in its results.

Mr. REIMAN passed round some plates given him by Mr. Brown, which were known to give a great deal of green fog. Half one plate he had developed with the sulphite of soda formula, the other half with common soda. In the first half was much green fog, but in that where the common soda was used green fog was absent; but its place was taken by a yellowish stain.

The CHAIRMAN thought that even green fog was preferable to an opaque yellow stain; but that green fog did not appear when the negative was thoroughly exposed, and plenty of bromide used.

Mr. REIMAN had intensified a green fogged negative by Monckhoven's formula, the result being a clearance of fog.

Mr. HENDERSON said that the cyanide would have that effect.

The CHAIRMAN's theory was that green fog is a fine deposit of metallic silver, which would be converted into a black deposit by the mercury solution.

Mr. HADDON said that plates giving green fog with the pyrogallic developer do not do so with the ferrous oxalate, but instead, there is a fine grey deposit, which, with the pyrogallic developer, would be green.

The CHAIRMAN had obtained green fog with the ferrous oxalate developer.

Mr. STUART had observed, when coating plates that had been used before, that a part of the old image sometimes remained, which it was impossible to remove, and that this would cause green fog.

Mr. BARKER found that if the following formula were used there was no green fog:—

1.—Rain water	1 ounce
Sulphate ammonia	1 „
Liquor ammonia	$\frac{1}{2}$ „
Bromide	30 grains

Add rather more bicarbonate of soda than will dissolve —

2.—12 grains bromide cadmium to ounce of developing solution.

Mr. HENDERSON had tried cadmium, both in emulsion and developer, and found the only advantage was that the plate developed rather blacker.

Mr. STARNES exhibited a camera and changing box combined; it was very simple in construction, the camera being the front part of an elongated box. There were two chambers in the bottom of the box to hold three dozen plates, the front one being for exposed, and the back for unexposed plates. After the picture is focussed, the glass is removed, and a light-tight back fastened on; the hand is then inserted through a sleeve in the back, and a plate removed from the back chamber and placed in the groove which held the focussing glass. When exposed, the plate is removed to the front chamber, and so on till all the plates have been exposed.

Mr. HENDERSON mentioned that he gave some partly prepared emulsion to Mr. Prestwich, with instructions how to proceed, and that gentleman had coated several plates, and on developing found them frill badly; he had, however, handed two of these to Mr. Henderson, who well washed one of them, and allowed it to dry. He then exposed both for three seconds, and, on developing, the unwashed plate frilled directly, while the other was apparently three or four times more exposed, and did not frill at all.

Mr. PRESTWICH had made enquiries, and found that the plates had been badly washed.

The following gentlemen were elected members of the Association:—Messrs. H. Baden Pritchard, T. Bolas, C. E. Abney, A. J. Cox, N. M. Phillips, C. H. Searle, and H. Richards.

BURY PHOTOGRAPHIC AND ARTS' CLUB.

THE first out-door meeting of this club was held at Whalley and neighbourhood on Thursday, the 29th ult., most of the members having their cameras with them. The first place of interest visited was the splendid mansion and beautiful park of Morton Hall, to which permission had been kindly granted by H. L. Taylor, Esq., the proprietor. Several views having been secured, the members resumed their journey, and soon arrived at Whalley.

The old church was the first object of interest, and soon many cameras were at work securing views from various points of sight, after which the fine old ruined Abbey afforded many choice subjects for both brush and camera, the cloisters attracting particular attention, several very fine views being taken. The members have to thank all parties having care of the church and abbey for the kind and courteous manner in which they were treated.

The party then drove to Mitton Church, where various views, both internal and external, were taken. A group of the members was taken by the hon. secretary, Mr. T. W. Livsey. After a refreshing and substantial tea had been partaken of at the Dog Hotel, Whalley, the party drove back to Accrington, and returned home by the 8.30 train, after having spent a very enjoyable day, forty views having been taken.

THE POSTAL PHOTOGRAPHICAL SOCIETY.

THE above has been founded as a postal society for the convenience of amateurs in different parts of the country, and with the following objects:—For the circulation of prints, negatives, &c. For the exchange of photographs, and of information on photographic matters, and for the general advancement of the science and art of photography.

It is to be noted that this society will in no way interfere with any society now in existence, but will rather tend to the advancement of existing societies, by bringing their members more into communication with each other.

Entrance fee, 2s. 6d., annual subscription, 5s.

Further information and a copy of the rules may be had on application to H. H. Cunningham, Hon. Sec., 7, Figtree Court, Temple.

Committee.—G. Allison, Stoke-on-Trent; F. C. Cowley, Brighton; S. G. Horton, Royal Military Academy, Woolwich; J. Pocock, 21, Ladbroke Grove, London, W.

The following are the principal rules :—

Each member shall send to the Secretary prints from as many of the negatives taken by him as possible, together with particulars of the kind of plate used, lens, exposure, light, locality, and any other interesting information.

No member shall send *less* than six prints annually for the benefit of the Society.

The affairs of the Society shall be governed by a committee of six persons (four of whom shall be residents in London), who shall be elected by the members of the Society. Three members of the committee to retire annually, but to be eligible for re-election.

Photographs sent in by members shall be circulated among the subscribers in scrap-books, together with note-books in which members may jot down useful hints or information, with criticisms on the photographs circulated.

The photographs in the scrap-books shall be numbered for reference, the names of the senders being also given unless they signify to the Secretary that they do not wish their names to appear.

No member shall keep a scrap-book or a note book for more than three days, at the end of which time both shall be forwarded, postage paid, to the member whose name stands next on the list sent with the books.

The name of any member not sending in six prints in the year shall be transferred to the list of honorary members.

Honorary members shall pay an entrance fee of 5s. and an annual subscription of 10s., and such members shall receive the scrap and note-books in their turn, but shall not be required to send in any prints for the benefit of the Society.

Talk in the Studio.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The last of the Technical meetings for the session will be held next Tuesday, July 25, at 8 p m., in the Gallery, 5A, Pall Mall East.

MIDNIGHT PHOTOGRAPHY IN A STEEL-WORKS.—A picture sent to us by Mr. Chas. P. Richards, and taken by the light of a Bessemer converter, possesses considerable interest. The whole area of the Bessemer pit is well lighted up, and the remarkable play of light and shade gives to the photograph a notable pictorial effect. An exposure of two minutes was given.

A RIDE THROUGH THE THAMES TUNNEL IN A PHOSPHORESCENT RAILWAY CARRIAGE.—At the present time a railway carriage painted inside with the Balmain phosphorescent paint is included in the train which leaves Liverpool Street station for Rotherhithe, *via* the Thames Tunnel, at 11.8 a.m. Although only one-half of the available space of the carriage is painted, the phosphorescent light is quite sufficient to enable the passengers to distinguish small objects when passing through the tunnel; and, moreover, the light is powerful enough to enable a person to read the indication of an ordinary watch. It is probable that the railway companies will be enabled to effect a considerable saving in gas and oil by using the phosphorescent paint.

THE little town of Fez has nearly got up a revolution on its own account, and the motive has been photography. It seems that the Sultan has a tolerably large family. The wives of his bosom and the ladies of his harem between them number four hundred. English manners spread quickly Eastward, and the four hundred have shown a taste to become professional beauties. They wanted their portraits taken, and the lord of the harem had no objection. Such an album might act as a reminder to him of the ladies of his choice. The only difficulty was that Fez was hitherto unprovided with a photographer. That, however, was to be overcome. There was sunshine in abundance, and there were the four hundred beauties all keen to pose and look lovely, and occupying their leisure in studying attitudes. The Sultan saw to the rest. He imported a photographer from France, and made the artist bring with him the necessary collodion and camera. The harem was in a state of great excitement, and the French photographer had his work pretty well cut out for him. But in the meantime a difficulty had arisen, and this was the complication that was near producing a revolution. In the Koran it is laid down that no likeness should ever be taken of a human being. Some of the Sultan's family were certainly unpopular, but their claim to being human beings could not reasonably be disputed. The report that they were to be photographed got abroad, and the inhabitants of Fez were resolved to prevent it. Public opinion ran so very high on this subject that it was thought wise to yield to the storm. The camera, which had been smuggled into the palace, was never set up in the operating room. The beauties of Fez were left unrecorded, and the French photographer, who seems to have been regarded as a sort of active principle of evil, had to be specially protected. It was very hard to keep him, and it was nearly impossible to get rid of him. At last he was smuggled out of the town disguised as an old woman, and peace once more reigns in Fez.—*Evening News.*

To Correspondents.

*** We cannot undertake to return rejected communications.

*** LESSONS ON CHEMISTRY.—A printer's error last week described the metre as equal to 29·37 inches: the metre is 39·37 inches.

CHARLES PETTITT.—Thank you.

T. B. HOWE.—We are much obliged for the cutting.

V. DE V. (Plymouth).—1. The work will be ready in a few weeks. 2. The difference may be roughly expressed by saying that the ferrous oxalate contains a larger proportion of iron than the ferric oxalate; the composition of the former being FeC_2O_4, and that of the latter $Fe^2(C_2O_4)_3$.

SULPHITE OF SODA.—1. We have found it to work well three months after being mixed; but much depends on circumstances. 2. It is to be recommended as affording security; but in this case, as in many other instances, it is possible to diverge widely from absolutely safe ground, and yet obtain fairly good results. 3. Yes.

Z. Y. W.—By careful and patient manipulation, whereby the print is stretched as regards the central parts. Of course there is a limit to the stretching practicable, but we have had no difficulty when working with glasses having a radius of curvature equal to thirty inches. By means of a stamping press and suitable dies, the proper curvature might be given at once.

ENLARGEMENTS.—We have had many complaints regarding this matter. Address a letter, giving full particulars, to the Inspector of Police, nearest station to —— ——.

BROMO.—1. Test a solution of the salt with red litmus paper; if it is alkaline, the paper will become blue. Gradually add a solution of oxalic acid until the solution does not change the colour of either red or blue litmus paper. 2. They often arise from imperfect washing before fixing.

F. COWLEY.—1. The numbers represent the relative times of exposure as nearly as we can estimate them, assuming it to be close on midsummer, and the atmosphere quite free from haze in each case. If you make a few trials in the early morning, when no trace of mist is to be seen, you will find the light to be surprisingly quick. We took midday as unity. 2. Try the experiment, and see which gives the best picture; using rather old collodion and a moderately strong developer. The *ten times plate* would be about seventy times quicker than the collodion plate we should employ for the purpose. 3. Enormously reduced, perhaps to one two-hundredth of what it was. Make a few trials for yourself. 4. Write to Messrs Jones and Barber, Alexandra Palace.

H. SPINK.—1. Multiply each number by twenty, and then assume that the quantities are given throughout in grains. 2. It would come to about the same thing, as the heat is seldom over 200° F. when the emulsion is boiled in the usual way. 3. We have not tried it yet, and should be much obliged if you will let us know how it succeeds in your hands.

"3988."—It is probably due to the separation of metallic gold in an extremely fine state of division. If it is as we suppose, the metal will finally settle down as a purple sediment.

SUSSEX.—1. On the whole it is to be preferred; but it is occasionally an advantage to be able to admit light from the south. 2. No. 3. It is desirable, but its practicability must depend on the manner in which you propose to construct the building. 4. That marked in violet ink, assuming that the right-hand side of the diagram is the North. 5. We cannot just now tell you the exact focus, but we have used it very successfully for landscapes on 8½ by 6½ plates.

SOUTH DEVON.—We believe not; you had better get one made from the description given in our columns.

ENDEAVOUR.—The pose is stiff and unnatural, while the lighting is such as to render it almost impracticable to obtain any details on the shaded side. Use a few sheets of old newspaper as a reflector.

JULIUS KOPP.—1. Any ordinary white enamelled paper will answer, provided that the texture is fine. 2 If too soft, some is liable to set off and damage the plate; and if too hard, it does not take the ink readily. 3. Certainly not, as complete insolubility would soon set in.

B. R. CLARK.—Remove the excess of acid by evaporating the liquor to dryness on a water bath.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1247.—*July* 28, 1882.

CONTENTS.

OZOKERITE AND PARAFFIN.

There is no substance of organic origin which displays such an indifference towards chemical reagents as paraffin, as at ordinary temperatures it is quite unaffected by strong nitric acid, sulphuric acid, or chlorine. Paraffin is a name applied by chemists to an extensive series of hydro-carbons, each one possessing a chemical composition corresponding to the general formula C_nH_{2n+2}, and ranging in physical condition from the gaseous state to the harder kind of paraffin wax, which melts at about 140° F.

The solid paraffin or paraffin-wax is, however, the form of this substance which is likely to do most service to the photographer or the photographic experimentalist. This substance is found ready formed in nature to a considerable extent, either occurring as crystalline granules, interspersed through earthy matters, as in the case of the so-called fossil wax or ozokerit; while Rangoon tar and analogous bituminous exudations contain abundance of paraffin wax. The principal commercial source, however, of solid paraffin is the so-called Bathgate mineral or bituminous shale, which is distilled at a low red heat; the crude distillate being subsequently fractionated, and the heavy portions refined by treatment with sulphuric acid, and crystallisation from exceedingly light paraffin or benzoline oil.

The best qualities of commercial paraffin wax melt at about 140° Fah., and consist principally of an hydro-carbon containing $C_{30}H_{62}$, and such a product is excellently well adapted as a waterproofing material for wood-work, paper, and textile fabrics, as no trace of oily exudation tends to separate from it. A well-made wooden box, if soaked for some half-an-hour in such paraffin heated to about 300° F., becomes so thoroughly saturated as to become a tank fitted for any photographic purpose not involving the use of hot liquids, and we have long had such a box in use to contain an electrotyping bath. It is well not to use nails in putting such a bath together, but either to dovetail or dowell the work. Paraffined wooden boxes made in a similar way are excellently well adapted for containing the nitrate of silver bath and other solutions which are easily injured by foreign matter.

A friend of ours, who had to send some dry plates to the Antipodes, wrapped the boxes carefully in paper which was well gummed at the folds, and, when the gum was dry, he dipped each package for an instant in a bath of paraffin maintained near its point of solidification. The plates thus protected arrived in better condition than others which were wrapped in lead-foil. This reminds us of the way in which ingots of sodium are sent into the market. Each ingot is dipped into melted paraffin wax, and this so far protects the metal from oxidation, that the coated ingots may be kept in an ordinary tin canister. Something of the same kind was attempted a few years ago with joints of meat; but it was found that the covering of paraffin was liable to become broken during the voyage from Australia.

The use of paraffin as a substitute for wax in rendering prints transparent was referred to in our columns some weeks ago, and our readers were cautioned against employing samples containing oily or viscous constituents. We have found that paraffin may replace white wax in the so-called encaustic paste used for facing albumen prints, and it is quite possible that it may prove a more effectual protective against damp than ordinary beeswax.

Stenhouse's method of waterproofing paper, cloth, and other textile fabrics with paraffin is of great practical value, and, as Dr. Nicol pointed out in our Year-Book for 1876, admirable temporary dishes may be made from paraffined paper, the edges of the sheet being folded up, and kept in position either by pins or a light frame of wood. Dr. Nicol also mentions that friction with paraffin wax is an excellent preliminary to coating a plate with collodion for the wet process. The plate is warmed so as to be a few degrees above the melting point of paraffin, after which it is rubbed over with a lump of the solid material, and the excess is polished off with a warm flannel. We have tried this, and found it to yield excellent results, the collodion adhering well during the development and washing; but when dry it can readily be stripped from the glass should a reversed negative be desired. The paraffin forms a chemically clean substratum, and covers up many impurities on the plate, rendering these impurities harmless. Paraffin has one decided advantage over albumen as a substratum; namely, that of not working the slightest mischief to the nitrate of silver bath.

Instead of employing a lump of solid paraffin and warming the glass, a twenty-grain solution in benzole may be used, this being merely poured on the cold plate, and all excess polished off as in the previous case.

SULPHITE OF SODA IN THE ALKALINE DEVELOPER.

Our readers will have perused with great interest the remarks by Mr. Herbert B. Berkeley on "Sulphite of Soda, its Uses and Abuses," in our last issue. It will be seen that, in the main, Mr. Berkeley and ourselves are in accord. His article, however, suggests to us a few further reflections on the question of the new developer.

The first of these has regard to the "colour of the negative." There seems to be a general impression that, apart from the colour of the shadows, and from the nature of the print which is got from a negative, there is some charm in certain colours of images. The more nearly the tint approaching to the colour of a wet plate negative the better the result is considered. This notion we consider is an entirely mistaken one. We would point out that the only qualities which have any practical influence on the nature of a negative are, first, the difference of actinic opacity between the most transparent and the least transparent part of the negative, or, in other words, the contrast; second, the number of shades between these two limits, which are correctly represented; and, thirdly, the colour of the most transparent parts of the shadows. The colour of the image (so as it is in all cases of equal actinic opacity) has no influence on the quality of a negative. The quality of a print is entirely governed by the first two of the three factors mentioned, and these being equal, the rapidity of printing is governed entirely by the third, the clearness of the shadows.

To take an example. If there were two negatives which gave precisely similar prints, and which each showed clear glass in the shadows, no matter how different the *images* were in colour, the negatives would be equally quick printing. We point this out because the "wet plate" character claimed for negatives produced by various developers is, we believe, much over-rated. The great object—next to the principal one of getting a negative which will give a good print—is to obtain clearness of the shadows; and although we consider the colour of image of little moment, we quite agree with Mr. Berkeley that it is better to prevent, by the use of sulphite, the yellow pyrogallic stain which is so common, than to cure it afterwards with alum and acid.

We now come to the matter of chemical fog. Here we have but to say that whatever has been Mr. Berkeley's experience, we have had one case in which chemical fog was distinctly produced by the use of sulphite: also that we believe our experience of the development of dry plates is sufficient to ensure our taking all necessary precautions against the action of light on the plate during manipulation. As regards the reliability of the chemicals, we may say that we used a mixture sold by the Platinotype Company, under the title of "sulpho-pyrogallol."

The next question is the vexed one of "colour fog." Doubtless Mr. Berkeley's explanation of the extended time of development partly explains it, but not entirely. We have found the protraction of the development but slight, and on keeping plates (parts of which had been entirely protected from light) side by side, one in the ordinary developer, the other in the sulphite, there was markedly more green fog visible in the one treated by the latter developer than by the former. Possibly this appearance may be in part due to the effect of the yellow stains in the one case covering to a certain extent the green fog. On the other hand, we have seen cases where plates giving green fog with the ordinary developer, gave a fog merging on red with sulphite. Again, however, we agree with Mr. Berkeley that in these cases the best course is to reject the plates.

With regard to what Mr. Berkeley is pleased to call the difference "'twixt tweedle-dum and tweedle-dee," in relation to the formula we gave, the distinction is pretty clear in our own minds. Nothing was said about "oxidization of the sulphite." What we had heard stated—no cause being given—was that the pyrogallic solution, mixed with sulphite, lost its power of development without any change of colour taking place, the sulphite having some deleterious action on the pyrogallic. As we have said, we cannot confirm this. Nay, on the contrary, we can almost positively deny it. It is evident, however, that did any such action take place, all that is necessary to prevent it is to keep the pyrogallic and the sulphite separate.

A slight advantage to be found from keeping the sulphite mixed with the ammonia is this: the tendency which pyrogallol has to oxidize is almost proportional to the alkalinity of the solution. It is desirable, therefore, to have a large amount of sulphite present in a developer strong in ammonia than in one which is weak. This is brought about if the ammonia and the sulphite are mixed.

We do not wish it to be imagined that we are not fully awake to the benefit to be derived from the new developer We regularly use it ourselves, and perceive that its advantages greatly outweigh those drawbacks which undoubtedly arise in certain cases. We believe, nevertheless, that the success of the innovation will be more assured by recognising these drawbacks and discussing them than by denying their existence, or passing them by in silence. There is nothing which discourages a man so much, when he is making trial of a new process, as to find in it some defect of which he has not been forewarned. When he knows beforehand, however, what difficulties may crop up, he is forearmed. In the special case in question he will know that the fault is not in the developer—which, in the vast majority of cases, gives perfect results—but in the plates.

One of the great advantages of the sulphite developer is that a large number of plates may be developed in the same solution. We have before now called the attention of photographers to the fact that, even with the ordinary developer, it is by no means necessary to throw the solution away after one plate has been developed, but that it may be used for three or four. Here, however, the limit is reached, unless an extravagant amount has been used at first. But with the sulphite it is different. Last Thursday we saw exhibited a couple of ounces of the new developer with which a dozen half-plates had been successfully developed, no addition, as we understood, having been made from the first. Certainly, we here have the expenditure necessary to develop a plate reduced to a minimum.

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

A Tour in the Tyrol.*

A guide is again necessary from Heiligenblut to Windisch-Matrei, and it is as arduous a day's journey as that from Ferleiten. You have, indeed, two passes to cross, and a rather difficult bit of walking on the way, called the Katzensteig, or Cat's path. The latter leads over the edge of a rock, at the base of which, and a few hundred feet below, rushes the Leiter stream. But it is not so dangerous as it seems, and any steady pedestrian would pass it without a second thought. We naturally take a photograph of the Cat's Walk at its worst; and our friends in front, when we cry a halt, do anything but appreciate our discretion in thus causing them to stop just at the nastiest part of the giddy precipice.

The Leiter Hütte, or hut, which we pass soon afterwards, affords a shelter for those undertaking the ascent of the Gross-Glockner, and here a supply of milk and black bread may be had. You are now under shadow of the magnificent bell-shaped mountain, and cross a soft snowy shoulder of it. Here a gap in the mountain side suddenly shows you a whole cluster of frosted peaks, seemingly within stone's throw, they are so close. It is as if you have been searching everywhere for them, as in a game of "hide and seek," looking high and low, round this mountain and down that valley, until at last you have hemmed them in from further escape, and find the big white giants all huddled together in a corner. "Come on, here they are!" you feel disposed to cry out to your companions.

It goes steeply down hill to the little village of Kals. There are two inns here, but both of them are very so-so, and we rest a couple of hours before assaulting the second pass. It is but a narrow mountain comb that separates Kals from Matrei—the Matrei Kalser Thörl, it is

* Continued from page 420.

called—but the ascent is very steep during the two hours that it lasts. The top is marked by a wooden cross, and a magnificent panoramic view of snowy ranges greets the traveller on either side. There is the Glockner group of mountains and the Venediger group, the snowy pyramids rising right into the heavens among fantastic cloud masses; green meadows and black pine forests in the plains below enhance the beauty of the snow spires, and the tiny farms and houses grouped about in the valleys, so near, apparently, as to be within pistol shot, induce the belief that you must have discovered fairy-land, and that these miniature habitations and microscopic buildings are the veritable dwellings of the elves and fays children talk so much about. No big rivers or broad torrents are there, but only slender threads of silver, and the little village church below, nitched apparently out of white chalk, could be shut up in a pill-box.

Windisch-Matrei has a first rate inn, with sleeping apartments well furnished, and a good kitchen; hence a stay of a few days is very agreeable. "Mine host" is also a capital fellow, and can give you some good travelling hints. The Gros-Venediger, a magnificent snow-mountain, is very accessible from Matrei, and, if you have time, he will assuredly send you up it. He is a terrible mountaineer, at any rate in theory, and if he has not been to the top actually himself, he has, at any rate, been half way up on two occasions, he assures you, and that is surely as good. We take a photograph of the street in front of the hotel, with a big black mountain towering above it, and include our host himself in the picture; but he holds the result will be unsatisfactory, and for a double reason: in the first place, there is a patch of snow a few feet below the peak, which usually melts in the summer time, and therefore has no right to be in the picture at all; while he himself—in the photograph he is shown not half an inch high—is conscious that his "Blick war nicht ruhig" (his glance was not steady) during the exposure, and hence the composition cannot be perfect. Despite all this, however, the little photograph turns out exceedingly well on development.

We have spoken, perhaps, a little too disparagingly about the commissariat in the Tyrol. If veal is but too often served up to the hungry traveller, the meat is generally toothsome and well flavoured. But there is trout to be had in the Tyrol, cheap and plentiful. "Will you have them blue or brown?" the neat-handed waitress usually asks you, and she means exactly what she says. When boiled, the delicate fish are of a pale blue tint; while fried or baked they naturally enough assume a brownish hue. Cooked either way they are delicious, and form a welcome change or adjunct to a veal and salad dinner. There is another dish, too, that they understand perfectly in these parts—namely, pancakes, and these can be obtained when meat and butter are not forthcoming. *An eingefülltes Mehlspeise* (a pancake stuffed with preserves) will satisfy anybody, and is a sound foundation for a day's walk. For drinking, there is capital beer to be had throughout the Tyrol, as well as palatable red wine (Tiroler), whose only drawback is that it is too good.

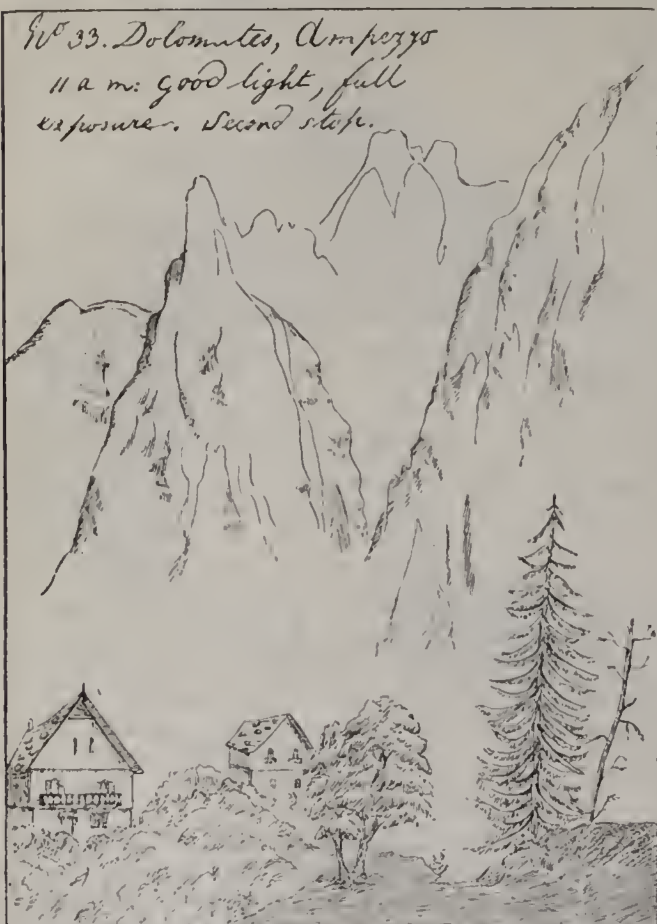
To the little market-town of Lienz is a march of sixteen or seventeen miles. Lienz is a most quaint place, with old public buildings surmounted by mosque-like cupolas, that give some parts of the place quite an Eastern look. Naturally, we take a picture of these cupolas, as also of another ancient edifice, an old inn. We give the sketch of the latter made by our artist friend in his note-book, and reproduced by the photo-etching process.

In setting down particulars, it will be seen that the number of seconds of exposure is not noted, but instead, the words, "full," "fair," or "short" exposure are employed. By having recourse, moreover, to the terms, "very short exposure" and "very full," we get five degrees, which are quite enough for anybody. There is only your own judgment to go upon in the matter, and we believe that if the time of day is noted and judgment passed at the time, in the above terms, this is a better criterion, when it comes to development, than if the exposures were expressed in seconds.

The latter plan often misleads, because the question of morning light, afternoon light, sunshine, or diffused light, have so much to do with the matter. A photographer can do no more than look around him, and, knowing the capabilities of his lens, his stops, and his plates, note then and there whether, in his idea, the exposure has been long or short.

And just another by-the-bye, while we are about it. The tourist photographer does well, as a rule, to spend his plates not upon the wonders of nature so much as upon subjects characteristic of the people and places he is visiting. A big mountain is only a mountain after all, and a monster cascade is but a cascade; when you look at photographs of them, they might have been secured in the Tyrol, Switzerland, the Pyrenees, Norway—well-nigh anywhere; but it is different if you photograph village streets, primitive churches, quaint cottages, and the like; these pictures hereafter are much more interesting, and they have each of them a story that comes vividly to the mind as you look at them. With gelatine plates at his command, the photographer, too, can now-a-days very well include figures in his pictures, without running much risk of spoiling them by shy children or giggling women, who used to be the bane of long exposures.

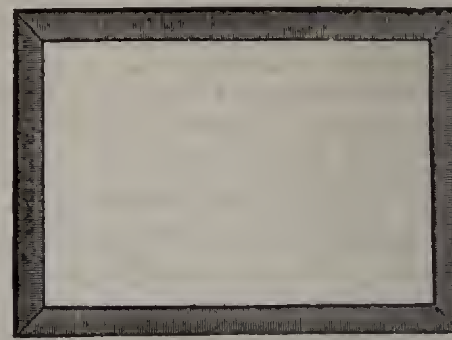
Lienz is in the Puster Valley, and a railway connects it with the main line that runs over the Brenner pass between Germany and Italy. But on the way back we are going to pay a short visit to the Dolomite mountains, those silver grey crags which have for the most part proved inaccessible to the hardiest mountaineer. We take rail to Niederdorf, and put up at the Höllenstein inn, a suitable name enough for photographic travellers, since Höllenstein is the German for nitrate of silver. Niederdorf is at the opening of the Ampezzo valley, and all the way to Cortina—a twenty-five mile walk—there is a succession of beautiful scenery. If you have but a few days to spare, you may very well walk one way (leaving your heavy packs at Niederdorf), and drive back by the diligence, which goes twice a day. Once fairly in the valley, you are surrounded by the mighty jagged spires of the Dolomites, which rise in fantastic shapes on all sides. Here is a view taken at the opening of the Ampezzo, which conveys some idea of their grandeur.



Your way lies through a magnificent pine forest (the little Toblau lake sparkling in the sun like a beautiful turquoise fittingly set in the silvery crags is a wonderful picture), and presently you come in sight of the famed Monte Cristallo, standing alone in magnificent splendour, and almost barring one's path in front. All the way there is a succession of grand and ever-changing scenes; now wild and gloomy, now supremely soft and pastoral.

The changing of plates must, of course, always be done at night, before retiring to rest. The plates should be packed up in fours or sixes, according to whether you carry two or three double dark-slides in your pouch; there is then no need of opening a packet more than once. You take out the fresh plates, and put up exposed films instead. A yellow and ruby paper to fold them in first, then some tin-foil, and finally a sheet of brown paper, blackened on the outside, should suffice to keep from harm even the most sensitive of gelatine films. Tin-foil is apt to break and get damaged when worn, and for this reason new foil should be employed at first; and as it is only once subjected to unpacking and packing, it ought not to suffer injury thereby. The plates should be packed in pairs, face inwards, and between the films a skeleton frame of cardboard should be placed, to keep them from harm, as shown in our sketch. The pairs themselves need not be separated.

The *mauvais quart d'heure* occupied by the tired photographer in changing his plates, when his companions probably are fast asleep, is the most disagreeable part of his lot. Our plan is to do it absolutely in the dark, for you cannot well trust a light, however feeble. Make your bed your work-table, for it is always available, and it is very soft. Place everything convenient to hand, as you



are accustomed to have them, never making a change, and then, with the single packet of plates before you, the dark-slides, and a broad camel's-hair brush handy, to dust the faces of the films prior to enclosing them in the slides, your troubles are reduced to a minimum.

From Niederdorf the rail takes you to Franzens Feste, a fortress guarding the neck of the valley (there is no photography permitted in the vicinity), and here is the junction with the Brenner line. Innspruck and Munich are reached in a few hours hence, and the way home is straight enough.

Another time we shall be happy to take the tourist-photographer another trip to the Tyrol (for there is plenty more to be seen in this delightful alpine country); but we must bid it adieu for the present, in order to act in the capacity of guide to Thuringia, where the German photographers meet in convention on the 23rd of next month.

FRENCH CORRESPONDENCE.

M. Enjalbert's Photographic Revolver—M. Duborg's Shutter—Photographic Exhibition of Paris—The Poitevin Subscriptions—Proposal of an International Association of Photography.

M. Enjalbert's Photographic Revolver.—M. Enjalbert, whose ingenious apparatus for working in full light, called the "tourist," is well known, has just invented a photographic revolver, the description of which may be read with interest. We have only seen a photograph of the instrument, giving a complete idea of its external appearance; and with regard to its internal mechanism, we can only judge of it by description here given. Its weight is 600 grammes, and its dimensions those of an ordinary pocket revolver, differing only in appearance by the barrel containing the lens having a larger diameter than the tube destined to contain the sensitive plates, in the form of ball cartridges. The plates are, unfortunately, of minute dimensions; one dare not say much on that score for fear of interfering with its portability, and an apparatus of this kind cannot be portable if the plates be larger. They are scarcely four centimetres square, so, in order to make use of such a small surface, it is necessary to work with great care. We found in a little portable apparatus of our own invention, and actually in construction, that the surface obtained, although four times as large, was rather too small: but we succeeded in enlarging the dimensions to 30 centimetres, the plates, made of pure gelatino-bromide, measuring 5 by 6 centimetres. By soaking in water before developing, they increase by natural distension of the gelatine, after which the water is replaced by the developer, and treated in the usual way. By this means we obtain a notable enlargement. To return to the photographic revolver. The lens is aplanatic, and its focussing point is regulated in such a manner that at the distance of five paces the further planes are found in focus. It is, in a word, automatic, and the angle it embraces is sufficiently wide to enable one to centre the image well, although not viewed in an absolutely accurate manner. The rapidity of the shutter is such that the shaking of the hand is not noticeable. The lenses of the objective are large compared with the plates, and allow of working with a great amount of light, and of taking instantaneous views even in the shade. The barrel tube contains twelve plates which change places after exposure by an ingenious mechanical contrivance. No doubt, by adapting gelatino-bromide films to this instrument, a considerable number might be introduced, at least treble those indicated by M. Enjalbert. It will be a great advantage to watch them increase in size previous to development. That will be capable of study when we have an apparatus of this kind in our possession. Of course these tiny results are expected to be enlarged, otherwise they would not be sufficiently useful. A simple enlarging process is, therefore, the indispensable complement to the use of the photo-revolver. It is awkward that this instrument is obliged to take the form of firearms. The inoffensive employment of murderous-looking weapons may sometimes cause considerable fear. Imagine anyone pointing his instrument in the direction of one of our rulers in order to take an instantaneous photograph. It would succeed in putting the police in a flutter. A traveller travelling with but one other by railway—what a fright he would have at seeing the other draw from his pocket this weapon, apparently to kill him! Without speaking at greater length on the singular situations, comic or tragic, which might be occasioned by the use of the photo-revolver, we say that the employment of pocket photographic apparatus, whatever form they take, so long as they are portable, and the results obtained are instantaneous and clear, require that the objects or living beings to be reproduced appear absolutely without restraint on the negative. As soon as we have the opportunity of studying M. Enjalbert's apparatus, we shall not fail to tell all we think of the photographic pocket pistol.

M. Duborg's Shutter.—Instantaneous shutters play a very important part in the practice of our art, and the numbers increase every day. A very curious collection might be made by collecting all the various forms of shutters which have been invented. In our preceding letter we spoke of two different shutters, both produced between the lenses of the objective. M. Duborg has invented an apparatus based on the same principle, but with a simplicity and lightness of construction hitherto unequalled. It is simply a small disc of thin metal blackened and attached to a rod capable of oscillating through the action of pneumatic bellows. Nothing is visible externally but the small box containing the bellows, and the India-rubber tube and pear attached, by which the disc inside is made to act. The same instrument may be adapted to different lenses. It will be seen how convenient this is. If an exposure of appreciable length be desired, the pear is pressed for the desired length of time; for a rapid exposure, the pear is taken in one hand and violently struck by the other, causing the disc to be sharply displaced and return to its position so speedily as to give an instantaneous exposure. For the size of this little apparatus, we have never seen anything in use equal to this charming little shutter.

Photographic Exhibition of Paris.—The forthcoming photographic exhibition at the Palais de l'Industrie promises well. It will take place in three large halls adjoining. A reading table will be reserved for the visitors, having spread out on it all the photographic journals and publications sent for exhibition. It is an excellent idea, not only giving great publicity to the representative works, but at the same time showing the great importance of the photographic press and writings. There is no charge made; the publication or work has only to be addressed *L'Exposition du Palais de l'Industrie, (photographic section), Paris.* The exhibition will take place during the three months, August, September, and October.

The Poitevin Subscriptions.—The Poitevin subscription list amounts to over 3,000 francs. It seems certain that the monument will be raised in a square in the town of St. Calais. The managing council of the place have just expressed a wish to that effect. We hope our esteemed colleagues in England will help us in this work, just as we should help them if they undertook anything by which we might glorify our art.

Proposal of an International Association of Photography.—A project exists for the formation of an international association of photography. To our mind a close and sincere bond is wanted to unite all those who take an interest in the photographic cause. LEON VIDAL.

WITH THE ECLIPSE EXPEDITION.

BY C. RAY WOODS.*

Souhag, May, 1882.

HOWEVER pleasant a voyage through the Mediterranean may be at this time of the year, the same cannot be said of an excursion up the Nile during the month of May. Interesting as, doubtless, it is likely to be, at a time when the dreaded Khamseen blows, scientific observations, nay, even the novelties to be seen in travelling, can scarcely be looked forward to with feelings of unmixed pleasure.

Whilst certain duties connected with the forthcoming eclipse have to be done, the members of the expedition have, of course, a good deal of time on their hands; and, with the exception of a short period during a smart gale whilst leaving the Bay of Biscay, life on board the "Kaisar-i-Hind" has been exceedingly pleasant. The rocking motion of a ship does not conduce to the taking of successful photographs; but no small amount of time and trouble, and by no means a few plates, have been not only exposed and developed in obtaining pictures of different parts of the ship, with occasional groups of the passengers and crew.

The principal necessity of a photographer is the possession of a dark-room, particularly when the slides are empty at starting. Our first impulse was to utilise our cabins; but mine happened to be very unfortunately placed in this respect, for, being on the main deck, a considerable amount of light streamed in at the top, in addition to that obtained from the lamp. The latter, had that been the only source of light, would have been convenient enough, for it was placed outside, the light coming through ground glass; but not having sufficient pillows to stuff into all the spaces through which the light streamed, I had to wait till all was dark, and the only illumination was a small amount of faint moonlight coming through the port-hole. Then the slides were filled, and two of them exposed with a drop shutter, in the morning, the subject chosen being an expanse of sea—which, by the way, was rather rough—a small passing vessel, and an almost cloudless bright blue sky beyond. As the sun shone brilliantly, a pretty picture was at least hoped for, though scarcely expected; but both plates turned out to be over-exposed, though taken with a small stop in about the tenth part of a second. The plates, it may be mentioned, registered 22 on Mr. Warnerke's sensitometer, and were much too rapid for the purpose. Had the circumstances under which they were developed been a little more favourable, they might have been saved; I resolved, therefore, to try no more developing till I had got a better dark-room. Application to the purser in the morning brought us luck. He was very ready to oblige, and accommodated us with an empty post-office cabin, which, with the help of our ruby cloth and orange paper, gave us a very convenient place to work in. We were turned out subsequently; but after leaving Malta another cabin was given us which proved still better. It was on the spar deck, and for the remainder of our voyage through the Mediterranean the port was never closed. The sash was soon covered with paper and cloth, and, by simply sliding it along, white light and plenty of fresh air could be readily admitted at will. Could we only have had a supply of water from a tap, instead of having it in tin vessels, no better dark-room could have been found to work in. Our developing-trays were made from some sheets of tinned iron obtained at Gibraltar, and many of our chemicals were obtained from the same place; whilst the stewards of the ship supplied us with plenty of clean bottles, for we did not think it advisable to open our chemical chest on the voyage.

The most picturesque subjects on which to try our art on board were certainly the Lascar crew When we went on board

* Read before the Photographic Society of Great Britain.

the ship at Tilbury, their costume reminded me of that of Drury Lane pirates; from thence to Gibraltar they were habited in incongruous mixtures of their own and weather-beaten European garments. During the gale in the Bay, when they wore oilskin hats and long coats of the same material, I thought they looked villainous; but we saw them at their best in the Mediterranean. Few good photos. were obtained of them, for we had some little prejudice to get over. One morning some of them were squatting on deck playing at cards, and, bringing up my camera and some quick plates, I was putting in the slide, and was just about to congratulate myself on the picture I should get, when they saw me and jumped up in alarm. Having brought the camera up, I contented myself with a group of a few of the passengers and such of the coloured men as came in the picture, but, not being in a direct line of the lens, thought themselves out of harm's way. With the men from India (I believe most of them come from Surat) the prejudice soon wore off, and some of them, who had probably seen the rough print I gave one of them, and were even anxious to have their likenesses taken; but with the Africans I never succeeded. On the Sunday we spent in the Mediterranean all the crew came out for parade, dressed in their smartest attire, with clean white trousers and tunics, blue sashes and red turbans, forming a most picturesque group. The chief of the Hindoos made energetic signs to me, which I rightly interpreted that he desired to have them photographed; and signs of pleasure appeared on many of their faces when I brought out my camera. I got some of them to sit down, whilst the others stood up behind, and got a pretty fair negative, only one man moving during the four seconds the cap was off the lens. The posing created a good deal of fun, one of them sitting down in front, with a little black goat in his arms, which kicked and struggled to get away, but was at length quieted. I then turned round my camera towards a group of negroes on the other side of the deck; but it created great consternation, and was the signal for such a dancing and shouting of "No sah! no sah!" that I thought it expedient to lay my camera aside before they took, as they seemed disposed to do, vigorous measures. I was rather sorry, for I wished particularly to get their chief, who was so smartly dressed that he looked like Solomon in all his glory, and seemed, by the airs he assumed, to be quite aware of it.

We have obtained various pictures of different parts of the ship, and I succeeded in getting an instantaneous picture from the mizenmast, climbing up with my camera fastened round my neck, and exposing it with a drop-shutter whilst holding the camera as steadily as I could in my hands. The picture obtained was fairly sharp, but very much under-exposed so far as the decks and the figures on it were concerned.

Our photographic work on board was very successful. The water was warm; but, with the plates I had especially prepared with hard gelatine and a double quantity of chrome alum, no signs of frilling appeared.

The heat we experienced on board was sometimes 80° in the shade, and in the railway journey from Suez to Cairo it rose to 90°. As not more than 110° in the shade is expected here, my own plates, I am confident, can be developed with impunity by simply cooling the water in porous earthenware pots. The damp sea air does not seem to have affected my plates, which develop free from spots; and some sensitized paper we took with us prints well. Toning has not been attempted, nor are we likely to try it, as it is not necessary for anything we are likely to do *en voyage*, either for private or scientific work.

In the Suez Canal we had a beautiful moonlight night, and all throughout the evening the ship was perfectly motionless. The scene from the bows of the ship was very good—the high banks of the canal on either hand, and in the centre another steamer, with its reflection in the water. I exposed a quarter plate for 72 minutes with the full aperture of my lens, and obtained a picture, very thin it is true, but with a fair amount of detail, and capable of intensification.

On arrival at Suez we were greeted with a sight of a most glorious sunset—a scene which only the pencil of an artist could do justice to. The camera was quite inadequate to the task of depicting the harbour, with the beautiful ruddy and purple tints of the adjacent hill and the delicate play of colour on the light fleecy clouds.

Speaking of clouds, either report speaks falsely regarding the clearness of Egyptian skies, or the weather here is exceedingly exceptional. Our first sight of Egypt, whilst passing through the canal, was signalised by a sky completely covered with heavy clouds; and soon the rain began to fall, dispelling the mirage that rendered the landscape so attractive. Whilst the sky in Upper Egypt has been, as a whole, remarkably clear, clouds have appeared at different times near the horizon, sufficient to spoil our observations, should there be any present at the time.

We got through the canal easily, owing to the energy displayed by the Egyptian Government and the English consuls out here, and, stopping at Suez and Cairo for a short time only, were soon on our way for Assiout, which we reached early on the morning of the 6th. Our heavy instruments were soon placed on the backs of camels, and our lighter baggage on donkey-carts, and a strange procession was seen winding its way towards the steamer. Camels, donkeys, turbaned natives, with a few Europeans in white helmets, formed an interesting scene, and, but for the necessity of having to see the cases safely on board, might have formed the subject for a good picture. The strength of the Arabs, as they exerted their powers to the utmost in carrying on board our heavy cases, seemed almost superhuman; and one no longer wonders how the Pyramids were built, if, as no doubt, they had such fine fellows as these. Our heavy cases have already brought us into trouble, for the authorities on the steamer did not care to take them on board; and a compromise was effected, some of them being towed behind in a small boat. The steamer had a large number of soldiers on board, and, being heavily weighted, grounded occasionally; and when evening came on, it at last fairly stuck. We got no the barge, to set an example to the soldiers, who were with difficulty persuaded to get out of the steamer. No progress, however, was made, and we had to remain motionless all night. After some delay in the morning, we were once more on our way, and, after sticking in the mud several times, have at last reached Souhag; and we may now consider our work to have begun.

It may interest members of the Society to know what we propose to do in the forthcoming eclipse, but I will first draw attention to the photographic work that has already been done in former eclipses. The photographic work attempted in previous eclipses may be divided into two classes; firstly, attempts to photograph the corona and prominences; secondly, attempts at photo-spectroscopy. The latter have hitherto met with but little success, but many of the former have been remarkably good.

The first attempt to photograph the corona was on the 7th of July, 1842, by Professor Majocchi, of Milan, who employed the Daguerreotype process. One plate was exposed just before totality, and an image of the thin crescent obtained. Another plate was exposed two minutes during totality, but no trace of an image was obtained. The light was also condensed by a lens on a sheet of bromide paper for two minutes during totality, but no sign of action was found upon it. The whole account of these experiments is somewhat vague, and the causes of failure are correspondingly uncertain.

In July, 1851, Dr. A. L. Busch, of Königsberg, during the eclipse on the 28th of that month, obtained a photograph of the corona on a Daguerreotype plate. A telescopic lens of 2·4 inches aperture and 2½ feet focal length was used, the plate being exposed for eighty-four seconds during totality. Although the image of the corona did not in this photograph extend far from the moon's edge, in fact not very far beyond the prominences, this photograph is by far the most valuable record of the eclipse of 1851.

Although several eclipses occurred between 1851 and 1860, no further photographic attempts were made until the latter year. During the eclipse on the 18th of July, 1860, attempts were made by Mr. Warren De las Rue, at Rivabellosa, and by Padro Secchi and Professor Monserrat at Desierto de las Palmas. Mr. De la Rue used a photo-heliograph with an object-glass of 3·4 inches aperture and 50 inches focal length, the image thus formed being enlarged by a Huyghenian eye-piece to about 3·8 inches diameter. Two photographs were obtained, each one being exposed for about sixty seconds, but only slight traces of the corona were obtained. This was undoubtedly due, firstly, to the large size attempted and consequent feebleness of the image, and secondly, though in a smaller degree, to the loss of light through the extra lenses. The only useful result obtained, therefore, in addition to the knowledge that the photo-heliograph is unsuited for the work required, was the fact that the photographic intensity of the light of the prominences is about 700 times less than that of the sun's photosphere. Padre Secchi and Professor Monserrat were more successful. Using the Cauchoix telescope belonging to the observatory of the former, the object-glass of which was 0·15 metre (somewhere about six inches) in diameter and 2¼ metres (about 7¼ feet) in focal length, four good photographs were obtained. Professor Monserrat, who conducted the phetographic work, as well as Mr. De la Rue, used the wet-collodion process.

In the eclipse of August 18th, 1861, attempts were made by Dr. G. Fritsch, Dr. H. Vogel, and Dr. W. Zenker to take photographs in the principal focus of a 6-inch refractor of 7 feet focal length; but owing to cloudy weather, the low altitude of the sun, and short exposures, only the prominences are visible. Colonel Tennant and Sergeant Phillips attempted at Guntoor to obtain photographs with a 9-inch reflector, but only the prominences were obtained, and scarcely any trace of the corona. Mr. F. W. Sutton was unsuccessful with a telescopic objective of 3½ inches aperture and 66 inches focal length; the plates were exposed six and seven seconds, but no image was obtained, either with the iron developer or a strong pyrogallic one. It is a question, however, whether the apparatus was really directed towards the sun, or whether it had shifted.

In the eclipse of August 7th, 1869, photography played a more prominent part, and some of the many attempts made on that occasion were crowned with success. Professor Himes, assisted by Messrs. Browne and Baker, at Ottumwa, Iowa, obtained several photographs of different phases of the eclipse, but only portions of the corona. Wet collodion was used, and an iron developer of medium strength; the pictures coming up rapidly being no doubt over-exposed for the prominences, and under-exposed considerably for the corona. Professor A. M. Mayer, at Burlington, obtained good photographs of the prominences, but only traces of corona; he having endeavoured to obtain, although using an equatorial of 6·4 inches aperture and 9 feet focus, a larger image by the interposition of an eyepiece. Messrs. Black, Fitzgerald, and Pourtales, at Springfield, Illinois, only obtained a series of superimposed images (the sun having been followed by hand), showing the prominences only. Professor Winlock and Mr. J. A. Whipple, at Shelbyville, however, obtained a really good image of the corona with a lens of 7½ feet focus and 5½ inches diameter. This was taken with an exposure of forty seconds, and, like all successful photographs of the corona, was taken without an eyepiece or enlarging-lens.

The eclipse on December 22nd, 1870, was, owing to the great state of solar activity, a very fine one; and the experience gained from previous eclipses rendered it unusually favourable for obtaining a photographic record. Lord Lindsay, using a reflector of 12 inches aperture and 6 feet focus, obtained an image, but the plate was so fogged that it was useless. Prof. Winlock, with Messrs. Willard and Mahony, were more fortunate, both the last-mentioned gentlemen obtaining good photographs of the corona. A still better photograph, showing more detail, was obtained by Mr. Brothers at Syracuse, the lens used being one of Mr. Dallmeyer's "rapid rectilinear" combinations of 4 inches aperture and 30 inches focal length; the aperture, however, being cut down to 3 inches. The negative showed a fair amount of detail, and was of more value than any that had been previously obtained.

It is from the photographs taken in 1871 by Mr. Davis (Lord Lindsay's assistant) at Baikul that we derive our most reliable notions of the coronal structure; and Mr. Hennessey and Captain Waterhouse, at Dodabetta, obtained most satisfactory photographs of the corona; in fact, those taken at the latter place are unsurpassed. Like many of the preceding, they were taken on wet plates; and though the effect is marred by photographic defects, such as streaks and scum-marks, in addition to halation, the actual details of the corona can be made out with certainty by comparing the negatives.

Of the eclipse of 1874 we possess no photographic records. During the eclipse on April 6th, Mr. Beasley, who was with Dr. Schuster in Siam, obtained, with an ordinary camera and lens of 13 inches focus, a series of images with exposures of 2, 4, 8, and 16 seconds respectively. The photographs, however, were poor in detail; and the most noteworthy feature about them, it is said, is the rapid increase in the extent of the corona with the longer exposure. In the last, the extent of the corona exceeded the diameter of the sun. One must recollect, the image of a sun by a 13-inch focus lens is very small.

In 1878, Dr. Henry Draper and Dr. Blackett obtained photographs of the corona; the first using wet plates, with a telescope of 5 inches aperture and 78 inches focal length, and the latter a camera of 6 feet 2 inches in length, with a lens having an aperture of 13 inches, Swan's dry plates being used. Other series of photographs were taken by Mr. Rogers, of Washington Observatory, and Prof. Harkness, at Creston. In 1878, however, the sun was comparatively quiescent, and similar coronal structure to that shown in the Dodabetta photographs was not obtained.

This year's eclipse will, it is expected, be more favourable. The sun has lately been showing greater activity. Larger spots and extensive prominences have lately been observed. With such a climate as that of Egypt (if, indeed, the khamseen does not interfere with our arrangements) it is hoped that good work may be done. Gelatine plates will be used; but as to whether they will be developed in Egypt is doubtful. The developing done in the Mediterranean, however, looks promising, and with the aid of freezing mixtures I personally entertain little fear. As, however, we expect a temperature of 110° in the shade, it will not do to be too hopeful; trial plates, when we get to work, will give us some idea as to what course it will be best to pursue.

I shall not attempt in this communication to give a complete account of our arrangements; by the time I write again, I shall be able to take photographs of our instruments, and thus save a deal of explanation; I do not think it probable, however, that it will arrive in time for the May number of the Journal, and it will therefore, I expect, be inserted in the same number (June) as a brief account of our photographic results is likely to appear in. Nevertheless, I will endeavour to state briefly what we propose doing.

In the first place, we shall endeavour to obtain photographs of the corona. This we do not consider to be by any means the most important part of our work; but such photographs will be useful for reference, even if they do not clear up moot points. For this work we shall use a camera with a lens of a little more than 5 feet focus, that would give an image of the sun about half an inch in diameter. No lens will be interposed to amplify this image, the inadvisability of such a proceeding having been amply demonstrated in previous eclipses. The direct image will be better, not only on account of the less loss of light, but also for orientation and measurement. The orientation will be performed by various methods, photographic and otherwise.

The plates to be used are about sixty times as rapid as wet collodion. Means will be adopted to prevent halation, advantage being taken of Captain Abney's communication to the Society in December last. This halation question is most important. By preventing it, we hope, firstly, to give good long exposures, and thus obtain an image of the corona to its utmost possible limit; secondly, better definition; thirdly, a clean edge to the moon's black disc; and, what is far more important, a more reliable record of those parts of the corona near the limit of the edge of the disc.

In what we hope will prove the more important part of our work we shall be trying a ground hitherto almost untrod. Photo-spectroscopic work during totality offers a fresh field, but one which is capable of yielding most important results should the attempt prove successful. An attempt was made in 1875 to photograph the spectrum of the light of the corona, but it failed with the methods then in use. Photography has been spoken of rather disrespectfully in scientific circles for such work since that occasion; but what was impossible then, we certainly hope to accomplish now, with the more rapid material at our disposal. A further attempt was made, during the same eclipse, with a prismatic camera, but only the corona appeared. With the plates we have with us, we hope to obtain a far better result with our prismatic camera; and strong reliance is placed on a spectroscopic camera, which I hope to describe, with the rest of our apparatus, in my next communication.

(To be continued.)

EXAMINATIONS IN PHOTOGRAPHY.

The Pass List of the May Technological Examinations in the City and Guilds of London Institute has just been issued, from which we extract the following particulars relative to the prizes and certificates given in photography:—

First-class Honours Certificates.—1st Prize—Walter Angus Watts, of Manchester, £5 and Silver Medal. 2nd Prize—Arnold John Spiller, of London, £5 and Bronze Medal.

Second-Class Honours Certificate.—Edwin Banks, of Liverpool.

First-Class Ordinary Certificates.—1st Prize—George Embrey, of Gloucester, £3 and Silver Medal. 2nd Prize—Ernest H. Farmer, of London, £3 and Bronze Medal. 3rd Prize—H. G. Templeton, of Gateshead, £2 and Bronze Medal. Harry Hinchcliffe, of Liverpool.

Second-Class Ordinary Certificates.—Arthur John Banks, Francis Caldwell, Augustus Rainger, and William S. Ramson, all of Liverpool.

Notes.

Although a larger edition was printed than on any former occasion, our Year-Book for 1882 is already out of print.

Mr. J. T. Taylor has corrected the last proofs of the new edition of Hardwich's photography, and its publication may be looked for very shortly.

Dr. Eder sends us Part III. of his important work on photography. It treats principally of optics, and we shall take an early opportunity of reviewing it in these columns.

We are glad to learn that "first-class honours" have been obtained in photography at the last examination of the City and Guilds Institute, by Mr. W. A. Watts, of Manchester, and Mr. A. J. Spiller, of London. A gift of five pounds is made to each of these gentlemen, while the former receives a silver, and the latter a bronze medal.

Liverpool is well represented in the pass list, no less than six candidates upholding the honour of their city. These are Mr. Edwin Banks, who secures honours, Mr. H. Hinchcliffe, who takes a first class certificate, and Messrs. W. S. Ramson, A. Rainger, F. Caldwell, and A. J. Banks.

The special artists of the *Graphic* and of the *Illustrated London News* both avail themselves of photography in depicting the stirring scenes now passing in Egypt.

Useful knowledge for the Tropics. A gentleman writes from India:—"Some gelatine plates I have had have done very well, and others of good name at home are quite useless here. I should say that the only plates really useful in India are those prepared with hard or hardened gelatine. The soft gelatine will not do at all. It is particularly annoying to find that makers who have been using a hard gelatine, and whose plates consequently answered well, change their gelatine, and their plates then become quite useless in the hot weather."

Our Indian correspondent adds:—"I find that with the thermometer above 90° F., and the temperature of ordinary cold water above 80° F.—water was 84° the other day in a cool porous jar—very few plates will stand without ice in the washing waters. Still there are those of several makers that do. I generally prefer the ferrous oxalate development, followed by alum, and then fixing."

"The A B C of Modern Photography" is the title of a handy sixpenny book issued by our publishers, containing the "Twelve Lessons on Elementary Dry Plate Photography" that recently appeared in these columns. The work has been carefully re-edited by the author, Mr. W. K. Burton, C.E.

We notice, in one of the recent reports issued by the Ordnance Department of the United States, some instructions as to the carrying on of photography for warlike purposes. No mention whatever is made of gelatino-bromide, and the military photographer is given the choice between wet plates and the tannin process. If North America is to maintain its character as a go-ahead nation, it must do better than this.

Major Armstrong, the chief instructor in telegraphy and photography to the Royal Engineers, will probably proceed to Alexandria.

A staff of Engineer officers have also been ordered to Egypt to commence a general survey, there being, as we pointed out last week, no trustworthy military map of the country. Several large cameras, together with other apparatus, will be included in their equipment, for photography affords aid to the military surveyor as well as being a means for the rapid production and multiplication of maps. During the march to Magdala, in 1868, the surveyors and photographers attached to Lord Napier's force accurately mapped out the whole 400 miles of Abyssinia through which the army passed.

Dr. Kaiser has exhibited to the Physical Society of Berlin a shutter of some novelty. On pressing a bulb with the hand, two swinging valves before the aperture of the lens are opened, and meet one over the other. Dr. Kaiser claims, moreover, that he can so alter the mechanism of the valves that one acts faster than the other, and in this way he can allow the light falling from the sky to act for a much shorter time than that coming from the earth. The doctor's mechanism is doubtless very ingenious, but the difficulty about the top light may generally be met in a much more simple manner by the use of a sky-shade or camera-peak, such as Mr. England always uses in landscape work.

A "special notice" in red ink, attached to the regulations of the next Exhibition to be held at Pall Mall, tells us the rules this year will be *strictly adhered to*, and, therefore, no picture will be received after 9 p.m. on Friday, September 29th. We sincerely trust this will be the case, and that late contributors will have their works sternly rejected; it is not fair that those who obey and those who disobey should be treated alike.

Sir James Hannen last week decided a case on purely photographic evidence. A witness having readily indentified the photographic portraits of respondent and co-respondent in a divorce suit, his Lordship said that in general he was not in the habit of relying on photographs as evidence of identity; but as the portraits had not been called in question by the counsel of the accused, he considered that the case had been proved.

You may carry special pleading sometimes too far. In commenting on the three great electric inventions of the day—the telephone, the storage battery, and the incandescent lamp—the French journal, *Electricité*, desires to point out that all three were really originated many years ago. It says:—"Graham Bell does not efface Riess, in spite of the recent Chancery suit; Faure cannot destroy Planté; and Swan, Edison, and the others cannot suppress the anterior labours of Changy." Undoubtedly we should give credit to the pioneers; but let us not be unjust in order to be generous. Riess, Planté, and Changy all will be recognised as great original workers; still it is very certain that if we had been without Graham Bell, Faure, Swan, Edison, and the others, there would, practically, be no such things at this moment as the telephone, the storage battery, and the incandescent lamp. Nay, more; had these latter *savans* never been, the names of Riess, Planté, and Changy would have been comparatively unknown.

Now that it has been decided to build an observatory on the top of Ben Nevis, upwards of 4,000 feet above the level of the sea, we sincerely hope that regular photographic observations will form part of the work to be conducted therein. Both France and Germany are before us in respect to official photo-astronomical work, and where we have apparatus—viz., in London, Greenwich, and Kew—the vapours of the metropolis cannot but interfere sadly with the delicacy of the results. The top of Ben Nevis is generally above the mists and fogs that at times envelop Scotland, and there can be little doubt that in the purer atmosphere at the highest point in the United Kingdom, more valuable and trustworthy photographic records could be secured than elsewhere.

The explosion in an albumen factory at Manchester, a short time ago, whereby the proprietor, Mr. Riley, met with his death, seems to have been satisfactorily cleared up by the Inspector of Explosives. It was rather difficult to understand how even very dry and finely-divided particles of albumen could explode, notwithstanding all we have learnt lately about the danger of all sorts of dusts when ignited. It turns out that Mr. Riley employed his albumen not for photography, but for thickening and fixing colours, and he employed, too, in his work large quantities of chlorate of potash and prussiate of potash; with these latter on the premises, the cause of danger was not so far to seek.

Sir Allen Young, writing a fortnight ago from the most northern point of Norway on his way north, says that the plucky little craft the *Kara*, with Mr. W. Grant on board, is still ahead of him, and has by this time doubtless reached Novaya Zemla. Arrived here, the *Hope* and the *Kara* are to join in their search for the the missing *Eira* and her crew. All hope to be home again in November.

Professor H. M. Paul ingeniously employs reflected light as a means of testing the vibration imparted to the earth by moving vehicles. His arrangement is a very simple one. He sinks a stout post some four and a half feet into the ground, and upon this is a plank supporting a reservoir of mercury—or, rather, of amalgam of tin and mercury. The surface of the mercury is obviously a mirror, and when any vibration is felt by the earth, the surface of the mercury is disturbed more or less. An object of a suitable kind is reflected upon the mercury surface, and when there is no vibration, this reflected image is, of course, sharply defined. As soon, however, as any vibration occurs, the image moves, and becomes more or less exaggerated.

Professor Paul has hitherto employed a telescope to note the amount of vibration, taking optical notes the while; but there is little doubt that photography would help materially in registering the degree of change or vibration. He has found that an express train passing at a distance of one-third of a mile affects the mercury very considerably for a space of two or three minutes, and a one-horse vehicle, passing at a distance of five hundred feet, caused a disturbance of the image on the surface of the mercury whenever one of the carriage wheels passed over a stone.

M. Charpentier tells us that the time elapsing between a person seeing a signal and being able to repeat it with his forefinger is about 13 hundredths of a second. With some people the interval is twice as long, but the above may be taken as the average. M. Charpentier terms the interval in question the "duration of luminous perception," and he measures it in a very ingenious manner. A black disc is set revolving at a given speed, and the observer faces it, having under his finger an electric key. There is a small opening or window in one part of the disc, and when this comes round opposite the observer, he sees a light shining through it. Immediately he presses the key, and an electric signal passes to the revolving disc. The disc is stopped, and the distance between the window and the record of the signal being measured, furnishes the result. The distance between the two points on the disc is, of course, easily turned into time, since the disc was revolving at a known speed.

TWELVE ELEMENTARY LESSONS IN PHOTOGRAPHIC CHEMISTRY.

No. II.—Reagents.

In the quantitative analysis of photographic chemicals, the following solutions will be required:—

Solutions in 6-ounce Stoppered Bottles.

Sulphuric acid (strong).
,, ,, (dilute).
Hydrochloric ,, (strong).
,, ,, (dilute).
Nitric ,, (strong).
,, ,, (dilute).
Acetic acid.
Potash.
Ammonia.
Ammonium sulphide.

Solutions in 2-ounce Corked Bottles.

Ammonium carbonate.
Ammonium chloride.
Ammonium oxalate.
Potassium antimoniate.
Potassium chromate.
Potassium iodide.
Silver nitrate.
Iron protosulphate.
Lead acetate.

Barium nitrate.
Sodium phosphate.
Tin protochloride.
Platinum perchloride.
Lime water.
Starch solution.

Each bottle should be labelled with the name of the reagent and its symbol; in that way it will greatly assist the student in learning the symbols of the various chemicals, and also save a great deal of time in taking notes of experiments. Labels can be had from philosophical instrument makers suitable for the purpose, but for those who prefer to make their own we append an example.

SULPHURIC ACID
(Strong)
H_2SO_4

Sulphuric acid, H_2SO_4.—About eight ounces will be required. The dilute solution should contain about one of acid to three of water, but in making it up the water must be placed in a beaker, and the acid added slowly, stirring the whole time; when cold, pour the mixture into a stoppered bottle.

Hydrochloric acid, HCl.—Eight ounces will be sufficient; the dilute solution may be made by mixing three parts of water to one of acid, no precaution being necessary in mixing as in the former solution.

Nitric acid, HNO_3.—Two solutions will also be required. The dilute solution is made up after the manner of the hydrochloric acid solution.

Ammonia, NH_3, otherwise known as *liquor ammonia*, when mixed with an equal volume of water, is of convenient strength.

Potash, KHO, better known as *caustic potash*.—About an ounce of the solid *stick* should be dissolved in six ounces of water.

Acetic acid, $C_2H_4O_2$.—The strong acid should be mixed with about two volumes of water.

Ammonium sulphide, NH_4HS, is obtained by passing sulphuretted hydrogen through a solution of ammonia till it is saturated; the solution should be colourless, or only of a slight yellow colour. Sulphide of ammonium is a test for iron, forming with it a black precipitate of iron sulphide.

Ammonia carbonate $(NH_4)_2 CO_3$.—A quarter of an ounce of the salt should be dissolved in two ounces of water; it is chiefly used as a precipitant of the alkaline earths.

Ammonium chloride, NH_4Cl, commonly known as *sal ammoniac*.—A saturated solution should be made up.

Ammonium oxalate $(NH_4)_2C_2O_4$.—One drachm dissolved in two ounces of water will be required; it produces with calcium salts a white precipitate soluble in hydrochloric acid.

Potassium antimoniate, $KSbO_3$.—One drachm must be briskly shaken with two ounces of water, and the solution filtered. It gives, with alkaline solutions of sodium salts, a granular precipitate on stirring.

Potassium chromate, K_2CrO_4, is a yellow salt, and should be neutral, or only slightly alkaline; five grains dissolved in two ounces of water is of convenient strength. It is used as an indicator for the volumetric determination of silver, and also as a test for salts of silver, forming a blood-red precipitate of silver chromate. When the solution of potassium chromate is kept in a glass bottle for some time, a yellow deposit of lead chromate is formed on the inside, by the combination of chromic acid with the lead in the glass.

Potassium iodide, KI.—Twenty or thirty grains dissolved in two ounces of water is a useful solution. It is a test for silver, mercury, and lead, giving pale yellow, scarlet, and bright yellow precipitates respectively. The scarlet mercuric iodide is readily soluble in an excess of potassium iodide. The lead iodide is dissolved by boiling water, but crystallizes out in beautiful golden spangles on cooling.

Silver nitrate, $AgNO_3$.—Five grains dissolved in two ounces of water is sufficient. It is a test for chlorides, giving a white precipitate, soluble in ammonia; with bromides, it gives a cream-coloured deposit, only slightly soluble in ammonia; while with iodides, a yellow precipitate, totally insoluble in ammonia, is formed. Hyposulphite of soda forms with silver nitrate a white precipitate, which soon changes to the black sulphide of silver.

Iron protosulphate (ferrous sulphate), $FeSO_4$.—Ten grains dissolved in an ounce of water is sufficient; but it will not keep longer than a month, from the fact that it absorbs oxygen from the air, and is converted into the ferric salt. If strong sulphuric acid is added slowly to a mixture of any nitrate and ferrous sulphate, a brown band is formed at the junction of the two liquids.

Lead acetate, $Pb(C_2H_3O_2)_2$.—Twenty grains should be dissolved in two ounces of water. This solution is a test for sulphides, forming a black precipitate of lead sulphide.

Barium nitrate, $Ba(NO_3)_2$.—A solution containing half an ounce dissolved in two ounces of water should be made. Its chief use is as a test for sulphates, forming a white precipitate insoluble in nitric acid.

Sodium phosphate (hydrodisodic phosphate), $NaHPO_4$.—Half an ounce should be dissolved in two ounces of water. It is used as a test for magnesium compounds, with which it forms a white granular precipitate in the presence of ammonia.

Lime water, CaO.—A piece of quicklime about the size of a marble should be powdered up and shaken with two ounces of water, and then allowed to settle. The clear liquid must be decanted off. Lime water is used as a test for carbonates. The substance to be tested is placed in a test-tube fitted with a perforated cork holding a tube bent twice at right angles, the outer end dipping into another test-tube containing the lime water. Hydrochloric acid is poured on the substance, when a white deposit formed in the lime water will indicate the presence of carbonates.

Tin proto-chloride (stannous chloride), $SnCl_2$, is prepared by boiling about twenty grains of metallic tin with two drachms of strong hydrochloric acid, and then diluting to two ounces of water. The solution will keep fairly well if a small piece of metallic tin is left in the solution. It gives with solutions of gold a purple precipitate, and with platinum a bright red solution.

Platinum perchloride (platinic chloride), $PtCl_4$.—A solution containing ten grains in an ounce of water will be required. It produces with ammonium and potassium salts a crystalline precipitate when stirred.

Potassium ferrocyanide, $K_4Fe(CN)_6$.—About ten grains should be dissolved in an ounce of water. This solution is used for distinguishing salts of iron; with persalts it forms a dark Prussian blue precipitate, while with the proto-salts it gives a pale blue precipitate.

A packet of litmus paper (purple) is required for testing acids and alkalies; a red colour is formed by acids, and a blue by alkalies. About a gallon of pure distilled water is required for making up the above solutions, and also the standard solutions, &c., required in quantitative estimations. Stills are sold on purpose for purifying water, but it is far better to buy distilled water from the druggist, taking care to test for chlorides before using it. Of course everyone knows that in testing for chlorides all that is necessary is to add a few drops of silver nitrate to the suspected water, which, if it be impure, will form a white milky cloud. Filtered rain-water is the best substitute for the above.

IODIDE IN EMULSIONS.

BY CAPT. W. DE W. ABNEY, R.E., F.R.S.

In your last number, Mr. A. L. Henderson writes acknowledging the advantages of the addition of silver iodide to an emulsion, and it is a matter of congratulation to myself that he has given his support to the introduction of what I think the sheet anchor of a clean emulsion, more especially as, if I am not deceived, he till recently ranked as opponent rather than as an advocate of its employment. Mr. Henderson's method of adding the iodide is not new, as he will see that the plan of mixing separately (after each emulsion has been washed) has been published by me several times, and, except for the trouble, it is an excellent way of adding it. It is also satisfactory to find that Dr. Eder, under certain circumstances, does not regard the addition of iodide as valueless, though in your leader of the 23rd June, you quote, apparently from Dr. Eder's older experiments, from which it appears that the addition of $\frac{1}{12}$ of iodide makes a boiled gelatine emulsion less sensitive, and is also the cause of thinner images than one containing only bromide. I must once more protest against this assertion. With my own emulsions the very reverse is what I find; but then, of course, there may be different ways of manufacturing. If an emulsion after it is boiled is of a bright yellow colour by reflected light, density and sensitiveness will assuredly be found, and this colour arises from a true double salt being formed. I have, perhaps, had more experience than most photographers with this double salt, and can now, as ever, recommend it to them. The great point is that the boiling should be continued sufficiently long, and that all chance of fog should be guarded against by the introduction of a *small* modicum of hydrochloric acid.

One fact which is worthy of notice is, that a bromo-iodide emulsion which has been boiled gives a greater range of gradation than one which has been prepared by the ammonia process, or than a pure bromide emulsion prepared by any method. Using the sensitometer, it will be found that with a boiled bromo-iodide emulsion showing 23, every number will show a different gradation; whereas with the other emulsions the first 5 to 8 figures will show the same density. With a bromide emulsion this might, perhaps, be due to a reversing action commencing, but not in the case of the bromo-iodide.

THE PHOTOGRAPHING OF MOVEMENT.

BY E. J. MAREY.*

THE excellent results secured by Mr. Muybridge by means of instantaneous photography, in analyzing the movements of men and animals, impose upon the physiologist a difficult task. The successive images must be compared one with another, each representing a different attitude, and classified in series according to the position, at the time, and in the space, corresponding to each.

Admitted that nothing has been neglected during the experiment; that, on the one hand, the marks to be reproduced by photography have been placed along the course run by the animal, so as to be able to calculate at once the position it occupies in the divided space; while, on the other, the moment at which each picture has been taken be determined, as is the case with photographs exposed at equal intervals. All these precautions taken, it is necessary, in order to draw from the figures the meaning they contain, to place them in order, so as to cover a strip of paper corresponding to the course run, with a series of cut-out images, of which each explains the position the trunk and limbs occupied in the space at each of the divided intervals of time.

Such representations gave birth to the similar figures introduced by the Brothers Weber, to explain theoretically a man's walk. In their works are to be seen silhouettes of men shaded with cross-hatchings of decreasing intensity, and imbricated so as to show the successive changes of position of the legs, arms, body, and the head, in the different phases of one step.

Until now, this mode of representation has been found

Reproduction of a photograph showing successive phases of movement of a man running.

to be the most effectual. It has been adopted by the greater number of classical treatises. It has appeared to me, and this conviction has been confirmed by experiment, that by means of photography it is possible to take on the same plate a series of successive images representing the different positions that a living being, proceeding at no matter what pace, has occupied during certain regulated spaces of time. Supposing, for instance, a photographic apparatus is set up by the road walked over by a man, and the first image is taken instantaneously. Should the plate keep its sensitiveness, we could after an instant take another picture showing the walker in a different attitude and place. This second image, compared with the first, would indicate exactly all the changes of attitude effected in the second instant. By repeating thus the images taken at very close intervals the succession of actions during locomotion would be obtained of perfect accuracy. In order to keep the plate sensitive for these successive impressions, it is necessary that everything in front of the apparatus be absolutely dark, and that the man or dog should come out white against a black background. But the blackest substances strongly lighted still reflect many actinic rays; I have therefore had recourse to a

* *La Nature.*

method suggested by M. Chevreul for obtaining a perfectly black field of vision. My screen is a cavity, the walls of which are black. A man dressed entirely in white, and strongly lighted by the sun, walks, runs, or jumps, while the photographic apparatus takes his image at shorter or longer intervals by means of a rotating shutter more or less rapid.

This same method may also be applied to the study of different types of locomotion; a white horse or a white bird will give a series of their attitudes in the same way.

The window, pierced in my rotating shutter, can be enlarged or decreased in size at pleasure, so as to be able to regulate the exposure according to the intensity of the light or the speed of the revolution of the disc. With contracted aperture and slackened rotation the results come out at greater intervals from one another. A quick rotation gives the images at lesser intervals, but with insufficient lighting, unless the window has been enlarged.

Finally, a drop shutter placed in front of the other serves to regulate the commencement and end of the proceeding.

The prints and negatives I have obtained, a specimen of which is produced above, have been executed at the physiological station of the Parc des Princes, where I was assisted in the work by M. G. Demeny.

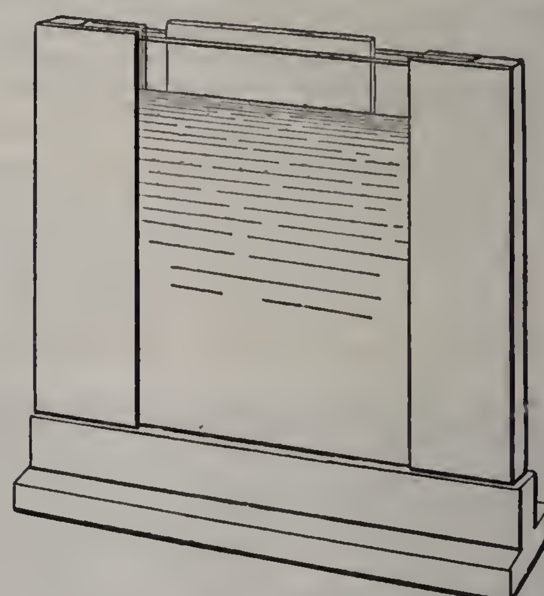
RECENT ADVANCES IN PHOTOGRAPHY.

BY CAPTAIN W. DE W. ABNEY, R.E. F.R.S.*

Now, there is another kind of development, which some call chemical development; and here I differ from some of my brethren who live on the other side of the water, in Germany, who have chosen to name as chemical development something quite different to what my idea is of chemical development. I say chemical development is only a development which is shown by a change in the colour or material of the substance acted upon, and not by a building-up process, such as we have had before us.

Now, I have something which I hope will show you what I mean by this chemical development. I have here a picture which has been printed on nitrate of uranium; I am going to use simply silver nitrate for a developer. I do not want a reducing agent in the developer in this case, because the uranic salt is reduced to the uranous state by the action of the light, and we shall have a picture formed of silver oxide, because the uranous salt will reduce the nitrate of silver to the state of oxide, and that of itself can be reduced afterwards to the state of metallic silver. This paper was exposed, just before you came to the lecture, to the electric light behind a negative. There is an outline of it now, but when I apply the silver, you will see that it springs out into vividness. It has been rather over-exposed, but this I do not mind, as I merely wish to illustrate a principle. The whole of that picture is formed by silver oxide reduced by the particles of uranium nitrate which have been acted upon by light, and by nothing else. The silver oxide reduced is an exact equivalent of the uranium salt which has been altered by light. That is what I call chemical development, and I know no other meaning for the term. It is impossible, except where you have a change in a large amount of the material that is acted upon by light. I hope I have made you understand the difference between this development and the development you saw just now. The gallic acid, in the one case, reduces the silver solution to the state of metallic silver; and, in the other case, the uranous image itself reduces it to the state of silver oxide; but still that silver oxide was only equivalent to the amount that had been acted upon by light, and nothing more. I have here a wet plate prepared. I dare say most of you know what a wet plate is, though some of you may not if you only began photography when the gelatine process came in. To such, I suppose, a wet plate is as much a matter of novelty as a Daguerreotype is to many who know what the collodion process is. I will ask you to bear with me, however, while I produce the picture, because I want to show you the use of the electric light. Of all the recent aids to photography, the electric light is one of the most powerful, because with it you can photograph by night or by day. In fact, in some of the advertisements I have seen it stated that they prefer to take portraits by night; I do not know why, but in a country town I saw an advertisement in which they said distinctly they preferred to take photographs by night, as it was more convenient. [An engraving was focussed on the camera-screen, and the wet plate exposed for twenty seconds.] A short exposure will do for this. Now I will try to show you the development on the screen. You see a cell there with water in it. Now I hope you will see the crystalline action taking place before you, and the image will be seen on the screen gradually coming out. A cell containing ferrous sulphate in solution, and a small quantity of glacial acetic acid, is focussed on the screen. The plate of sensitized (and now exposed) collodion is fairly transparent. After placing a piece of yellow glass in front of the lantern, the plate is immersed in the cell, and the image is seen gradually being built up.

There is another mode of development which our friends across the water have chosen to call chemical development, though I cannot agree with them, and that is the method which is called alkaline development. I dare say I could very rapidly demonstrate that to you. The *rationale* of the alkaline development is, that when you have a strongly oxidising agent in the presence of an alkali and a silver compound, solid or in solution, then you have the last reduced to the metallic state. Such an oxidising agent we have in the pyrogallic acid, and the alkali generally used is ammonia. Now, this kind of reduction is evidently useless unless it can discriminate between a compound which has



Cell for demonstrating Process of Development.

been acted upon by light, and one which has not. When pyrogallic acid is used in order to make this discrimination—or, in other words, in order that those parts acted less on by light may alone be reduced—something more has to be added, which is usually a solution of a bromide of an alkali. This restrains the reduction, inducing the change to take place in the part acted upon by light. I may say that without a restrainer the tendency is for these parts to be first reduced, but the action extends to that which has not been acted upon by light. It has been usually said that alkaline development is only available for bromide of silver, and until recently I dare say that was the case—or, rather, it was not the case, but it was thought to be so. I hope on a future occasion to show that iodide of silver is as amenable to alkaline development as bromide of silver, although not so rapidly, and that chloride of silver is very amenable to alkaline development, giving, in fact, most beautiful pictures. The plate I am going to expose now is a bromo-iodide plate. I have shown you this form of it, simply because it is transparent. I have here a negative, and the sensitive plate behind it, ready prepared. Now I expose it to the light from the magnesium wire for a few seconds. I will take a cell, in which I will place some of the alkaline developing solution. The pyrogallic acid and bromide are mixed, and to which the ammonia is ready for adding; I mix a small portion of this latter with the pyrogallic acid and bromide—the bromide, remember, being for restraining purposes. I place the plate in the cell, which is seen in focus on the screen. The picture is one of Mr. England's beautiful statuary studies, and you can see the outline of the bust gradually appearing. That, I say, is another case of physical development.

* Continued from page 407.

Now, I want to show you why I say it is physical development. I throw on the screen a slide, which is a picture of a young lady, seemingly cut in half, part of her figure being intense, and part not intense. This difference in intensity was produced by exposing a plate behind a negative, and then, before development, coating a portion of the plate with bromide of silver. The top layer thus had no exposure whatever, and yet you see where the unexposed film is, there we have the picture very much denser than in the case where there was only the one film. This shows that here we have a case of physical development, for the image is built up from the film itself, being partly fed, as it were, from the film which had received no exposure. There is thus crystalline action taking place in the film, just as much as there was in the silver reduced from the nitrate of silver. I want you to understand why I object to the words chemical development, when we are talking about alkaline development.

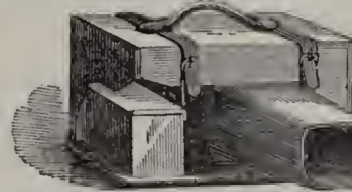
There is another mode of development, which is now very much in vogue, and that is, with ferrous oxalate. In this case we have an organic salt of iron in the ferrous state, which is capable of reducing silver bromide, iodide, and chloride to the metallic state, whilst itself is reduced to the ferric state. That was a development which also required a restrainer. If I had had time, there were several more experiments I should have gone through, but I must omit them. There is, however, another kindred developer, which, I think, is one of the most recent advances in photography, about which I am supposed to be lecturing. I speak of it with great tenderness, because it is my own child. I have now got an iron developer, which is capable of being used without any restrainer whatever. I call it ferrous citro-oxalate ; it is rather a long name, and some of my audience may not understand it, but I will tell you how it is made. You take a solution of citrate of potash, and then you add ferrous oxalate to it, till no more will dissolve ; the resulting compound is probably citrate of iron, but in a stronger form than is usually found, and much more energetic than that form which was recently recommended by Dr. Eder, to whom I shall have to refer more at length presently. I propose to use some of that same paper which I used just now. Its use for the purpose I have in view is a novelty. This paper can be developed by the alkaline method, or by the ferrous oxalate method, or by the ferrous citro-oxalate method ; it is an excellent paper, and was prepared, as I described, about two years ago at the Photographic Society, before the gelatine papers came into vogue ; it gives a very clear picture, and I dare say that you will also see that it gives very satisfactory negatives. I expose a piece of the paper behind a negative to the light of the magnesium wire again. The negative I used in this case was kindly lent me by Mr. William Bedford. It is rather a dense one, and requires longer exposure than I should have given to a thinner negative. The exposure is now given, and on withdrawal from the frame, it apparently is a perfectly blank piece of paper. [The paper was wetted and placed on the developing stand already described, and brushed over with ferrous citro-oxalate without any bromide being added. The lantern was covered with yellow glass, and the light of the disc thrown on the paper.] You see it is beginning to develop ; see how beautifully it comes out. This, I say, is a novelty in photography, for here we have an iron developer which needs no restrainer, and a paper which can be developed by an energetic developer. I think I may claim that as an advance over the calotype process.

I must defer what I have to say on other developers to the next lecture ; but, before I close, I am gratified to be able to bring before the meeting some very early calotypes taken by my distinguished friend, Mr. James Glashier, who is President of the Photographic Society, and who has worked at photography from its very earliest beginning. These are some of his beautiful fern impressions he got with the Talbotype, and printed afterwards. I will ask the members to look at them, as being early examples both of Talbotype and calotype—the one being developed pictures on iodide of silver, and the other being the printing process of the negative on chloride-of-silver paper, such as Talbot first introduced. I have also to show you Mr. England's developed Daguerreotype. I will undertake to say that under the circumstances it is a very good Daguerreotype indeed. Of course, a lecture-room is not the place to show all the niceties of the art—and, in fact, it is very difficult to demonstrate before such a large audience ; but I hope those experiments which have, luckily, all been successful, will, at any rate, have afforded some instruction to the junior members of the photographic world.

(To be continued.)

PORTABLE DARK ROOM FOR DRY PLATE PHOTOGRAPHY

The invention shown in the accompanying engraving is a portable dark room, consisting of a box made of suitable material, and provided with straps and a handle for carrying, and having an aperture from which a flexible sleeve of proper material projects from



the box. The opening and sleeve must be of such size as to permit the plate-holder of the camera to be passed through them into the box. Two compartments, provided with lids, are located at either end of the box, one containing dry plates that have not yet been exposed, and the other the exposed plates.

The operator passes the plate-holder through the sleeve into the box, opens the frame, and deposits the exposed plate in its proper compartment, and takes a fresh plate from the opposite compartment and places it in the plate-holder, which is then withdrawn. In this manner the plates are placed in or removed from the plate-holder without being exposed to light or dampness. While manipulating the plates with one hand the flexible sleeve is held against the arm with the other hand, so that no light can pass into the box by accident. The box also serves as a receptacle for transporting plates. This ingenious device, which is described in the *Scientific American*, is patented by Mr. John Serdinko, of New Braunfels, Comal county, Texas.

Correspondence.

ATTITUDES OF ANIMALS IN MOTION.

Dear Sir,—In reading the lecture delivered by Mr. Muybridge before the Society of Arts, one cannot but be struck with his refreshing assurance at the commencement, where he says that artists of all ages have been inaccurate in their " notions " of depicting animals in motion. After reading the article, and seeing the pictures of the animals he has photographed in this month's *Century*, I am of opinion he is not warranted in his attempt to lecture artists.

An artist paints simply an *impression of motion* as he sees it, as it is impossible for him to see the sub-division of motion, or a single section of a stride ; and until we are endowed with further visual powers, we must be content.

When a horse rises to a fence it is impossible to see him in the stiff awkward positions represented in the photographs. The pasterns look especially unreal, though they may be correct. Again, fancy a bird in flight painted with its wings folded under it, or a dog with his legs gathered together as if in a knot. These may be right photographically, but wrong artistically. To give a notion of a hunting field with horses and pack in full cry, they must be painted as we see them, with limbs stretched to their utmost, " tearing away like mad."

Another illustration. If the spokes of a wheel in motion are perfectly seen as represented by instantaneous photography, and an artist were to paint them so, we should have no idea of motion, for they always appear to us as a blurred circle.

Instantaneous photography, in many instances, might be termed " photographic jugglery ; " or, " a glimpse of the unseen "—a practical illustration of a line from Longfellow, that—

" Things are not what they seem."

The lecture and illustrations are undoubtedly of great interest to the scientist or the curious as studies of analysis of motion ; but beyond that, I fear, will be of little use. Probably they may be the means of starting a new school of fanatics in painting who will stand the chance of being laughed at for their pains in trying to depict what may be right photographically, but is never seen with naked eye.

Persons who are interested in this matter should study the pictures referred to (not in the zoopraxiscope, but simply as they are), and I leave them to judge whether they seem correct with their ideas of animals in motion.—I am, dear sir, yours truly, T. Prothero.

REMARKS ON GREEN FOG, AND ON THE DEVELOPMENT OF SILVER CHLORIDE.

Sir,—There are several errors in my communication of last week.

At the top of the second column, for "change" read charge.

In the next paragraph it is difficult to arrive at my meaning, owing to the sentence following "six to twelve minutes" commencing with a capital T. There should be a small t, and a full stop after "on this point."

Further on, in same paragraph, instead of "intensity when acquired," read "intensity to be acquired."

There are other errors of minor importance; and allow me to say that I do not care to appear to write of "pyrogallic" and "alkaline pyrogallic."

Perhaps I may take this opportunity of penning a few thoughts which occur to me in connection with Captain Abney's remarks on sulphite of soda and green fog.

On Sulphite of Soda and Green Fog.—Shortly after the publication by Captain Abney of his theory of the cause of green fog, it occurred to me that the solubility of bromide of silver in the sulphite might account for the increased amount of green fog which many have testified follows the use of sulphite in the developer. I came to the conclusion, however, that such theory is hardly admissible, for, did we accept it, we should have to account for the fact that many plates do not give green fog when the same developer is used. Such a theory seems to me to place sulphite of soda in the position of being the cause, or initiator, of green fog, which it certainly is not. It would be somewhat inexplicable that, in some cases, sulphite of soda causes green fog, while in other cases it does not do so. Is the bromide not dissolved in the latter instance, and why? If so, would not the addition of bromide of silver to saturation in the sulphite used be an interesting experiment?

I think, however, it will be found that green fog is purely the effect of the pyrogallol developer. If the iron developer be used, the fog will be grey; if pyrogallol be used, the fog will be green. The green colour is due to organic matter derived from the pyrogallol.

Captain Abney's remark upon the effect of fixing in white light is interesting; but, according to his theory of the effect of silver salt in solution, should there not be fog when using ferrous oxalate equally as when using alkaline pyrogallol—not green fog, but grey? It would seem, judging by Captain Abney's experiment, that bromide must have been acted on by light before it can produce green fog.

With respect to Captain Abney's experience with the water which supplies the Riffel hotel, I think he takes the right view in attributing a benefit to use of water containing no lime salts. What a "messy" developer did Davanne's "sacharate of lime" make, even with dry collodion plates. But yet the use of distilled water will not enable one to arrive at the results produced by sodic sulphite in the water. There may be an improvement in the appearance of the developer; but that is not everything.* Altogether, I rather doubt whether many who have used sulphite in the developer have been able to appreciate its many advantages. Though Captain Abney puts in the form of a question the following—"Can it be that sulphite of soda and carbonate of lime form sulphite of lime and carbonate of soda?"—I do not intend to appear to inform him of the fact of which he is fully aware, but merely state that such is the case.

Silver Chloride and the Alkaline Developer.—Captain Abney's remarks upon the development of chloride plates are to me especially interesting. Here, again, we have proof that my views on this subject, with which Dr. Eder disagreed in the spring of last year in your columns, are not so altogether unworthy of consideration as that gentleman would have had your readers believe.

Among other statements in which my writings were entirely misrepresented, or ignored, was that oft-repeated assertion of Dr. Eder's, that I *failed* (*sic*) to develop chloride plates, owing to having used the *alkaline developer*; and all this in the face of my equally often repeated statement that I had *succeeded* with such development, though I had failed to observe sufficient reason for advocating the use of chloride instead of bromide of silver. To the readers who took the trouble to judge of the merits of the case, by reading what appeared on both sides, at the time to which I refer, this method of reasoning *lucus a non lucendo* must have been almost as amusing as that of Mr. Weller, sen., when giving his opinion at the close of the Pickwick trial, and lamenting: "Oh! Sammy, Sammy, my boy! why weren't there a halibi!"

As you yourself remarked in a recent leading article, there is a great deal too much of dogmatic assertion in photographic literature and elsewhere. Because a man fails to produce certain results in a certain way, is no reason why he should declare the method proposed to be an impossible one—especially when another, presumably not addicted to stating falsehoods, asserts his opinions and experience to the contrary. At any rate, here we have Captain Abney using an *alkaline developer*, almost identical with that used by myself for chloride plates in my experiments four or five years ago. Will Dr. Eder forthwith proclaim that Captain Abney *cannot do what he has done?* Or will he wisely come to the conculsion that what was "sauce for the goose" is *not* "sauce for the gander?"

Perhaps he will naively state that his view of this case has been all along that alkaline pyrogallol is a good developer for chloride *negatives*, but not for chloride *positives*; if so, I would remind him that my statements at the time referred to were especially stated to apply to the development of negatives, and not to that of positives. However, I do not think Dr. Eder will attempt any such defence of his position, since he has repeatedly stated that the use of alkaline pyrogallol results in hopeless fog.

What Captain Abney says of the sensitiveness to the ultra-violet rays, fully bears out what I have many times expressed, viz., that when the light is brilliant, and the subject an open one, the rapidity of chloride (alkaline pyrogallol being used) will compare for sensitiveness favourably with that of silver bromide. Such conditions are likely to prevail largely in such a locality as that visited lately by Captain Abney. I cannot refrain from quoting the sentence which brings Captain Abney's remarks on this subject to a conclusion:—"These experiments also showed me that chloride plates are *excellent* for *ordinary landscape work*, giving detail and density as before stated." The italics are my own.—Faithfully yours,

Herbert B. Berkeley.

* An interesting experiment, illustrating the action of sulpho-pyrogallol when made alkaline by ammonia, is to add twenty or thirty minims of the solution to an ounce of water, and then to drop in a minim of strong ammonia. A pink tint will at once be formed; this presently becomes decolourised, and the solution for a short time remains about as colourless as it was before the addition of the ammonia; it subsequently begins to absorb oxygen with exhibition of a straw tint.

Proceedings of Societies.

London and Provincial Photographic Association.

At the meeting held on the 20th inst., Mr. J. Barker in the chair,

Mr. W. K. Burton said he had made a number of experiments with the sulphite of soda developer against Mr Cowan's citric acid formula, with the view of ascertaining which gave the best results, and he gave a most decided preference to the citric acid. His plates contained chloride.

Mr. Cowan preferred the citric acid, but would not altogether condemn the sulphite formula. He thought different results were obtained with different makes of plates.

Mr. Mackie exhibited a transparency cut in halves—one half having been developed with a part of 2 ounces of pyrogallic citric acid solution, in which Mr. Cowan had, some six or seven months ago, developed eight plates, which was handed to another person to keep. He left it one hour in the solution, and the other half for five minutes in a fresh sulphite solution. Both halves were fully developed, that with the old pyrogallic looking much like a pyrogallic developed wet plate.

Mr. Coles exhibited two negatives—one developed in the ordinary light of the dark-room, the other being covered up, and only looked at occasionally. The uncovered one was perceptibly fogged. He also showed a transparency taken by the light from the window while developing was going on.

The Chairman described a visit paid some years ago to Mr. Slater, the ghost photographer. A vague undefined picture was shown him as the ghost's portrait, and he was informed he could obtain similar portraits if he intensely wished for them; but, needless to say, he had never succeeded. He, however, produced a wet plate negative, in which the sitter, a lady, was shown in two distinct positions; he could not account for this in any way, and was certain no previous exposure had been given.

Mr. Henderson had also seen Mr. Slater operate, and in this case the ghost turned out to be a clot in the collodion. Some years ago he was troubled by ghostly images on his negatives, and upon making an investigation found there was a small hole in the cover of his bath which acted as a lens, and he obtained pictures of the roof of his room previous to exposing the plate.

The following gentlemen were elected members of the Association:—As honorary and corresponding members—Dr. Eder, Dr. Monckhoven, Capt. Pizzighelli, Capt. Toth, and Dr. Vogel. As ordinary members—Messrs. G. H. Garret, J. E. Bliss, H. Reynolds, John Stuart, A. Seward.

Talk in the Studio.

The Prince of Wales as Commodore of the Royal Yacht Squadron.—We hear that Messrs Boning and Small recently had the privilege of attending at Marlborough House, and were successful in securing some good pictures of H.R.H. the Prince of Wales in his new character of Commodore of the Royal Yacht Squadron.

The Enjalbert Camera.—Mr. A. R. Dresser, of Upper Norwood, who writes in strong terms of approval of this camera, says:—"I found the camera a little trouble at first, but got my hand in very soon. The day was dull, but I had not one plate spoilt, which I think very good for my first trial, and I must say I would not give up my new 'Enjalbert' for any two cameras in London, as I have not seen one that works as well for so many plates, for you can carry sixteen plates, camera and all, with about six or eight pounds. I find it does not do as well for pictures on end, as it is apt to get moved if not very careful; but I spoke to Messrs. Marion and Co., and they are going to make an alteration I suggested, and then it will be all right. I have been out three times, and only got into trouble once, and that was by taking two pictures on one plate. There is a little trouble at first in focussing, as you have to move your focussing glass for each picture, unless it is the same focus, and then there is a scale to work it by. But still I am sure anyone who had one for a week would not give it up on any account. I trust some of your readers will buy it, and then I am sure they will thank me. I am only an amateur who does a little photography for pastime, but like to help my friends along who also like to dabble in that way. While I am writing, I may as well put your readers up to a dodge of my own, which I have told to two professionals, who both found it to work well. It is for reducing black parts in negatives, or halation. My plan is, take one quart of water, put in half-an-ounce of sulphuric acid, then soak your negative in that for half-an-hour or more till film is soft, then take a fine piece of old linen and rub over parts that want reducing with your finger, and you can work it down as thin as you like; a little practice, and it comes out all right; only try it and see.

Perception of Colour.—Mr. J. W. Swan writes on this subject to *Nature*:—"Happening to be reading out of doors, while the sun was shining on my book, I noticed that patches of weed on the lawn appeared peculiarly conspicuous in their difference of tint from the grass. The same patches of weed close-cropped to the level of the grass were ordinarily scarcely observable from difference of colour. Now, as I looked up from my book—my eyes dazzled with the glare—they appeared to me to have a strong blue tint. My attention thus being drawn to the point, I extended my observations, with the following results, which, if new, will doubtless prove interesting to some of your readers. I found that if the eye was exposed for two or three minutes to the action of a very strong light, *by looking at a sheet of white paper*, while bright sunshine fell on it, the capacity of the eye for perception of colour was curiously modified, under certain conditions. For example: if, on the instant after the exposure of the eye to strong light, as described—solarization I will call it—flowers of various colours, placed in a shady part of a room, were examined, a pink rose appeared the colour of lavender; dark crimson sweet William, almost black; magenta snapdragon, indigo; scarlet poppy, orange; the eye was, in fact, red-blind. After a minute or two, the eye recovered its normal sensibility to red, and the flowers assumed their natural colour. In order to ascertain that the ?mal-perception of colour, under the conditions described, was due to the action of strong light on the eye, and not to any other circumstance, I repeated the experiment, allowing the solarization to take place on one eye only, the other eye being kept shut until the moment of making the observation. I then found, as before, that the solarised eye was red-blind to objects in a subdued light for a minute or two after solarization, but sensitive to blue, and in less degree to yellow, while the non-solarised eye was perfectly normal in its perception of all the colours. By alternately closing and opening the solarized and non-solarized eye, the difference in colours perceived by the two eyes was extremely striking—the rose was, as seen by one eye, pink, by the other eye, blue. It must be remembered that the effects described were produced when the flowers were observed in a room not strongly lighted. When a corresponding experiment was made with the flowers *in the sunshine* instead of in the shade, it was found that a reverse effect was produced—that every colour, and red particularly, was intenser to the solarized eye than to the non-solarized eye, as was readily seen by alternately shutting and opening them. To the solarized eye a red rose-bud was deep red, to the other eye, light red. The red of the poppy was deeper and more vivid to the solarized eye. A calceolaria was orange chrome to the solarized eye, lemon chrome to the non-solarized eye. A viola was dark violet to the solarized eye, a colder tone of blue to the non-solarized eye. I found that after the insensibility to dimly-lighted red and orange (the effect of solarization) had worn off, a reverse condition succeeded. For example, Venetian red, which was a dirty brown, as seen the instant after solarization, appeared gradually to change to a full vermilion. I found also that portions of the solarized eye that had escaped the solarizing action behaved like the non-solarized eye. I leave the explanation of these slight observations to those within whose special field of study they naturally fall, only remarking that the power of the eye, fatigued by solarization, to perceive blue light, and light of no other colour, under the conditions described, seems to suggest that the eye, like almost all matter sensitive to light, is more sensitive to blue rays than rays of lower refrangibility.

The Crystal Palace School of Engineering.—A few days ago we had occasion to visit this School, which is located, as our readers are doubtless aware, in the south tower of the Palace. It was the dinner hour, but many of the pupils were busily engaged on work of their own—electrical and photographic pursuits being evidently most popular just now. One of the students, Mr. A. H. Whinfield, was engaged in photographing a group of his fellow pupils, and he gave us a very effective picture of the chemical lecturer and his assistant, taken while they were setting out and arranging apparatus on the lecture table. This picture was necessarily made with a very short exposure; but it must be remembered that the sides of the tower are wholly glazed, and exposures are much shortened when made above the slight surface mist which generally remains close to the ground. The Electrical Department of the School, which has recently been organised by Mr. J. W. Wilson, the principal, is now in active operation, and it is likely to be considerably extended before long.

To Correspondents.

*** We cannot undertake to return rejected communications.

F. COWLEY.—We are obliged for your appreciative letter.

T. W.—A mixture of castor oil with collodion; add a few drops to the pint.

BEDFORD.—1. We cannot recommend one particular firm, since we know a dozen good makers. 2. Get Abney's "Photography with Emulsions."

VERY TALL.—We fear our readers would not fully appreciate your story; explain it to Her Majesty's Marine Forces.

CONSERVATIVE.—Consult "Payne Jennings" in the "Studios of Europe;" his whole method is there explained.

SUSSEX.—1. We should make it about two-thirds the depth of that on the north side, and nearly as long. 2. It had better extend from the eaves to the ridge, as you can easily block any portion by suitable blinds. 3. The common window-glass answers quite well, provided it has no yellow cast. You would do well to obtain a few samples from a glass merchant, and roughly test them by placing them over a sheet of sensitive paper, the whole being then exposed to light. 4. Yes; but if your camera will not extend sufficiently, you can leave the front combination in its place, and work with the stop behind the lens. The bright screw thread, as laid bare by the removal of the back lens, should be covered with a ring of black paper or velvet. 5. If you use a stop ¼ or ⅜ of an inch in diameter, you will obtain all the depth of focus you are likely to require. In some cases the swing back will be useful.

SHAH YEHAN.—If you mean to employ photography, the best method would be to take a negative and reproduce copies by photo-lithography; but this would involve a considerable expenditure of time; or, perhaps, the papyrograph would answer your purpose. For information about this latter, you should write to Messrs. Zuccato and Woolf, Charterhouse Street, London, E.C.

HENRY O'NEILL.—We will endeavour to gather information regarding the matter.

AMATEUR (Blackheath).—1. Obtain the "A B C of Modern Photography," by W. K. Burton, price 6d., this being published at our Office. 2. No thoroughly satisfactory method has yet been published. 3. "The Art and Practice of Silver Printing," by Robinson and Abney, is issued by our Publishers, price 2s. 6d.

W. K.—The reason is that our Publishers have no more left. See the first note this week.

C. CLARK.—1. We are pleased to hear that the negative is likely to be found. 2. Our Publishers will give you full information.

BRIGHTONIAN.—Neither print so deep, nor carry on the toning to such an extent.

W. G. (Dublin).—1. It is made by melting together india-rubber and shellac, and it is not convenient to prepare it oneself. Your best way will be to write to the maker, Alfred Jeffries, Limehouse, London. 2. You will find full particulars in an early number, probably next week.

A. F. COX.—Received with thanks.

S. G.—Soak the sample of paper for a few hours in a weak (slightly acid) solution of aniline red (magenta dye), after which wash thoroughly several times in hot water. Any wool fibres which may be present will then be found to have retained the dye, while the linen and cotton fibres will be colourless. A solution of picric acid may be used instead of the aniline red.

S. DEAN.—One surface of the sample of glass has become thoroughly disintegrated by the action of the weather, and your difficulty is not to be wondered at. You had better have your studio entirely reglazed.

R. RICHARDSON.—1. You must considerably increase the proportion of silver nitrate, and it is probable that one-fourth more may be about the thing. 2. They arise from the use of dirty plates. 3. Quite unnecessary. 4. Because it invariably contains a trace of acetic acid. 5. Ammonia is rapidly decomposed by chlorine, nitrogen being liberated; but unless an excess of ammonia is present, the dangerously-explosive chloride of nitrogen may be formed.

PHOTOGRAPHS REGISTERED.

THE EVERY-DAY FORMULARY.

THE GELATINO-BROMIDE PROCESS.

Emulsion.—A—Nitrate of silver 100 grains, distilled water 2 oz. B—Bromide of potassium 85 grains, Nelson's No. 2 gelatine 20 grains, distilled water 1½ oz., a one per cent. mixture of hydrochloric acid and water 50 minims. C—Iodide of potassium 8 grains, distilled water ½ oz. D—Hard gelatine 120 grains, water several oz. When the gelatine is thoroughly soaked, let all possible water be poured off D. A and B are now heated to about 120° Fahr., after which B is gradually added to A with constant agitation; C is then added. Heat in water bath for half an hour, and stir in D. After washing add ⅞ oz. alcohol.

Pyro. Developer.—No. 1—Strong liquid ammonia 1 oz., bromide potassium 160 grains, water 80 oz. No. 2—Pyrogallic acid 30 grains, water 10 oz. In case of an ordinary exposure mix equal volumes of the solutions.

Iron Developer.—Potassium oxalate solution (1 and 4) 80 parts, ferrous sulphate solution (1 and 4) 20 parts, distilled water 20 parts. To every 4 oz. of the mixed developer add from 5 to 30 drops of a ten per cent. solution of potassium bromide, and 30 drops of a solution of sodium hyposulphite (1 and 200).

Substratum or Preliminary Preparation.—Soluble silicate of soda 1 part, white of egg 5 parts, water 60 parts. After heating, let it settle and filter.

Cowell's Clearing Solution.—Alum 2 parts, citric acid 1 part, water 10 parts. Edwards adds enough of a strong solution of perchloride of iron to give the preparation the colour of sherry.

Fol's Backing Sheets.—A chromographic paste is prepared with gelatine 1 part, water 2 parts, glycerine 1 part, and a very small addition of Indian ink. Strong paper or shirting is coated with this mixture, and the sheets are laid, face downward, on waxed glass to set. One of these pressed into optical contact with the back of the glass is an effectual preventive of halation.

THE WET COLLODION PROCESS.

Cleaning Preparation for New Plates.—Alcohol 4 oz., Jeweller's rouge ¼-oz., liquid ammonia ½-oz.

Film-removing Pickle for Old Plates.—Water 1 pint, sulphuric acid 4 fluid oz., bichromate of potassium 4 oz.

Substratum.—The whites of 2 eggs are well beaten up with 6 pints of water, and 1 dr. of liquid ammonia is added.

Negative Collodion for Iron Development.—Alcohol 1 pint, pyroxyline of suitable quality 250 grains, shake well and add ether 2 pints. *Iodize this by mixing with* one-third of its volume of following:—Alcohol ½ pint, iodide of ammonium 80 grains, iodide of cadmium 80 grains, bromide of ammonium 40 grains.

The Nitrate Bath.—Water 14 oz., nitrate of silver 1 oz., nitric acid 1 drop. Before using the bath coat a very small plate, and allow it to remain in the bath for about twenty minutes.

Normal Iron Developer.—Water 10 oz., proto-sulphate of iron ½ oz., glacial acetic acid ½ oz., alcohol ⅞ oz. The amount of proto-sulphate of iron may be diminished to ¼ oz. when it is desired to obtain full contrasts, or may be increased to 1 oz. when contrasts are likely to be unduly marked. When a new bath is used, the quantity of alcohol may be reduced to ¼ oz.; but when the bath is very old, it may be necessary to add rather more than recommended above.

Intensifying Solution, or Re-developer.—Water 6 oz., citric acid 75 grains, pyrogallic acid 30 grains When used, add a few drops of the silver bath solution to each ounce.

Eder's Lead Intensification.—After the negative has been well washed it is immersed in distilled water 100 parts, red prussiate of potash 6 parts, and nitrate of lead 4 parts. When the negative has acquired a yellowish white appearance it is again well washed and immersed in liquid sulphide of ammonium 1 part, water 4 parts.

Cyanide Fixing Solution.—Potassium cyanide 200 grains, water 10 oz.

Varnish.—Shellac 2 oz., sandarac 2 oz., Canada balsam 1 dr., oil of lavender 1 oz., alcohol 16 oz.

THE FERROTYPE PROCESS.

Collodion.—Ammonium iodide 35 grains, cadmium iodide 25 grains, cadmium bromide 20 grains, pyroxyline 70 grains, alcohol 5 oz., ether 5 oz.

Bath.—Silver nitrate 1 oz., water 10 oz., nitric acid 1 drop.

Developer.—Ferrous sulphate 1 oz., glac. acetic acid 1 oz., water 16 oz.

Fixing Solution and Varnish.—Same as for the ordinary wet collodion process.

PRINTING PROCESSES.

Albumen Mixture for Paper.—White of egg 18 oz., add 500 grs. ammonium chloride dissolved in 2 oz. of water. Beat into a froth, allow the mixture to settle, and filter.

Sensitizing Solution.—Nitrate of silver 50 grs., water 1 oz., sodium carbonate ½ gr.

Acetate Toning Bath.—Chloride of gold 1 gr., acetate of soda 20 grs., water 8 oz.

Lime Toning Bath.—Chloride of gold 1 gr., whiting 30 grs., boiling water 8 oz., saturated solution of chloride of lime 1 drop. Filter when cold.

Bicarbonate Toning Bath.—Chloride of gold 1 gr., bicarbonate of soda 3 grs., water 8 oz.

Fixing Bath.—Sodium hyposulphite 4 oz., water 1 pint, liquid ammonia 30 drops.

Reducing Bath for Over-Printed Proofs.—Cyanide potassium 5 grs., liquid ammonia 5 drops, water 1 pint.

Encaustic Paste.—Best white wax 1 oz., oil of turpentine 5 oz.

Sensitizing Bath for Carbon Tissue.—Bichromate of potash 1¼ oz., water 30 oz., ammonia 1 dr., methylated spirit 4 oz.

Enamel Collodion.—Tough pyroxyline 120 grs., methylated alcohol 10 oz., ether 10 oz., castor oil 20 drops.

Mountant for Prints.—A freshly prepared solution of the very best white gum.

Collotypic Substratum.—Soluble glass 3 parts, white of egg 7 parts, water 10 parts.

Collotypic Sensitive Coating.—Bichromate of potash ½ oz., gelatine 2½ oz., water 22 oz.

Collotypic Etching Fluid.—Glycerine 150 parts, ammonia 50 parts, saltpetre 5 parts, water 25 parts.

CONTENTS.

DARK-SLIDES *VERSUS* CHANGING-BOXES—THE ENJALBERT

"Shall it be double backs or a changing-box?" is a question many times asked by the amateur, and sometimes by the professional, photographer, when he is about to provide himself with a new fit-out for working dry plates in the field. The question is not easily answered. Each system has its advantages. With dark-slides there is probably less chance of danger to the plates from light, the manipulations are more easily performed, and, moreover, the number of plates and the consequent slides may be reduced as much below the maximum as is considered desirable. The changing-box, on the other hand, has its advantages, quite as decided as the slides. The apparatus is less bulky and lighter; at least, when many plates are to be used. From our experience with both methods and with various-sized plates, our opinion is that for sizes up to whole plate, the two plans are about equally good; but that for larger sizes the dark-slides are decidedly the best.

When these are used it is a great advantage to have some means of changing plates without waiting for darkness, as it is not always convenient to have a number of double backs sufficient to carry all the plates for a day's work. We were greatly struck some time ago by the ingenuity and simplicity of a box which Mr. A. Cowan exhibited, which was constructed to hold his whole "kit," and which was so contrived that the slides could be emptied and again filled, the arms and hands being inserted through sleeves into the box, and the manipulations being guided by the sense of touch only. It is wonderful how easy it is with a little practice to change even large plates in total darkness. All that is necessary is to know exactly where everything is, so that the hand may be laid on it at once.

A new camera and changing arrangement has recently been introduced, and is so ingenious, and, so far as we have been able to judge, efficient, that we believe a description of it will be of use to our readers. It is sold under the name of the "Enjalbert" camera.

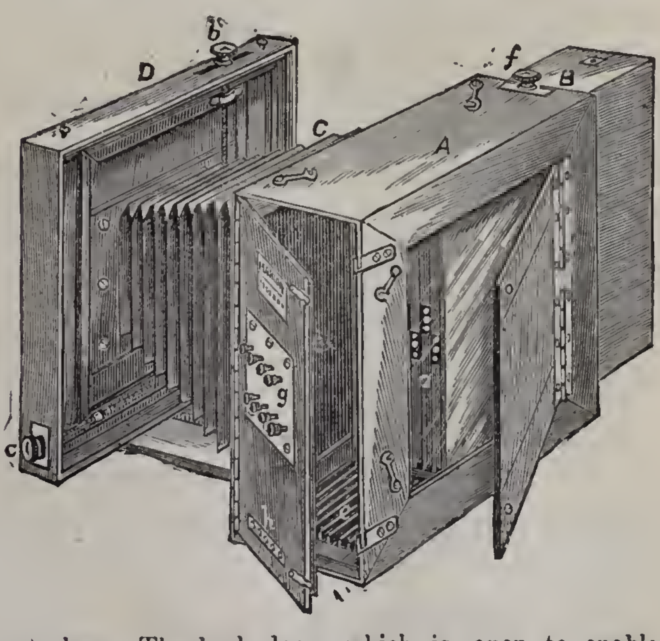
In place of the simple groove into which, in the ordinary camera, the ground glass slides, there are several—eight, if we recollect rightly. These are very narrow, and it will thus be seen that the ground glass may be placed at any one of eight different distances from the lens.

A box of such a size that it fills the width of the whole of the grooves is supplied. I believe we shall give our readers the best idea of the arrangement by saying that this box is arranged somewhat like a chest of drawers, there being eight drawers, each forming the carrier to hold a plate.

We shall now describe the working of the apparatus. When the camera is placed in position, the chest of drawers is withdrawn—not taken entirely away, but drawn so far to the side that the ground glass may be placed in whichever of the grooves is desired. Of course, in practice, No. 1 is first used. After focussing, the ground glass is removed and placed in a spare groove provided for its reception. The back of the apparatus is closed by a door, so that the whole inside of the camera is in total darkness. The box of plates is now slid home once more. There are catches whereby it is possible to take hold, from the outside of the camera, of any one of the drawers. The catch corresponding to the groove in which the focussing glass was placed is actuated. If now the chest of drawers be again withdrawn, a plate in its carrier will be left in the position formerly occupied by the ground glass, and all that is necessary is to make the exposure.

As is usual in such cases, the operations sound far more complicated in a written description than they really are. We found on trying the apparatus that it worked with the greatest ease.

We append an engraving which will make the arrangement clear.



The back door, which is open to enable focussing to be performed, and the side door, which can be opened to take out the box of plates, either for changing or for development, are both shown ajar, so that the arrangement of drawer-shaped carriers and catches may be distinctly seen. The camera is made to open to a great length, so that a long-focus lens may be used. This is a great advantage, and one too often overlooked with modern cameras. The *possibility* of using a wide angle conferred by modern lenses, and most advantageous when used with discretion, is too often abused, and the principal object in a landscape is so dwarfed as to spoil the artistic effect.

All the necessary motions are effected in the Enjalbert in most ingenious ways. There is, in addition to those usually provided, one to enable two exposures to be made without re-focussing, should two negatives of the same subject be desired. It will be at once evident that as the plates are each at a different distance from lens than the others, a re-adjustment must be made to bring a second plate into the same place before occupied by the first. A scale and vernier are cut on the sliding part of the camera, and it is only necessary to observe this to be able to move the back part of the camera just the right distance nearer to or further from the lens without using the focussing glass at all.

When packed up, the plate-box is slid home, the ground glass is placed in the spare groove, the back and side doors are closed to keep everything safe, and all is folded up, the space occupied being but little more than that taken up by an ordinary camera without any slides.

SOME APPLIANCES FOR THE COATING OF PAPER.

Five or six months ago we described several arrangements more or less likely to prove useful as aids in spreading even layers of sensitive material on paper, and among these we mentioned the roller apparatus ordinarily used in the cold curing of spread india-rubber fabrics. Through the kindness of the Secretary of the Society of Arts, we are now enabled to place before our readers two woodcuts representing the spreading and curing arrangements of a rubber factory, these blocks being taken from a *brochure* on the rubber industry which has recently been issued by the Society.

The diagram of the cold curing machine (fig. 1) almost explains itself, the slate roller, A, carrying up the fluid to

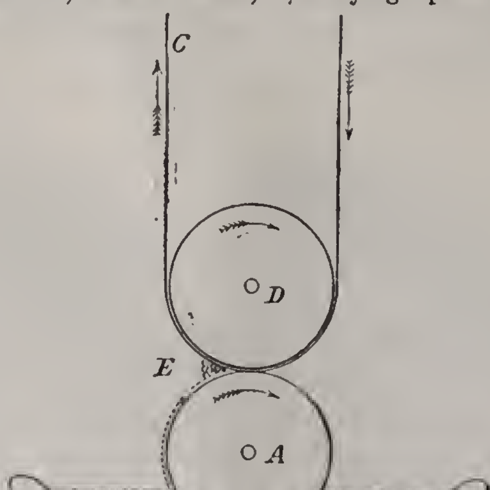


Fig. 1.

the point E, as indicated by the dotted lines, while the fabric, C, is led in a contrary direction, and against this wave of fluid.

We have tried the apparatus in question, and find it especially adapted for making carbon tissue and transfer papers; but the lower roller must be heated a few degrees over the setting point of the gelatinous mixture. It is curious to note how much freer from bubbles the coating is than when the usual tissue machine is employed; it being understood that reasonable precautions are taken This apparatus is also well adapted for preparing gelatino-bromide or gelatino-chloride paper, but there are doubtless cases in which a gelatino-bromide mixture might advantageously be applied to paper by means of the usual tissue machine, a convenient form of which is represented by fig. 2.

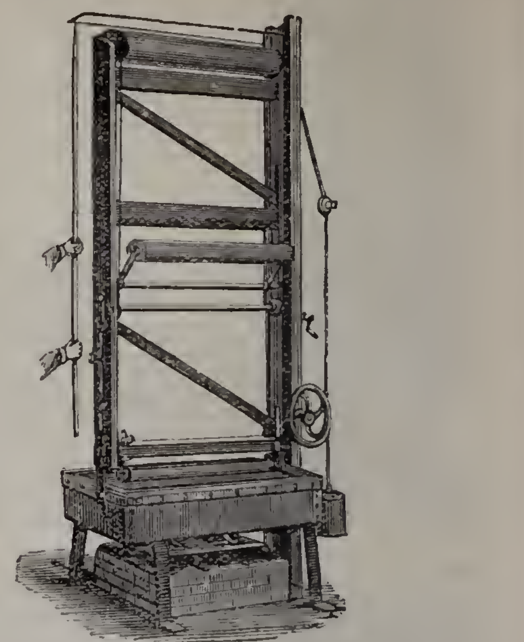

Fig. 2.

A strip of paper is placed over the whole system of rollers, the ends of the strip being cemented together so as to form a continuous or endless band. The height of the system of rollers carrying the paper band is now so adjusted that the paper just skims the surface of the gelatinous mixture contained in the trough, and the rollers are set in motion. The small roller shown in front, and mounted on projecting arms, is intended to keep the band tense, notwithstanding its expansion by the action of the solution. Persons wishing to prepare a small quantity only of coated paper will probably find this apparatus more especially adapted to their wants than the india-rubber curing machine just described, although it must be remembered that the latter apparatus is adapted for coating plates as well as paper or flexible material. It is, of course, understood that in this latter instance the top roller is not used, the plate being quickly drawn over the bottom roller, so that the direction of the motion communicated to the plate shall correspond to that of the paper or fabric in the previous case.

Fig. 3 represents the arrangement employed for spreading india-rubber paste on cloth or other fabric, the paste being placed behind a scraper, B, so that a guaged thickness, D, is laid on the cloth when it is drawn under the scraper. The shaded part, A C, represents a steam box

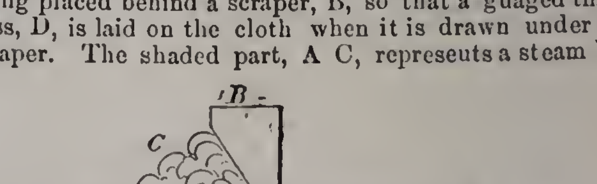

Fig. 3.

intended to assist in the drying of the rubber paste, and it appears to us that this apparatus might easily be rendered available for coating paper with gelatinous mixtures. Let us suppose that a set emulsion is thoroughly broken up into a smooth paste as suggested by Mr. Whaite on p. 151 of our present volume, but the paste is piled up behind the scraper instead of being applied with a brush. If the strip of paper be now drawn forward at a proper rate, the united action of the scraper and the hot chest should result in the production of an even coating; a level setting table being of course provided beyond the hot chest. This method of carrying out Mr. Whaite's idea will, we think, prove of considerable practical value.

Mr. Whaite's original arrangement is represented by fig. 4, the lower table serving to support the sheet while

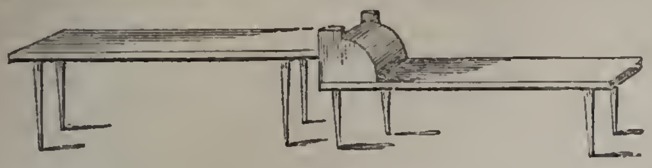

Fig. 4.

it is being roughly covered with broken-up emulsion by means of a stiff hog-hair brush. After this the sheet is steadily drawn over the curved face of the hot water box, so as just to melt the emulsion; the top table being merely a level support on which the film can set.

On a future occasion we shall indicate to our readers other well-known methods of spreading even layers of soft materials, as a knowledge of these methods may do good service to the photographic experimentalist.

SULPHITE OF SODA IN THE DEVELOPER.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.

Mr. H. B. Berkeley is always so close in his reasoning, that, with the Editor's permission, I should like to say a few words *in re* his remarks which appeared in your last number. As to green fog, Mr. Berkeley says: "I think, however, it will be found that green fog is purely the effect of the pyrogallol developer. If the iron developer be used, the fog will be grey; if pyrogallol be used, the fog will be green. The green colour is due to organic matter derived from the pyrogallol." In effect, then, as the only thing that grey fog can be, is reduced silver, therefore the green fog is also due to reduced silver *plus* something else which is due to the pyrogallol. Regarding the matter which composes the green fog, Mr. Berkeley and myself are at one, since I have already demonstrated that green fog can be converted into grey fog by treatment with ferric bromide or other similar iron compound, when followed by ferrous oxalate. The genesis of the green fog is where we differ. I don't admit that, if with pyrogallic acid development you get green fog, that with ferrous oxalate you get grey fog. If green fog is caused, as it is usually, by forcing out the image on an under-exposed plate, I have not found that grey fog is produced when using ferrous oxalate. I think we must go further back than the development to arrive at the initiatory liability for the advent of the green fog. With some gelatines you always get it, whereas with others you don't. In the one case, "forcing" with ammonia will produce grey fog, in the other green, and in these cases the grey or the green fog will only be intensified by the addition of sulphite of soda.

Let us see how this occurs. If you have any solvent of (say) silver bromide, and use it in development, the silver salt, by the nature of things, must be reduced to the metallic state, and be precipitated somewhere, and that rapidly. If within range of molecular attraction, the silver will be precipitated on the nearest previously reduced metallic silver; if not, it will be deposited on a blank space which bears no image, and with the dye caused by the action of the developer on the gelatine will cause a green metallic deposit. This is the case when an under-exposed picture is developed. If sulphite be used, it is quite possible that the developing solutions are so altered in character that the green fog may be absent, and only give a tendency to increased grey fog. The experiment I quote about green fog being caused by fixing in daylight, Mr. Berkeley argues, should equally apply to a ferrous oxalate developed negative, the fog in this case being grey. Suppose that both negatives were fairly washed, this would not be so. Ferrous oxalate in dilute solutions is not a developer at all, but a destroyer of the image, or rather it prevents any visible action of light, for the reason, I suppose, that as fast as the bromide is reduced, the silver itself is converted to silver oxalate, the act of developing reducing the ferrous salt to the ferric state, and so on. The fact remains that perfectly bright pictures can be fixed in daylight if ferrous oxalate development has been used, which is not the case when alkaline development has been employed. For my own part I think that sulphite is an unmitigated blessing to photographers, and if I get green fog I don't mind it, as there is the cure for it at hand. Personally I have not been troubled with any fog lately, and certainly the use of sulphite has, with me, not induced it; but then I have not under-exposed my plates, and it is only then when it is most apparent. I am glad that we have an authentic statement from the inventor of the sulphite developer that *one* of its uses is to render innocuous to the pyrogallic acid the lime salts usually present in water. Another use of the sulphite is the fact that bromide of silver *is* soluble in it; for, whether it tends to give green fog or not on an under-exposed plate, it must of necessity give an intensity to the image which it would not otherwise have. Some eight or nine years ago I showed how an ordinary collodion negative, taken on an iodide plate, could be intensified by the use of a solution of silver chloride in ammonia and a reducing agent, and the solution of bromide in the sulphite must have the same effect. My remark, that, if we had such water here as we had at the Riffel, sulphite would be abandoned, was only intended to apply to the fact that if photographers could obtain such limpid solutions of alkaline developer, they would be loathe to make any other addition. Mr. Berkeley makes a happy defence of the position he assumed regarding chloride of silver plates, and my success with them has fully impressd me with their more than fleeting value. If we take the ultra-violet of the spectrum, and compare a chloride with a bromide-gelatine plate, the former has decidedly the best of it as regards exposure; at least, the batch I had out with me in Switzerland told me so.

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

A Tour in the Thuringian Forest.

The photographers of Germany have of late made it their custom to meet once a year in convention, and on the present occasion the meeting is to be at Eisenach, in the Grand-Duchy of Saxe Weimar, on the 23rd of this month. Eisenach, a little old-fashioned town, is situated in the very midst of the Thuringian Forest, and may be taken as a convenient head-quarters whence many interesting and delightful tours can be made. That it is a holiday ground little known to the British tourist will of itself be a recommendation; while the fact that it is the home of many of the legends known to us through the Brothers Grimm invests it with a romance equal only to that possessed by the Harz Mountains and the Black Forest.

Thuringia makes a convenient trip for a fortnight. By the Flushing route, Eisenach can be reached in thirty hours, traversing Hagen and Cassel. There are some capital hotels there, of which the Rautenkranz is our favourite; for Eisenach has many visitors in the summer, although it finds no place in Mr. Cook's tours. Indeed, the Thuringian Forest is in no way an obscure district. It is classic ground in history—the cradle of Germany—for its Landgraves, whose castles still top many a height, were the first great independent chieftains. The late Prince Consort was bred and born in Thuringia, and much of the beautiful country is described by Her Majesty in her book relating to the early days of the Prince Consort.

When we first knew Eisenach, more than five-and-twenty years ago, it might have been taken for a bit of old London during the last century, with its crooked, queerly-paved streets, its cramped buildings, scanty oil lamps, and antiquated watchmen. Long, dark thoroughfares were lighted —if one may use the term—with a couple of feeble lanterns, one at each end of the street, swinging on wires across the road, and supplied with oil sufficient to last till nine o'clock in the evening, for at that hour all good people were supposed to be in bed, and, so the authorities argued, it would be foolish indeed to burn oil for the bad ones. There are still plenty of quaint dwellings and relics of old-German architecture that would make valuable camera pictures in the town, albeit it has been considerably moderuized of late; and two such objects we may at once point out—viz, the residence of Martin Luther, and the house where Sebastian Bach, the composer, was born.

But it is the neighbourhood of Eisenach to which the photographer will turn with most interest. The black pine woods and forests of beechen green that clothe the Thuringian mountains, the deep-shaded vales, the moss-grown defiles, and cool grottoes, their soft, verdant walls decked with purple foxglove and yellow gentian, the grey ruins that crown the hill-tops, and the pleasant shooting-boxes that here and there peep forth from the greenery—all these will serve to make a holiday tour in this district pass agreeably. As tourist-photographer you should be the happiest of mortals in such a paradise. Enjoying yourself on a summer's tour, it is some satisfaction to know that you can carry back with you a reminiscence that will serve to call up the pleasures of your journey once more; to know that you can bring home a cap-full of bright sunshine with you, stored up in the film you are exposing; to be assured that you have not seen the last of the glittering landscape at your feet, that plashing waterfall among the leaves, or the quaint old village through which you have just strolled.

THE WARTBURG.

One of your first plates will be exposed at the old Wartburg. The sturdy castle, with its walls standing grey and grim, as they have done these seven centuries past, almost overshadows the town. It stands on a leafy pedestal, as proudly as in the days when, an impregnable Burg, it sheltered from harm worthy Martin Luther. The Castle of the Wartburg was in the great Reformer's mind when he exhorted all to put their trust in God, as in the stout walls of a fortress.

"Ein feste Burg ist Unser Gott,"

is the beginning of Luther's famous hymn.

The Wartburg appears at its best, to our thinking, not from Eisenach, but from a point exactly opposite the town, as it is sketched here; the walls are steeper, and its position, rising from the waving foliage, the only pile in the undulating landscape, is most romantic.

There is plenty to see inside the castle. A sentry keeps watch and ward up here, pacing the ramparts beside a battery of old guns. The guns and the sentry are of some use, though, for he can command a view over the whole town, and it is his duty, on the first sight of a fire, to discharge one of the guns, and thus call the attention of the burghers below. You enter the castle through a heavily mailed gate, and then immediately on your right of the courtyard is the quaint tenement that Luther inhabited, and where he translated a large portion of the Bible. It is difficult to secure a view of the house, because the courtyard is so narrow; we carried our camera some yards beyond the house, and then secured a view looking back at the portals of the castle, and showing Luther's house on the left. The room that the Reformer inhabited is still intact, his bedstead, footstool, and jolly old flagon; but it was not easy, we found, to get permission to take a picture of the interior. He must have been a cheery, light-hearted, genial soul, good Martin Luther, a friar who took anything but a black view of the world, for his poems and hymns tell far more about smiling nature, its bright green woods and chattering songsters, than of vaulted cell and cold penitential observances. It was while on his way home from the Diet of Worms in 1521 that the Reformer was waylaid, and compelled to exchange his monk's robe for the trappings of a soldier, in which he was carried, half friend, half foe, to the Wartburg. A legend tells us that while in his room here, translating the Bible, the Evil One came, time after time, to tempt him to desist, until at last Luther, quite out of patience, hurled the inkstand at his tormentor. The ink obviously did little damage to Satan's dusky skin, but it stained the white wall beyond, and there are marks of it still; only the blackened plaster has since been removed by relic hunters, and now there is but a big hole in the wall to testify to the event.

The rest of the castle is for the most part modern, having been restored by the present Grand Duke. The halls are well worth a visit, however, especially the Hall of Song, which stands, it is said, upon the same spot where the famous singing contest of the Minnesingers or troubadours took place in 1207, an incident utilised by Wagner in his opera of Tannhäuser. At this contest, which was instituted by Duke Hermann, passion waxed so high among the Minnesingers that it was decided the least skilful of them should die. Walter von der Vogelweide was the victor, and Heinrich von Ofterdingen the vanquished, but although measures were taken to erect a scaffold on the castle, the latter was in the end spared his life by intercession of the duchess. When Walter von der Vogelweide died—he was no character of fable—he left a sum of money to be expended in the purchase of seed to be strewn upon his grave that the birds might gather there, and four cavities were wrought in his monument to supply the warblers with water.

Elizabeth's Fountain, just at the foot of the Wartburg, should not be forgotten by the photographer. The old stone structure is green with moss, and the spot so overgrown with trees and foliage that it is easily passed over. You will want a lot of exposure, for no daylight comes from above, only the green sheen that passes through the verdant foliage; we exposed a collodion emulsion plate for three minutes, and could get no result. But a little trouble may well be taken over the subject, for this same Elizabeth it was who spared the troubadour's life, and the spot is the scene of a touching legend. As Elizabeth was returning from Eisenach one day, on an errand of mercy, which was no other than that of conveying baskets of food to the sick and wounded of an enemy besieging the castle, she was met by her husband, the Landgrave. He had long suspected Elizabeth's errand, but, despite entreaties and threats, she still continued the merciful mission.

"What have you there?" he cried angrily, tearing back her cloak.

The basket became uncovered before his eyes, and lo! its contents had changed to white roses.

A pleasant excursion is through the Mary-Valley, or Marienthal, and Annathal to Wilhelmsthal. A little brook runs through the green meadowland of the valley, and on both sides are picturesque hills and big grey rocks. On one of these is a capital M, in very large type indeed, that may be seen for miles. You must have a photograph of this, for the big rock above is called the Princess Rock, and thereby hangs a tale. A princess is imprisoned therein, so the story goes, kept in durance vile by some wicked old genius who allows her "a day out" but once in a hundred years, and then only at midnight. So delighted is she at seeing the beautiful world again, even in the dark, that she is invariably taken with a fit of sneezing, crying "Tischeu" no less than twelve times running. Should anyone happen to be there at the time, and politely say, as is the custom in Germany, "Gesundheit," or "Wish you better," in reply to every sneeze, then the princess will be released. Nobody has done this yet, but once a carter, it is said, passing along the road below with his team, and hearing violent sneezing going on, did answer "Wish you better" as many as eleven times; but when it came to the twelfth, his patience was exhausted, and he called out rudely, "Oh, go to the devil!"

Further on is the Anna Thal—the rock at the entrance marked with a capital A—apparently a moss-grown fairy grotto, but in fact a narrow defile and thoroughfare. The way hither has been through the most romantic of glens, over-shadowed by forest trees, and if any pictures are taken, exposure, exposure, exposure, must be the watch-word. Even when rays of sunlight escape the leaves overhead and fall into the deep hollow way, dappling the soft green moss with patches of gold, the light is exceedingly non-actinic; in fact, we confess, that repeated attempts on our part have never resulted in a well-exposed plate. The Dragon's defile, as the narrowest part is called, it is impossible to depict in the camera, for the path is so narrow two people cannot walk abreast. It is simply a cleft or fissure in the rock through which you walk, the strip of blue sky above being at times quite excluded by the verdant creepers and luxuriant greenery that fall in festoons overhead. Supreme quiet reigns in this cool retreat, its green walls of moss tufted with ferns and glistening with drops of moisture. For a hundred yards or so this cold grotto-like pathway continues; then presently you emerge again into the beech wood, the warm air floating towards you laden with the perfume of meadow-sweet and wild briar.

Another object on your way to Wilhelmsthal worthy of photographing is the big hollowed rock—Landgrave's Hollow—where a party of horsemen are said to have lain *perdu*, when contemplating an attack on the Wartburg; while Wilhelmsthal itself, with its lake, gardens, and homely little palace, will make some nice little pictures. There is a tolerable inn here, where you can refresh before returning to Eisenach, the walk back being through the Landgrave's defile, a forest pathway almost as romantic as that through the Annathal.

(*To be continued.*)

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

How did Daguerre Discover Mercurial Development?—The Difficulties of the Daguerreotyping Days—Peripatetic Photographers.

How did Daguerre Discover Mercurial Development?—Mr. Sims, of The Grove, Clapham Common, writing to a contemporary, has taken exception to Captain Abney's description of the manner in which Daguerre accidentally discovered that the image on the silvered plate could be developed by means of the vapour of mercury. Captain Abney, it will be recollected, in his lecture before the Society of Arts, stated that Daguerre, in the course of his laborious experiments to discover some method by whic the exposure could be reduced, happened one night to place a plate in his chemical cupboard, and in the morning found an image fully developed, which phenomena he afterwards traced to an open bottle of mercury. Mr. Sims, commenting on this, says:—"First of all, I would call attention to the fact that, although mercury does throw off vapour at a comparatively low temperature, it is not sufficient to make the image upon the Daguerreotype plate take a positive form. We must suppose, therefore, that the cabinet in which Daguerre kept his bottles was unusually hot, and, therefore, unfit for the purpose—or that there is some mistake or oversight in Captain Abney's description. The description I read some time ago, but in what publication I cannot now say, but think it was a publication by Lerebours and Co., of Paris, during Daguerre's lifetime, and to the following effect: Daguerre had made a camera image upon a silver plate, prepared with vapour of iodine. This image was, of course, a negative one, the light having converted the yellow iodate into the sub-oxide. A process of fixation, without at the same time destroying the image, was unknown to Daguerre at this time, and what he must have most earnestly longed for was a positive image, because his and Niépce's surfaces were opaque. So, in order to preserve the image he had made, he put the Daguerreotype plate, with the impression upon it, into a small drawer, that it might be kept from the action of the light; that in this same drawer there was, or had been, a bottle of mercury which had been upset, and the particles of mercury had become diffused very generally over the whole inside of the drawer, by its having been continuously opened and shut; that on his again going to look at the image on the plate he saw a positive image where the molecules of mercury had attached themselves, and that was the very part upon which the light had acted, and which before had formed the dark lines of the image." The discrepancy at this distance of time is perhaps not a very important one; but as a matter of historical accuracy it would be interesting if the point could be satisfactorily settled. We might, however, in passing, ask whether Mr. Sims is not slightly in error when he says that "although mercury does throw off vapour at a comparatively low temperature, it is not sufficient to make the Daguerreotype plate take a positive form?" Robert Hunt, in his "Researches on Light," says: "In forming a Daguerreotype image it is not absolutely necessary to heat the mercury. Faraday proved that mercury was volatilized at common temperatures; and Moser has pointed out that if the Daguerreotype plate, after it is taken from the camera, is placed over a vessel of cold mercury for some hours, the image will be brought out in the same manner as if the mercury had been warmed." This being the case, in the absence of positive evidence on the subject, we should be inclined to believe in Captain Abney's version of the story rather than in Mr. Sims'. Certainly the reason advanced by the latter against the "chemical cupboard" theory has no weight in the face of Robert Hunt's statement.

The Difficulties of the Daguerreotyping Days.—The remark of Captain Abney in the lecture referred to above, that the plate requires the most elaborate polish such as even a silversmith can scarcely give them, carries one back to the old times when the Daguerreotypists had to contend with troubles such as would appal the modern practitioner of the art accustomed to the "sweet simplicity" of gelatine plates. In a copy now before us of the *New York Daguerrian Journal*, the first photographic periodical published, we find a large portion of the space devoted to various methods of cleaning the plates. One writer gives a most elaborate account of his experience, remarking that, at the outset of his career, the difficulty of procuring good plates was so great that he instructed a Connecticut manufacturer to prepare a roll of silver plated metal with pure silver. A pound of this material cost nine dollars, and it must have been with considerable satisfaction that the American Daguerreotypers recovered soon after a supply of English plated metal of a very superior quality, and, to use the words of the writer, relieved us from the toil of making and plating one plate at a time, an expedient we were compelled to resort to to command material to meet the pressing demand for portraits. The writer then goes on to say: "Having it now in our power to obtain good plated metal, a more rapid mode of polishing than that attempted by Daguerre was attempted as follows." The description of this "more rapid mode" which does follow would occupy more than a page of the News, and, therefore, we will content ourselves with saying that the mode embraces rolling the plates on a steel die highly polished, annealing, the use of a lathe with a wheel suspended after the manner of a grindstone, to say nothing of most elaborate directions in regard to the preparation of tripoli rouge, rotten stone, and lampblack. The photographer who grumbles now at a little trouble deserves, if such a thing were possible, to be transported back some five and thirty years, and he would at once become reconciled to his present easy circumstances.

Peripatetic Photographers.—We fancy, if a census could be taken of the peripatetic photographers, the number would be found to be rather astounding. We recently had occasion to travel by road from Kennington to Hampton, and gathered an experience which was decidedly novel. The day was Sunday, and the weather fine, and, doubtless anticipating plenty of customers, a whole army of photographers prepared itself for the emergency. The advanced guard was met at Clapham Common, a strong battalion had stationed itself at Putney Heath, a goodly contingent was to be seen on Barnes Common, the picturesque road of the river Thames from Richmond to Petersham was lined with sharpshooters, while at Hampton Green was stationed the main body. Here, not only male, but female photographers were hard at work; the air was literally etherial, save when a whiff of cyanide unpleasantly saluted one's nostrils. And then the dark boxes and tents! Rouch, Howard—not to speak of England and Maxwell Lyte—were not to be mentioned by the side of the astonishing collection which it was our privilege to see. The perambulator variety, in which a tent had been mounted on an old perambulator frame, was evidently a favourite; but the box species, in which the manipulations were carried on by means of sleeves, ran it hard. The operators who used the boxes, we must confess, excited our wonder and admiration. They despised such weak-minded subterfuges as covering the head with the focussing-cloth and looking through a yellow glass window, and boldly faced collodion and cyanide fumes by watching the operations through a hole in the top of the box. This hole was just large enough to admit the eyes, and round the edges was placed a pad, against which the forehead and nose were pressed so as to exclude the light, and in this position, with ether ascending into the eyes and mouth and nose, almost excluded from air, did the hardy photographer work. We ventured to ask one gentleman whether he did not find the collodion fumes rather unpleasant, and he almost took the question as one reflecting upon his skill. In the course of a desultory conversation with two or three, we were made aware of the fact that your peripatetic photographer is on manipulative points one of the most sensitive of beings, and we therefore advise all who seek to know something of the bye-ways of photographic life to proceed cautiously. It may give some idea of the extent of this out-door business when we say that we counted nearly seventy cameras, and to each was attached, in the way of photographer, assistant, and touts, an average of four persons; there could not have been less than three hundred individuals engaged in photography in one day in the particular line of route. What proportion this formed of the number at work in the metropolis at the same time we must leave to the speculator in statistics to discover.

WITH THE ECLIPSE EXPEDITION.

BY C. RAY WOODS.*

Cairo, May 24th, 1882.

The eclipse is now over; the instruments are packed, and the expedition is on its return. The results obtained have exceeded the most favourable hopes that were entertained, and another field for the gelatine dry-plate process—a process increasing in usefulness day by day—has been opened up. Not only do the results obtained fully repay the trouble and pains that were expended on them, but are, in addition, so full of promise that, if properly followed up on future eclipses, many another discovery may yet be added to the many that photography has been the means of imparting to the increasing store of scientific knowledge.

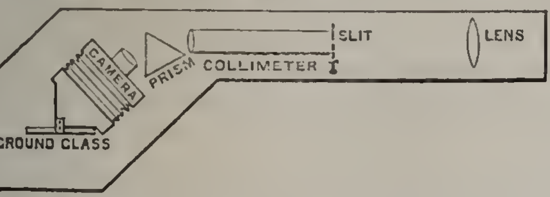
As stated in my previous letter, it was proposed to take not only photographs of the corona, but an attempt, at least, was to be made towards obtaining a permanent record of the coronal spectrum. An idea of the apparatus used may be gathered from the accompanying illustration. The lens used for photo-

graphing the corona was the front glass of a Dallmeyer's rapid rectilinear. The back lens being removed, a focus at a distance of a little more than five feet was obtained. A long mahogany box (AA), four feet seven inches in length, and six inches square in section, carried the mount and lens at one end, whilst at the other was screwed a quarter-plate pocket camera, by Meagher, with rack-and-pinion motion, forming a sufficiently fine adjustment for a lens of so long a focus, whilst a coarse adjustment could be obtained, if necessary, by the movement of the tube containing the lens in another tube screwed into the flange that held it in its place. Across the camera, coming as close as possible to the slides without interfering with their free movement, a fine wire was stretched, in order that a line might be impressed on each plate, rendering the orientation easy. This long camera was mounted on a photo-heliograph stand (S) lent by the Transit of Venus Committee, and, with the other apparatus about to be described, was driven equatorially by clock-work (F), and occupied, together with the spectrum apparatus, the position held by the photo-heliograph that had been removed to give place to it. Above this camera a shorter one (B) was placed, destined to photograph the corona, analysed by a glass prism. The lens (D) was a single one of 4 inches

* Continued from page 439.

aperture and 22 inches focal length, but stopped down to 2 inches aperture. In front of this lens was screwed a brass box (c) containing the prism, set at the angle of minimum deviation for G. The camera had a swing-back of about 45°, in order to bring all parts of the spectrum into focus at the same time; and, although the lens used was corrected, the angle mentioned did not give more latitude than was found to be necessary. This camera was so mounted that it could be placed at any angle to the longer one between about 10° and nearly 90°, and was finally adjusted at such an angle that the green rays fell in the centre of the ground glass. The slides were constructed to carry plates $4\frac{1}{4}$ inches by $1\frac{3}{4}$ inches in size. This camera carried no slit, and the spectrum of the corona would therefore consist of a series of rings.

A third piece of apparatus used was a slit spectroscope and camera in the accompanying diagram. It consisted of a



collimator, ten inches long with a platino-iridium slit* of three-quarters of an inch in length, but capable of being partially opened or closed, or opened one-third at a time. In front of the slit was placed an achromatic lens of about 2 inches aperture, and about 10 inches focal length, to throw the sun's image on the slit. One prism of 60° was used set at the angle of minimum deviation for (G), and a small camera with a corrected lens and a back capable of a very considerable swing. It had been originally intended that these pieces of apparatus, which had been adjusted and fastened down to a board, should have been placed on a horizontal stand, and the image of the sun thrown on to the slit by means of a siderostat; but, fearful that the latter might require special attention, it having been damaged on the journey, this was abandoned, and the board, with its attachments, was screwed on to the long camera, and driven by the same clockwork which guided the other instruments. The alteration proved to be a wise one; for a larger amount of light was thus received by the lens, and, in addition, all three pieces of the apparatus were so compactly arranged that they were all under control without a change of one's position being rendered necessary.

* The illustration here is not strictly correct, the slit being flat and of the usual construction, and not barrel-shaped as here represented.—C. R. W.

All difficulties were not at an end, however, when the apparatus was once up; for, though the material of which the cameras were made was well seasoned, no small amount of trouble was occasioned by the warping of the wood. When the thermometer stands at over 100° Fahr. in the shade, when the sand registers a temperature of 140°, and the iron and brass work of the instruments are so hot that they cannot be handled without cloths, the best wood is likely to be guilty of vagaries. Slides had frequently to be meddled with, and smoothed every time they were used to ensure their moving easily. Rackwork would occasionally get out of order, and the utmost care had to be taken to prevent the sand getting into the clockwork and fittings, and to keep things generally in working order. On the eve of the eclipse, however, everything seemed satisfactory; preliminary experiments and rehearsals had been gone through, and the morrow was looked forward to with confidence, though with anxiety. A few days before the eclipse an attempt was made in the early morning to photograph the spectrum of the moon in the spectroscopic camera; and this having been accomplished satisfactorily in the space of seventy seconds, very little doubt was entertained that the plates were sufficiently rapid to perform the task that was required of them. The light of the corona is more intense than that of the moon, and the plates were fifty times as quick as wet collodion—the only process that had hitherto been used in attempting to obtain a record of the coronal spectrum.

On the morning of the 17th lenses were cleaned, final adjustments were made, the slides which had been filled the previous evening were tried and found to work easily, and every one waited with suspense, glancing at the chronometer now and again for the time when it would be necessary to commence operations. The inhabitants of the neighbouring town of Souhag had deserted their homes, and were grouped near the encampment, from which they were kept at a respectful distance by the soldiery, looking with wonder at the strange shadow that was obscuring the sun. The dahabeahs of the gentry at anchor in the river, the slope of the embankment, and the steamer kindly placed at the disposal of the astronomers by the Khedive, were crowded with anxious faces; a buzzing murmur came from all as they glanced now at the rapidly diminishing sun, and now at the observers standing patiently by their instruments; the very animals seemed interested, and the feathered creation cackled loudly and gathered round the tents as if anxious for human sympathy. The sun was rapidly becoming a mere crescent; a slide was placed in the long camera, and by means of a slit passed rapidly across the lens, exposures were made on the same plate at intervals of two minutes, for purposes of orientation. Two exposures had been made, when it was discovered that the clock had not been stopped, as was necessary for obtaining successive images. The error was repaired, and three more exposures made on the same plate. The omission, however, was not without its use; for the two images so very nearly overlapped that the second one obtained shows how well the clock was driving. This task done, the slide was taken out and laid aside, the instrument was once more pointed to the sun, and the clockwork again put in motion. As totality approached, the slides were put in their places, positions were taken up, and nothing remained but to wait carefully for the signal to commence.

Three plates were exposed in the long camera, the first for ten, the second for twenty-three, and the third for three seconds, these plates being very rapid. A rapid plate, sensitive from the green to the ultra-violet, was placed in the spectroscopic camera, and exposed during the whole of totality. A plate, sensitive right down to the red, was likewise exposed for the whole of totality in the prismatic camera.

The amount of diffused light during the totality was at least twice of that given by the moon when full, but it was of a strange bluish tinge. That part of the corona nearest the sun was of a dazzling brightness, so dazzling indeed that in the short gaze of six or seven seconds, permitted during the long exposure, but little idea of the general character of the corona could be obtained. To the right of the sun, at a short distance from it, appeared a brilliant object, which was speedily recognized as a comet; but so unexpected was this phenomenon, that not even approximate measurements were taken of its position—an observation, however, which was happily rendered quite unnecessary by the accuracy with which the plates registered its position, size, and shape.

Totality over, and the slides closed, a little breathing-time was taken, and then, as the sun once more appeared as a crescent, another slide, containing a slow plate, was placed in the long camera, and three successive images obtained at intervals of two minutes, the clock meanwhile being stopped. This done, nothing more remained but to lay all the slides carefully aside, whilst taking a short interval of rest between exposing the plates and, as photographers will allow, the less easy task of developing them.

Precautions had to be taken agains running, blistering, and frilling in such a hot climate as Egypt, and materials had even been taken out to prepare freezing mixtures. The Nile water, however, was not very warm, and plenty of cool, clear water could be obtained from the large porous earthenware vessels that acted both as filters and coolers. Plates which had been developed previous to the eclipse, and belonging to the same batches, showed no signs of the aforementioned faults, so that the freezing mixtures were abandoned. Nevertheless, it was still thought advisable to have at hand other materials, such as collodion, alcohol, and even chrome alum, in a case of emergency; fortunately, however, not only were none of these required, but development could not be carried on at home with greater impunity. Water, when once cool, takes some time to get sufficiently warm to spoil plates which have no tendency otherwise to frill, and the cabin, which had been fitted up as a dark-room, was itself half below the water-line.

The two orientation plates were developed first, and, though very much over-exposed, in spite of the rapid exposure given, were well brought out with plenty of bromide of potassium in the developer. The developer used was the ordinary iron developer, made up with ferrous oxalate and a saturated solution of oxalate of potash. These, the least important, having been successfully developed, the corona photographs were developed; but these being very much over-exposed nearest the moon's edge, and equally under-exposed further away, required considerable care. The ten-seconds one had had a slight shift, and a double image was produced; but the second image was somewhat faint. The longest-exposed plate did not suffer from any such defect, and the image obtained is very clear. Some parts of the corona extend in the photograph to a distance of two diameters; the head of the comet is clear and defined, whilst its scimitar-shaped tail is perfectly distinct. So bright, however, was the sky at the time, and so quick the plates, that a veil extends over the two plates. The third plate was also over-exposed for the parts nearest the moon's disc; but the prominences are clear, and it is altogether a useful photograph. The comet also is visible, but not so distinctly as in the two others. The backing, though thick, did not entirely prevent halation; in fact, the extent of the halation shows how very much the plates were over-exposed for the bright parts. The next plate developed was that in the spectroscopic camera. The apparatus was so adjusted that the image of the sun, when the instrument was pointed to it, fell right across the centre of the slit, and this was the case at the time of the eclipse, the whole length of the slit being open, and its width at the time being $\frac{3}{10}$ of a millimetre. After the eclipse, the instrument was pointed to the bright sky, and portions of the slit, $\frac{1}{8}$ of an inch at each end, were opened, and a reference spectrum on both sides of the coronal spectrum obtained. On development, a continuous spectrum with bright lines was seen; the H lines being very bright and prominent. The plate exposed in the prismatic camera was also successful, and exhibited a continuous spectrum with a number of bright rings due to the prominences. As most are aware, the comet has been given the name of "Tewfik," in remembrance of the favours bestowed on the expedition by the Khedive, to whose help and attentive foresight, with those of his staff who accompanied us, so much of the success of the expedition is due.

The other work accomplished during this eclipse has already been to some extent made public—so much, of course, as could be done so soon after the event; and as it is not of a photographic character, it need not be entered into here. Suffice it to say that the work done in the short time during which totality lasted has more than realized the highest hopes that one dared entertain.

Notes.

The Trieste "Great Exhibition of Industry and Art" was officially opened on Tuesday.

Dr. Eder, who has just returned from Trieste, tells us the Exhibition is delightfully situated on the sea-shore, facing the blue Mediterranean. Immediately behind the fine building rise green hills covered with vines and fruit trees, the "Campagna" of the city. "There is little connected with photography in the Exhibition," adds Dr. Eder, "but what there is I will describe at a future time."

The Royal Engineers, who include in their number a staff of trained photographers, sailed for Egypt this week.

The silver medals awarded by the Vienna Photographic Society to Mr. G. M. Whipple, B.Sc., Director of Kew Observatory, to Mr. Walter Woodbury, and to the Platinotype Company, have been forwarded to us for transmission to their proper destination. They represent very handsome workmanship.

"The readiest way to identify a negative is by its defects," a practical man tells us. When a series of plates are much alike, many minutes may be wasted in picking out a particular one, if you go by pose or position; while, on the contrary, if you seek to identify by a pinhole, a tiny comet, or other similar defect in the film, you can make the selection at once.

Signalling by sunshine is again being resorted to with much success in Egypt by our army of occupation. In a sunny land, the system has many advantages over the electric telegraph, for you can signal by mirror over an enemy's head, and he is powerless to cut communication. But some system of recording the signals—it should be feasible by photography—is still wanted.

The method of signalling by the heliograph may be explained in a few words. A circular mirror—a ten-inch mirror suffices to send a signal visible to the naked eye at fifty miles—is set up facing the far-off station with which communication is desired, and a few feet in front of the mirror is erected an upright iron rod. The iron rod has a sliding button, which can be moved up and down the rod. An observer places himself behind the mirror, and looks through a hole in the centre provided for the purpose: he looks in the direction of the far-off station, and while he does so, an assistant slides the button up the rod until it is seen by the observer behind the mirror. The button is, in fact, like the foresight of a rifle, and, as soon as it has been properly placed, all that is necessary to send a signal is to bend the mirror so that sunlight is reflected on the button. As the distant station is in a line with the button, you may be sure the ray of sunshine you reflect will travel straight to it.

Several cameras were in readiness on the arrival of Cetewayo at Plymouth yesterday, but we have not yet seen any of the resulting pictures.

We shall next week give a specimen of Ives' photo-engraving process in these columns, one of the few practical methods at present capable of transforming a half-tone photograph into a type block for the printing press. The process, which emanates from America, is a secret one, and although the results are still far from perfect, they are quite promising enough to lead one to hope for better things in the future. That our readers may best judge of the capacity of the process, we have chosen as specimen a portrait, from life, of Mr. Walter Woodbury, which has been kindly placed at our disposal by the Editor of the *Philadelphia Photographer*, Mr. E. L. Wilson.

Mr. Wilson writes us from Philadelphia that his trip this spring to Egypt has been a great photographic success. He is now busy developing the large series of plates exposed on his journey, and is fairly delighted with the successful issue of affairs. His expedition proves effectually—if any proof were wanted—that gelatine plates may be used with advantage in the tropics. Since Mr. Wilson interviewed Arabi Pasha in his wanderings, and depicted many of the towns and seaports now being spoken of by our Special Correspondents, his collection of photographs should prove very valuable just now.

Light seems to play an important rôle in the drying of oils and paints, and it would be an interesting investigation to the photographic chemist to find out what principle it is in linseed and other oil which is so sensitive to the action of light. Oil dries by taking up oxygen from the air, but with pure oil this takes place only under the influence of light or heat. Light is the first and most important drier of oils, however, according to the *Railroad Gazette*, and heat is but second to it.

Our Belgian contemporary makes a sensible suggestion —and, to do him justice, he generally is sensible when he is not applauding his own country, or vaunting the art treasures (?) of the Brussels *Musée*—respecting the writing of the name of the man who first secured a photograph in the camera. Historians are unable to agree, it seems, as to the nature of the accent which should be employed, whether *grave* or *aigu*, some setting the word down Nièpce, and others Niépce. To settle the difficulty, our contemporary suggests that both are to be right, and the word in future written Niêpce, namely, with an accent *circonflexe*.

The *Archiv* tells us something of the sad death of the African traveller, Siegfried Langer, who was recently murdered by Bedouins. It seems that it was while securing a photograph—for every pioneer carries a camera now-a-days—that he was suddenly fallen upon and killed. Three Bedouins in his company were occupied in prayer at sunset, and left to himself for a few minutes, he proceeded to focus a view in his camera, unfortunately with his back to the people. Suddenly they fell upon from behind and stabbed him, Langer, although well-armed, being doubtless too much encumbered by the dark cloth to make use of his weapons.

The pigeon-post with micro-photographic dispatches would be a capital means of communicating along the Suez Canal, should this thoroughfare be unfortunately interrupted by the enemy. The only difficulty would be the securing of trained pigeons ; but it is not too late even now to set about establishing an ærial post of this nature.

A thermometer that will indicate the thousandth part of a degree Centigrade is promised us by M. Michelson, who has demonstrated the principle upon which his very sensitive instrument is constructed before the French Physical Society. He does not employ mercury or spirit for his thermometer, but something that expands still more in the presence of heat, viz., hardened rubber or ebonite. The instrument is in the form of a spring, which is made of platinum on one side and ebonite on the other, and as the latter dilates some ten times more than the former under heat, there is naturally exerted a rise and fall in force every time a rise and fall of temperature takes place. The force exerted is communicated to a delicate lever or arm, and this, reflecting a beam of light from a lamp, magnifies the force that has been developed, and renders the change easily readable to the eye. Edison, it may be remembered, employed rubber for a similar purpose.

Gun-cotton has played a conspicuous part in our operations in Egypt. You may blow a gun to pieces, or at any rate render it unserviceable, as quickly as it could be spiked in the olden time, by merely thrusting a cake of the explosive into the muzzle of a cannon, and detonating by electricity. Our tars who landed at Alexandria all employed guncotton to destroy the guns in the batteries in this way. This is the military guncotton we are speaking of, manufactured in the form of *papier maché*, and pressed into any handy shape. But collodion cotton, which is soluble in ether and alcohol, is also attracting attention as a military explosive, for by its means military men obtain an agent more violent still. Photographer's gun-cotton will dissolve in that terrible substance nitro-glycerine, and together they form a jelly which goes by the name of blasting gelatine ; this in all probability will be the explosive of the future.

Major Waterhouse writes that he is still working at his sand photo-engraving process, and, according to the proofs he furnishes, not without some success. It would be difficult to describe the *modus operandi* more briefly or to the point than does the Deputy Surveyor-General of Ordnance for India. "I am working on just the same lines as before: pigment print transferred to silvered plate—treated after development with bichromate solution—then grained with stearined sand, emery or glass powder, according to the grain required—dried—graining powder removed—black-leaded—electrotyped."

A critic of M. Zola's novels declares them to be endowed with "the brutal justice of a photograph." Perhaps this accounts for the fact that the French novelist is at this moment the most extensively read author in Europe.

M. Charpentier's statement which we published last week, that an average person may perceive and repeat a signal in the short space of thirteen-hundredths of a second shows pretty plainly that a photographer ready to expose can secure a picture of the most rapid phenomenon—unless it is an electrical discharge—by watching his opportunity and working the shutter by hand. This is a matter worth knowing in these days, when all sorts of electrical communications are proposed to secure exposures at the right time. Indeed, in our experience of photographing torpedo explosions, and buildings blown down by gunpowder or dynamite, we have never met with an instance yet in which the exposure could not be perfectly well controlled by hand.

Multiply the height of your model with the focus of your lens, and divide by the distance he is from the instrument. This is the simplest way, according to Dr. Vogel, of getting at the size of the resulting photograph. It is merely a question of doing a rule-of-three sum. If the model stands 5 feet 6 inches, or 66 inches, and the focal length of the lens is 10 inches, while his distance from the camera is 15 feet, or 180 inches, then 66 multiplied by 10, and divided by 180, will give you the result, which is 3·6. In this case, then, the photograph of your model would be a little more than three inches and a half high.

ON INTENSIFYING WITH THE FERROUS-OXALATE DEVELOPER, AND CERTAIN OTHER METHODS OF INTENSIFICATION.

BY F. STOLZE.

Having made further trials with the mercurial ferrous oxalate intensifier, I am more and more convinced of its excellence. Its power of rendering forcible contrasts is considerable, and, at the same time, one need not fear its causing the picture to disappear in the developer, being, therefore, much easier to work with than the cyanide of potassium developers. It is preferable not to use the developer too concentrated; the whole process can then be closely watched, and during the proceeding the amount of intensification lies in one's own hand.

Although, theoretically considered, the desired intensification must be unlimited, as by repeated strengthening more mercury will be stored up, the experiment still shows that when it approaches a certain limit, its progress is not quite so simple as it at first sight appears. In the case of a very thin negative, should it not be fit for printing after using this intensifier, it will form a good base upon which to work the silver intensifier with gallic or pyrogallic acid. It acts exceedingly well if the order of things be reversed, the gallic or pyrogallic intensification being performed first. All those who have tried the silver intensifier know well that negatives made from very thin emulsion often give with gallic acid a deposit so decidedly yellow as to hopelessly spoil the negative. Although this yellow deposit disappears in the sublimate bath, it reappears, unless it was previously very slight, in ammonia or cyanide of mercury. This does not happen with the oxalate developer. As a trial, I intensified half a very thin, useless negative with gallic acid until all the deep parts were stained a dark reddish brown. This entirely disappears when treated with the sublimate, and with the ferrous oxalate showed a very faint yellow tint in the depth; the faint yellow, I believe, would also have vanished had it stayed longer in the sublimate bath.

As mention has been made of the gallic intensifier, it may be desirable to many to know how to prevent the yellow and brown colouring. As with pyrogallic acid, the addition of salicylic acid proves beneficial.

The following is a good formula:—

Alcohol	120 parts
Gallic acid	10 ,,
Salicylic acid	0·5 ,,

The silver and glacial acetic solution must not be mixed long before using, as it becomes cloudy, and throws down a precipitate.

Questions are constantly arising with regard to Monckhoven's intensifier, whether the chemically-pure crystallized cyanide of potassium must be employed in its preparation. An answer is readily found. If it is highly necessary to adhere to the original recipe (1,000 parts water, 20 nitrate of silver, 20 cyanide of potassium), decidedly use the pure; but if a similar result only is desired, the ordinary cyanide of potassium will answer just as well. First dissolve the silver in some of the water, then add as much of the concentrated cyanide in solution, until the resulting precipitate is again nearly dissolved, after which sufficient water is added to make the solution up to the required volume.

Dr. Eder desires attention to be drawn to the fact that, if the changing from yellow to brown will not take place, it only needs the addition of a little more cyanide of potassium in solution. This is important after long usage of the fluid, the proportion of free cyanide becoming quickly reduced, particularly if the negatives are not carefully washed after treating with sublimate. Under these circumstances the bath may be quite spoilt, while a slight addition of cyanide puts it all right again.

FERROUS OXALATE REDIVIVUS.

BY W. T. WILKINSON.

There is a disposition in some quarters to advocate the return to ferrous oxalate development, especially by manufacturers of plates, who, from some reason or another, cannot make emulsion free from chemical fog, in which case pyrogallic development is fatal to the production of clean negatives, whilst ferrous oxalate at least yields clean shadows, even if the quality is not there.

In advocating ferrous oxalate development stress is laid upon the following points: first, it is used by the best continental houses; secondly, it is simpler, and less time is required to get printing density; thirdly, the same solution can be used for the development of several images. But nothing is said about the very important factor of latitude in exposure, for the reason, I suppose, that there is none, especially in the case of under-exposure.

Comparative quality is also ignored, but I am at any time prepared to prove that with a really first-class plate, such as Wratten's, Edwards', or the Paget, it is not possible under any circumstances to get as good a negative with ferrous oxalate as with pyrogallol; but there are nevertheless in the market plates with which the best results are obtained *vice versa*, but simply because they are of faulty manufacture.

Being always open to conviction, after reading the recent able arguments in favour of ferrous oxalate, the good quality negative, and the celerity with which printing density can be obtained, as against pyrogallol, I tried the following experiment. Two of Swan's plates, 6½ by 4¾, marked twenty-five times, were exposed in the studio for three seconds each, the subject being a cricketer in white flannel. One was developed in ferrous oxalate, the other by the sulpho-pyrogallol formula, given by me two or three weeks ago, the results being that the one developed by ferrous oxalate required fifteen minutes to get density, and was only barely exposed sufficiently; the other, developed in sulpho-pyrogallol, was sufficiently dense, and in the fixing bath just under four minutes, and was, if anything, over-exposed, but has no tendency to flatness. Two of Wratten's plates were afterwards treated in the same way, except that they, being slower, received five seconds' exposure each; but the results were the same, except that the Swan's, under pyrogallic, gave veiled shadows, whilst Wratten's did not. Upon examination, after fixing, the ferrous-oxalate negatives are harsh and dirty-looking, with a great suggestion of want of continuity; but the pyrogallic negatives are soft and full of detail in lights and shadows, especially the Wratten.

For my own practice, this experiment disposes of the claims of ferrous oxalate development to simplicity and quality of negative (when first-class plates are used). The third point is not worth arguing; but I have often, when copying or developing an accumulation of exposed plates, developed six plates in four ounces of pyrogallol solution. It is also claimed that the surface of a ferrous-oxalate developed negative takes the retouch easier. Well, it has need to do so, as they require far more than a pyrogallic-developed negative does.

My experience with ferrous-oxalate development is that it requires a much longer exposure, is tedious in development, and even with plates exhibiting only a slight tendency to green fog, does not give the best negative; in fact, it is only useful as a manufacturer's developer, enabling a faulty batch to be utilized.

There is one very important point not yet touched upon, viz., latitude of exposure. It is very well to say, in case of flatness from over-exposure, intensify with mercury; but for good work that will not do. As for under-exposure, that is quite hopeless; but, with pyrogallic, care and plenty of bromide will give any amount of latitude, both for over and under-exposure; of course, taking the standard from the time required under what is termed a "normal developer."

RECENT ADVANCES IN PHOTOGRAPHY.

BY CAPTAIN W. DE W. ABNEY, R.E. F.R.S.*

At the last lecture I had the honour of giving here, I introduced to your notice the ferrous citro-oxalate developer, for which I claimed the advantage that it was able to work without any restrainer whatever. To-night I propose to bring before you another developer, which is also able to work without a restrainer; but before I do that, I should like you to take note of an improvement, which has been lately introduced by Mr. Berkeley, in the ordinary alkaline developer. With the pyrogallic acid solution is mixed four times the weight of sulphite of soda. The action, apparently, is this—the sulphite of soda absorbs the oxygen with greater avidity than does the pyrogallic acid, thus leaving the pyrogallic acid free to do its work, and, consequently, we have a developer which remains uncoloured for a very long period indeed. I hold in my hand a bottle which was presented to me by Mr. Berkeley, some time ago, which I read was made up on October 13th, 1881. This contains four times the quantity of sulphite of soda than it does of pyrogallic acid. Here is another bottle of pyrogallic acid, made considerably later—some time in January—and you will see the difference in colour between the two. The one is slightly yellow in tint; the other, a deep muddy brown. I consider that this introduction of sulphite of soda into the developer is one of the most remarkable improvements in alkaline development, and I hope that those practical photographers present will not hesitate to try the formula which Mr. Berkeley has lately published.

I now propose to show you the practical use of the developer to which I referred when I commenced. It is a new one, but has not been used to any very great extent, I am afraid, on account of the high price it used to fetch. I refer to hydrokinone; the first quantity I bought cost me 12s. a drachm, but I am happy to say it is now only 8s. an ounce, and one grain of it goes so far that it is as active as two grains of pyrogallic acid, for it is a much more powerful absorber of oxygen than pyrogallic acid; an advantage with it is, that you are able to use it without any restrainer. You can even develop chloride of silver without adding any soluble alkaline haloid to it, which photographers know is essential when using even a very weak pyrogallic and alkaline development. To illustrate this, I have an opal glass plate which is covered with a film of collodion containing chloride of silver. Until quite recently, this was a film which it was almost impossible to develop by the alkaline or iron methods; but, thanks to Dr. Eder, we are able now to develop chloride of silver exactly in the same way as we can bromide of silver. To save time, I gave the plate a short exposure just before the lecture. In this cell I have now simply hydrokinone and ammonia, and I think you will see that it develops the plate without the slightest trace of fog. I have taken an opal glass as the background, so that you will be better able to see the result; it comes out very gently and gradually. Thus you see that this new developer works without any restrainer whatever, even when such a troublesome salt as silver chloride is used. Not having any restrainer, it is able to give a better detail, and allow a shorter exposure in the camera than if the ordinary alkaline developer was used. This development is applicable not only for collodio-chloride, but for collodio-bromide plates, or for gelatino-bromide plates—in fact, any plate with which you work, even iodide. [The perfectly developed image was then shown.]

I promised last lecture that I would show you how very easy it was to develop iodide of silver with either the alkaline or the ferrous oxalate developer. You saw in my last lecture how we could develop the iodide with silver and gallic acid, but it becomes a very different thing—at least, it was always so considered—when you have to develop a plate containing simply iodide with nothing but an oxalate developer, such as I have here. In this frame I have a paper which is coated with pure iodide of silver, not a particle of bromide or chloride in it; I will give it a slight exposure, and I propose to develop it on the screen before you. I will simply immerse it in water, and use some of the same ferrous citro-oxalate which I introduced to your notice last week. It will be apparent with what facility the iodide of silver can be developed. The paper, where viewed in the yellow light, is apparently colourless, although really it is yellow. If everything be correct, you will see that we get an image developing out rapidly, which is formed of pure metallic silver, reduced from the sub-iodide at first, and then led, as it were, from the adjacent iodide. [The picture was fully developed.] We now have a practical demonstration that you can develop iodide just as easily as you can bromide, which is a desideratum when you come to consider the composition of gelatine plates, with which we may have to deal more fully in subsequent lectures. Having fulfilled my promise with regard to this, the next point I wish to call the attention of the meeting to is the action of sensitisers. I should like to explain to some of you who are not initiated in the mysteries of photography, what a sensitiser is. I will throw a diagram on the screen, and then you will be able to understand better what I mean. When you have chloride of silver, for instance, exposed to light, you have a new compound formed, which is called sub-chloride, or argentous chloride

$$(Ag_2Cl_2 = Ag_2Cl + Cl),$$

and chlorine liberated. This chlorine is a very obstinate thing to eliminate, if you do not give it something that can take it up; for instance, if you place perfectly dry chloride of silver in vacuo, without any trace of organic matter present, you will find, if it is exposed to brilliant sunlight for months, you get no darkening action. If such a white powder was submitted to you, to test by its darkening, you would say at once that it was not chloride of silver, because it was not darkened, since one of the tests of chloride of silver, amongst chemists, is, that it shall darken in the light. Here I have a little bulb of it which was prepared, dried carefully, and sealed up, the vacuum being made by means of a Sprengel pump. This tube has been exposed for months to light, and it is as pure a white as the very first day it was put into the bulb. Another experiment was made at the same time; a bulb was prepared, but in using the Sprengel pump, unfortunately, as I then thought, a small globule of mercury got in the vacuum, and was sealed up with the chloride; the consequence was, that the chloride of silver immediately darkened; although the mercury was not in contact with the chloride of silver, the chlorine flew to the mercury, and formed chloride of mercury. This is an instructive experiment, showing that merely in the presence of something that will mop up the chlorine, chloride of silver will darken. Here is another darkened bulb, which is chloride of silver, which was sealed up, not in vacuo, but in hydrogen. Now, hydrogen, as you are perfectly aware, can combine with chlorine to form a gas, which we call hydrochloric acid, so, when the chlorine was in the presence of hydrogen, it combined with it, instead of returning to re-combine with the sub-chloride of silver.

$$Ag_2I_2 = Ag_2I + I.$$

On the screen is a diagram showing these reactions of the two other haloid salts of silver. I have already shown you the diagram of silver chloride, and its splitting up by light. Silver iodide splits up into silver sub-iodide and iodine.

$$Ag_2Br_2 = Ag_2Br + Br.$$

Silver bromide, when exposed to light, splits up into silver sub-bromide and bromine.

Now, in order that there shall be a ready darkening of either of these, you must have something which will absorb the iodine or bromine (or, in the case of the latter, allow it to escape), whichever you expose to the light. Now, the image which you just now saw developed on the iodide is, before development, precisely the same as the darkened image on the chloride; it is a matter simply of degree. Of course, if you took a few shot, and hid them in a bushel of flour, you would not be able to know that there was anything black in the flour; in the same way, if you alter two or three particles of iodide into sub-iodide, or chloride into sub-chloride, you do not notice it, because they are so mixed up with the particles that are not altered. It is these little altered particles that are the nuclei for the developed image. In order to show the use of sensitisers, I have prepared a sheet of paper, a quarter of which has been washed over with that vulgar beverage, beer; another quarter with potassium nitrite, and another quarter with gum; the fourth quarter has nothing on it. Now, all these are—but in greater or less degree—absorbents of iodine and bromine, and you will see, when I expose the paper and develop, that there is a decided increase of sensitiveness where those substances have been applied. You may say, "According to what you have said already, the particles not coated with anything ought not to develop," but you must recollect that we are in contact with air, and air contains moisture, and if you have chlorine, for instance, in the presence of moisture, light is able to split it up into hydrochloric acid and oxygen, so that, in the case of a paper like this, you have a sensitiser present, but only a feeble one. This paper is the bromo-iodide paper that I introduced to your notice some little time ago. I have marked on the different quarters of it what is the sensitiser on each. I will brush it over with this ferrous citro-oxalate developer, and we

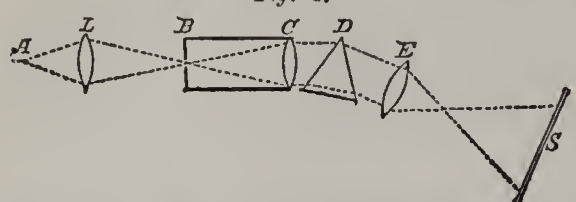
---

* Continued from page 445.

shall see if there is any difference in the rapidity of coming out. The part coated with nitrite is coming out very rapidly, it has a very inordinate affection for iodine and bromide; the vulgar beverage beer does not seem to be doing its duty as it ought to be now the gum is flashing out; now the beer is coming. You see the nitrite came out first, then the gum, and then the beer; finally, that in which the sensitiser was merely the air and the paper; and you will see, when the picture is finished, there is a vast difference in the amount of development. If there had been no moisture in the atmosphere, if it had been exposed in dry air, there would have been no action whatever where it was not coated with some sensitiser. Here, then, we have a proof that a sensitiser is necessary in order to give the greatest possible sensitiveness, and I hope that this will explain to you what I shall have to allude to further on.

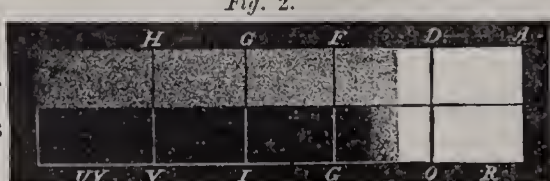
I next have to call into use the spectrum. Here we have it on the screen, and I have produced it by the same arrangement of apparatus as if I were going to use it for photography. You will see that we have a tolerably clear spectrum. We have the light, A, and a lens, L, to throw the image on the slit B. and then the lens, C, to make the rays parallel, then a single prism, D, then a photographic lens, E, which focusses the spectrum on the screens. Now I want to point out to you not only that we have red, green, yellow, blue, and violet rays, but we have rays beyond the violet also which we cannot see, but which, by an artifice, I shall be able

Fig. 1.



to show you. For instance, if I place this card on this screen, you see we have a vast extension of the spectrum beyond the violet; but if I take away, it is absent. The reason of that is, that I have brushed on this card a solution of sulphate of quinine, which lowers the wave light of the ultra-violet rays, making them visible. I was anxious to bring this spectrum before you for this reason, that it is the principal part of the spectrum which is useful to photographers, though I do not believe they are aware of it. When we expose one of these haloid salts of silver to the spectrum, it behoves us to know what part of the components of light it is that acts upon the haloid salt. Now, a very simple way is, of course, to place a film containing the haloid salt in the spectrum. But what I want first to point out to you is, that we must go upon scientific principles in dealing with the facts that come before us, and the main principle is the principle of work. When you have what you call light radiating from a source, be it the sun or be it a gas flame, it is only when its radiant energy is stopped or absorbed that you are able to get any work out of it at all; that is to say, supposing you have a transparent glass plate, you know that the light, as you call it, passes straight through the plate, without leaving a very visible effect on the glass. But if you have a red glass, why does it appear red? Simply because a part of the rays have been stopped; but what becomes of those rays that are stopped? They must take one of two forms, or, rather, the work they do must take one of two forms. The work they can perform may be shown by the heating the glass, or else the energy must be exhausted by doing chemical work upon the substance on which it acts. The effect then is this, if you have an haloid salt of silver, the principal part of the energy which is radiated, and which is absorbed, does chemical work, and it is only those regions of the spectrum which are absorbed which are capable of doing chemical work. I cannot show you a better example than I have upon the screen. The second part of the

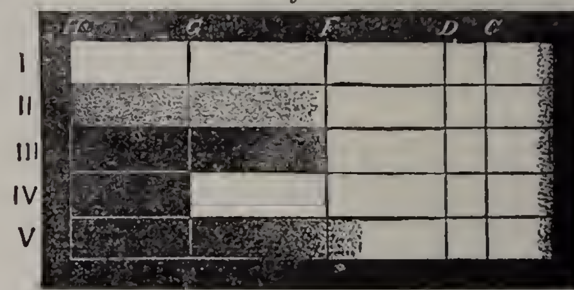
Fig. 2.



slide shows the whole spectrum, taken with a substance which I shall be able to show you by-and-bye. You see the darkening caused by the light; at the far end we have the ultra-violet rays, and at the other end we have the red rays. In front of the slit of the spectroscope was placed a cell of bichromate of potash, and you see it cuts off, not only the blue and the violet, but a part of the green, and leaves the red and yellow intact (B, fig. 2).

Now, photographers know that those beautiful prints that go by the name of carbon prints depend for their manufacture on the fact that bichromate of potash is altered by light in the presence of organic matter. Here we have the spectrum taken on carbon tissue in which you will see the absorption exercised by bichromate of potash exactly coincides with the work done on the bichromate (A, fig. 2); notice that the part of the spectrum which is impressed ends exactly where the bichromate absorption begins. I think that is a very excellent illustration of the work done by radiation. I propose now to pass two or three films through the spectrum (I., fig. 3), to see what kind of work we may expect to be done with them. First, we have a film of chloride of silver (II.), and you will see that the violet part of the spectrum towards the yellow is subdued, whilst the other parts pass through. Next, we have a bromide film (III.), in which you see some parts of the spectrum are cut off which before were visible. Next, I take iodide (IV.), where you see the violet is cut off entirely, leaving a trace of blue, which was not the case with the bromide. Here,

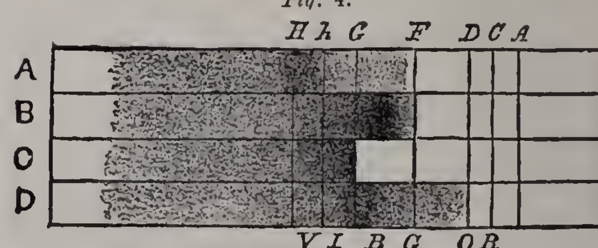
Fig. 3.



again, we have the bromo-iodide (V.) cutting out the blue, going right into the green. That is interesting, because I propose to show you next the fact that the absorption coincides with the work done on the films themselves.

I have here a board with four strips of paper upon it—the first coated with chloride of silver, the second with bromide of silver, the third with iodide of silver, and the fourth with bromo-iodide of silver. I will expose each of them for twenty seconds, to the spectrum, and develop them before you. In order to recognize the parts acted upon, there are strings put across the different parts of the spectrum. [The exposures were made, and the strips damped and placed on the developing board.] I brush each strip over with the ferrous-citro-oxalate developer. [The prints developed rapidly, the chloride taking rather longer than the others to appear.] The chloride sometimes takes a little longer to develop, and I ought to have given it a little longer exposure, because it is not quite so sensitive as the other salts. Here are the four spectra (fig. 4). The maximum sensitiveness of the chloride, A, is about the line H on the spectrum. The iodide, C, goes as far as G; the bromide, B, half-way between G and F, and extends down as far as B; the bromo-iodide, D, extends as far as F in the spectrum. I think I can show you this more directly by photographs taken in the spectrum, in a more accurate manner than is possible in a lecture experiment. When I passed the different silvers over the spectrum, I only passed the haloid salts in the state in which they are usually prepared photographically,

Fig. 4.



but now I wish to show you how different coloured salts of silver can be obtained. Let me take bromide, for instance. Here you have the ordinary form of bromide, such as you saw developed on the screen—the red or orange bromide. By boiling it, as you do with gelatine emulsion, you can change the molecular condition into a grey-blue form, such as you see here. From what I have told you of the principle of work and absorption, you will be quite prepared to learn that these particular forms are sensitive to different parts of the spectrum; so they are, but their maximum place of sensitiveness is but very slightly changed; that is a point worthy of attention. Again, we have two forms of chloride, the ordinary form, which, as a rule, is decidedly yellow by transmitted light; and the other is the blue molecular form, which is got by boiling. Once more, we have the iodide in the yellow form, and also the blue form. Now, I will show you photographs which were taken to show the maximum of the different haloid salts (fig. 5). The first one is the red form of chloride (No. 1), and you see that the maximum sensitiveness is half-way between H and *h* in the violet part of the spectrum; if we go to the boiled chloride (No. 2), you see it has the same place of maximum intensity as the orange, and that the intensity is very great as far down as the yellow line, D. We next come to the red form of bromide (No. 3), and we see that its maximum place of sensitiveness is half-way between G and F. When we come to the blue

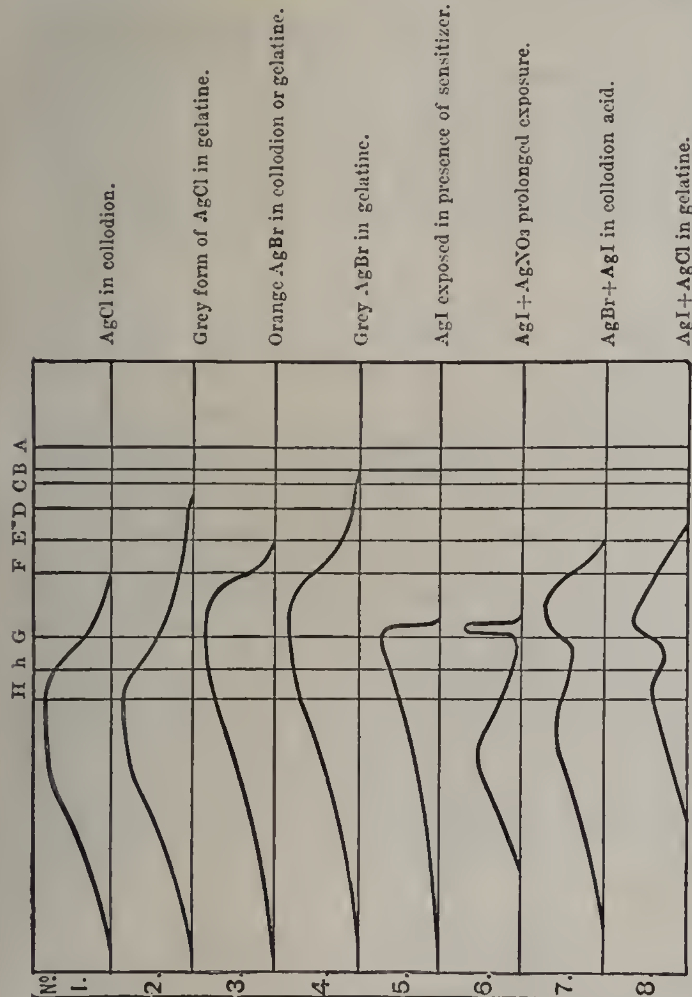


Fig. 5.

form (No. 4), we have an immense extension towards the red; but still it retains nearly the same place of maximum sensitiveness between G and F. Next, we have the yellow form of iodide (No. 5), and it shows that it ends sharply at G. There is no spectrum impressed beyond G. In one case, where I gave it a very prolonged exposure, I got what is called a reversal of the image; but still the iodide spectrum is cut off at that particular point (No. 6).

(To be continued.)

Correspondence.

ANALYSING THE MOVEMENT OF ANIMALS.

Sir,—Permit me to say a few words in reply to Mr. Protheroe's remarks in your last. He admits that Mr. Muybridge's photographic results may be of importance to the physiologist; but the bearing of his remarks would show that artists can learn nothing from the photographs. Seeing that physiologists have been shown by Mr. Muybridge positions never dreamt of in their philosophy, it certainly is obvious that something very novel has been brought before them by these instantaneous pictures of animals in motion. And now as to their relation to artists. I am not going to argue that painters and draughtsmen might learn something by a study of Muybridge's pictures, though I fully believe that they would, and awkward as some of the silhouettes appear to modern minds, the *bas-reliefs* at the Crystal Palace—reproduced, I believe, from Assyrian artists—certainly show one or two positions not unlike the most awkward (?) of Muybridge's. What I wish to point to is a particular reason why Mr. Muybridge should seek to "lecture" artists, to borrow a phrase of Mr. Protheroe.

"Nothing so inartistic, so vilely realistic, as Muybridge's silhouettes can be conceived," howl the chorus of artists. Good. My reply is, there is nobody more illogical, more inconsistant than artists. I mind me of the great controversy about the "Roll Call." Miss Thompson's horse in that picture was fallen upon by a whole army of painters, and their argument was that whether the steed seemed natural or unnatural in the picture, its position was simply impossible. No animal could possibly assume such a pose; the position of its legs was ridiculous—abnormal—untrue. At that time they were all for fact, just as now they are all for art. When, therefore, as the result of his experiments, Mr. Muybridge tells us Miss Thompson was right, and her painter critics were wrong, there is, I contend, some ground for Mr. Muybridge to lecture. Of course, it is still open to any painter critic to argue that Miss Thompson's picture is inartistic altogether; but on this point, fortunately, I need not say a word, for the lady painter has certainly more supporters among artists of high rank than she has detractors.—Faithfully yours,

Brighton.

Dear Sir,—For the sake of truth, and for the benefit of credulous mortals, statements such as those made by Mr. Muybridge, in his paper to the Society of Arts, on the subject of the attitudes of animals in motion, should not be permitted to pass unchallenged.

Apart altogether from the question of the utility to artists of the photographs themselves, I wish to prove that, wonderful as are the data upon which the above-named gentleman founds his inferences, those inferences, though in a somewhat different way, are more astounding still.

Among other startling novelties, we are asked to believe that a man in running or jumping always alights on the heel first; the horse, we are assured, does the same. Not being very well posted up in the technology of animal mechanism and comparative anatomy, I will leave Mr. Muybridge's quaint and curious specimen of the solidungulata in peace, merely remarking that, as the heel of a man corresponds to a horse's pastern, the ball of his foot to its fetlock, and the point of his toe to its hoof, I fail to understand how a horse is like a man in its manner of alighting on the ground; that is, if the author of the new movements is right about the man.

En passant, allow me to remark that Mdlle. Rosa Bonheur is notorious for her enthusiastic and careful study of animal mechanism and motion, and were all works of art to be looked at with a total disregard of the effect of perspective foreshortening, certain very clever photographs might, like a certain limb, be the object of the fingers of scorn and injustice. Rosa Bonheur is not a photographer—more's the pity for photography—and on the lines laid down by Mr. Protheroe she has done her duty honestly and well.

But to return to my mutton, *i.e.*, man. He can run and jump—naturally, and as men always do—with naked feet, on a course smeared with an ointment composed of butter and black-lead, without soiling his heels. With his toes alone protected, a course of broken glass cannot break his skin. In running to any extent, and in easy high jumping on a level course, birds' eggs, small bladders, and detonating packages attached to the heels remain intact. The *os calcis*, in short, cannot be employed in running and calcining at one and the same time. Had Mr. Muybridge said that 999,999 runners out of every million were very positive that, in running, they never came down on their heels, save when they stumbled, and that the millionth man strained courtesy to a painful extent, he would have been, to my very humble thinking, much nearer the truth than he was.

I was at first sight a good deal puzzled with several apparent discrepancies between instantaneous photographs and facts, but was able in a very short time to see that the sun was absolutely right, and that John Leech, Tenniel, Linley, Sambourne, Corbould, *et hoc genus omne*, were not very far wrong. I do not know whether Mr. Muybridge possesses a coat of arms, but if not, I would suggest, "On a field vert, an eagle, or, displayed, improper highfaluten."

With regard to Mr. Muybridge as a photographer, and Mr. Muybridge as logician, the quotation, to my mind, seems apt :—

"Hic vertex nobis semper sublimis; at illum
Sub pedibus nox atra videt, manesque profundi."

I remain, sir, yours truly, H. B.

GREEN DEPOSIT ON NEGATIVES.

Dear Sir,—Referring to the green deposit on negatives in my last letter, I exposed another plate from the same dozen on a group, developed the same with sulpho-pyrogallol, but used the ammonia-glycerine solution of Mr. Edwards' instead of Nelson's. Result: a beautifully clear and detailed negative. Now that set me thinking, and I came to the conclusion that the plates were not at fault (as some allege). It seems to me to lie between the ammonia and sulphite, or the bromide and sulphite. You know I said I had excess of bromide when developing the negatives I wrote to you about. Could not some experiment be made to prove whether any reaction takes place between bromide and sulphite or ammonia and sulphite of a nature calculated to affect silver bromide? Also, has the glycerine any effect?

The deposit does not seem to have had any effect, except to slow the printing, and I think thereby making the picture harsh. I may mention that since writing my last I have removed the deposit by some hours' soaking in common alum and citric acid.—I am, faithfully yours,

W. E. D. Jones.

IODIDE IN EMULSION.

Sir,—Captain Abney does not seem to have grasped the point of my letter which appeared in the Photographic News of the 21st. I did not say that iodide made an emulsion quicker; on the contrary, I have found that a small quantity, say 1 per cent., did not slow the emulsion sufficiently to be of any great disadvantage, but a large amount slows in proportion to the quantity used, *i.e.*, when the iodide and bromide are formed together; but if made separately and mixed before coating, the same result is not produced. I have lately made a batch of emulsion (purposely slow) which gives such density, that plates when developed with 1 8th grain of pyrogallic are too dense in the high lights before the half tones are sufficiently developed. Had I added 75 per cent. of iodide emulsion, coated very thinly, or mixed other substances that would separate the bromide, the density would have been reduced (closeness and fineness of deposit tends to give greater density).

I have long known, although contrary to the recognised theory, that a wet collodion negative is softer when developed with a weak reducer. I have fully developed a 5 by 4 negative with 5 minims of a 14 per cent. solution of sulphate of iron, without requiring any great increase in exposure.

It would appear that a small quantity of iodide in a bromide emulsion, when cooked a long time, will have the same effect as a larger quantity emulsified a short time. I do not take colour as the proof, but actual working; nor have I formed any definite theory to account for this, for it seems that the iodide has the power of re-converting bromide into iodide. Captain Abney does not explain what he means by "not getting clean negatives with pure bromide." If the shadows are not clear, then I can only suggest an unsafe light by which the plates are prepared, or over-exposure.

I may add another advantage in using iodide mechanically mixed with bromide of silver—viz., it acts like a screen of yellow glass to the more sensitive compound, especially the under strata.

I have lately improved a method of cold rapid emulsification, by which, in one hour or less, according to temperature, an emulsion can be made giving plates twice the speed of any plate in the market.

I intend to give the formula and discuss the merits of the same at the next meeting of the London and Provincial Photographic Association on Thursday, the 10th, when all interested are cordially invited.—Yours truly,

A. L. Henderson.

DRYING NEGATIVES.

Dear Sir,—In reference to your recent leader, I may mention the following as an aid to expedite the drying of gelatine negatives.

My plan is to merely use a squeegee of pliant rubber or chamois leather to expel the loosely adherent water from the film.—I am, dear sir, yours truly, A. W. Hosmer.

STAINS ON GELATINE NEGATIVES.

Dear Sir,—Having heard so much said of late about the stains on gelatine negatives caused by the use of pyrogallic acid in development, I may be excused for throwing in a small mite for the benefit of my fellow-workers.

If a plate, after fixing, shows a brown or yellow stain, place it, after washing, into a dish containing a very dilute solution of nitric acid, when all stain will immediately disappear, and a clear, bright negative will be the result. Over-dense negatives are easily reduced in the same manner. It may also be applied to parts of negatives with effect.—Yours faithfully, J. E. Walker.

Proceedings of Societies.

Liverpool Amateur Photographic Association.

The monthly meeting of this Association was held on Thursday, the 27th instant, at Clare Mount, Wallasey, the house of the Rev. H. J. Palmer, Hon. Secretary.

The members met in considerable force on the landing stage, and it had been arranged that a competitive trial of the numerous instantaneous exposures devised by associates should be made on the way to New Brighton. An inexorable downpour of rain, however, rendered instantaneous work out of the question, and the members made the best of their way to the place of meeting to enjoy the hospitality of Mr. and Mrs. Palmer.

At the evening session the Rev. T. B Banner took the chair. The minutes of the June meeting having been read and confirmed, the Hon. Secretary read a communication from the Hon. Secretary of the Photographic Postal Society.

The Rev. H. J. Palmer asked the members present to give the result of their experience with the sulphite of soda developer.

Mr. J. H. T. Ellerbeck thought it utterly useless, except in cases of incorrect exposure.

Mr. E Twigge spoke somewhat strongly in its favour.

Mr. R. Crowe had exposed a plate and then divided it into two pieces, one of which he developed in the ordinary way of pyrogallic, and the other with the sulphite developer. The former portion resulted in a perfect negative, but the latter was dirty and fogged, and had to be greatly forced with ammonia.

He thought that in many cases a peculiar greyness and smokiness affected the film.

Mr. P. H. Phillips said that he found the presence of sulphite of soda in ferrous oxalate of no advantage to the development, but of unquestioned value as a preservative of the developer. He added that he had found Captain Abney's accelerator of great use in the case of some plates of his own make. In order to show the effect of this preparation, two plates were exposed and developed under precisely similar conditions of time and light and developer, one of the two having previously been treated with the citrate of silver solution. The latter on development had proved very much the better negative.

Mr. Ellerbeck proposed that a Council meeting be held at an early date to select the presentation print for 1882, so that it might be delivered to the members at the annual meeting in November.

After some discussion, the resolution was seconded and carried. It was, however, decided by a vote of the members present that the selection of the presentation print should not be made until after the November competition.

Mr. E. Newall asked the Hon. Secretary if he could give any further information on the subject of Morgan's paper for negatives.

The Rev. H. J. Palmer said that it would be in the recollection of members present that during the last meeting a telegram had been received from Messrs. Morgan announcing an important discovery just made by them, which would result in a considerable improvement in the paper in question, and of which particulars would be transmitted in due course. He had written again and again to Messrs. Morgan and Kidd for the promised particulars, in the hope that he might have taken some of the paper with him on his annual tour in Switzerland. No further particulars had been received from Messrs. Morgan and Kidd, and not even an acknowledgment of the receipt of his inquiries.

Mr. E. P. Houghton, on a discussion arising as to the time and place of the next summer meeting, invited the Association to meet at his house, Stonebye, New Brighton, during the month of August.

The Chairman proposed that Mr. Houghton's kind offer of hospitality to the Association should be accepted, and this was carried *nem. con.*

Mr. Ellerbeck having exhibited a fine series of prints, resulting from negatives taken during a recent tour in Germany, remarked that clouds seemed to be unusually easy of attainment in landscape negatives this year.

Mr. H. N. Atkins exhibited a very clever instantaneous shutter of his own devising and manufacture, for use between the lenses of a doublet.

Messrs. Newton and Co. sent for exhibition a shutter of the simplest construction, to be used between the lenses of a doublet, or in the place of a diaphragm in a single lens.

The Chairman proposed a vote of thanks to the Rev. H. J. Palmer for his hospitality, and the meeting shortly after separated.

London and Provincial Photographic Association.

A meeting of the above Association was held on Thursday, the 27th ult., Mr. J. J. Briginshaw presiding.

Mr. G. Smith exhibited an alpenstock camera-stand which he termed the Brattice stand; its weight was one pound three-quarters; the principal improvement was the introduction of a second strut in the leg, which gave it great rigidity, the struts being alternately pull and thrust; and another improvement was that instead of the pins of the head going through a plate into holes in the wood, sockets were soldered to the plate, and so prevented any shaking.

Mr. Cowan exhibited negatives made from parchment jelly prepared by Mr. A. Collier; he found it gave a good emulsion, and kept the bromide well in suspension, the difficulty being that it gave pits.

Mr. Brown had also tried a sample of this jelly, and preferred it to any gelatine he had yet tried, if he could only get it strong enough.

Mr. Collier said it could easily be made stronger by adding more cuttings, and at the request of the Chairman he gave the method of preparation, which was as follows:—Wash 3 pounds of parchment cuttings first in hot water then in two or three changes of cold water, then boil in three quarts water for three hours, carefully skimming it from time to time, then strain through three thicknesses of flannel. His idea in using it in a jellified state was that there was no risk of decomposition while drying; it did not decompose during the boiling process. With reference to the pits he attributed them to grease, and thought that if Mr. Cowan had cut the top and bottom parts off, and only used the centre portion of the jelly, he would not have been troubled with these plague spots.

Mr. Brown thought that pits are caused by some portions of the emulsion setting quicker than others.

Mr. Henderson attributed them to carbonic acid gas caused by the plates taking a long time to set; he had tested for grease by keeping gelatine in a liquid state for some days, then allowing it to set, and cutting away the top and bottom portions; but this did not save the pits.

Mr. Cowan said he had prepared an emulsion from a bottle of solution handed him by Mr. Henderson; he had followed the direction for making a plate as rapid as an ordinary commercial plate. He only used heat sufficient to dissolve the gelatine, and let the emulsion stand for one hour. He gave a plate the same exposure as a commercial plate, and found they were both alike, the plate prepared from Mr. Henderson's solution being, if anything, the more dense.

Mr. Henderson promised at the next meeting to give the details of the process. He then exhibited a number of negatives taken without a lens, but by a pin-hole in a piece of cardboard. His first exposure was fifteen seconds, but he had now reduced this to five seconds; he had also taken a number of negatives in an ordinary plate-box; he first made a hole with a needle in the side of the box, but found that the thickness of the wood obstructed the field; he then cut a hole in the box and substituted a thin piece of brass with a pin-hole in it. With this instrument he obtained very good results, the figures in the streets being sharp.

Mr G. Smith found that, to get a fair picture, it was necessary to give a long exposure; but did not see any reason why, for ordinary amateur work, the system should not be used.

Mr. Haddon, speaking upon the theory that the image of the last thing seen by a person dying a violent death is depicted upon the retina, said that experiments had been made in Germany which cast light on the question. A rabbit's eyes were bandaged; it was then placed so that it looked full at the window which illuminated the room, and the cloth was removed from one eye. The head was then cut off and removed into a darkened room, when a perfect representation of the window was depicted on the retina. The dead eye was then exposed in the same way, with precisely similar results. The image can be fixed by soaking the retina in alum. If the light is yellow, it has little or no effect on the visual purple.

Lieutenant H. Dockrell, R.N., Dr. Stracey Forrest, Messrs. Henry Stevens, Horatio W. King, and G. I. Lee, were elected members of the Association.

This being the first committee night, the following gentlemen were elected as officers for the year ensuing:—

Trustees.—A. L. Henderson and W. E. Debenham.
Treasurer.—W. B. Prestwich. *Curator.*—A. Haddon.
Secretary.—C. B. Cutchey.

Talk in the Studio.

The Guilds Examination.—Captain Abney, R.E., F.R.S., examiner in photography, says: "I cannot report any improvement in the result of the examination. Some of the candidates who sat knew absolutely nothing either of the practice or theory of photography; others showed a practical knowledge of the gelatine process, and of that alone, showing that their training had been neglected. On the other hand, there are some exceptionally well-answered papers in both grades, and these show that in some cases the teaching has been sound, and the practical work well carried out."

The Wedge Photometer.—In a communication to the American Academy of Arts and Sciences in May last Prof. Pickering has some remarks upon the use of a wedge of shaded glass as a means of measuring the light of the stars. He considers that, while it has been maintained by some writers that it is not a new device, "the credit for its introduction as a practical method of stellar photometry seems clearly to belong to Prof. Pritchard, director of the University Observatory, Oxford." Various theoretical objections to this photometer have been advanced, and many sources of error suggested, but Prof. Pritchard has made the best possible reply to them by measuring a number of stars, and showing that his results are in very close agreement with others obtained elsewhere by wholly different methods. His photometer "consists of a wedge of shade glass of a neutral tint inserted in the field of the telescope, and moveable, so that a star may be viewed through the thicker or thinner portions at will. The exact position is indicated by means of scale." The measure of the brightness of the star is made by bringing it to the centre of the field and moving the wedge from the thin towards the thick end until the star disappears. Stars must always be kept in the centre of field to insure the readings being comparable. But Prof. Pickering makes the ingenious suggestion that this photometer may be further simplified by substituting the earth's diurnal motion as a measure of the position of the star in the wedge at disappearance. "It is only necessary to insert in the field a bar parallel to the edge of the wedge, and place it at right angles to the diurnal motion, so that a star in its transit across the field will pass behind the bar and undergo a continually increasing absorption as it passes towards the thicker portion of the wedge. It will thus grow fainter and fainter, until it finally disappears." Then the interval of time from the passage behind the bar until the star ceases to be visible becomes a measure of its light, and the time will vary with the magnitude. As in Prof. Pritchard's form of the instrument, it is only necessary to determine the value of a single constant. Prof. Pickering adds some suggestions with regard to observations with this photometer, and recommends them to the attention of amateurs.—*Nature.*

Cooling and Air-purifying Apparatus.—A new method of cooling rooms by what may be termed a chemical lung, or punkah, might prove useful in India and other tropical countries. The following is a description of the apparatus:—Attached to the frame of the punkah is an endless blind, passing round rollers, at the top and bottom. The bottom roller is a trough, which contains a solution of a caustic alkali. At the very swing of this punkah a wheel and ratchet arrangement causes the rollers to revolve, thus drawing the sheet or blind through the solution. The wet sheet, swinging to and fro, takes up from the air the sulphurous and carbonic acid gases, as well as some organic matter. Brought to the test of experiment, this plan appears to work successfully. In a small room, 18 feet by 15 feet, and only 8 feet high, fifty jets of a gas-stove were set burning for an hour, with the windows and doors of the room closed, and to make it still further unfit for animal life, a quarter of an ounce of sulphur was burnt in it. The punkah, charged with caustic soda, was here set to work, and in ten minutes the temperature was reduced from 85° to 70°, and the air was made sufficiently fresh and pleasant for twenty persons crowded in the room.

Dangerous Device in Shape of a Cigar Lighter.—The following letter from the *New York Public Ledger* is reprinted in the *Chemical News*:—"Mr. Editor,—As I stepped from the platform of a car this morning (corner of Seventh and Filbert Streets), I came upon a motley crowd, listening to the harangue of a bright fellow, who entertained his audience somewhat after this manner:—'Only five cents. I offer you, gentlemen, something entirely new—a new kind of cigar-lighter. Cut off a small piece (about the size of a pin's head), place it upon a cigar or the contents of a pipe, as I do now, apply a drop of water, and it will at once take fire. We generally use water to *put out fire*, but here I will use it to make a fire,' and then, dipping the pointed open knife into the gutter, the orator touched with it the bit of cigar-lighter lying upon the tobacco, and, presto! it took fire almost immediately, and burned with an intensely yellow flame. The vendor continued, 'Once kindled, the flame will not go out till your pipe is lighted. Only five cents.; who'll take the next?' The writer of this took 'the next,' with the view of examining the contents of the vial and reporting to you, The vial (an '$\frac{1}{8}$th homœopathic vial,' covered with marble paper), contained several very small sticks of the metal sodium. Little did Sir Humphrey Davy imagine, when he made his brilliant discovery of the alkali-metals, that ere the close of the century one of them would be hawked about the streets to light cigarettes and pipes. Insurance men can tell a sorrowful tale of the loss of life and property caused by the household use of friction matches. But what if papa should leave within reach of the children metallic sodium, a material that must always be handled with great care, even by those best acquainted with its properties. I trust that you will give the above immediate publicity, that people throughout the country, being forewarned, may leave the 'new cigar-lighter' severely alone, and that our efficient mayor may, if possible, prevent the retailing of metallic sodium in the streets of Philadelphia.—Yours, &c., R. A. Fisher." [Some three or four years ago sodium was sold in the streets of London as a cigar-lighter.—Ed. P.N.]

To Correspondents.

*** We cannot undertake to return rejected communications.

W. Hart.—It is impossible not to feel thankful that there is at least one bright spot in the general darkness. We have made a note of it, and sent your letter to the offending parties.

W. C. Tate.—It is an insoluble basic per-sulphate of iron, and we presume that the solution from which it was filtered worked fairly well.

Engraver.—Thank you for calling our attention to the paragraph. We had already recognised it as having been reprinted from the Photographic News, notwithstanding the circumstance of it being accredited to another publication.

Peter Collins.—You can only register a device or design, not working improvements. In your case the only way will be to take out a patent.

Enquirer.—Notwithstanding what you say, we have but little doubt that they arise from defects in the glass. It is not a rare thing for numerous specks of imperfectly vitrified material to exist on the surface of a plate, and if these particles contain excess of alkali, defects are almost certain to arise.

T. B. E.—You will find full particulars as to its preparation on page 546 of our last volume.

B. Biden.—1. When it is treated with strong nitric acid, metallic silver is dissolved out. 2. By a prolonged treatment with *aqua regia* (nitrohydrochloric acid). 3. When the melted iodide of silver is allowed to cool, a notable contraction occurs at the solidifying point, and the solid iodide contracts regularly until the temperature of 142° Centigrade is reached, when it expands considerably and becomes crystalline.

N. O. P.—1 It is well to remove the size as completely as possible by repeated treatments with boiling water. 2. It is caused by the gradual crystallisation of the material. 3. No.

Samuel Baker.—1. For your purpose it is best prepared by heating the usual mixture of potassium chlorate and manganese dioxide, and it is just as well to pass it through a wash bottle containing water. 2. Troublesome and uncertain.

W. J. W.—There have been many well authenticated cases in which fatal poisoning has resulted from absorption through the skin, and you should take care to always wash your hands very thoroughly immediately afterwards.

A Troubled Amateur.—So purely and entirely a matter of taste as to be beyond our province. As an amateur, who does the work without pay, you may legitimately carry out your own ideas. Were you a professional photographer it would be policy to consult the wishes of your customers as far as practicable.

Vera.—1. Follow one set of directions or other, but do not attempt to effect a compromise between them. 2. It is your own fault, as you were cautioned beforehand. Throw all down the sink, and try again.

Thomas Arnold.—Results of highest excellence have been obtained, but few persons have been uniformly successful.

John Farmer.—The MS. and specimens are to hand, and shall be attended to immediately.

W. Oppenheimer.—1. Rather wide of the mark. 2. Certainly not, as it contains a large proportion of gold. 3. Quite the reverse. 4. The thinnest kind in the market will suit your purpose. 5. Dilute with about three times its volume of water. 6. An efficient mill is required; one of the most convenient kinds consisting of a pair of granite rollers revolving against each other at different rates. 7. Not at present, as the patent has yet nearly a year to run.

Taunton.—No doubt many others like yourself have dark tents they would like to dispose of, but we fancy customers will not come forward very readily. 2. Glycerine does not injure the bath so long as it is free from impurities; but it is very injurious to the dark slide, as if you saturate the wood with it, the slide will always be damp. 3. The single view lens is generally admitted to be the best, provided that the characteristic defects to which you allude do not interfere.

CONTENTS.

A PHOTOTYPE BLOCK FOR THE PRINTING PRESS.

According to our promise of last week, we place before our readers a specimen of Ive's photo-engraving method as adapted for printing by the letter-press method. The satisfactory production of phototype blocks adapted for

printing together with type has long been regarded as an ideal or goal to be aimed at.

More than thirty years ago Paul Pretsch produced, by his method of inducing the reticulation of a film of bichromated gelatine, some of the finest press blocks which have been yet seen; but those who have practised his process since have failed in obtaining the same depth of tone and vigour. Gustave Re in Berlin, and Dallas in London, now make typographic blocks commercially, and, judging from their appearance, one may conclude that they are made by one form or the other of the Pretsch method.

A very characteristic Pretsch-block print is included in Husnik's recent manual of photo-engraving,* the print in question being a view of the Ring theatre at Vienna, which building was, as our readers will remember, recently destroyed by fire. The granulations, or recticulations, are extremely fine in the case of this print, and the detail is so minute that smalll inscriptions on the adjoining houses are easily legible. There is, however, the fault common to almost all phototypic block prints made from half-tone negatives, namely, the absence of vigour and bold contrasts, the general aspect recalling a print from an over-exposed negative. Pretsch prints are, in ordinary cases, extremely difficult to print from, the grain being so fine as to become clogged up with printing ink unless the greatest care is exercised; and in ordinary cases the difficulty of obtaining satisfactory impressions when the block is worked along with the type at the ordinary machine is so great as to preclude their use for newspaper and general illustration.

The Pretsch process may be modified by the addition of various substances to the sensitive mixture, and the subsequent treatment of the exposed film; but these variations appear to have no importance whatever, as equally good printing grains can be obtained by the use of plain bichromatized gelatine, and soaking in water. The following outline of the Pretsch method for the production of type blocks may be of interest to our readers.

A sensitive gelatinous mixture is prepared by dissolving six parts of gelatine in thirty parts of water, and one part of powdered ammonium bichromate is stirred into the solution. A piece of plate glass, which is all the better for having been previously coated with a collotypic substratum, is now levelled in the drying cupboard—a temperature of about 50° C. being suitable in most cases. When the plate has reached the full temperature of the hot cupboard, some of the gelatine preparation is poured on and spread with a strip of paper, about 30 grains being allowed for each square inch of surface. When the plate is dry it is exposed under a negative, about six times the exposure which would be required for a silver print being given. When the exposed plate is soaked in water, the reticulation and granulation of the gelatine rapidly set in, and in a few minutes an exact reverse of the required printing block will result. The next step is to allow the plate to become partially dry, and to deposit copper on it by the electrotype process so as to form the printing block. It is, perhaps, a more certain proceeding to take an impression from the reticulated film by means of softened gutta-percha, and to send this cast to an electrotyper or a stereotyper to be reproduced in metal.

Our readers will have noticed that a large proportion of the war pictures now appearing in the *Illustrated London News* are *fac-similes* of the original sketches of the artists. It is extremely likely that the existing taste for faithful

* Die Heliographie, von J. Husnik, Hartleben, Liepzig.

representations of distant occurrences will ultimately culminate in the general use of photo-typography for journalistic illustration.

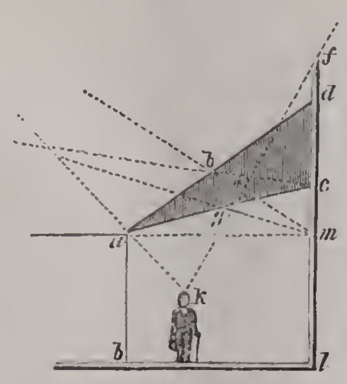
ON THE INCLINATION OF GLASS ROOFS IN THE STUDIO.

Our esteemed friend Dr. H. W. Vogel has lately returned to this subject, and he publishes in the *Notizen* some very interesting remarks that are well worth perusal. Repeatedly, says Dr. Vogel, I have taken the opportunity to speak in these pages upon the construction of studios, and have touched upon nearly all the leading points in the question. I have come to the conclusion that for portraiture a low studio lighted from the north is preferable to all others, a statement which has been confirmed in the course of fourteen years, since the printing of my first treatise and numerous new experiments.

Lately the question of studio construction was again under discussion in the *Verein zur Forderung der Photographic*, and the superiority of a north-lighted studio from ten to twelve feet up to the glass was acknowledged. Another point came up in the course of speaking, viz., the height of the back wall of the studio. This measurement, of course, fixes the inclination of the glass roof. The question is now, whether a steep or slightly oblique glass roof be preferable.

The first point agreed to by the speakers was that a more inclined roof greatly facilitates the flowing off of rain and snow, consequently is kept cleaner than a horizontal surface. A more important question was how the more inclined may be compared with the horizontal with regard to lighting. Herr Reichard, who had lately exchanged his old studio with flat roof for one having a slanting one, declared that with the latter he could obtain harmonious lighting much more easily. In course of the discussion, however, it appeared that the cause of better lighting in Reichard's new studio was to be found less in the loftiness of the roof than in the high situation of the studio itself. The old one was two stories high, and opposite to a lofty building which greatly influenced the lighting on account of the many reflections acting upon the studio. In the new one nothing interfered with the north lighting, and there was no reflecting action to combat with; hence the more harmonious illumination.

Herr Schaarwächter remarked that in working in studios with steeply inclined glass roofs he had found the light was too dispersed, and that, under certain conditions, it was difficult to obtain a distinct shadow side to the face. It is, however, not difficult to compare the effects of a steep with that of a slightly inclined roof in point of lighting, by means of a diagram. Let *a b c* represent the section



of a north lighted studio with roof *a c* inclination one foot in four, while *a d* is much more slanting (rising three feet in four). If the back wall, *l f*, is in both cases the same height, it is clear that a person's head receives the same amount of top light through the open glass roof, whatever may be its inclination. By drawing lines through *a* and *f* meeting at *k*, the angle of light received will be found to be the same, whatever slant the roof may have, as it is regulated by the wall behind. The more slanting roof will assuredly cause less reflection than the other. As, however, blinds are usually drawn down to about one half the length (somewhere about *h*) the difference is practically very slight with regard to the top light.

Of course, with the front lighting, as the roof is raised in inclination, so must the side wall be elevated to the amount of *a c d*. By this means some of the front light is lost, which would otherwise fall on the sitter. This is observable when the roof blinds are drawn up, but scarcely so if they are pulled down, as they usually are. Therefore, under such circumstances, the elevation of the roof but slightly influences the action of direct light.

It is different with regard to light reflected from the back of the studio, *c l*. Take, for instance, a point, *m*, and another at *g*, bisecting *a c*, the angle of light taken in from the flat roof is considerably less than the angle *a m h*. Therefore, with the slanting roof, the back wall is much better lighted. The steeper the roof the greater the reflecting surface.

Herr Schaarwächter is quite right in saying that through the inclined glass roof there is more dispersed light; in certain circumstances this may be desirable: in others, not so.

The discussion next turned on the possibility of having blinds fixed more horizontal than the inclined roof. This has a remarkable influence, as may be seen on referring to the diagram. Supposing the inclination of the roof to be *a d*, and the blinds slanting at the angle of *a c*, it is easily seen that when they are drawn back to *g*, the amount of light which *m* receives is not greater than with a flat roof. By such an arrangement, also, the back wall, *d c*, will be quite shut out, and its reflecting rays will have no effect upon the sitter, *k*. A studio with strongly inclined roof, by having the blinds arranged more horizontally, obtains less reflected light and deeper shadows.

Upon certain occasions the blinds must be fully drawn up—seldom for single portraits, but more often in groups. In such cases, the inclination of the roof takes no part.

COLOURED PHOTOGRAPHS ON GLASS.

BY W. M. ASHMAN.

It has frequently been said that the public have a weakness for colour. Whether a taste in that direction may be considered a weakness when laid on photographs, or otherwise, I do not wish to argue. Photographers will always consider their finest plain photographs to be quite equal to good coloured work, and much better than the majority they come in contact with. The colourist's opinion will be *vice versa*; while the amateur and many others consider it an open question whether photographs should be touched in any other way than ordinary spotting. *Quot homines, tot sententiæ.*

Photographers are grumbling a good deal about the dullness of trade, and, to my mind, they have to blame themselves, and not the public, for there appears to be a feeling amongst them that their productions must be accepted by their patrons just as they choose to serve them up, no matter how that may be, and one may find many instances where the style of work has not considerably changed during the last ten or twelve years. In fact, we do not progress with the times. Observe the difference between a dull-looking draper's store, and one teeming with novelties. In the first case, you may not see a customer enter if you wait for an hour; whilst the other will be blocked with patrons as long as the observer chooses to stay. *A priori*, there must be some reason for this difference, and doubtless it will be found in the fact that the general public thirst after anything fresh. Photographers would do well to draw the moral, for the same all-suffering community seek after novelties in photography as keenly as they do in the matter of dress, and those who can supply the novelties will not have occasion to grumble about the dullness of their business. Take, as an in tance, portraiture by electric lighting. Most of us agree that it is a costly method; but as the public are ready to pay, why should we object? I do not advocate the universal adoption of the daylight extinguisher for our studios, but, for the sake of novelty, I hold that we should stir up our friends, the electricians, to provide us with a suitable and reliable method of lighting by electricity at a cost that will assure us a profit on the outlay, and at some future time I hope to be able to say something more on the subject of electricity in the studio. I could point out numerous instances where the success of an individual has been attained by the early adoption of a new idea, but will content myself by mentioning one or two recent exploits, and I ask pardon from those gentlemen whose names I may mention. Never has there been such a success in photographic literature in so short a time as achieved by Mr. H. Baden Pritchard's "Studios of Europe." And why? Because the style is fresh, at the same time conveying as much information as a book written after the old pattern. Who has not heard or seen the photographs of the "Flying Dutchman," by Messrs. Marsh Brothers; the "Athletic Sports" by Messrs. Hills and Saunders; and last, though not least, "Derby Studies," by Mr. A. L. Henderson? The enormous sales in each of the above cases being sufficient evidence that people are ready to appreciate in a substantial manner anything of real merit and novelty.

As I have previously stated, the public have a weakness for colour, and a highly commendable weakness it is. We have tried to satisfy their cravings in this direction with some exquisite water colour and oil work, also with some that is not exquisite (shall I include collodion transfers covered up, or shall I leave it unsaid?); but there still remains a form of coloured photograph which, if properly treated, looks exquisite, and has to a great extent the charm of novelty. Many have added to the revenues of the Patent Office, and, under different names, the pictures have been produced; but never to my knowledge have they been fairly put before the public of this country, and pushed as cameo vignette and allied shapes were a few years ago. Some time during the early part of last year our Editor gave us a very simple formula for producing these pictures, but I think the artistic conditions therein to be complied with might deter some from making the attempt. Let those of my readers who have not read the article in question turn to page 133, March 25th, last year's volume of the Photographic News, wherein they will find the process briefly described. I have obtained excellent results by this process, but find by a slight modification that I can get still better results. Make up the following: Nelson's No. 2 gelatine, 30 grains per ounce of water, or Henderson's hard gelatine, 15 grains per ounce of water; this is the mounting solution for attaching the print to a glass plate. Next weigh out solid paraffin 2 ounces, white wax 2 ounces, Canada balsam 5 ounces; dissolve on water bath. This mixture is for the purpose of rendering the photograph transparent, and allowing the oil colours to permeate. The other articles required will consist of a stock of crystal glass plates, either in sheets or convex, to suit the fancy; squeegee; rectified spirits of turpentine (spts. terebinth rect.), a bottle of thinning oil (fine poppy oil), an assortment of oil colours in tubes, brushes, palette, &c. Take an unmounted print of warm tone, by preference printed on ready sensitized paper, and place it in a flat dish; the print may be treated dry, but it will be found better to place it in warm water for a couple of minutes previously, then blotting off the superfluous liquid. Warm up the mounting solution, and pour it into the dish. After the print has soaked, say a minute or two, place the glass plate, previously cleaned and dusted, into the solution, and attach the print in the same manner as in making carbon transparencies, gelatinized prints, &c.; or perhaps the best plan would be to put the print down as collodion positives used to be transferred to leather, viz., attach one end to the glass plate held in the left hand under the solution; a squeegee held in the right hand is then drawn gradually up the print, expelling both air and excess of solution by the same operation. The glass plate should be held so that the top inclines outwards, and the print underneath; you can readily see if the work is being carried out satisfactorily. If only ordinary care is taken, no air-bells will form; should there be any, they can be easily removed by drawing the print away from the plate under the solution, and putting it down again. The print should now be covered with a piece of blotting-paper, some flexible material such as American cloth, and well squeegeed. It may now be put aside to dry spontaneously, which, under ordinary circumstances, will occupy about eight hours. It is important that the print be quite dry before the next operation. When thoroughly dry, rub away a portion of the paper with fine sand paper or No. 0 glass paper, working with a circular motion. This not only renders the print thinner, but, in breaking up the outer surface, allows it to be permeated more evenly and readily.

Melt the wax compound on the water bath at as low a temperature as possible, immerse the plate in it, and allow it to remain at the same temperature for half an hour or longer if necessary. When perfectly transparent it should be removed, and when cool enough the excess rubbed off both sides. It is now ready for painting. An ordinary retouching desk is the best form of easel to employ. A certain amount of artistic skill is required to paint the picture thoroughly, but if anyone will try the experiment he will be surprised at the result obtained. Small details, eyes, lips, &c., should be painted on the back of print, using a sufficient amount of thinning oil to keep them transparent. Strong lights, whites, &c., should be also put on the print in body white, likewise the light in eyes. When this has been done, adjust a second plate behind the print, and secure it with gum paper sufficiently to allow of working upon it. Mix body colour with all the colours to be laid on the back of second plate, and, in laying them on, be careful not to go beyond the outlines, otherwise the effect of blurring will take place. If the first attempt is not satisfactory, the colour may be easily removed with a piece of rag moistened with the turpentine, and the operation repeated. When the picture is painted to the operator's satisfaction, all that remains to be done is to bind the two plates together with gum paper to exclude the dust, cover the back up with white paper, and fix it in a suitable frame.

EXAMINATION IN PHOTOGRAPHY.

A fortnight since we published the names of those who had passed the recent examination in photography under the auspices of the City and Guilds of London Institute. We now publish the particulars and the questions.

Instructions.

The Candidate must confine himself to one grade only, the Ordinary, or Honours, and must state at the top of his paper of answers which grade he has selected. He must *not* answer questions in more than one grade.

If he has already passed in this subject, either in the first division of the Elementary, or in the Advanced Grade, he must select his questions from those of the Honours Grade.

The number of the question must be placed before the answer in the worked paper.

A few questions accurately and fully answered will secure higher marks than a large number of questions imperfectly answered.

Ordinary or Pass Grade.

1. Describe the manufacture of pyroxyline, giving a formula which will produce one suitable for wet plates. As far as you can, describe the chemical changes that take place.

2. State the reason of the addition of iodide of potassium to a

wet plate sensitizing bath, and show your practical acquaintance with the wet process by giving a formula for such a bath suitable for hot weather.

3. Give an outline of the platinotype process, and, as far as you are able, the theoretical explanation of the reaction that takes place in developing the image.

4. What are the drawbacks, if any, to a lens which embraces a very wide angle?

5. How should you prepare a gelatine emulsion to give slow plates? Give a detailed description of the process you would adopt.

6. When a stereoscopic negative is printed, the two pictures have to be divided, and reversed as regards right and left. Show why this is.

7. When silver chloride is exposed to light it blackens. Describe what happens to this darkened chloride (1st) when treated with nitric acid, (2nd) with sodium hyposulphite, (3rd) with ammonia.

8. What are the chief characteristics of silver iodide, bromide, and chloride when used photographically? Describe them as fully as you can, more especially as to their behaviour with acid and alkaline development.

9. Give the theory of toning as far as you know it, and detail any experiments which may throw a light on it.

10. Describe a process for the production of developed paper negatives, giving a detailed account of the mode you would adopt of developing the image.

11. A carte-de-visite negative is handed to you from which a 12 by 10 print is to be produced for colouring upon. How should you execute the order?

12. I have two lenses, one of 12-inch focus, and another of 8-inch focus, and I have to make a copy of a map of exactly equal size. I find that with the first lens I have to use a diaphragm (stop) having an aperture of $\frac{1}{4}$-inch diameter to get good definition, and with the other a diaphragm having an aperture of $\frac{3}{16}$ inch diameter to attain the same definition. Give the relative exposures necessary, supposing the light not to vary.

13. I wish to make an emulsion which shall contain 10 grains of silver iodide, 100 grains of silver bromide, and 15 grains of silver chloride. How much of sodium chloride, ammonium bromide, potassium iodide, and silver nitrate must I weigh out from these quantities. The combining weights may be taken as follows:—

$Na = 23$ $N = 14$ $Br = 80$ $K = 39$
$Cl = 35{\cdot}5$ $H = 1$ $I = 127$ $Ag = 108$
$O = 16$

Honours Grade.

1. Give the plan you would adopt to ascertain the effective aperture of a doublet lens when a stop is used.

2. Show how you would calculate a "table of enlargements" with a lens of 12 inches equivalent focus; give the distances of the conjugate foci, from the optical centre of the lens, when enlargements of 3 and 7 times the original have to be made.

3. Give your explanation of the matt stains which sometimes occur on a wet plate negative when the plate is kept a considerable time before development.

4. Give the theory of ferrous-oxalate development, and give the different methods of preparing the developer.

5. In a gelatine emulsion there is usually an excess of soluble bromide after washing. What effect will this have on the sensitiveness of the plate, and trace theoretically the reasons of the modifications it may induce.

6. Describe in detail the reproduction in photo-engraving on a copper-plate of a line engraving.

7. A phosphorescent tablet emits light which has no violet or ultra-violet constituents. If this source of illumination be used with a sensitometer, it is found that a wet plate is only $\frac{1}{10}$th the sensitiveness of a gelatine plate, and yet when the former is compared with the latter by exposure in the camera, it is found that no such difference exists. Explain the reason of this, and also describe the mechanical details of some sensitometer, showing how you would obtain the values of the graduation.

8. It sometimes happens that silver nitrate contains impurities; how should you detect them? State how you can obtain pure silver nitrate from ordinary silver coins, giving details of the operations that would have to be gone through.

9. Write out, as far as you can, an explanation of solarization, halation, and reversal of the image on a photographic plate.

10. When you mix sodium hyposulphite with a ferrous-oxalate developer, what chemical reactions occur?

11. I have an emulsion containing silver bromide. I apply to six different portions of it the following:—Chlorine water, iodine water, bromine water, and solutions of iodide of potassium, chloride of sodium, and bromide of ammonium. What will happen in each case?

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

A Tour in the Thuringian Forest.*

A three hours' walk from Eisenach brings you to the little market-town of Ruhla. Ruhla is noted for its meerschaum pipe factories, and there is not a tobacconist, however humble, in this country, who has not heard of Ruhla meerschaum. The way lies past the bald, long-backed Hörselberg, where, as everybody acquainted with Tannhäuser knows, the goddess Venus holds her court. A shrubless, uninteresting mountain to look at, one scarcely feels tempted to waste a film over it; still, the other day, when we witnessed Tannhäuser at her Majesty's Theatre, and saw the Hörselberg depicted like one of the sharply-peaked Dolomites, we certainly wished we had a photograph to forward to the scenic artist with our compliments. The Wartburg, too, was shown in the scene like a red-brick Elizabethan mansion, we remember—a still more unpardonable error. If a poet or composer localizes his legend in some romantic district, in order to add to its interest, surely it is not for the scene-painter to do his utmost towards spoiling the story again.

A few miles past the Hörselberg, where a bit of grey cliff is seen through an opening in the green trees, is the Wittgenstein, of which you certainly must get a picture. If you can secure a little out-building or cottage in the foreground, all the better; for, truth to tell, it will help to make a picture, for the rock and foliage are scarcely material enough. There used to be a castle upon the rock, so they say, in which a baron once lived with a lovely daughter. The lovely daughter was, of course, in love, and every evening a dapper young knight came a-riding to see her. There was to be an elopement, only the baron found it out just in time, and slew the cavalier as he rode towards the castle to fetch his bride. The body was brought to the young lady, and, as was only to be expected of her, she died outright at the sight of it. For a long time afterwards the slain knight came riding a coal-black charger to the Wittgenstein at night, wandering through the castle searching for his lost love; and it was only with the aid of the Evil One that the baron was at last successful in banishing him to another height—the Rittersberg—which lies not far off, and where he is still to be met in the small hours upon his sable steed. The princess, however (for so she is usually called now), still inhabits the Wittgenstein, and is evidently a person well worth knowing; for one night some musicians returning home to Ruhla stopped at midnight under the rock, and serenaded her. Scarcely had the first note sounded than a little old man, with a grey beard, appeared, and asked for whom the honour was intended?

"The Princess of Wittgenstein," was the reply.

"Very good!" said the dwarf; "play on!"

The musicians obeyed, and gave the princess such a concert as she had not heard for many a day, and when it was all over, out came the dwarf again, and presented each with a freshly-gathered sprig of oak. Some toyed with the branch, and pulled off the leaves one by one, while others carried them awhile, and then threw them heedlessly away. Only one pinned the twig carefully in his hat. He soon forgot all about it, however, and he was startled next morning when his wife asked him what the

* Continued from page 453.

yellow thing was he brought home with him last night; then he came to look at it more closely, and found the oak twig had turned to burnished gold. The others, of course, ran off to search for the leaves they had thrown away, but the branches were nowhere to be seen.

Ruhla is full of quaint pictures, the houses, built of black oaken beams and white plaster, being peculiarly well adapted to the camera. It is a long straggling street at the base of a green valley, and on either side rise smiling gardens and verdant woods. A clear little brook runs through the middle of the street, dividing the Duchy of Saxe-Weimar from that of Saxe-Gotha, so that the opposite rows of houses belong to two different dukedoms.

One of the principal heights of the Thuringian Forest, the Inselsberg, some 3,000 feet high, is close to Ruhla. Indeed, you can ascend it in three hours hence. There is a capital view of the Thuringian Oberland, and a good hostelry now exists, where one may pass the night comfortably. A carriage drive leads thence in a couple of hours to Rheinhardts-brunn, where the Duke of Gotha has a palace, and where his brother, the late Prince Consort, resided for many years before he found a home among us.

Rheinhardts-brunn is well worth visiting, with its castle and pretty flower gardens hidden away in the depths of a thick forest, like Rosamond's bower. The patches of green meadow-land and mountain streams that make this portion of the Thuringian Forest so picturesque, render it also pre-eminently a game country. Deer are still common in Thuringia, as are also wild boars, while the roebuck is to be met with very frequently. Even bears are not unknown, and at the Wartburg some years ago was an animal that had been captured in the forest.

A pretty spa—Bad Liebenstein—is not far off, reached in a short drive through the forest roads. In the summer there is quite a fashionable company here, and as Saxe-Meiningen is close by, the Meiningen dramatic company, which made a sensation in London last year, frequently come over to play. But the place is a little too trim to please—we secure a photograph of the Hotel Müller, which looks like a palace, so that we may boast a bit of its grandeur to our friends when we get home—and the photographer will do better to take his camera into Altenstein (another principality), three miles off, where there are some wonderful natural rocks and a cave of colossal dimensions.

From Liebenstein, by rail and trap to Schmalkalden—a most picturesque town, but very dirty—and thence on foot to Oberhof, leads one into the Oberland of Thuringia. Let not the photographer in his wanderings hereabout, when a day's journey may take him into three or four different dukedoms, omit to get a picture of one of the old toll-bars or frontier-bars, which still exist in many parts of the country. They are "bars" in fact, as well as in name, and they are oft-times very ingeniously constructed. They are weighted at one end, generally with a big stone which keeps the bar open, while a chain at the other extremity permits the bar to be pulled down with the utmost ease. Here is a picture of such an one. The Germans are

a somewhat phlegmatic people, and like to take things easily, and toll-bars are therefore usually so constructed that the toll-keeper need not go out of doors to close the thoroughfare; and he generally expects those who pay toll to hand it in to him at the window, so as to reduce his trouble to a minimum.

Of the inn at Oberhof—the village stands at as high an elevation as Chamonix—we take a picture, but not of the duke's shooting box (we forget, by the way, which principality we are in, we have changed so many times), for we find it to be indeed nothing but a square box-like edifice of white plaster when we have brought the camera to the spot. The wind blows very keenly up here, and the efforts we make to keep our little camera steady are not very successful. It will not bear more than a few pounds' weight of granite, and these fail to give perfect rigidity. Absence of contact between the base of the camera and the triangle is often a cause of shaking, and we have found the wedging of paper or of a rubber washer between to improve matters vastly. But the best plan to secure rigidity is to have a camera and triangle—or, better still, base-board—so true, that perfect contact is ensured throughout. One wants the camera to rest upon as broad a base as possible, and for this reason the ball-and-socket joint met with in many French cameras is unsuitable for out-door work. They are convenient, and may be serviceable, if ball-and-socket are pretty big, for the studio; but directly the apparatus is exposed to the least wind, it shivers like an aspen leaf. To the out-door photographer, stable apparatus is indispensable, and one of the first things to be done with a new camera and stand is to see that they fit closely together, and that the camera is upon a tolerably broad base.

From Oberhof, another day's walk in the forest, over the Schmücke, where there is a better inn than at Oberhof, and a most delightful view, leads to Ilmenau. This little town was a favourite resort of Goethe, and on the Gickelhahn hill, up which we climb, is a little summer-house where the great German poet dwelt, and where he wrote many of his poems. In fact, his Ode to Night, or *Nacht-lied*, was scribbled one evening on the door of the wooden erection, and from time to time he was wont to renew the pencilled characters. After his death, the authorities, anxious lest any harm should come to the relic, had the handwriting photographed, and it is very well the precaution was taken, for but a few months afterwards the house, or a great portion of it, was destroyed by fire. Here is the poem :—

" Ueber allen Gipfeln
Ist Ruh'
In allen Wipfeln
Spürest du
Kaum einen Hauch.
Die Voegel schlafen im Walde ;
Warte nur balde
Ruhest die auch.

The little hut has been renewed, and, setting up our camera among the pine stems, we secure a picture of the primitive habitation. It is quite at the top of the hill, and, as far as the eye can reach, there are the waving pine tops over which Goethe must ofttimes have gazed when he took up his solitary habitation here in the Thuringian Forest.

We have left one of the finest "beauty-spots" to the last. This is Schwarzburg, a sylvan retreat in the principality of yet another princekin—His Serene Highness of Schwarzburg-Rudolstadt. Schwarzburg is within a day's walk of Ilmenau ; but, as the walk is not very inviting, we recommend a drive. Schwarzburg has a palace and a very good inn, and from the hostelry you enjoy one of the finest forest views in Europe. We may say that not even in the Black Forest have we beheld such leafy luxuriance, such a vast wealth of undulating foliage. It is as if one were surrounded by a sea of waving boughs and dark green branches, the palace of gleaming white upon one one of the eminences standing out like a rock in mid-ocean. A solitary fox, his long tail sweeping behind him, may be seen scampering across some deep-shadowed vale, and roebuck in twos and threes come out to feed in the soft green glades that fringe the forest. Schwarzburg has acquired a great reputation of late, and therefore hotel expenses are rather heavier than in Thuringia generally ; but you may dine off wild boar or forest venison, and drink better wine than they give you at most of the hotels on the Rhine, at a less cost than these pretentious hostelries are in the habit of charging.

ON GREEN FOG.

BY HERBERT B. BERKELEY.

The great importance of this subject may, I hope, be my excuse for again returning to the question of green fog and its causes, real and alleged.

I do not altogether admit that the development must be "forced" with ammonia in order that green fog may appear. Even with a mildly alkaline developer, hardly capable, one would think, of dissolving bromide, with some plates green fog is produced ; though I admit that with under-exposed plates and long development it occurs in its worst form.

Then, as to the theory of bromide in solution being the cause, for which we are indebted to Captain Abney, and which certainly seems exceedingly plausible. Have we not heard of green fog produced by ferrous oxalate? Captain Abney believes that in all these cases hyposulphite has been added to the ferrous oxalate. Perhaps so ; I have no knowledge one way or the other. But we have also read a statement to the effect that carbonate of soda not only produces "pyro. stain," but also may cause green fog. Presuming this to be the case, what shall we say to the solution theory? Shall we say that, when bromide of ammonium is used, carbonate of ammonium is formed? Or shall shall we put the solution of the bromide down to the soluble bromide pure and simple.

Captain Abney cannot concede that ferrous oxalate produces a grey fog where alkaline pyrogallol would cause a green fog ; but when we treat a not too virulent case of green fog with ferric oxalate, and then re-reduce with ferrous oxalate, is not the result of such a nature as to make the ordinary observer declare that the "fog has all gone"? It is the peculiar character given to the reduced silver by the pyrogallol that makes the fog so evident. Had ferrous oxalate been used, the fog would have escaped notice, and *perhaps less* silver would have been reduced.

I have observed that when green fog is treated with ferric oxalate, the silver being re-reduced by a weakly alkaline developer, the green fog returns in pronounced form. Of course, this may be said to favour Captain Abney's view, for silver oxalate is very soluble in ammonia. The experiment would be worth trying, using only pyrogallol and carbonate of soda as the reducer, for, I believe, carbonate of soda is not a solvent.

Captain Abney very truly states that some gelatines result in green fog, while other kinds do not—at least, so it would appear. Perhaps it might with still more truth be said that less rests with the gelatine than with the treatment that gelatine—or, more particularly, the emulsion—has received, for we find plates made with a certain batch of gelatine sometimes giving green fog and sometimes free from it—at least, I understand this to be the case. We also find one man swearing by a certain make of gelatine, while another condemns it altogether.

One thing I cannot quite get over in regard to the "solution and deposition theory," and that is the fact that with certain plates, and, perhaps, with certain gelatine, green fog is absent, though a strongly alkaline developer may be used. Now, adhering to the theory, we must presume one of two things: either that the gelatine prevents the solution of the bromide, or that the bromide is not in a very suitable state for solution ; or, on the other hand, that the silver dissolved is restrained by the nature of the gelatine from depositing itself on the surface. In connection with this hypothesis it has occurred to me that perhaps Colonel Stuart Wortley's collo-glycerine restrainer might be of advantage for replacing the soluble bromide in the developer. It would seem likely that a colloid restrainer would do much in preventing the deposition of silver. At the same time, a less liberal dose of sulphate of ammonia than is contained in Colonel Wortley's solution might be advisable with sulpho-pyrogallol, for the sulphate is itself a restrainer of a powerful character.

Returning to the "deposition theory," if we allow that a certain portion of bromide is dissolved, but not deposited again on the film, we must look for it in the developer or on the sides of the dish or of the developing-glass. Can it be that it has in these places escaped our notice? *

For my part I am inclined to believe that there is a state of the gelatine which especially favours the reduction of the silver salt when the developer is applied ; and when pyrogallol is used it lends a character to the reduced silver. It may be, too, that the silver thus reduced forms a convenient nucleus for any silver which may be dissolved by the developer ; but I take it, this latter is not the cause of the appearance, but merely a secondary action following upon it.

Is it really true that manufacturers are at their wits' ends with regard to green fog ; and are they despairing

* It may, of course, be supposed that when the plate is in a suitable state the *whole* of the silver is deposited on the *image*, no matter how broad the spaces unacted upon by light may be ; and that only when a plate entirely unacted upon by light is placed in the developer would, what I will call, the abnormal deposition ensue, the deposit in this case being, possibly, rather grey than green. With dry collodio-bromide, and with both alkaline and hydrosulphite development, it was no uncommon experience, when forcing a plate, to find nearly all the bromide dissolved away, these parts becoming grey and transparent ; yet neither the density of the image (which was generally thin) nor the deposit on the shadows, was suggestive of a deposition action. Indeed, not many years ago, I believe the "deposition theory" of alkaline development was considered rank heresy. Was the reduced silver in those days mainly present in suspension in the developer, or upon the glass—for no dish was used as at present? My only object is to look at both sides of the question, and to arrive at the truth, if possible.

of its banishment? If so, I wish they would try one or all of these things:—The use of a really hard but absorbent gelatine (what a comfort this is in many ways, all who have used it will concede): secondly, drying in a current of air pure, and of the normal temperature; and thirdly, the use of precipitated iodo-bromide, the hard gelatine being added after the boiling and washing of the precipitate. I should say that the first two precautions will go a long way towards avoiding green fog, especially if the gelatine be added to the emulsion containing extremely little gelatine, and after this has been boiled in the acid condition, the whole being afterwards well washed. I am certain, however, that a precipitation plan might easily be conducted on a large scale.

Captain Abney's remark on the action of dilute solutions of ferrous oxalate is interesting. It certainly seems curious that, supposing the effect to take place which he has thought probable, any trace of ferric oxalate formed by the initial reduction is not, by its mixture with the bulk of the dilute ferrous oxalate, at once placed beyond the possibility of again exercising an oxidising action; for the dilute ferrous oxalate would then appear able, metaphorically speaking, to snap its fingers at the exertions of its antagonist, ferric oxalate. But surely the hyposulphite in excess should at once reduce any ferric oxalate formed to the ferrous state, so that, however small the quantity of iron salt present, it would not be rendered inert (as a reducer) owing to its being converted into the ferric state. Perhaps extremely dilute ferrous oxalate is almost inert as a reducer, and certainly so when there is plenty of hyposulphite eager to gobble up the haloid salt. It also seems to me probable that when hyposulphite is in excess, ferrous sulphite may be formed, a secondary reaction of the tetrathionate—which I believe may be formed—upon the ferrous oxalate produced in the first instance. I have my reasons for supposing this, but I will not enter into them at present.

I did not intend my statement in regard to the precipitation of lime salts by sodic sulphite to be taken as an assertion that such precipitation is an actual benefit. It may be so; but I have no proof. Sodic sulphate, which is always present, throws down calcic sulphate from hard water, but not to any marked extent, except under certain conditions; and ammonia throws down calcic hydrate. If two bottles be taken, each containing the same amount of water, a little sodic sulphite being placed in one of them, then if an equal quantity of ammonia be dropped into each it will soon be observed that while the bottle which contains the sulphite adds nothing to the very slight amount of precipitate present (due to sulphate), the other bottle will soon present a clouded appearance (due to precipitation of calcic hydrate). It is thus evident that the lime salts in the former case remain in solution. It is easy to understand that the absence of any insoluble hydrate might be of great advantage for securing a clean and structureless film.

I know that Captain Abney prefers to consider alkaline development as purely physical; therefore I must not be misunderstood when I suggest a trial of what I will call a purely physical reduction of silver on a bromide plate. Let the ammonia used be saturated with silver bromide; then, taking a plate not prone to green fog, let the usual alkaline developer be made with the silver-saturated ammonia, or, if the instant reduction of the silver be feared, this might be flowed over the plate first. Let one half of the plate have been entirely exposed to light, while the other half remains unexposed. Then let the developer be poured on. The result of this experiment might be interesting, especially were another plate identical with the other developed with a like developer, but with ammonia free from silver bromide. Should this suggestion commend itself to Captain Abney, perhaps he will take the trouble to try it.

It is amusing to read the alternate praise and blame bestowed upon sodic sulphite in the developer; even those who formerly thought there was nothing like it, at times recanting and favouring us with their decided opinion that their quondam friend is a fraud—simply wormwood and gall, and fit only to be classed with that photographic preparation which at one time went by the name of "ground bone and sand." It is the old story! Photography cannot be encompassed by formulæ, and I suppose it will always remain a fact that circumstances alter cases, so that what in one case is "food," in another case will be "poison." However, I must say that I believe it is a great mistake to throw the blame of certain evils upon sodic sulphite, when it would be fairer to look nearer home. Certainly with a good gelatine plate qualities can be got unattainable by other means. "Pyro. stain" is never absent when sulphite has not been used, neither is the quality or colour of the image so good. This quality of colour is important, not because it necessarily affects the character of the resulting print (though in the case of silver chloride paper this may be), but because the printing intensity of "wet plate" colour is so much more easy of estimation than that sickly non-actinic tint which commonly prevails with ordinary alkaline development.

With respect to the reply of the editor to my criticism upon his suggestion to mix the sulphite with the ammonia, instead of with the pyrogallol, which appeared in a recent number, I was perfectly well aware that it was not alleged by any that the solution, as recommended by me, oxidized to the extent of darkening; but we are quite at liberty to assume that the effect complained of—if there be any justice in the complaint at all—has been due to the oxidation of a large proportion of the sulphite into sulphate. Certainly, this would have a restraining action, so that the image would not appear for perhaps a considerable time. At any rate, this theory is more plausible than any other, which must be pure hypothesis. The fact that pyrogallol in solution of sodic sulphite has been known, in many cases, to retain its developing power, is alone sufficient proof, to my mind, that there can be no prejudicial effect on the developing power of the pyrogallol brought about by the action, *per se*, of sodic sulphite. But sodic sulphite will be liable to change, wherever it be; and so, I say, little difference is there, in the case in point, "'twixt tweedle-dum and tweedle-dee."

Notes.

The British Association meets at Southampton on the 23rd inst. Dr. C. W. Siemens is the president-elect.

"With a Camera at the Italian Lakes" will be the title of our "By-the-Bye" next week.

The Collotype illustrations that appear weekly in *Life* are printed at the *Moniteur* office on the Quai Voltaire, Paris; about eighteen hundred copies are issued at a time.

One of the officers of the 7th Dragoon Guards takes with him to Egypt a small camera that packs in a sling case, and is no larger than the field-glass carried by our staff-officers. He will employ Pumphrey's gelatine films for the work, since they are lighter to carry and less perishable than gelatine plates. The camera will be used for reconnaissance, and similar purposes.

The fine Grotto of Adelsberg has just been photographed by means of artificial light by Herr Rottmayer, of Laibach, in Carinthia. Gelatine plates were of course employed, and for illumination phosphorus and saltpetre were used. The phosphorus was simply laid upon a little heap of saltpetre, and set burning when the time for exposure arrived.

Our Parisian contemporary, *La Nature*, is engraving in its pages a series of photographs of animals taken by M. Pierre Petit at the Jardin des Plantes, the Zoological Gardens of the French metropolis. If not so grand and terrible as the pictures of wild beasts drawn from the imagination, with which our youth are wont to form their first impressions of lions and tigers, the engravings have at any rate the quality of truth about them.

Our readers will be glad to learn of the safe arrival of the Arctic yacht *Kara* at Novaya Zemlia. She was found there by Sir Allen Young in the *Hope*, when he arrived on the 19th of last month. Mr. Grant, when we visited him on board the *Kara*, told us that the *Eira* must be found by the middle or end of September if they are to find her this year, so there are two months wherein to make the search. The last heard of the missing ship was in July last, when she was spoken on the Novaya Zemlia coast by a Russian captain.

We print to-day the questions set at the recent photographic examination. Any of our younger readers who wish to test their theoretical and practical knowledge cannot do better than sit down with a few sheets of paper before them and try their hands at answering as many of the queries as they can.

Once more the question of utilising the heat rays in place of fuel in our everyday life has cropped up. At a popular fête in the Tuileries garden, on Monday, a printing machine was set in action by the concentration of the sun's rays; while, to illustrate another application, water was boiled and coffee made by sunlight. The sunshine is concentrated by means of a mirror, and thus made to heat a little boiler, thirty to forty minutes sufficing to evolve steam with a summer's sun. To M. Mouchon is due the idea of making practical use of sunshine in this way, and it is hoped that an apparatus may be constructed whereby a soldier or sailor in the tropics may supply himself daily with distilled water.

Mr. Ireland, one of the vice-presidents of the Dundee Society, whose "Three Weeks in Norway" will be found in another column, has sent us some fine examples of his work this year in Scandinavia. His views are quite remarkable for their clearness and softness—we see Mr. Ireland emphasizes the brightness of the weather in Norway—and some of them (to wit, the coast views about Molde) are really gems of pictures. We ourselves shall have something to say about a tour in Norway shortly.

A secret developer, called Eternat, has made its appearance with much pomp and circumstance in Germany; this preparation has just been examined by Dr. Eder, who found it to be an ordinary ferrous oxalate developer. There is, however, something to be learned from the directions for using the Eternat.

The stock solution is kept in a clear glass vessel, and should be protected from the action of the air by a layer of petroleum oil, a portion of the solution being drawn off by means of a syphon as required. This is ultimately returned to the stock receptacle, and as the vessel in question is kept in a well lighted place, the reduction of the ferric oxalate to ferrous oxalate takes place progressively, the developer being thus ultimately restored to its original condition; but occasional additions of oxalic acid (Renovator No. 1) must be made to balance the decomposing action of light. This is very good in theory, but the busy photographer would hardly care to wait for the light to restore his developer. In order to make the "Eternat" as deserving of its name as possible, provision is made for removing any accumulation of soluble bromide which may make it slow in action. This is done by means of a soluble silver salt (Renovator No. 2).

Mr. F. Gutekunst, of Philadelphia, forwards us two magnificent pictures of monster proportions, one of them, the Capitol at Washington, measuring no less than 53 by 18 inches. The pictures are unmounted, so that the skilful manner in which the prints are joined is emphasised, and half an hour's careful study of them has not qualified us to say with certainty where the blending of the photographs takes place. In a word, we must acknowledge that the panoramic effect is perfect.

Nor can we speak less highly of the artistic quality of the photographs themselves. Some are disposed to think that but little taste and knowledge of art can be displayed in depicting architecture or panoramas, but this proceeds usually from the fact that they have never occupied themselves with such work. In Mr. Gutekunst's picture of the Capitol there is a harmony and delicacy of lighting, without which the magnificent picture would be but a vulgar print of a somewhat monotonous building; he has contrived to show forth its fine proportions under a smiling light, and thus produce a grand and impressive picture of a pile, as it is in all probability rarely seen by the spectator.

The exaggerated accounts transmitted by special correspondents from Egypt have caused the military authorities to draw up some strict regulations to govern these gentlemen in the field. Their number is to be considerably reduced, and it is contemplated granting to each individual a species of passport, enumerating the conditions on which the privilege is granted, and containing, as instant means of identification, a photographic portrait. The Russian War Office made a regulation of the same sort at the time of the Russo-Turkish war.

As the portrait of a correspondent at home will scarcely represent that of the same correspondent in the field, after the latter has been roughing it for a few months, it would be well, in order to make the regulation of any value, that photographs should be taken by the military authorities on the spot, at the time of issuing the passport. Since every convenience for the taking of portraits, as well as for fulfilling every other branch of photography, is now at the disposal of our army photographers, the service could be quickly fulfilled.

Indeed, seeing the completeness of the travelling photographic waggons that now accompany our army in the field, and the excellent training that Sapper-photographers undergo, surely some very valuable applications of the art might be made in the matter of identification. Several Egyptian spies are reported to have been captured of late, provided with "safe conducts" from the British general, which had either been surreptitiously obtained on some excuse, or stolen from their rightful owners. Our army photographers could take a portrait, and supply a print, in a couple of hours, so that if such pictures were required for appending to "safe conducts," they would be forthcoming without delay.

Already preparations for observing the next Transit of Venus are in active progress. M. Guénaire, photographer to the Nice Observatory, sailed last month for Patagonia, where no less than three parties of French observers are to be stationed. We believe M. Guénaire will have recourse to the Daguerreotype process, as neither collodion nor gelatine images can be relied upon when very minute and accurate measurements have to be made.

Lieutenant Darwin, R.E., late Honorary Secretary of the Photographic Society of Great Britain, has been selected to proceed to Brisbane, to watch the Transit of Venus from that spot. Captain Macinlay, R.A., goes to Jamaica, and Lieutenant Thomas, R.A., to Barbadoes, so that there will be no lack of observers to represent this country.

The Transit of Venus takes place on the 6th December next, and, as the phenomenon will be partly visible in this country, it will be looked forward to with considerable interest. Our readers are aware that the estimate of the sun's distance from the earth is based upon former observations of the phenomenon, and is now reckoned to be 92,880,000 miles. It will be the endeavour of astronomers and photographers on the next occasion to verify this estimate.

Mr. W. K. Burton recently showed us a shutter with releases arranged at different heights, so that an exposure of one-fifth, one-eighth, or one-tenth of a second could be obtained, according to the momentum acquired by the falling shutter, before its opening passes the lens. By inclining the shutter, it is easy to prolong the exposure to nearly a second.

By burning a thin thread which holds back the shutter, all vibration of the apparatus which does not arise from the actual movement of the falling part is avoided; but, to realize this advantage to the fullest extent, the thread must be stretched in a direction which exactly corresponds with the direction in which the shutter is to move.

An ordinary cigar-lighter or fusee is best for firing the thread, and if the thread has been converted into pyroxyline, so much the better. Waterproofing with an alcoholic solution of the resinous product obtained by nitrating milk-sugar is also an advantage.

Sir Thomas Parkyns, whose name is well known as an accomplished amateur photographer, and who has lately given much attention to the manufacture of a steam tricycle, anticipates being able to reach a speed of fifteen miles an hour with his most recent vehicle. Unfortunately, the English law, which specifies that a steam carriage traversing an ordinary road shall be preceded by a man bearing a red flag, does not permit of the vehicle being used on our highways.

TWELVE ELEMENTARY LESSONS IN PHOTOGRAPHIC CHEMISTRY.

No. III.—Photographic Chemicals.

Acetic acid, $C_2H_4O_2$, is the essential constituent of vinegar; the liquid known as *glacial* acetic acid contains 99 per cent. of the real acid, and is obtained by distilling sodium acetate and sulphuric acid. It may be recognised by its odour of vinegar, and also by heating with alcohol and sulphuric acid, when the characteristic odour of acetic ether will be produced.

Citric acid, $C_6H_8O_7$, is obtained from fermented lemon juice. The latter is neutralised with chalk, and the insoluble calcium citrate is decomposed with sulphuric acid, the sulphate of calcium is filtered off, and the citric acid crystallised out after evaporation. The acid is very soluble in water and alcohol, and when heated with strong sulphuric acid it gradually blackens, with evolution of carbonic oxide, which burns with a blue flame.

Gallic acid, $C_7H_6O_5$, is prepared by boiling powdered nutgalls with extremely dilute sulphuric acid, and then allowed to cool, when the gallo-tannic acid in the galls is decomposed into grape sugar and gallic acid, which crystallizes out in yellow needles. Gallic acid is sparingly soluble in cold water, although readily soluble in hot water. When added to a solution of perchloride of iron it produces an inky-black precipitate, and with ammonia it forms a red brown solution which darkens when shaken in the air.

Pyrogallic acid, $C_6H_6O_3$, is manufactured on the large scale by heating gallic to about 200° C. (392° F.), by which means it is split up into carbonic anhydride and pyrogallic acid. It is very soluble in water, alcohol, and glycerine, and may be distinguished from gallic acid by its property of producing a dark brown colour when an alkaline solution is shaken in contact with air. Pyrogallic acid is not, strictly speaking, an acid, and its solution will not redden litmus paper; thus it is termed by chemists *pyrogallol*.

Hydrochloric acid, HCl, is an aqueous solution of the gas formed in the preparation of sulphate of soda from common salt and sulphuric acid. The acid is recognized by its property of reddening litmus paper, forming a white precipitate with silver nitrate, and its pungent odour.

Nitric acid, HNO_3, is prepared by distilling a mixture of potassium nitrate and sulphuric acid. Strong nitric acid has a specific gravity of 1·42; while the acid known as "fuming nitric" should have a specific gravity of 1·52, and often possesses a yellow colour, from the presence of nitric peroxide. The acid may be detected by its property of producing red fumes when heated with metallic copper, and a brown colouration with a solution of ferrous sulphate.

Sulphuric acid, H_2SO_4, is produced by the oxidation of sulphurous anhydride; on the large scale it is manufactured by allowing sulphurous anhydride, steam, air, and nitrous fumes to mix in a series of leaden chambers, where they all react to form the acid, which collects at the bottom of the chambers. The acid in this condition is somewhat dilute, so in order to concentrate it, the acid is placed in a platinum still and distilled till it is of the specific gravity 1·82, when it is in the condition known as "commercial acid" or "oil of vitriol." It generally has a brown colour, from the presence of organic matter, and it also contains an appreciable amount of lead. Pure sulphuric acid is obtained by distilling the commercial acid, thus freeing it from lead, organic matter, &c. The acid may be identified by its property of blackening sugar, and producing a white precipitate with a solution of a barium salt.

Alcohol is, correctly speaking, the name of a series of organic compounds; but that which is generally understood by "alcohol" is ethyl alcohol, C_2H_6O, or C_2H_5HO, or spirits of wine, and is obtained by the fermentation of sugar in presence of yeast.

Methylated spirit is a mixture of three parts of ethyl alcohol and one of methyl-alcohol—a liquid obtained by the distillation of wood. The object of adding the methyl-alcohol is to prevent the use of the spirit for manufacturing intoxicating liquors.

Spirits of wine should be of specific gravity ·825, containing 10 per cent. of water; while absolute alcohol (which is prepared by distilling the above with quick lime) is of specific gravity ·794, and should not contain a trace of water. Ethyl alcohol may be recognised by its property of producing the characteristic odour of acetic acid when heated with a mixture of sulphuric acid and potassium bichromate.

Alum, $AlK(SO_4)_2.12H_2O$, or $AlNH_4(SO_4)_2.12H_2O$, is a double sulphate of either potassium or ammonium and aluminium; the alums are made by adding a solution of aluminium sulphate—prepared from clay and sulphuric acid—to a solution of sulphate of the alkali. The potash alum is generally found in commerce, but ammonia alum is occasionally met with, and can be distinguished by its power of evolving ammonia when treated with a solution of caustic soda or potash. Both potash and ammonia alum produce a white precipitate with a solution of barium chloride, and a violet colour with a solution of logwood.

Chrome alum, $CrK(SO_4)_2.12H_2O$, is obtained as a secondary product in the oxidation of substances by potassium bichromate and sulphuric acid, and is formed in the bichromate battery. This salt forms large dark purple crystals, which exhibit a ruby colour by reflected light. Chrome alum may be identified by its property of being oxidised when heated with nitric acid and potassium chlorate; the presence of chromic acid being afterwards proved by the addition of a solution of acetate of soda and lead acetate, when a yellow precipate of lead chromate will be formed.

Ammonia liquor is a solution of ammonia gas (NH_3) in water, one volume of the liquid containing about six hundred volumes of the gas in solution. The ammonia is obtained by heating a mixture of ammonium chloride and lime, and the solution is formed by passing the gas thus formed into water. The liquid is generally known in commerce under the name of *liquor ammoniæ fort.*, and is of specific gravity ·88, containing nearly 30 per cent. of ammonia. The only impurity that is likely to be present is the carbonate, which is formed by direct combination with the carbonic acid present in the atmosphere. Ammonia is recognised by its well-known pungent odour, and its property of bluing litmus.

THREE WEEKS IN NORWAY.

BY D. IRELAND, JUN.

A question which comes up yearly, and which wants some care in deciding, is that of—where are we to go this summer? Having spent three weeks very enjoyably in Norway last year, we decided to pay another visit to this interesting and beautiful country, selecting, of course, a different route. Wishing to get on the road before the run of tourists arrived, we crossed the North Sea, in the end of June, to Gothenburg, in the south of Sweden, and thence by rail to Christiana. Having neglected to secure rooms beforehand, we found on our arrival all the best hotels full. Only staying a night here, we went by rail to Eidsvald, a three hours' journey, at the foot of the Myösen Lake. The railways in Norway are few and of recent construction, and the travelling very slow (fifteen miles an hour); but the arrangements, like those all over the Continent, are far ahead of our own, both as regards the luggage system and the attention paid to the personal comfort of the passenger. On the journey the heat was oppressive, and we were very much surprised and pleased at finding that a couple of tanks of iced water filled the spaces ordinarily occupied by the lamps. Arrived at Eidesvald, we got on board the steamer *Kong Oscar*, which landed us, after a pleasant sail of eight hours, at Lillehammer, at the head of the lake. The guide-book informed us that the water at the head is thirteen feet higher than it is at Eidsvald, so that we had been sailing up hill all day.

At Lillehammer we got our four-wheeled carriage a *trille*, and commenced our journey proper. Coming up the Myösen, we got an instantaneous view or two; but we found a grand subject for the camera at Lillehammer in the shape of a splendid waterfall, about a mile from the hotel, and on which we exposed four or five plates. At night we did our first changing, which was by no means easy; for Norwegian houses have a superabundance of windows, and the doors are very badly fitted. One would hardly expect to have much difficulty about keeping out the light at night; but from the middle of June to the end of July there is sufficient light all the night through to read or even photograph by, some of our best negatives having been done betweeen the hours of five and six a.m. and seven and eight p.m. After considerable trouble we succeeded in getting everything made light-tight, and emptied and re-filled the slides. We afterwards dispensed with the lamp, adopting the plan of covering one-half of the window with double ruby paper, and pinning up double black calico over the other half. This answered admirably, and we always had an abundance of light to work by, which is a great thing, and perfectly safe, too, which is a greater. We usually changed plates about eleven or twelve p.m., and had always plenty of light. The plates used were Wratten and Wainwright's ordinary 12 by 8, and we could not have wished for better. One double slide was always kept filled with instantaneous films for emergencies; but they are of little use for ordinary landscape work.

We drove about fifty miles a-day, changing horses every eight or nine miles. From Lillehammer to the end of the Gudbrandsdal—two days' journey—the scenery was very pleasing. The Romsdal commences at Mölmen, and the scenery from there to Veblungsnaes is grand in the extreme. During this part of the journey the camera was in constant requisition, every turn of the road bringing fresh beauties before us. The difficulty was, not in finding subjects for the camera, but what to leave undone. From Mölmen to Veblungsnaes we exposed during the day seventeen plates, and could have had as many more. The weather, too, was all that a photographer could desire—bright and clear.

The principal feature of this valley is the Romsdal Horn, an immense mountain with a curiously shaped peak, not unlike a rhinoceros horn. We passed this rather late in the evening, but a couple of plates were successfully exposed on it. Two hours afterwards we arrived at Veblungsnaes, prettily situated on the fjord at the entrance to the Romsdal. Here we made the acquaintance of a gentleman who spoke English fairly well, and having read in the never-failing *Murray* that some glaciers were to be seen at the entrance to the Romsdal, we asked him if he knew of a glacier in the neighbourhood, and he at once replied, "Oh, yes!" On asking where it was, he said, pointing to the opposite shore of the fjord, "Right over there!" Now, we thought, this is a splendid opportunity, and will be a good chance for getting some photography done; and accordingly decided to sail over the next day. In the evening, while speaking to a young gentleman connected with the hotel, the glacier was again mentioned, when he at once remarked, "Ah! I met the gentleman a little while ago who told you about it, and I am afraid there has been a little mistake; he thought you were wanting a man who puts in glass, you know. So our glacier transformed itself into a glazier, and our hopes of getting some photographs of that remarkable formation were reduced to *nil*.

A twelve hours' sail from here, in one of the numerous little steamers which run on all the Norwegian fjords, landed us in Molde, near the sea coast. We ascended a hill at the back of the town, and were charmed with the view, which, indeed, is said to be the best of its kind in Europe. At your feet lies the little town on the shore of the island-studded fjord, while on the other side, about thirty miles off, tower range upon range of snow-covered peaks, from east to west, as far as the eye can reach. A panoramic view was taken of this on four plates (12 by 8), and these negatives are amongst the best.

The steamers which run to the North Cape call here, and we sailed down to Bergen in one of them, the *Olaf Trygveson*. Some drop-shutter work was done on the way down, and the results were fair, plenty of density being easily obtainable by using glucose in the developer. A couple of days were spent in Bergen, of which a magnificent view is to be got by ascending the hill to the north. A large fish-market is held in Bergen twice a-week, and we were successful in obtaining a good instantaneous view of it.

We left on Saturday morning, and arrived in Newcastle on Monday morning, after a quick run of fifty-two hours. Altogether sixty-eight exposures were made, and—thanks to the excellence of the plates—not a single failure had to be recorded. The best negatives were those which got a full exposure (over-exposed, in fact), and which were developed with a small quantity of the ammonia bromide solution in proportion to the pyrogallic.

RECENT ADVANCES IN PHOTOGRAPHY.

BY CAPTAIN W. DE W. ABNEY, R.E. F.R.S.*

The next spectra are exceedingly interesting—to me, at all events—and I should like them to interest you. They represent a new form of molecule. I believe very few people know anything about them. The peculiarities of the mixture were discovered by me, and a paper about them sent to the Royal Society a very short time ago. That molecule is this: It is not a combination between iodide and bromide in the ordinary acceptation of the word, that is to say, it is not $Ag_2Br_2 + Ag_2I_2$, or not simply one equivalent of each of bromide and iodide of silver added together, but an absolute combination, Ag_2BrI, or a double molecule, which has been formed, and on which the spectrum has a totally different effect. You will see (No. 7) that, instead of having the maximum intensity at G, its maximum is far into the green, and it has a minimum about G. In the same way, another molecule is formed by a combination of molecules of chloride of silver and iodide of silver, and that, too (No. 8), has no maximum about G, but has a minimum there, which is the place where the maximum sensitiveness is found in the ordinary iodide of silver.

I will try and explain how these last curves are produced; if you take iodide and bromide of silver together, and expose them to the spectrum, what happens is this: first of all, iodine and bromine are liberated. What becomes of the iodine and bromine? The bromine immediately attacks the sub-iodide of silver, and forms a new molecule, Ag_2BrI; the bromine undoes the work of the iodide as fast as it is done, so that we have, in the place of maximum intensity of the iodide, the least work done. In the same way with the chloride. The chlorine liberated from the chloride undoes the work which is done by the iodine; the consequence is, that in the place of maximum intensity of the iodide we have a diminution of intensity in the case of the double salt; in other words, the dry bromo-iodide of silver is less sensitive for the spectrum about the part G than any other part of the spectrum to which it is sensitive. In order to prove that, I will tell you a little experiment which was carried on by myself. Chloride of silver was absolutely blackened in the light, and sub-chloride was formed; then it was treated with iodine again, and it became a uff colour. When this new molecular form was placed in the spectrum, we got exactly the same result as we do here, showing that we have a new molecule of chloro-iodide of silver. I think this will very likely throw a great deal of light upon some of the phenomena which are met with in ordinary dry-plate work.

Nw I crave your attention to one thing. You may ask if chlorine always undoes the work done on the iodide. The fact is, that it does not, if you have free nitrate of silver present; since this salt is able to take up the iodine and bromine, therefore the bromine cannot act on the sub-iodide of silver; it leaves it there, and you have the impressed spectrum totally different; in fact, the bromide and iodide spectrum are superposed one on the other. There are a great many facts I could show you to prove this. We come to the conclusion, then, for sensitiveness, you must have a sensitizer present. In gelatine plates, you may say that gelatine is a sensitizer, but it certainly is a very feeble one; anyhow, if you want to get sensitiveness in a plate, you must have a sensitizer present which will mop up, not only iodine, but bromine. When this is the case, bromine cannot go and destroy the work done on the iodide.

Before concluding this part of my lecture, I may also say that I have found that the printed image and the developed image have precisely the same characteristics. Thus, if you get pure iodide of silver, you get the termination of both the printed and developed spectrum close to G. A curious thing with regard to iodide is this: if you have the smallest trace of impurity in it, it is immediately shown in the spectrum by a prolongation below G, and you can go to the chemist and tax him with having given you iodide which is not pure.

Now there is one point that has exercised the minds of a great many photographers, and that is the illumination of their dark rooms; and I hope I may be excused if I go over what may be apparently well trodden ground, but I believe there are many here present who have no absolute certainty as to why they are using certain glasses to glaze their developing rooms. I want to show photographers the absolutely safest light they can use in developing their pictures. Here we have a spectrum, and beyond it you see the fluorescent rays. I will ask Mr. Woods to pass through the spectrum one or two glasses. First of all we will take ruby glass (No. 2), and you will see that when it becomes very bright indeed, there is a certain amount of blue light comes through the glass; I can see a trace of yellow, and a trace of green. Now I will take the yellow glass; here is one which photographers are very fond of; but I dare say you will see that there is a great deal of blue light comes through that. That was the ordinary glass used for photographic dark rooms within the last half-dozen years, and people were perfectly content if they glazed their rooms with it. But there are yellows and yellows, and I will show you the difference between two. Now we will have a magenta (No. 4), which you see cuts off a great deal more light. The next (No. 6) is a stained red glass, which cuts off the green, too. Now there is one combination which I wish to show you, because people often complain that their photographic studios are not safe as to light, and that they use ruby glass and get foggy plates. I have great doubt about fogging bromide plates with proper red glass where ordinary precautions are taken, though not with the ruby glass, which lets blue light through. If people would only use the spectroscope with a strong light, they would very soon see where their glazing is at fault. Now, I will throw on the screen the light through a piece of blue glass (No. 1), and I think you will see that there are bands in the red and yellow; there is plenty of blue coming through, and some green. Now I will ask Mr. Woods to give us a combination of stained red and blue; you see a red line, and nothing else. If photographers want to be absolutely safe, let them glaze their studios with cobalt glass and stained red, and they will get nothing but the light of that

* Continued from page 461.

particular refrangibility which I will warrant is totally unable to affect any gelatine plate—of the ordinary type, at all events. You may glaze and glaze with ruby, but you will never get rid of blue light entirely. Of course it diminishes with every thickness you take. If you want to use ordinary plates, which are not so sensitive that you cannot look at them, my advice is to use a combination of stained red (No. 6) and ruby glass (No. 2), which

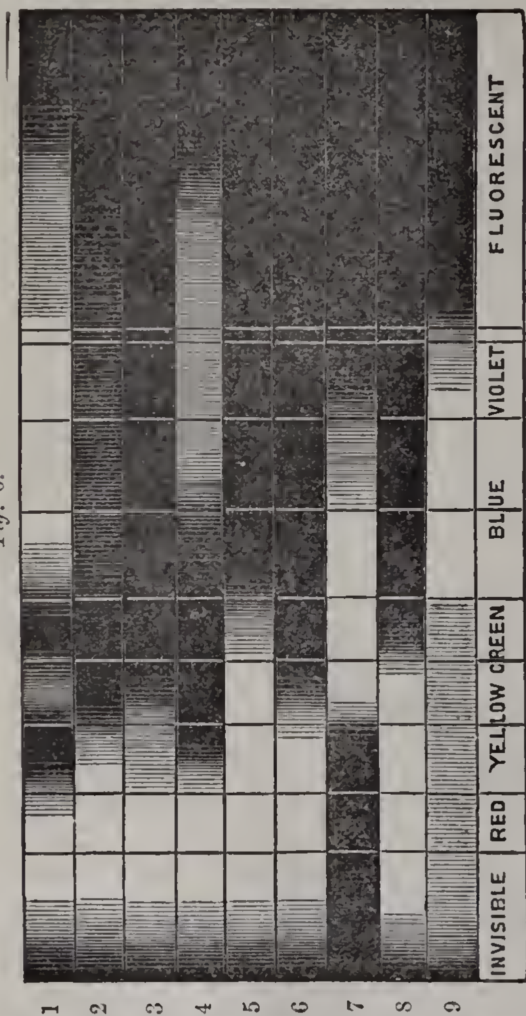


Fig. 6. 1, Cobalt glass; 2, ruby glass; 3, chrysoidine; 4, magenta; 5, flashed orange; 6, stained red glass; 7, bottle-green; 8, aurine; 9, quinine.

will give you a comfortable light to work in, for it cuts off the blue, and leaves the red in a brilliant patch. Those who are using that combination ought to have nothing to fear; but if they still fear, let them use a combination of cobalt (No. 1) glass and stained red glass (No. 6), and then they will only get the colour of that narrow strip of light which you saw just now. I should like to show you the green glass in the spectrum (No. 7), that you may judge what kind of light gets into it. It was at one time seriously recommended as an admirable thing for not trying the eyes, and for being safe to use in the developing room. A combination of red and green is a fairly safe light for iodide plates or ordinary plates, but not for gelatine plates, which are extremely sensitive. Next we come to a series of pretty colours, which may be very useful to us. Here is the spectrum of magenta (No. 4); the yellow is cut out entirely, and the green, leaving the blue, violet, and orange. Now I will try aurine (No. 8) and chrysoidine (No. 3). Here you see the blue is gone entirely. Some have said that the ultra violet rays go through aurine; but I will leave it to you to say whether they do or not. There is no trace here of the ultra violet rays when I apply this card with the sulphate of quinine on it. They should appear if there were any. We have next a combination of magenta and aurine, which is a perfect red light, and is very good indeed for the photographic studio. I think I may say, without a breach of confidence, that I believe a certain "ruby medium" in the market is made according to the directions that I gave some time ago. You may ring the changes of combinations of these glasses; you may have scarlet and aurine, or magenta and aurine, and either one or the other will give you this red band only. If all other means fail, the photographer may use the ferrous oxalate developer. You will see that it cuts off the blue light, at all events. I should not at all mind developing a plate in such a light as that. In fact, you may bring the most sensitive plate out into a white light, when developing in a dish, with a covering of ferrous oxalate over it. I hope that, having seen spectra, you will lay to your heart what I have been saying to you about the glazing of your dark rooms. I thought this was a subject that I ought not to pass over without some reference.

In 1874 we had a most astouishing discovery made, and that was, that by dyeing a film of sensitive collodion you were able to get an increased action by the spectrum. In common with others, I took up that subject and investigated it, and I wish to draw your attention very briefly to it to-night, because I think it is one of the advances made in photography which ought not to be passed over. If you take one of these aniline dyes, such as a blue dye, and expose it to light behind a piece of black paper, with an aperture in it, such as I have here, you get an image on the dye, such as you see. What is the meaning of that? The meaning is that the dye is oxidised, for if you apply an oxidising agent you get the same result. Dr. Vogel found that if you dyed plates with some of these fugitive dyes—they were all fugitive to a great extent which he used—he was able to obtain an extension of the impressed spectrum exactly in those parts of which the dyes absorbed, and he introduced the term optical sensitiser to describe the fact. Now, I am going to quarrel with that expression, because he explains it in this way; he says, in effect, that the sensitive aniline dye is able to take up a vibration, and to direct it to something else; in other words, that when light has done all it can in endeavouring to bleach a dye, that its period is transformed, and it does something else on the silver salt which is in contact with it. Well, that is not a philosopical way of looking at things, because if you could only arrive at the principle, you might just as easily arrive at that principle of perpetual motion, which is a thing which I am not prepared to admit. Now I honestly say, that for a long time these experiments staggered me, and the arguments Dr. Vogel brought forward seemed fully to justify his term of optical sensitiser as applied to the dye stuff; but eventually I was able to come to a different conclusion, and that conclusion I wish to put before you. If you have a substance which is oxidised in the presence of an haloid salt of silver, what do you expect? You expect that the haloid salt of silver would be reduced. If you place pyrogallic acid in contact with the haloid salt of silver, and help it to be oxidised by ammonia, you expect that the haloid salt of silver will be reduced, and I lay the action of the dye to precisely the same principle as the pyrogallic acid, which helps to develop the image; in other words, the oxidation of the dye causes a reduction of the bromide of silver, or iodide of silver, as the case may be, and simply provides a nucleus on which development can take place. I wish, however, to point out that Dr. Vogel has an objection to my explanation. He says, "Oh, but you require time to bleach things; you require time to alter them." So you do; you require time to blacken the chloride of silver; nevertheless, the slightest exposure to light begins the change in it, and so the slightest exposure to light begins the change in the dye, and on this principle, of course, the action of dyes upon sensitive films can readily be explained.

I have got behind the screen three pieces of sensitive bromide paper, one dyed with a blue dye, and another with eosine, the third pure bromide of silver without anything. I propose to develop those on the screen. I must give this rather a longer exposure

Fig. 7.

than last time, because blue dye takes away the sensitiveness to a material extent. You can see the colour; it is somewhat of a lavender grey, which no doubt will show that it absorbs exactly in the same position where the extra length of the spectrum is developed. In the eosine, I dare say you notice a peculiar dimming of light about the green; this is a very fluorescent dye, and it is in that position where we shall expect the action to take place. I will, however, show you where the absorption takes place of these two dyes we have used. This is a spectrum of the dye; it lets the ultra-violet rays through; in the green we have a great cutting off. Here we have the cyanine, which is a different colour altogether. It cuts off the yellow, and also the green; therefore, on the principle of work, we should expect that where absorption takes place in the dye, there dye would be oxidised, and the silver reduced in consequence. I now expose the three slips of paper above alluded to, and I will develop them before you. [The papers were developed in yellow light, as before.] The impression of the spectrum on the eosine dyed paper flashes out; the part in the green comes out very strongly indeed. The blue dyed paper shows, besides the ordinary spectrum of the bromide, a band in the yellow. Finally, we have the undyed paper. The above diagram shows the effect obtained on cyanine blue. Here you see the marked difference in the three cases.

(To be continued.)

UP THE HILLS IN SOUTH WALES; OR, WHERE *NOT* TO GO WITH THE CAMERA.

BY GEORGE BRADFORDE.

Scotland's beauty is proverbial. Her wild, untrodden glens, her towering mountains, her heath-clad vales, her romance, and her grandeur are known to every one. The tourist looks upon her rugged features in awe. The casual, used-up man of the world is even awakened to a sense of insipid admiration when he is medically advised to seek her invigorating air, taste of her heather honey, and sip gently of her mountain dew. The smoke-bound cockney has even a vague idea that Cremorne in its most perfect form was nothing to the *ultima thule* of Britain. That is where I should like to go with camera. Excuse the above outburst, because I have been—— please read the above title once more.

Every one knows that the "odd jobs" that crop up in the general routine of a portrait business—in the out-door line, I mean—are usually attended with sundry difficulties that the professional landscape photographer, when told about them, can only hold his sides and laugh at. For instance, fancy, if you can, a manager of a branch of a big firm borrowing a tripod, background, &c., from the manager of another branch, for the purpose of doing an outside job. On examining the lot, the operator found that there was no screw for camera or tripod. "Bah! what about that?" cried manager No. 1 (who knew as much about photography as a cat about Greek); "get a piece of rope, and tie them together." There are some absurdities that people cannot laugh at, and I fancy this is one. It is quite enough to give you a pain in your face at once, and a sleepless night after, to the tune of—"Tie them together, man; tie them together!"

When one takes all the worry of our profession into consideration (the vagaries of sitters and people who know better, you know), one cannot wonder at medical statistics showing that there are more photographers in lunatic asylums in proportion to other callings.

I have been to Ty-new-ydd!

My manager (don't think that I have mistaken myself for Jumbo) turned up a little late, so that we were just in time to get a nice interesting view of the train as it smoked away from the station. I expect this effect was the cause of being at church or chapel on the previous Sunday night. I can think of nothing else, our departure being fixed at eight something on Monday morning. After having a queer little journey upon a queer little line, where we had to change carriages as often as a utility man has to dress in a five-act play, we steamed up the hills and arrived at our destination amidst torrents of Welsh mountains of mist and stray mountain sheep, the latter about the size of cats and as dingy as Skye terriers.

Now I must explain to you that we did not come out to this Heaven-forgotten place to take views; had such been the case we would have taken our farewell at once. The bleak, uninviting hills, the angry-looking stream in the valley, the patches of pasture with "there and here" a sheep—some with one horn, some with none, some with one eye, and some without a tail (so bellicose are they that they generally get more or less delapidated before they reach the years of maturity), was not the place for a landscape artist to loiter in. In short, I may say, the horrid place is there in all its barren and depressing bleakness and squalor, without a particle of the grandeur and awe that strike one upon first beholding the gloom and sternness that shroud Glencoe. No, sir, we came to photograph the natives for club pictures.

If the scenery was bad, what shall I say about the general tone of the natives? They were absolutely beautiful! It was "pay Monday," and their faces shone as the "shiners" did in their pockets. There were only seven fights and a half, on the level patch on the hill, at the back of the Blandy Arms, during the afternoon. It was sweet—so innocent—to see them go up the hill like lions—tearing off their coats in genuine fury, hurling defiances of a blood-curdling description at one another, and then, when their wind was spent, to come down undamaged, pick up their late discarded garments, and settle down into their normal state like lambs.

As ill luck would have it, the weather broke just as we commenced to put together our backgrounds (?). Down came the mountain mist in clouds, then a high wind that drove it away, and left us as a comfort sundry showers of icy rain. A more miserable day I never tried to do work upon. Now, who but madmen would insist that good pictures could be taken under such circumstances—a puny background tied to a wall and built around with great stones, a camera pitched upon a slope with one leg of the tripod built up with pieces of slate, the camera and focussing cloth held in position by two stalwart pitmen? During the exposure of one picture there came a great gust of wind and flapped the background from its bearings with a crack that made the sitter think his head was split. Another time, the camera, in spite of holding it tight down, managed to rear up on its front leg like an unmanageable steed that was impatient to be off. Take all this into consideration, along with the flouts and gibes of jocose onlookers, and sharp-edged stones that I had to pick my way amidst, then ask me if I should like to go there again, if you dare!

The second day was not much better than the first—black, cold, and miserable still. "You must do them," were my orders. But what folly to insist upon such impossible things. From my inmost soul I pity the poor fellows that "must do" such things. Still, take the negatives one and all, and everything considered, what with pencilling the wavy background, stopping down floating hair, flying ribbons, shutting mouths, putting in eyes, and retouching all over, and then vignetting very close, I dare say they will pass in a crowd.

Some people would think that had we done nothing those two days, and waited for the third, which proved exceedingly fine, it would be better for all parties. Of course, that is a matter of opinion.

The Welsh are very interesting, but not picturesque. Certainly I did not expect to see them in sugar-loaf hats, short petticoats, and home-spun hose; but it was less than I expected to find them, loafing and smoking like Durham pitmen. They are homely, affable, and make even too much of strangers. They make plenty of money, their only difficulty being to spend it. They live in a groove that there seems no possibility of getting out of. I can assure you, sir, there is plenty of room for those philanthropists who gather so much money to send abroad to open a very useful scheme here. I do not allude to those missions that ram tracts and religion down your throat by main force; but were there evening schools, penny readings, lectures upon foreign travel, &c., it would do a deal for the position of the people "up the hills." It speaks well of them when they are so willing to go in for club pictures. A little of this suggestion put into practice would have a more beneficial effect than the closing of the hotels on Sundays for travellers as well as residents.

But I wander. I merely meant by the above that the inhabitants of the hills are not so bad as they seem—or their scenery! I do not include the whole of Wales—only Ty-new-ydd, and that is one of the places where *not* to go with the camera, unless you want to take portraits and make money—only choose better weather than we did.

Correspondence.

STAINS ON GELATINE NEGATIVES.

Dear Sir,—Seeing so much said about stains on negatives, I tried my old solution of sulphuric acid (half ounce to one quart of water). After the negative is taken out of the hyposulphite, I pour some of the sulphuric solution over it, and the negative clears at once, but the negative must not be put in it to soak. I find it clears the negative, and makes it look like a wet negative. I also find it better than using sulphite of soda, as it makes just as clear a negative as if you use the sulphite. I don't find it does any harm, or hurt the negative at all. I have used it now for some months, so have given it a fair trial. I am not chemist enough to know how it acts, but I find it does all I wish, and makes nice clear and good printing negatives.—Yours truly, A. R. Dresser.

FERROUS OXALATE DEVELOPMENT.

Dear Sir,—I notice in this week's News an article on—or, rather, against—the use of ferrous oxalate as a developer. Mr. Wilkinson, the able writer of the article in question, seems to be of the opinion that ferrous oxalate has only been revived by certain manufacturers whose plates will not bear pyrogallol without exhibiting various defects, the principal of these being fog. Now, as I wrote a letter on this subject some weeks back, I may, perhaps, be allowed to reply to some of Mr. Wilkinson's assertions.

In the first place, allow me to state that I have no connection whatever with any manufacturer of dry plates, and that therefore any predeliction of ferrous oxalate cannot be attributed to that quarter; also I am not in the habit of using second-class plates, unless Mr. Wilkinson places those of Wratten and Swan on that list, which I am sure he cannot. Now, my experience is almost exactly opposite to his. I find that, with good plates, having a fairly thick film of gelatine, I can obtain ample density with ferrous oxalate after an immersion of about four or five minutes. With poor plates, on the other hand, for which, according to Mr. Wilkinson's theory, ferrous oxalate is specially adapted, I cannot, as a rule, get density under ten or fifteen minutes. I, however, never use such plates in practice.

What I maintain is, then, that with a full exposure and good plates, ferrous oxalate constitutes a better developing agent than pyrogallol, in that one readily gets clear and brilliant negatives, without any traces of green or other fog, and also that the negatives are of a better printing colour, and quite free from yellow staining. Moreover, if a so-called normal developer be used in the first instance, the addition of a very minute quantity of sodium hyposulphite, or the employment of a stronger ferrous solution, will bring out details that are wanting through slight under-exposure, while bromide has even more restraining power in the case of over-exposed plates than it has with pyrogallol. In the case of much under-exposed plates, Mr. Wilkinson probably knows as well as everyone else that to produce out of them good negatives is equally impossible with both developers. I cannot, therefore, understand anyone maintaining that the oxalate developer allows of no latitude in exposure.

As to Mr. Wilkinson's remarks upon the quality of the several negatives he experimentally developed, I think that he can scarcely have given the ferrous oxalate a fair trial, as "harsh and dirty-looking results" are not the ordinary results of its employment. In fact, I think most people who have given it a trial will agree with me when I say that softness and harmony are peculiar to its use.

Why mercury intensification should not do for good work, I again am at a loss to understand. In the days of wet collodion nearly all negatives were intensified some way or another; and why should it be otherwise with gelatine?

In conclusion, I have only to add that all my work being of the landscape, or at any rate, out-door genus, it is just possible that one reason for the apparent discrepancy of Mr. Wilkinson's and my own experiences may be that while he has been experimenting exclusively with portraits, mine has been all out-door work; from which it may perhaps be concluded that the oxalate developer is more suited for the latter than the former. I do not, however, pretend to account in this way for Mr. Wilkinson's rather sweeping assertion that with "a really first-class plate it is not possible under any circumstances to get as good a negative with ferrous oxalate as with pyrogallol." If some other correspondents would report on their experiences as to the comparative merits of the two agents, I think the results might be highly interesting, if not valuable.—I remain, yours truly, A. A. Campbell Swinton.

ROYAL CORNWALL POLYTECHNIC SOCIETY.

Sir,—I beg to call the attention of your readers to the fact that August 22nd is the last day for receiving exhibits by the appointed agents for the forthcoming Exhibition of the Royal Cornwall Polytechnic Society, to be held at Falmouth on September 5th. I shall be happy to forward prize lists and prospectus to intending exhibitors. Carriage this year will be paid by the Society from the respective agents to Falmouth and back. All exhibits must be delivered into the hands of the agents carriage paid.—I am, sir, yours, &c., Wm. Brooks,

Member of Committee R.C.P.S

Laurel Villa, Wray Park, Reigate.

Proceedings of Societies.

London and Provincial Photographic Association.

At the meeting held at Ashley's Hotel on Thursday, the 2nd inst., Mr. W. Coles in the chair, the following question from the box was read:—"Has anyone present had any experience with ferric oxalate as an intensifier or reducer of gelatine negatives?"

No one seemed to have any experience, but Mr. Debenham found that if a very weak and much over-exposed negative was first treated with bromide and mercury as in Monckhoven's formula, then with Schlippe's salt, he obtained a negative with good printing density, and further, that he believed the result to be permanent.

Some very fine enamel portraits were passed round by Mr. Henderson, who read a letter intended for publication in the Photographic News, and said that in consequence of the correspondence he would defer his promised demonstration till the next meeting.

Mr. W. K. Burton passed round some very fine prints mounted in optical contact with glass, two mounted with glass of a bluish tinge having an especially fine effect.

The following were elected members of the Association:—Rev. S. Rosenthall, Mr. G. Smith.

Amateur Photographic Association.

The annual meeting of this Society was held on Wednesday, the 2nd inst., at York House, York Place, Portman Square, the Right Hon. Lord De Ros in the chair.

The minutes of the last meeting having been read and confirmed, the following members were elected:—Right Hon. Lord Emlyn, Sir Spencer Maryon Wilson, His Highness Veeracarala Vurmah Elia (Rajah of Cochin), Lieut. John Drummond, Messrs. C. W. Prescott, R. C. Carr, Alexander Poole, F. Galton, F.R.S., A. R. Dresser, P. H. B. Bedingfield, and R. Heron. Sir Spencer Maryon Wilson and Mr. Charles Stephens were elected members of the council.

The Secretary then laid before the meeting the pictures for the current year, and Mr. Glaisher read his report, in which all the photographs were arranged in six classes.

Mr. Glaisher remarked that he and his colleague (Mr. Howard) were pleased to find that, although the contributions received last year were high above the average, those of this year were still higher. He called attention to the fact that the number of pictures this year, in the highest class, was no less than 187 against 108 in 1876, 90 in 1877, 73 in 1878, 111 in 1879, 90 in 1880, and 158 last year. The following is an abstract of Mr. Glaisher's report.

Class 1 contains 187 pictures, contributed as follows:—C. Stephens 19, Right Hon. Lord de Ros 1, F. Beasley 25, R. Murray 8, F. Brownrigg 7, F. Lloyd 1, W. S. Hobson 8, W. D. Howard 1, W. Adcock 10, J. H. Ritchie 1, T. R. Shervinton 3, F. S. Schwabe 9, J. Board 2, General Sladen 2, Rev. H. Palmer 1, R. O Milne 9, W. Vanner 6, W. Muller 10, Major Chadwick 6, R. Leventhorpe 14, A. Watkins 1, H. T. Simmons 2, J. C. Hannyngton 3, J. L. Ranking 3, F. H. Shaw 1, G. Brook 4, G. de la Hoyde 3, S. Norman 6, Major Pearson 1, A. Pringle 10, J. W. Robinson 1, E. J. Jackson 2, S. de Brath 2, G. W. Palmer 5.

Class 2 contains 168 pictures contributed as follows:—C. Stephens 6, Right Hon. Lord de Ros 6, F. Beasley 24, R. Murray 1, T. Brownrigg 1, F. H. Lloyd 3, W. S. Hobson 11, W. D. Howard 3, W. Adcock 6, J. H. Ritchie 3, T. R. Shervinton 2, F. S. Schwabe 1, G. W. D. Green 1, J. Board 5, A. Hill 3, Rev. H. Palmer 8, R. O. Milne 10, W. Vanner 3, W. Muller 5, Major Chadwick 5, R. Leventhorpe 5, H. T. Simmons 4, J. C. Hannyngton 9, J. L. Ranking 3, F. H. Shaw 3, G. Brook 2, G. de la Hoyde 4, S. Norman 3, Major Pearson 5, A. Pringle 9, J. W. Robinson 1, E. J. Jackson 2, S. de Brath 2, G. W. Palmer 4, S. R. Majendie 4, and A. R. Dresser 2.

The remainder of the pictures are comprised in classes 3, 4, 5, and 6.

Nearly all the negatives received this year are gelatine plates, and although in many respects superior to the old wet plates, Mr. Glaisher, called attention to the fact that they are often wanting in vigour and crispness.

The following prizes were awarded:—C. Stephens, first prize, a large silver goblet, for Nos. 22, 4, and 2; S. Norman, second prize, a water colour drawing in frame, for Nos. 5 and 9; F. Beasley, for Nos. 366, 382, 385, and 401, a water colour drawing in frame; W. S. Hobson, for Nos. 258 and 259, a large album elegantly bound; F. S. Schwabe, for Nos. 16, 29, and 30, an oil painting in frame; G. Brook, for Nos. 2, 3, and 5, a silver goblet; R. Leventhorpe, for Nos. 59, 63, 64, and 66, a silver goblet; W. Adcock, for Nos. 1, 2, and 8, an oil painting in frame; G. W. Palmer, for Nos. 3, 4, 6, and 7, a large album elegantly bound; Right Hon. Lord de Ros, an album elegantly bound; W. Vanner, for Nos. 61, 65, and 67, an album elegantly bound; and W. Muller, for No. 780, an oil painting in frame.

Certificates of honourable mention were awarded to General Sladen, A Pringle, T. R. Shervinton, T. Brownrigg, Major Chadwick, J. C. Hannyngton, S. de Brath, Rev. H. Palmer, J. H. Ritchie, J. L. Ranking, G. de la Hoyde, R. Murray, and R. O. Milne.

A vote of thanks proposed by Lord de Ros, seconded by the Earl of Rosse, to the referees, for the able manner in which they had fulfilled their unusually arduous task in the arrangement and classification of the pictures, and especially to Mr. Glaisher for his report, was carried unanimously, as was also a vote of thanks to the chairman, proposed by Capt. Lewis and seconded by Mr. Howard.

Sheffield Photographic Society.

The usual monthly meeting of this Society was held on Tuesday, the 1st inst., Mr. Dakin, Vice-President, in the chair.

The minutes of the last meeting having been discussed and confirmed, and other formal business transacted, an excursion was proposed to Beeley and the Oak Forest, near Rowsley, to take place on Thursday, the 17th, when a good attendance of members is expected.

A discussion arose upon the question—"Are we to have another exhibition?" After various arguments *pro* and *con*, it was ultimately decided to have one in the early part of next year, date and other arrangements to be considered at a future meeting. It is hoped that every member will contribute, and will exert himself to produce some good work in the meantime.

Mr. Rawson mentioned that he had had sent to him some dishes made of paper pulp, which were indestructible, and suggested that if they could be supplied white, similar to porcelain, they would supersede all other kinds, being only about two-thirds the price of the *papier mache* dishes, and more durable.

The Secretary was requested to endeavour to get the makers to supply some samples, so as to introduce them.

After an exhibition of negatives developed by various processes, and a discussion thereupon, the meeting adjourned.

Talk in the Studio.

The Dangers of Electric Lighting.—Two men who endeavoured to enter the gardens of the Tuileries, during a recent fête and display of fireworks, by climbing over the fences, incautiously made an effort to raise themselves by holding on to some wires forming part of the system of illumination by electricity. Both received immediately a shock which killed them.

The *St. James's Gazette* says:—"Cetewayo refused to allow himself to be photographed when he visited the House of Commons the other day; and it would be interesting to know from what cause his refusal proceeded. He may have been in a hurry to get home, or he may have wished to be taken in another costume from that which he was wearing, or he may have thought that there were enough photographs in existence of him already, seeing that they are exhibited in all the shop-windows at present. On the other hand, his reluctance may have arisen from superstitious motives; and if so, the circumstance is worthy the attention of anthropologists. At the other end of the world from Zululand, Catlin found the North American Indians very unwilling to let him take their portraits, since they were under the confirmed impression that the images he proposed to carry away on paper or canvas were in reality their souls." Perhaps the dusky monarch was terrified by the array of cameras that awaited his disembarkation.

Electric Lights in Sea Fishing.—A French paper reports a trial by Government permission of an electric lure for sea fish. It consists of an electric light in a glass globe with a device for sinking it the desired depth. As soon as the light is turned on, the sea in its vicinity is illuminated brilliantly, and the fish, over whom light is well known to exercise an irresistible influence at night, come eagerly, and sometimes in large schools, within the rays. They may be seen from above disporting themselves in the unaccustomed brightness, and little dreaming of the sinister purpose with which the little fête is organized for them. It is then that other fishing boats, armed with nets, come up and set to work at the unconscious victims, which they surround as well as they can without interfering with the apparatus connected with the lighted globe. It may be supposed that this device is calculated to operate with much deadly effect whenever it is used; and there seems to be much doubt whether it will ever be allowed as a recognized kind of fishing within territorial waters. Indeed, the license granted by the Government is said to be merely provisional, and for the purpose of testing the new machine.

Indirect Determination of Chlorine and Bromine by Electrolysis. By L. P. Kinnicutt (*Amer. Chem. J.*, 4, 22-25).—The chlorine and bromine having been precipitated together by silver nitrate, the mixed precipitate is heated in a porcelain crucible at a temperature just sufficient to melt it; and the crucible having been cooled and weighed, a piece of platinum-foil connected with a platinum wire is placed in it so as to rest on the melted silver salts. Dilute sulphuric acid (1 part concentrated acid to 3 parts water by volume) is then poured into the crucible until it is two-thirds full, and a second piece of platinum-foil attached to a wire is placed in the acid solution, care being taken that it does not touch the mixed silver salts. The zinc pole of a two-cell Bunsen battery is then connected with the platinum-foil resting on the silver salts, and the carbon pole with the platinum-foil just mentioned. Decomposition begins immediately, and, when it is completed, the reduced silver remains at the bottom of the crucible in the form of a porous mass, which is to be washed, dried, fused, and weighed with the usual precautions. The author finds that this method gives better results than the usual process of reducing the mixed chloride and bromide by heating in hydrogen, or the conversion of the bromide into chloride by heating in a stream of chlorine-gas.—*Journal of the Chemical Society.*

To Correspondents.

*** We cannot undertake to return rejected communications.

R. G.—Will make enquires and let you know.

Pyro.—Thank you for your kindly note; send your specimens by all means.

W. H. (Swindon).—1. Your conclusions amuse us extremely. 2. Our publishing office. 3. A good resolution certainly.

W. Barrington.—The gentleman you refer to is a photographer.

X. Y. Z.—See the Formulary this week.

L. Wood.—The mineral consists principally of alumina, the best samples containing only traces of silica and oxide of iron.

A. Donald.—1. Not till the Medical Schools open in October. 2. No doubt the thread is broken; examine it carefully with a magnifying glass.

Paraffin.—1. Yes, it makes admirable cells for a battery, and we have some that that have been in use for several years. 2. Undoubtedly. 3. It is lighter than water.

Camel.—Not having had experience, we cannot say; but it would certainly be wise to make use of a glass vessel for the first experiment.

C. T. T.—1. Hydrochloric acid would certainly be liberated, but it would ultimately be removed by the oxide of silver. 2. A moderately strong solution of shellac (or sealing wax, if you prefer it) in methylated spirit.

Mariner.—Very much shorter than in the first case; perhaps half.

T. W. Waring.—1. It is obtained by the action of nitric acid on carbolic acid. 2. Use a cylinder of magnesia instead of lime. Although the light is not quite so intense, there is a considerable gain as regards convenience of working.

Alexander Bidwell.—It is evident that you have been working without any definite ideas as to the arrangement of the apparatus. The relation of the arc, the condensers, and the objective must be such that the luminous image of the former shall coincide with the optical centre of the battery, and the position of the diaphragm opening may be taken as corresponding sufficiently near to the optical centre. These being rigidly adjusted, the negative and the screen must be so placed as to secure the requisite degree of amplification.

Bath.—We have tried the sample, and find that it leads to the markings you refer to. Put it on one side for future reduction, and make up a fresh solution.

Oxalate.—It will not dissolve in the quantity named unless the solvent be made hot, and in this case about half will separate out on cooling.

Royal Exchange.—It is impossible to consider that you were harshly used, as you could hardly expect to be allowed to inconvenience a large number of passengers in a crowded thoroughfare.

C. Davey.—It is probable that it would be more convenient to cover it with some inert powder, as starch, before the setting; and if you moisten the place with glycerine you will have no difficulty in making the powder adhere.

J. Snell.—Not for some months.

One Hardly Dealt With.—It is merely a question of business, and depends on the price paid; but the real reason is no doubt the great truthfulness of the portrait. If you give a re-sitting, and, instead of actually taking a fresh negative, you retouch all traces of the ravages of time out of one of the present negatives, the picture will probably be approved of; and you may not only look for a large order, but also expect to be talked of as an unusually clever photographer.

L. C. M.—Certainly not, as an ordinary magnifying glass, costing sixpence, will prove much more useful.

Robert Rawson.—1. Nitric acid is best, but only add enough to give an exceedingly faint reaction. The paper should not turn red immediately, but only after about half a second. 2. The salt has become partially oxidised, and therefore unfit for use. 3. Write direct to the office of the company.

Ceramie.—The only way will be to carefully study the firing, so as to ensure an approximately equal temperature; but in any case, the position of the tile should be occasionally reversed.

P. C.—Such conduct would be ungentlemanly and dishonourable, although strictly legal.

L. Tollington.—1. There is evidently no ammonia left. Keep your stoppers tied down in future. 2. Use oil colours by all means.

C. M. Milford.—It is chloride of silver, and contains about three-fourths of its weight of precious metal.

Norma.—1. A carbon print would be most suitable in such a case. 2. A cold saturated solution.

PHOTOGRAPHS REGISTERED.

THE EVERY-DAY FORMULARY.

The Gelatino-Bromide Process.

Emulsion.—A—Nitrate of silver 100 grains, distilled water 2 oz. B—Bromide of potassium 85 grains, Nelson's No. 2 gelatine 20 grains, distilled water 1½ oz., a one per cent. mixture of hydrochloric acid and water 50 minims. C—Iodide of potassium 8 grains, distilled water ½ oz. D—Hard gelatine 120 grains, water several oz. When the gelatine is thoroughly soaked, let all possible water be poured off D. A and B are now heated to about 120° Fahr., after which B is gradually added to A with constant agitation; C is then added. Heat in water bath for half an hour, and stir in D. After washing add ¾ oz. alcohol.

Pyro. Developer.—No. 1—Strong liquid ammonia 1 oz., bromide potassium 160 grains, water 80 oz. No. 2—Pyrogallic acid 30 grains, water 10 oz. In case of an ordinary exposure mix equal volumes of the solutions.

Iron Developer.—Potassium oxalate solution (1 and 4) 80 parts, ferrous sulphate solution (1 and 4) 20 parts, distilled water 20 parts. To every 4 oz. of the mixed developer add from 5 to 30 drops of a ten per cent. solution of potassium bromide, and 30 drops of a solution of sodium hyposulphite (1 and 200).

Substratum or Preliminary Preparation.—Soluble silicate of soda 1 part, white of egg 5 parts, water 60 parts. After beating, let it settle and filter.

Cowell's Clearing Solution.—Alum 2 parts, citric acid 1 part, water 10 parts. Edwards adds enough of a strong solution of perchloride of iron to give the preparation the colour of sherry.

Eder's Method of Intensification.—The negative is first whitened by being soaked in the usual saturated solution of mercuric chloride, and, after a thorough rinsing, it is immersed in the following:—Potassium cyanide 10 parts, potassium iodide 5 parts, mercuric chloride 5 parts, water 2,000 parts.

The Wet Collodion Process.

Cleaning Preparation for New Plates.—Alcohol 4 oz., Jeweller's rouge ¼-oz., liquid ammonia ½-oz.

Film-removing Pickle for Old Plates.—Water 1 pint, sulphuric acid 4 fluid oz., bichromate of potassium 4 oz.

Substratum.—The whites of 2 eggs are well beaten up with 6 pints of water, and 1 dr. of liquid ammonia is added.

Negative Collodion for Iron Development.—Alcohol 1 pint, pyroxyline of suitable quality 250 grains, shake well and add ether 2 pints. *Iodize this by mixing with* one-third of its volume of following:—Alcohol ½ pint, iodide of ammonium 80 grains, iodide of cadmium 80 grains, bromide of ammonium 40 grains.

The Nitrate Bath.—Water 14 oz., nitrate of silver 1 oz., nitric acid 1 drop. Before using the bath coat a very small plate, and allow it to remain in the bath for about twenty minutes.

Normal Iron Developer.—Water 10 oz., proto-sulphate of iron ½ oz., glacial acetic acid ½ oz., alcohol ¾ oz. The amount of proto-sulphate of iron may be diminished to ¼ oz. when it is desired to obtain full contrasts, or may be increased to 1 oz. when contrasts are likely to be unduly marked.

Intensifying Solution, or Re-developer.—Water 6 oz., citric acid 75 grains, pyrogallic acid 30 grains. When used, add a few drops of the silver bath solution to each ounce.

Eder's Lead Intensification.—After the negative has been well washed it is immersed in distilled water 100 parts, red prussiate of potash 6 parts, and nitrate of lead 4 parts. When the negative has acquired a yellowish white appearance it is again well washed and immersed in liquid sulphide of ammonium 1 part, water 4 parts.

Cyanide Fixing Solution.—Potassium cyanide 200 grains, water 10 oz.

Varnish.—Shellac 2 oz., sandarac 2 oz., Canada balsam 1 dr., oil of lavender 1 oz., alcohol 16 oz.

Printing Processes.

Albumen Mixture for Paper.—White of egg 18 oz., add 500 grs ammonium chloride dissolved in 2 oz. of water. Beat into a froth, allow the mixture to settle, and filter.

Sensitizing Solution.—Nitrate of silver 50 grs., water 1 oz., sodium carbonate ½ gr.

Acetate Toning Bath.—Chloride of gold 1 gr., acetate of soda 20 grs., water 8 oz.

Lime Toning Bath.—Chloride of gold 1 gr., whiting 30 grs., boiling water 8 oz., saturated solution of chloride of lime 1 drop. Filter when cold.

Bicarbonate Toning Bath.—Chloride of gold 1 gr., bicarbonate of soda 3 grs., water 8 oz.

Fixing Bath.—Sodium hyposulphite 4 oz., water 1 pint, liquid ammonia 30 drops.

Reducing Bath for Over-Printed Proofs.—Cyanide potassium 5 grs., liquid ammonia 5 drops, water 1 pint.

Encaustic Paste.—Best white wax 1 oz., oil of turpentine 5 oz.

Sensitizing Bath for Carbon Tissue.—Bichromate of potash 1¼ oz., water 30 oz., ammonia 1 dr., methylated spirit 4 oz.

Enamel Collodion.—Tough pyroxyline 120 grs., methylated alcohol 10 oz., ether 10 oz., castor oil 20 drops.

Mountant for Prints.—A freshly prepared solution of the very best white gum.

Collotypic Substratum.—Soluble glass 3 parts, white of egg 7 parts, water 10 parts.

Collotypic Sensitive Coating.—Bichromate of potash ½ oz., gelatine 2½ oz., water 22 oz.

Collotypic Etching Fluid.—Glycerine 150 parts, ammonia 50 parts, saltpetre 5 parts, water 25 parts.

Various.

Luckardt's Retouching Varnish.—Alcohol 300 parts, sandarac 50 parts, camphor 5 parts, castor oil 10 parts, Venice turpentine 5 parts.

Matt Varnish.—Sandarac 18 parts, mastic 4 parts, ether 200 parts, benzole 80 to 100 parts.

Printing on Silk.—Remove all dressing from the fabric by boiling in water containing a little potash, dry, and albumenize with ammonium chloride 2 grammes, water 250 cubic cents., and the white of 2 eggs, all being well beaten together. A 70-grain silver bath is used, and the remaining operations are as for paper.

Cyanotype Printing.—Water 1 oz., red prussiate of potash (ferricyanide) 1 dr., ammonio citrate of iron 1 dr. Prepare and preserve in the dark. Float the paper and dry. Fixation by mere soaking in water.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1250.—*August* 18, 1882.

CONTENTS.

OPAL GLASS AS A SUPPORT FOR POSITIVE PICTURES.

The special qualities which so notably render paper valuable as a support for positive photographic impressions are lightness and flexibility, both of which qualities are of very considerable importance in ordinary cases. When, however, a picture is intended for framing, these special points are of no great importance, and a more satisfactory result can generally be attained by using opal glass as a basis for the photograph. The advantages of this are considerable, as not only is a picture likely to be far more permanent on an impervious support such as glass, than when on a damp-holding material like paper, but the uniformly even tint and surface of the finely-grained opal glass is not liable to change of colour or darkening by the action of light and time. Another advantage of opal glass depends on the ease with which portions of the impression can be removed by means of ink-eraser, or other abrading substances, without in any way injuring the basis on which the picture has been made.

A circumstance which often serves to render pictures on opal glass more brilliant than prints on paper, is the fact that, in the former case, the image is entirely on the surface—a condition which it is not easy to completely fulfil with paper photographs.

Within the last twelve months the price of the finely-ground opal glass has been reduced to a small fraction of that formerly demanded, so that there is at present no obstacle to its use even for low-priced work.

Opal glass serves as a good basis for pictures by the collodion process, the so-called carbon method, the dusting-on-process, or the gelatino-chloride method of Eder; and by one or the other of these proceedings the photographer can produce any kind of picture which may be required. In every case it is desirable to coat the glass with a thin substratum of insoluble gelatine, the following mixture being suitable:—

Gelatine	... 50 grains
Water	... 15 ounces

dissolve, and add—

Chrome alum	... 8 grains
Water	... 1 ounce

It is important that the glass should be thoroughly clean and free from grease when the substratum is applied, and this is best ensured by first treating with a moderately strong solution of caustic soda, and afterwards with nitric acid. The plates ought to be very thoroughly rinsed, but it is not advisable to dry them before applying the gelatinous mixture. When the substratum is dry, the plate can be used for either one of the methods named; the collodion process being in many cases the quickest and most convenient for the general photographer to adopt. A good negative collodion which has ripened by age may be used, but it is generally well to dilute it with about one-fourth of its volume of un-iodised collodion. The ordinary negative bath answers well, and either an iron developer or a pyrogallic developer: but the latter is to be preferred. The following has given good results in our hands:—

Pyrogallic acid	... 30 grains
Citric acid...	... 15 ,,
Glacial acetic acid ...	... 1 drachm
Water	... 10 ounces

It is better to use hyposulphite than cyanide for fixing; and after thorough washing the picture may be toned in a chloride of gold bath containing about one-third of a grain of the chloride and one grain of acetate of soda to each ounce.

As regards the production of carbon pictures on opal, there is but little to be said excepting that a reversed negative must be used unless a reversal of the picture is of no consequence, as a double transfer to an opal plate is seldom satisfactory. When the carbon print is to be vignetted, care should be taken that the edges of the shade are so arranged as to cut the light off from the picture very gradually, because feeble radiations do not produce so marked an effect as might be supposed.

A series of articles giving full details as to the gelatino-chloride process were commenced in the Photographic News during September last, and we cannot too strongly recommend those of our readers who wish to obtain the most perfect series of gradations, together with the most extensive range of tone, to adopt this process. The chloride emulsion method certainly involves more extensive and complex preparations than either of the others, but the superiority of the results is such as to fully compensate for the extra labour.

Any part of a picture on opal glass can, as already remarked, be readily reduced in vigour by friction with a piece of ink-eraser, and this circumstance renders opal glass of great value when artistically vignetted portraits are required. It is convenient to provide an assortment of rubbers and stamps made of the eraser, some being tapered like a pencil, and mounted; while others are so cut as to present broad flat surfaces.

Opal glass is subject to two disadvantages: these being its considerable weight, and its liability to fracture; but thin sheets of celluloid may be used instead of opal glass in special cases. The surface of the celluloid can be easily roughened or ground by means of pumice powder applied with a cork; and although celluloid consists mainly of pyroxyline, it resists the solvent action of the collodion perfectly, provided that it has been properly roughened and coated with the gelatine substratum recommended above.

PHOTO-LITHOGRAPHY AND PHOTO-ZINCOGRAPHY.

BY MAJOR J. WATERHOUSE, B.S.C.,
Assistant Surveyor-General of India.

MY friend the Editor having asked me to again contribute to the NEWS a short series of papers on photo-lithography, I have endeavoured to bring together some of the latest information regarding it and the kindred process of photo-zincography, derived from such published sources as are available, and from my own experience, limited as it must necessarily be by long residence at a distance from the great centres of progress, and my consequent ignorance of the later industrial development of these processes, though I fear that in their pure and simple form they have made but little progress since I wrote upon them in the twelfth volume of this journal, fourteen years ago. This is to be accounted for by the fact that there was not much scope for improvement by the very nature of the processes and their limited application, which has led to their being superseded to a very large extent for all ordinary purposes of book illustration by the photo-block, Woodbury, collotype, and heliogravure processes, the three latter having the great advantage of perfectly reproducing the delicate gradation of photographic half-tone, so that now the principal use of photo-lithography seems to be in Government cartographic and printing establishments for the reproduction of large maps, plans, and drawings, and to a limited extent commercially for similar work, and for the reproduction of old printed books, and miscellaneous drawings and prints not requiring the superior delicacy and finish of collotype or heliogravure.

Still, with all its defects, photo-lithography is the most suitable and useful process for the reproduction of a large class of subjects, especially maps and drawings of large size, which have to be taken in several sections, and can be turned to very good account for many artistic purposes by applying to it the resources of the skilful lithographic draughtsman and colour printer. The old prejudice against retouching in any photographic process has, I believe, done much to hinder the development of a process which is capable of being made an efficient auxiliary for producing pictures combining all the essential accuracy and truthfulness of photographs with the artistic adjuncts which can soften and relieve the crudeness and want of pleasing effect so often characterizing them.

It is scarcely to be expected that photo-lithography will become more extensively used for general purposes, in face of the powerful rivalry of the newer processes of collotype and heliogravure; but a short *resumé* of the details of the various methods may re-awaken some interest in the process, and be of use to present and future workers; and in that hope I write these papers.

The history of photo-lithography and photo-zincography has been so often written, that there is no necessity for my repeating it, and I shall therefore enter at once on the practical consideration of the subject, commencing with—

The Preparation of the Original.—"With a good original and a good negative, photo-lithograpy is simple child's play," said to me, some years ago, one of the most successfull photo-lithographers I have ever met. At that time the difficulty was to get the good original; the use of photography for reproductions was by no means extensive, and its requirements were but little known. Owing to the introduction of the various photo-block processes now so largely used in the illustrated journals as a substitute for wood engraving, the necessity for suitably-drawn originals has been recognized, and the conditions of success are better understood.

As a rule, photo-lithography is only suited for the reproduction of subjects in black and white, such as manuscript pen-and-ink drawings, maps, plans and charts, prints and engravings, in line, stipple, or chalk—for much the same class of subjects, in fact, as are suitable for treatment by ordinary lithography, only bearing in mind that the original must represent the finished result. The camera will not correct and beautify faulty drawing, as the lithographer is often expected to do, though a good deal may be done by skilful touching up.

From time to time various endeavours have been made to reproduce on stone the delicate gradation and half-tone of a photographic negative from nature, or, rather, break it up, and give it more or less the appearance of a chalk drawing; but they have all been more or less unsatisfactory, and rough work of this kind is now done almost entirely by collotype and heliogravure.

The photo-lithographer has usually nothing whatever to do with the preparation of the original, and as often as not is called upon to reproduce printed or manuscript originals quite unsuited for the process. In such cases he can only make the best of them with the means at his command; but when circumstances permit of the original being prepared specially for the purpose, attention to the following rules, originally drawn up for the guidance of draughtsmen in the Indian Survey and Public Works, will be found conducive to success.

1. The drawings should be made on white smooth-surfaced paper, fresh tracing cloth, or, best of all, fine Bristol board. When possible, the drawing should remain stretched on the drawing board, and in any case should be kept as clean as possible, and free from pencil marks, creases, and wrinkles. Little defects which may scarcely be noticed on the original, frequently attain undue prominence in the photograph.

2. The best ink to use is Indian ink, which should be freshly and evenly rubbed down, and be sufficiently thick to give a good full black line. A little yellow pigment such as gamboge, or preferably, burnt sienna, is sometimes added, and Capt. Hannot recommends rubbing down the ink in a very weak solution of bichromate of potash. In adding yellow to the ink, care must be taken to use some substance which will not spread beyond the lines, especially when drawing on tracing cloth.

3. The lines should be firmly and clearly drawn, not too fine or too close together. Even the finest lines must be quite black. Light effects must be produced by making the lines thinner, and increasing their distance apart, and not by the use of pale ink. In removing pencil marks after the drawing has been inked in, great care must be taken not to destroy the blackness and firmness of the lines by too much rubbing; otherwise they will appear quite rotten and broken when reproduced.

4. Cross-hatching and shading should be open, and in firm clear lines, not too close together or confused by fine lines. Intensity of shade should be shown by an increase in the thickness of the lines rather than by their being placed close together. It must be borne in mind that throughout the process there is a tendency for the lines to thicken, so that if they are too close they are liable to block up in the printing, and the work will appear heavy and unsightly. This rule also applies while shading, the darker portions of which should be drawn in thick distinct lines, but not crossed and recrossed with fine lines.

5. In drawing maps, it is better to leave river courses, coast lines, lakes, ponds, or tanks, blank, and not filled in with fine lines. They may be indicated on the original by a pale wash of blue without detriment to their reproduction.

6. Similarly in mechanical or architectural drawings, ruled tints and shades are better left blank on the original, or shown by light tints of blue, violet, or aniline red. Engraved tints in lines or dots can be transferred on the stone afterwards, and will have a much neater effect than tint lines reproduced directly from the original.

7. Washes of any colour, except pale blue, violet, aniline red, or other colours which will not reproduce,

are absolutely inadmissible in drawing for reproduction by photo-lithography. If necessary, outlines may be drawn in some pigment which will reproduce black, such as strong red, brown, yellow, orange, or green. Details required to be shown in the original, but not in the copy, may be drawn in pale blue, aniline, violet, or red. Spots, stains, and details not required to be reproduced, can be painted out with Chinese white.

8. Whenever possible, the original drawings should be on a larger scale than the reproduced copy. Defects in drawing are lessened by reduction, and the result generally is finer and sharper than a reproduction to scale would be.

9. In preparing drawings for reduction, care must be taken that the lines, lettering, and detail are drawn of sufficient thickness and size relatively to the scale of reduction, so that they may be clear and distinct, and in proper proportion together when reduced, and not be so small as to be either quite lost or illegible. Thus, if it be required to reduce a drawing to one-fifth the scale of the original, every line must be drawn five times as thick, and the writing and details five times as large as required in the reduced copy. Sufficient space must also be left between lines of shading or cross-hatching to prevent their blocking up and running together in transferring and printing. Practically, it is sufficient to draw the original from about one and a-half to twice as large as the copy to secure all the advantages of reduction, and the originals will also serve for reproduction if necessary.

10. It will save confusion and mistakes if the scale on drawings intended for reduction is shown in terms of a single unit of measurement as inches, feet, miles, &c., and not as relative to any second unit, as inches to a foot, mile, &c. It should be shown simply as scale of feet, miles, &c.

11. Drawings or tracings intended for reproduction should not be folded, but kept flat or rolled. Folding causes creases which give shadows on the negative in reproduction, and these may obscure and spoil other details. It is a good plan to pass a creased drawing through a copper-plate or lithographic press before copying.

12. It must be borne in mind throughout that photography will only produce a *facsimile*, and that, as a rule, the original will not be in any way improved upon. Rough, coarsely-drawn work will not appear like fine engraving, or bad writing like letter-press or copper-plate, and therefore, in making drawings for publication, care must be taken to give them the requisite degree of neatness and finish before they are copied, so that the result may be fit for immediate issue, and not require alteration and touching up, which causes delay and expense, besides deteriorating the work before it is printed.

The essence of these rules may be given in a few words:—*White Smooth Paper—Black Ink—Firm, Open Drawing.* Success in the after processes depends entirely upon the perfection of the original drawing and its capability of giving a negative with clear, transparent lines on a perfectly opaque ground; and this cannot be done unless these essentials are carefully observed.

In some processes of photo-lithography, and more particularly photo zincography, by the bitumen processes, now being worked in Paris by the Topographical Brigade at the Invalides under the direction of the Commandant de la Noë and Captain Biny, a transparent original or tracing is used for printing by contact. Such originals should be drawn on fresh white or bluish-white tracing paper of even grain, free from spots or stains, with a good thickness of ink, so that the lines may be quite opaque. The addition of a little yellow to the ink is sometimes recommended. This should be burnt sienna or chrome yellow in preference to gamboge. Great care must be taken to keep the back of the paper clean and free from marks, which might print through.

Old tracing paper is not suitable for these drawings, being generally yellow and brittle.

The tracings should not be coloured, and, as far as possible, should be drawn entirely in firm or dotted black lines; but if the use of colour should be obligatory, lines may be drawn in vermilion, burnt sienna, chrome yellow, and dark green.

Tracing paper is preferable to tracing cloth, which is not so transparent, and shows a strong grain of the cloth.

If drawings are not on too thick paper, they may be made transparent by applying a mixture of one part of castor oil and five parts of spirit of wine. The oil may be removed afterwards by soaking the drawing in spirit of wine.

When type is used for lettering drawings for reproduction, care should be taken to get a fine, clear, black impression. The paper should be indented as little as possible by the type, otherwise the hollows cause shadows which thicken out the letters when reproduced.

It is advisable, if possible, to pass typed drawings through a lithographic or copper plate press before they are copied.

Typing is often done on little slips of paper cut out and pasted in position on the drawing. This saves the denting of the drawing paper; but unless the typed slips are of very thin paper, shadow lines will be thrown round the edges of the slip, and require touching out on the negative.

In typing tracings for contact printing the ink lines are often too pale. The Commandant de la Noë has found an ingenious way of overcoming this by powdering over the freshly-printed names with red bronze powder. This adheres only to the lines, and makes them perfectly opaque. M. de la Noë has also invented a type stamping machine, which is most effective in giving a very clear sharp image without indenting the paper. The type-holder has a rocking motion over a cylindrical support on which the drawing is placed, so that the type is in contact with the paper only when making its impression.

When drawings are prepared specially for reproduction, there need be no difficulty in taking all the precautions necessary for producing good results. It often happens, however, that the photo-lithographer is called upon to copy old prints or manuscripts which may never have been suitable for the process, or, if suitable when fresh, have become dirty and stained by age. With entirely unsuitable subjects nothing much can be done, but with proper precautions, originals that are only dirty and stained may be cleaned and made fit for reproduction.

Yellow or otherwise objectionable spots should be carefully covered over in the spaces between the lines with Chinese white, and, when possible, weak lines should be strengthened.

Old engravings and lithographs may be bleached by immersing them in a solution of chloride of lime or eau de javelle (1 to 10 or 15 of water), then soaking them in water for some hours, after which they are treated with a weak solution of hyposulphite of soda, and finally well rinsed with clean water.

Another plan is to sprinkle finely-powdered salt all over the engraving, then squeeze lemon juice upon the salt so as to dissolve most of it. Boiling water is then poured on till the salt and lemon juice are washed off. The surface will then be quite clean and free from stains. The engraving should be allowed to dry without heat, and gradually, on a board or other smooth surface (*Spon*). A short soaking with very dilute hydrochloric acid (1 to 20) or acetic acid, followed by plentiful washing, will clear up a print very much.

Mr. W. Brooks recommends the use of "Holmes' Ozone Bleach" as superior to any chlorine bleaching, and not so liable to injure the original by traces of chlorine remaining in the fibres of the paper. The best strength is about one part to ten of water, and the engravings may be left in it from half-an-hour to four hours if very brown. With a stronger solution, the time would be somewhat less. After all the stains are removed, the bleach is poured off, and the print well washed in several changes of water or in running water for about two hours, then blotted off and dried.

Grease stains, if fresh, may be removed with chloroform, benzine, or ether, or with a weak alkaline solution of caustic potash or its carbonate. Old stains can be removed with a more or less strong solution of potash applied at the back of the subject.

Iron moulds and ink spots may be taken out with solution of oxalic acid or salts of sorrel.

Originals printed or drawn on rough paper may be smoothed in a copper-plate press, and if dirty, should be carefully cleaned with india-rubber or bread, with the precautions noted in the foregoing Rule 3.

(*To be continued.*)

FRENCH CORRESPONDENCE.

Some Recent Patents—M. Borlinetto on Photographic Instantaneity—Captain Biny's Latest Experiments—Poitevin Subscriptions—Legal Proprietary in Photographs.

Some Recent Patents.—As we have already stated several times, we patent here every possible thing, and M. Hutinet has just patented a system of distinguishing gelatino-bromide plates one from one another. With the aid of bichromated gelatine, or, in fact, any other similar paste, cardboard cuttings, or any other distinguishing mark rendered impermeable by gum lac, are stuck on the surface of the plate. This is the whole thing. The idea may be excellent, but really patents are greatly abused, of which this is a striking example. M. Lapré has just invented and patented a match-box photographic apparatus. Do not imagine, estimable readers, that this is a pocket camera. It is simply a match-box having a receptacle for invisible photographs, rendering them visible by means of a gaseous emanation. A special drawer at the back of the box contains the substance destined to cause the invisible image to appear. Take notice, however, that M. Lapré's patent is annulled by the sole fact that he has omitted to name the preparations used, and the patent law enjoins that the patented processes must be fully described under pain of being rendered void. M. Paul Edouard has taken out a patent for the production of portraits on opal glass. A sheet of thick cardboard is covered with a thin solution of gelatine, dried, and afterwards coated with a thick film of collodion treated with chloride of silver, and again allowed to dry. A picture is printed and fixed on this surface, and subsequently applied to a plate of opal glass or porcelain covered with gum, by softening the gelatine in hot water, thereby causing the paper to be detached, leaving the print on the glass. And this M. Paul Edouard has thought worthy of patenting. Really, the ignorance of the greater number of these inventors must be very great, since they imagine they have found out what everyone knew and practised years ago. We will not enumerate any more of these discoveries.

M. Borlinetto's Remarks on Photographic Instantaneity.—M. Borlinetto, professor at Padua, has written telling us of his experiments made with M. Paul Boca's chronometric shutter, and has sent an instantaneous print about 7 by 5 inches in dimensions, in which it is easy to see that the people in movement in the foreground are not so sharp as those at the back. This evidently proves that the same length of exposure gives different results according to whether the planes farther from or nearer to the objective are reproduced. A veritable and complete instantaneity cannot exist in any case, and one cannot realise reproductions having an equal degree of sharpness unless with lenses regulated so as to produce an automatic effect; and further, the angular variations of a being in motion would be more appreciable nearer the objective. It is therefore necessary, in order to reproduce instantaneously moving figures, to take account of rapidity of exposure required to give as sharp definition as possible of persons and animals nearest to the lens. M. Borlinetto reckons the exposure at $\frac{1}{500}$ of a second for figures traversing the field of vision in the foreground.

Captain Biny's Latest Experiments.—Captain Biny, whose very remarkable works we have before had occasion to speak of, has just made some new experiments of great interest. He holds, in the preparation of gelatine plates in daylight, that the nitrate of potash must be first eliminated from the emulsion, as the cause of crystallization occurring on the surface of plates treated with bichromate of potash. Theoretically, nothing seems easier of employment as reagents acting one upon the other than neutral chromate of silver, ammonia, bromine, and gelatine. Practically, too, we are assured that the experiment is exceedingly simple. The two following mixtures are taken:—

A.—10 per cent. solution of ammonia saturated with chromate of silver...	80 c.c.
Gelatine	5 grammes
B.—Alcohol	10 c.c.
Distilled water	10 c.c.
Bromine	2 grammes

The gelatine is dissolved in the solution of ammonia by the aid of a spirit lamp, until the lumps have disappeared, when it is allowed to cool down to 30° or 35° C., and the liquid B is added in daylight. It is then vigorously shaken, and the chromated emulsion is made. It is filtered twice, and spread on plates covered with soluble glass. The plates must be allowed to dry upon a horizontal surface during the whole of one night, in a dark place, and the next day one can state with certainty that they show no trace of crystallization. They only contain gelatino-bromide of silver mixed with chromate of ammonia, but no bichromate. In order to use the plates for negatives or positives, they must be washed in complete darkness until they have lost all the chromate of ammonia, and be left to dry in a dark, ventilated place; thus gelatino-bromide plates will be made, having the advantage of being prepared in daylight and in a short time. Captain Biny has remarked: 1st, that the ferrous oxalate developer containing 10 per cent. of hyposulphite of soda preserves its properties for months; it is, he says, very active, and does not fog the plates. 2nd, the same developer, acting after the ordinary oxalate, without hyposulphite, upon a negative half developed, transforms it into a positive. This fact is very curious, and is worthy of being more closely studied.

Poitevin Subscriptions.—The Poitevin subscriptions already exceed 4,000 francs. It is probable that the sum will be devoted to the raising of a monument in a public square at St. Calais, a town in the department of Sarthe where Poitevin studied. The municipal council of that town have just granted 500 francs, and have nominated a committee to collect local subscriptions.

Legal Proprietary in Photographs.—The law relating to the proprietary of photographic works has just received a support in favour of French photographers. Two conventions have just been signed, one between France and Belgium, and the other between France and Switzerland, by which it is stipulated that photographic prints shall be treated on the same terms as works of art. After this it will be impossible in France to encounter a legal difference between French photographers. Leon Vidal.

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

A Visit to the Italian Lakes.

"The Italian lakes may be done in a day; you start early from Milan to catch the first boat from Como, land at Menaggio, take omnibus across to Lugano lake, steam from Porlezza to Lugano, whence a trap is taken to Luino, on the Lago Maggiore, where you arrive in time for the last boat to Pallanza or Baveno." This was the advice given us, we remember, exactly twenty-four years ago by a travelling Briton who was "rushing" the Continent, and to whom we had turned for advice; and if we repeat it here, it is not to urge any of our readers to take it, but to show how convenient to one's hand the Italian lakes lie. Moving leisurely with a camera—and a camera, if it makes one move leisurely, has, at any rate that advantage—you can see the lakes very well in a week, so that the tour may be taken as an addendum either to a Swiss, Tyrol, or Italian trip.

Coming from Switzerland you may either take the new railway over the St. Gothard, or, if you prefer the old-fashioned diligence travelling, which has much to recommend it, cross either the Simplon or the Splügen. From the Tyrol, the best plan is by Verona to Lecco; while if you are in Italy, Milan makes the best starting point. We will choose the last-named city, its many-pinnacled cathedral, each pinnacle a statue of white stone, being one of the most charming architectural objects at which a camera can be levelled. An hour's journey brings you to the shores of Lake Como, and there we take steamer forthwith. The town of Como has little to recommend itself to the photographer, who will do well to make his first stopping-place either Cadenabbia, Bellaggio, or Menaggio. All these spots are within a couple of miles of one another, and are delightfully situated beside the deep blue waters. Our quarters have always been at an *albergo* at Menaggio; for from the terraced vineyards above the little port is seen a panorama that, in our experience, has not its rival in Europe. There, in the clear sunshine, lie the azure waters at your feet—a glorious mass of colour, dotted here and there with tiny white-canopied boats. To your right is the green promontory of Bellaggio, dividing the rich blue expanse into two portions; while right opposite, reaching down to the verge of the lake, is the bright little town of Varenna. Along the shores are picturesque villas, half hidden by the massive foliage that fringes the blue water. The upper part of the picture is filled with the velvet outline of a range of hills that rise high above the lake, while as foreground are the green clustering vines that shut out Menaggio, with the exception of its diminutive port, and the sailing craft drawn up upon the strand.

This picture we have in two successive years sought to do justice to with the camera, but in vain; and here we may at once say that in no country is photography so disappointing as in Italy. The wealth of colour and gorgeous contrasts that seduce the eye are naturally lacking in our sun pictures, and it is the former that are so characteristic of Italy. Still, a picture of Mr. Woodbury's which we have seen—he has fixed his point of view nearer Cadenabbia—reproduces the soft sweetness of the picture we have attempted to describe, and indicates much of its charm. He has secured the trellised vines as a foreground, and loses none of the beauty of Bellaggio Point.

The arm of the lake on the other side of Bellaggio is termed the Lago di Lecco, the town of Lecco being romantically placed at its termination. A charming view of the town may be had from the opposite shore. We embarked camera and stand in one of the white-canopied boats, and landed whenever a presentable picture presented itself. As the boats are flat-bottomed they are easily dragged from the water, and we frequently employed our craft in this position as an attractive and steady foreground. The tiny white houses of Lecco, the line broken by green tufted trees, are so bright and clear seen across the placid lake, that Lecco looks like a fairy city, the idea being still further countenanced by the lofty and massive mountain rising beyond, whose every outline falls upon the lake.

The northern end of Lake Como is flat and marshy, so there is no need to visit it; but if you take the camera ashore at Bellaggio, be sure you secure a picture of the town of Varenna opposite, whose spires and buildings seem to rise out of the still water. The trim villas at Bellaggio and at Cadenabbia, with their white marble landing steps, gay flags, and numberless verandahs, are too modern and too town-like to tempt the photographer; but some of the village ports, with their swarthy sailors in striped shirts and broad straw hats, will make a picture.

From Menaggio it is a nine mile walk through green luxuriant country to Lake Lugano. The deep greenery of the vineyards and maize fields are most refreshing to the eye, for it is generally very hot hereabouts. The sunny land of grapes and figs is before us, and a more rich and fertile country it would be difficult to conceive. At times the road leads through the narrow street of a village, and children with legs and arms as brown as mahogany come clustering round with a plaintive cry of "Carità, Carità!" In the background are dark-eyed women, and black-bearded men whose attire requires merely the addition of a belt and a pair of pistols to make them into brigands of the conventional type. Indeed, we are now passing a country as famous as that of Rob Roy in Scotland, for around the shores of the Lake of Como and Lecco passes the action of Manzoni's world-renowned work, "I Promessi Sposi." These men, in their rough picturesque costumes, we can well picture as the Bravi, or outlaws, that the Italian Sir Walter Scott has described; and the mountain pathways, rocky terraces, and green sequestered nooks we pass, are fitting scenes for the enactment of a drama like "The Betrothed."

Strong stone-built dwellings, bearing a date several centuries back, with coats of arms now crumbling to decay wrought over their lofty portals, and delicate green vines climbing about the portico, and seeking an entrance through the barred windows; little white-washed cottages, with painted frescoes executed by the village artist, and representing some saint or holy personage; tiny chapels, with altar-pieces and models of our Saviour on the Cross, such are the most striking objects in the villages and hamlets we pass through.

Half-way, we come to the little Lake Piano, beyond which a glimpse of Lake Lugano is seen. You cannot do better than set up your camera here on the high road, at the moment you sight the little lake. A farm out-building serves for the left of the picture, and then you look at Lake Piano through a gap in the trees, which serves to frame the sheet of water in a most picturesque fashion. The border of the high road which becomes a portion of the foreground does not detract from the view, for it helps further to localize the spot. Indeed, with the little picture lying before us now, we can realize very keenly our tramp along that pleasant road.

There is a steamer from Porlezza, on the shores of Lake Lugano, to the town of Lugano; or if you have time, and there are several in the party, it is not more expensive to be rowed there. The journey, in these latter circumstances, but takes two hours, and it is a most pleasant one, gliding close under the precipitous banks, and almost under shadow of the leafy fig trees which seek to dip their dark green branches into the cool water. Here and there you pass a cluster of cottages hanging like swallows' nests to the high banks, with which the only communication is by water, for the sides of the lake are too steep for any road between Porlezza and Lugano. These village scenes are most inviting to the photographer, but they are all so picturesque that it is difficult to make choice. You are now on the confines between Italy and Switzerland, so that it is well to make no mystery when you land with your apparatus, for fear of raising the suspicions of the Italian Custom House officers; the Swiss Custom regulations—Lugano is in Switzerland—are not so strict.

That green smooth-topped hill, shaped like a bell, rising precipitately from the shores of the lake at the foot of the glittering little town, is the Monte Salvatore; it is but two thousand feet high, by no means an arduous climb, and commands a magnificent view of the lovely district below. From the top you seem almost surrounded by water—for the mountain is on a promontory almost running into the lake—and beyond are green fields and vineyards; far away to the north, may be seen the snowy spires of the Alps. The violent contrasts between the dark green and the hazy snow outlines are difficult enough to manage in a photograph, and only skilled photographers are likely to succeed with such a scene.

Some quaint bits of Italian architecture are to be found in Lugano itself, with which the photographer may busy himself during a brief stay. To Luino, on the banks of the Lago Maggiore, is rather further than from Menaggio to Porlezza, and, if it is hot weather, as it usually is, we recommend a conveyance, which is easily found. The country is still of a luxuriant green, the road, for the most part, overshadowed by trees and shrubs of magnificent growth. Steamers ply frequently on the Lago Maggiore, and to Pallanza—an Italian town with arched market-place and piazzas—is but an hour's journey.

Maggiore's banks are not so lofty and picturesque as those of Lugano and Como; but the gorgeous colouring of the shores at eventide is not to be surpassed. The translucent, ultramarine water, with the white cottages and villas at its margin—nitched apparently out of chalk—is a magnificent sight, and art aids nature in the colouring wherever it can. The smart steamers of the lake are manned by grand officers in gold-laced caps and white trousers, and the flat-bottomed wherries drawn up on the sunny strand, with their snow-white canopies, red cushions, and coloured flags, make the landing-places gay and picturesque to a degree.

The photographer, like most other visitors, will be tempted to visit Isola Bella, one of the Borromean islands, which is famous for its tropical plants and shrubs, for its terraced gardens where myrtle trees, aloes and cacti, as well as the sugar cane, may be found growing. But he may well leave his camera behind him, for the gardens are very trim—inclined to be mathematical, in fact—and scarcely likely to give a satisfactory picture. In any case, permission should be asked before landing, for Isola Bella is private property.

Pallanza is within a few hours' drive of Domo d'Ossala, at the foot of the Simplon, or the St. Gothard railway may be reached by taking boat to the northern end of the lake.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Daguerreotypes and Mercury—Balloon Photography—Cheap Albumenized Paper.

Daguerreotypes and Mercury.—An old Daguerreotypist, writing in reference to the volatilzation of mercury at low temperatures, says:—" Your remarks in the News of the 4th inst., calling attention to the doubt which appears to exist as to how Daguerre really did discover mercurial development, reminds me of my early experience with Daguerreotype plates, when the development with mercury caused me at first no end of perplexity. In my anxiety to have the very latest improvements, I got a mechanic to construct for me a conical metal developing dish on the pattern of those used by the American Daguerreotypists, then as much the pioneers of the photographic art in regard to Daguerreotypes as the English now are with respect to gelatine plates. The conical dish was made, the mercury was poured in, the spirit lamp was applied to the apex (the cone was of course inverted), the plate was placed on the top, but—not the shadow of a ghost of an image would appear. Ten minutes was supposed to be the orthodox time; but half-an-hour, an hour, and more, were equally useless. The mercury obstinately objected to volatilize, and this, too, when the thermometer, the bulb of which went to the bottom of the cone, registered a high temperature, and the spirit lamp was kept burning the whole time. I was in despair; I sought counsel of my instructor in the art, but the master was no wiser than the pupil, and he was forced to confess that he could not explain the reason. At last it so happened that in one of my experiments I left the plate over the mercury so long that it went clean out of my recollection, and when I again thought of it and rushed to see the result, I found that the prolonged heat had burst the bulb of the thermometer, but had at last developed the picture. This gave the cue as to what was in fault. The metal of which the cone was made was far too thick, and though the portion nearest the flame became hot, the temperature of the bulk of the mercury was scarcely affected. I must own that the discovery was rather a shock in the face of what Mr. Robert Hunt had written on the subject, and to me throws considerable doubt upon the "chemical cupboard" theory of Captain Abney, or rather his authorities, unless the temperature of the cupboard was unusually high. And yet mercury does volatilize at the common temperature, and can even develop a picture, though not in the way desired by the Daguerreotypist. It is a curious fact that Daguerreotypes which are kept covered over by the same piece of glass and left undisturbed, will, in the course of time, set off the image on the glass, thus showing that those portions of the picture to which mercury is attached have given off fumes. I believe that this is the first time the phenomenon has been recorded, but I should think it must be familiar to most photographers who have had old Daguerreotypes to copy."

Balloon Photography.—Balloon photography may before long furnish the latest novelty in the way of sun pictures. Why should not the attempt be made to photograph London as seen from the balloon? If the latter was kept stationary, there should practically be no difficulty. A view of the whole of London, from Shepherd's Bush to the Isle of Dogs, from Muswell Hill to the Crystal Palace, would be a decided curiosity, and, after all, it is only a matter of length of rope. Such a picture would probably require Sam Weller's memorable "patent double million magnifyin' gas microscopes of hextra power" to enable any one to make out the details, but this would only add to the curiosity. Any way, London in sections could easily be represented, and be of use to map-makers. In fact, there is no reason why such balloon pictures should not be able to save a good deal of trouble in the way of surveys. An ordnance survey is a matter which takes an interminable time; and in places where rapid building is going on, the map when produced is, owing to the necessary delay, very incomplete. It was mentioned in the House of Commons a few days ago that the survey of Great Britain now going on would not be completed for some years—a statement which was received with laughter, and it would certainly be desirable if some method could be devised to hasten the proceedings. The Parisians attach considerable importance to balloon photography, and the Academy of Aerostation are at the present time organizing means to carry out the idea, the corporation of Paris voting £40 towards the cost. The Balloon Society meeting at the Westminster Aquarium appears to devote itself to every subject save that of ballooning, or it might take up the matter practically. Whether the Corporation of London would be found guilty of the extravagance of voting, say, £50 in furtherance of such an object may be doubted, even though a balloon picture of London would contain a representation of the extreme tip of the Griffin's tail.

Cheap Albumenized Paper.—The difficulty which manufacturers of albumenized paper have always felt is, what to do with the yolks of the eggs they use. This added considerably to the cost, for at whatever price they might offer the yolks to the pastrycooks—the only consumers—they could not get rid of all their stock. There was also the drawback that the yolk of an egg exposed to the action of the air is one of the most unstable substances, for unless it is speedily made use of, it passes into a stage which necessitates instant removal. Latterly the yolk of the egg has become an important agent in the dressing of skins, and the drawback to the manufacture of albumenized paper is at an end. A further advance in regard to the use of the yolk may now be noted. According to a French chemist, M. Carles, the yolk is as efficacious when in complete putridity as when fresh. The leather dresser cares nothing for unpleasant odours; all he concerns himself about is homogeneity and richness in fatty matters. To get rid of the former, some collectors of the yolk apply water, and, to raise the density (thus lessened), a few handfuls of marine salt; others have recourse to alkaline sulphates, alum, &c., to retard putrefaction. None of these matters seriously affect the skins; but they undoubtedly diminish the value of the mucilage by lowering the proportion of oil of the egg, and it becomes an important matter for the leather dresser to ascertain how far this proportion has been altered. To ascertain the purity of the mucilage, measurement of density is of course fallacious. The presence of foreign salts is best detected by comparing equal quantities of typical yolks and of suspected mucilage. But the surest, if not the quickest, plan is to determine successively, in a few grammes, the quantities of water, organic matter, and mineral salts; lastly, the proportion of fatty matter. This is the advice of M. Carles to the leather dresser. The photographer is interested in it to the extent that the more valuable the yolks of eggs become, the cheaper should be albumenized paper.

Review.

Ausführlichen Handbuch der Photographie, Part III., by Dr. J. M. Eder. (*Knapp, Halle, Germany*).

This third part of Dr. Eder's exhaustive work on photography fully maintains the high reputation of the author. It treats of lenses in a most thorough manner, not only imparting the history and theory of photographic objectives, but describing minutely, one by one, the well-known lenses of the different makers with which photographers are familiar. Many forms of lenses that possess merit, and yet have passed into the limbo of forgottenness, are here not only discussed, but depicted along with the most modern forms of instruments with which we are acquainted. In a word, Part III. of Dr. Eder's work is the most perfect treatise on photographic lenses extant.

A chapter on the testing and choosing of lenses is not the least valuable portion of the pamphlet. Dr. Eder carefully points out the defects to be found in faulty lenses, and how they are to be discovered; and in many cases he makes valuable comparison between the well-known instruments of commerce.

We heartily commend the work to all thoughtful photographers. The parts are to be purchased separately for 2s. 6d.

COLD EMULSIFICATION WITH UNIFORMITY.

BY A. L. HENDERSON.*

It is not my intention to lay an elaborate or exhaustive paper before you; I would rather court a discussion, and try, if possible, to elucidate the curious action that takes place when bromide of silver is formed in the presence of gelatine in an acid or alkaline state.

I have previously stated that if bromide of silver is precipitated in an aqueous solution, it only requires time to soften the particles; but if an alkali or acid is introduced, this softening effect will take place much quicker; heat will also help it.

Now, it is well known that gelatine being a very variable complex substance (no two samples being alike), great difference must take place when a precipitate of bromide of silver is made in gelatine. If we use a small quantity of gelatine to begin with, more or less of it is decomposed before the desired result is obtained.

I venture to say that boiling or stewing is not only unscientific, but uncertain. Now, if we add something that will prevent decomposition, one element of failure is got over.

Of the various substances tried, I find alcohol and ammonia the best.

Here I have a solution of gelatine 10 grains dissolved in 1 ounce of water; when the gelatine is dissolved by gentle heat, I add ammonia carbonate 20 grains (the ammonia causes effervescence):—

Bromide of potassium	150 grains
Iodide " "	2 "
Alcohol	3 ounces
Ammonia ·880	60 minims

Mix ammonia and alcohol before adding to gelatine.

This may be kept in bulk, ready for use; it will keep a long time good. When it is quite cold, I stir in—

Nitrate of silver	200 grains
Water	2 ounces

I occasionally shake it, and in one hour it will be ripe enough for all ordinary purposes; in fact, when finished, it will give results twice as rapid as most commercial plates. The maximum sensitiveness seems to be reached in about ten hours. No further advantage is to be derived by prolonging the emulsification, except that of convenience.

It should be apparent that, to have a large reservoir of emulsion made in this way, to draw from daily, or at will, adding fresh to keep up the stock, perfect uniformity must be obtained.

To the above quantities I add 4 to 5 drams of dry gelatine, and warm gently to dissolve the same. When the gelatine is thoroughly dissolved, I stir in 12 ounces of warm methylated alcohol (100°). The emulsion, when cool, will precipitate on the bottom of the vessel; it is to be broken up and well washed in a running stream from two to twelve hours. Make up bulk to 8 or 10 ounces.

Gelatine dissolved in alcohol, ammonia, and water, will not set so firmly as the same amount of gelatine in water; yet, if the salts and ammonia are removed by precipitating with excess of alcohol, the gelatine recovers its setting powers.

* Read before the London and Provincial Photographic Association.

Notes.

The Technical Meetings of the Photographic Society are to be continued throughout the year on the fourth Tuesday in every month.

The French Government has decided on spending no less a sum than £18,000 upon the astronomical and photographic expeditions sent out to observe the transit of Venus.

A costly album. Colonel Oswald, of the Canadian Volunteers, presented as a prize at the Shoeburyness meeting an album containing 220 views of Canadian scenery valued at £60.

The well-known photo-astronomer M. Janssen has been nominated President at the next meeting of the French Association for the Advancement of Science.

This Association meets, contemporaneously with the British Association, at La Rochelle. A memoir on the photometry of light of different colours is among the papers to be read, and is likely to interest photographers

The Duke of Albany is expected at Southampton when the British Association meets there next Wednesday. His Royal Highness is President of the General Local Committee.

Some time ago we announced a winter Electrical Exhibition at the Westminster Aquarium. It opens on November 1st, and prizes will be given, among other things, for the "best application of electric light fittings to photographic studios."

The good people of Sunderland cannot, apparently, make up their minds whether it is a wicked thing to take photographs on a Sunday, for last week, when a photographer was indicted for so doing, "the case was *dismissed*, on payment of costs." Of course the magistrate must have known what he meant by his decision, though we frankly admit we do not; but then a judge, being wise by tradition, naturally knows more than most of us.

The mirage was frequently observed by the French army in Egypt early in the century, and it is interesting to find that one of our special correspondents has now witnessed the optical phenomenon. Sandy plains are particularly suitable for the formation of the mirage, the eye generally witnessing a vast lake in which trees and villages are to be seen reflected. The phenomenon is due to the heating of layers of atmosphere, and consequent unequal refraction of the sun's rays. All pronounced objects appear as if they were in an immense lake, the aspect of the clear sky completing the illusion.

The correspondent of the *Standard* tells us that the mirage he saw, brought into view all the forts round Aboukir Bay—even the white flags flying over each could be distinctly seen. The forts looked like so many islets rising out of a glassy sea. Around these, white specks showed where the Egyptian soldiers were busily engaged on their entrenchments.

The *Deutsche Photographen Zeitung* has reproduced our tour in Thuringia under the title of "Eine Tour durch den Thüringer Wald mit der Camera."

The Royal Cornwall Polytechnic Society's Photographic Exhibition opens early in September, and next Tuesday is the last day for receiving pictures. We hear that during the gathering Mr. William Brooks will lecture on "The Rise and Progress of Photography."

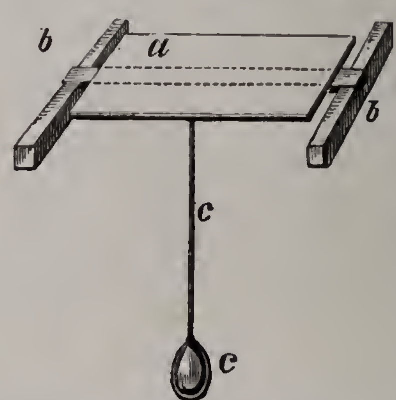
The portrait of Mr. Woodbury, by Ives' process, which we were able to publish last week through the courtesy of Mr. E. L. Wilson, of the *Philadelphia Photographer*, has brought us numerous enquiries as to the nature of the method and the possibility of practising it in this country. We may mention, therefore, that the patent for Great Britain is still unsold, and that any application respecting it, addressed to our office, will receive attention.

It is to be feared that next week's meeting of the British Association at Southampton will not be a brilliant success. The inhabitants, says *Truth*, do not seem disposed to show hospitality to the visitors, and there is still a very large deficiency in the amount required to pay expenses. Lord Mount-Temple is to entert.in a party at Broadlands, and it is expected that a garden party will be given there. Canon Wilberforce has already issued invitations for a garden party on the largest scale in the grounds of the Deanery.

A notice, which only reached us on Wednesday, gives the particulars of a dry plate competition to be held at Eisenach, in Germany, during the convention of German photographers. Manufacturers and dealers may both compete, and those interested will find particulars on another page. The plates must reach Eisenach, carriage paid, on the 20th inst., so that competitors should send immediately. Parcels forwarded express on Saturday afternoon would probably reach Eisenach during the night of the 20-21 August, but it would be better still to send this evening, viâ Flushing.

In our *Studios of Europe* we mentioned that MM. Benque et Cie., in their Paris studio, employ a rocking tray, or rather table, set in motion by a pendulum, for developing their gelatine plates. The oxalate developer is used, and after an idea has been gained from one of the plates as to strength of developer, &c., half a dozen clichés are put together in a tray upon the rocking table and developed at the same time.

MM. Benque et Cie. have the same arrangement at their Trieste studio; and our friend Dr. Eder, who lately visited the establishment, sends a sketch of the rocking table. Here it is. The table, *a*, rests by means of triangular



wooden supports, or trunnions, upon the cross-pieces, *b b*, and if the weight, *c*, is moved, attached by the rod, *d*, to the bottom of the table, the latter naturally oscillates. One developing tray after another is put on the table as the work of development necessitates.

Captain Pizzighelli, of the Austrian Engineers, has made an exhaustive report of the present state of photography for the use of the Austro-Hungarian War Department. The report appears in the official magazine of the Artillery and Engineers published in Vienna. Our readers are familiar with the name of Captain Pizzighelli as an earnest co-worker of Dr. Eder.

It is interesting to compare the prices charged for cartes and cabinets in the various capitals of Europe. Paris at present secures the highest prices for cartes-de-visite, several studios in the French capital making a charge of thirty francs for a dozen portraits. It is only fair to say that this, in most instances, is for *carte emaillées*, and that Paris houses *du premier rang* are to be found with prices commencing at 20 and 24 francs (say sixteen to nineteen shillings) per dozen cartes.

In London, first-class studios almost invariably charge a guinea; in Berlin, generally fifteen marks or shillings; and in Vienna, about the same or a little less. In the smaller capitals, such as Brussels, Munich, Pesth, Dresden, &c., the prices are less, just as with us in England, where the best studios in the provinces charge more moderately than in town.

In the case of cabinet portraits, many studios charge for the sitting; but supposing a dozen pictures are required, the highest fee in Paris would be 80 francs, and in London three guineas. Some of the best Paris houses do not, however, ask more than 40 francs per dozen, while with us in London from 31s. 6d. to £2 2s. are prices quoted by first-rate houses. Thirty marks or shillings a dozen is the Berlin price in the best studios, and fifteen florins (say 25s. 6d.) in Vienna.

"I always insist on a broad base to my camera," says Mr. England. Out-door photographers who desire their apparatus to be free from vibration might well make a note of this.

The photo-chemical laboratory of the Vienna Technical High School has just come into possession of a valuable relic—the first camera that Daguerre sent to Germany in 1839. It bears a label with Daguerre's own handwriting upon it. The first Daguerreotype camera introduced into England, in the same year, is, we believe, at this moment in the possession of Sir Hussey Vivian.

Another photographic relic of value in this country belongs to Mr. H. P. Robinson, of Tunbridge Wells, this being the first silver bath made use of by Archer in the collodion process.

Sulphate of iron, acidified with acetic acid, is declared by M. Le Bon to be a most powerful antiseptic, more so indeed than carbolic acid. Photographers, who always have a stock of the two former by them, should note this.

An immovable head-rest is advertised in a continental contemporary, adapted for restless sitters. We do not know its action, and, truth to tell, have little curiosity to try its powers. "No one moves in our portraits," used to be the proud boast of a Texas photographer; and he brought about the result, if we remember rightly, by cocking a pistol at the sitter, and threatening to blow his brains out if he so much as moved an eyebrow.

TWELVE ELEMENTARY LESSONS IN PHOTOGRAPHIC CHEMISTRY.

No. IV.—Photographic Chemicals.

Albumen is the principal constituent of white of egg and the serum of blood. White of egg consists of cellules containing a solution of sodium albumenate, together with sodium chloride and calcium phosphate. In order to prepare pure albumen, the white of fresh eggs is briskly agitated with water, whereby the cellular compound separates out, and the sodium albumenate enters into solution. To remove the mineral substances a small quantity of basic lead acetate is added to the solution, producing a bulky precipitate of lead albumenate, which is thoroughly washed in water, and carbonic acid gas passed through the pasty mass. The carbonic acid decomposes the lead albumenate, forming lead carbonate, which separates as a precipitate, leaving the albumen in solution. In order to free it from the last traces of lead, a few drops of an aqueous solution of sulphuretted hydrogen are added, and the solution heated till the albumen begins to coagulate. It is then filtered, and evaporated at a temperature not exceeding 110° F.

When a solution of albumen is heated to 140° F. (60° C.), a white flocculent precipitate of an insoluble modification of albumen separates, the chemical composition of which is apparently the same.

Commercial albumen is simply dried white of egg, and consequently contains a considerable portion of mineral salts.

Ammonium bromide, NH_4Br, is produced when hydrobromic acid is neutralized with ammonia. The salt is very soluble in water, slightly deliquescent (*i.e.*, absorbs water), and gives off brown fumes of bromine when heated with strong sulphuric acid.

Ammonium chloride, NH_4Cl, commonly known as *sal ammoniac*, is manufactured by neutralizing the ammoniacal liquor obtained from the gas works with hydrochloric acid, and, after evaporating the liquid, the residue is heated to sublimation, and the salt condensed, in iron domes, in the form of a white, tough, crystalline mass. The chief impurity which is met with in commercial ammonium chloride is iron, for if a strong solution of the salt is allowed to stand, a brown flocculent precipitate of oxide of iron will be deposited on the bottom of the vessel.

Ammonium chloride forms a white precipitate with a solution of silver nitrate, and evolves ammonia when treated with caustic soda or potash.

Cadmium bromide, $CdBr_2H_2O$, is prepared by dissolving cadmium oxide or carbonate in hydrobromic acid, or by attacking the metal cadmium with bromine water, and the salt crystallizes in white efflorescent (*i.e.*, gives off water) needles, which are very soluble in water and alcohol. Cadmium salts form with a solution of ammonia a white precipitate soluble in excess, and, with ammonium sulphide, a yellow precipitate, insoluble in excess.

Cadmium iodide, CdI_2, is made in a similar way to the above salt, substituting hydriodic acid for the hydrobromic acid.

Copper sulphate, $CuSO_4 5H_2O$, is prepared on the large scale by roasting sulphide of copper, and treating the mixture of cupric oxide and sulphate with dilute sulphuric acid, the crystalline product being obtained by evaporating the liquid. When copper sulphate is heated, it gives off its water of crystallization, and the blue crystals give way to a white powder. A solution of copper sulphate forms with ammonia a white precipitate of cupric hydrate, which re-dissolves, on adding excess, to a brilliant blue liquid; if ferrocyanide of potassium be added, a chocolate brown precipitate will be produced.

Ether, $C_4H_{10}O$, is prepared by distilling a mixture of alcohol and sulphuric acid, when the latter, having such a strong attraction for water, subtracts it from the alcohol, and thus leaving the compound known as ether. On the large scale, ether is prepared by heating a mixture of equal quantities of alcohol and strong sulphuric, and then gradually adding thirty parts of alcohol, and distilling, when the ether will condense, together with traces of alcohol and sulphurous acid. The crude product is mixed with a weak solution of potassium carbonate, which dissolves the alcohol, and absorbs the sulphurous acid, leaving the ether, which is of lower specific gravity than water, to rise to the top. The upper liquid is drawn off, and distilled with quicklime, when absolutely pure ether distils over. This process is very dangerous, from the fact that a mixture of ether and air is explosive, and, when distilling, a certain amount is very apt to escape condensation. For greater safety the heat should be applied through a water bath.

Methylated ether is prepared in the above way, substituting methylated spirit for the alcohol. Pure ether is of specific gravity ·74 at 0° C., and boils at 95 F. It dissolves oils and fats, and may be identified by its characteristic odour of collodion.

Gelatine is obtained from bones, hide, horn, hoof-cartilage, &c. On the Continent gelatine is made by digesting bones in dilute hydrochloric acid, whereby nearly the whole of the mineral matter, consisting of calcium phosphate and carbonate, is dissolved out; it is then washed in running water for some hours, and the cartilage, which consists for the most part of ossein, is boiled with water, converting it into gelatine. In England, gelatine is prepared from buffaloes' hides. The skins are first treated with water to wash them, dried, and cut up; the pieces are then soaked in lime-water for some time, and afterwards thoroughly washed in running water, and then boiled in water, and allowed to stand, when the clear liquid is decanted off, and cooled down, the resulting jelly being finally dried on nets. Gelatine is very variable in composition, from the fact that it is a mixture of two substances—glutin and chondrin—in different proportions; and since glutin is more soluble than chondrin, the solubility of a given sample of gelatine will depend chiefly upon which of these two substances is in excess. Glutin produces a white precipitate with a solution of mercuric chloride, while chondrin behaves in a similar way with lead acetate.

Dry gelatine is a yellowish substance, elastic, vitreous, hard, and brittle. When a gelatinous solution is heated for a long time it loses its power of setting, and is gradually converted into meta-gelatine—a substance apparently having the same composition as gelatine.

Gold trichloride, $AuCl_3$, is obtained by dissolving gold in a mixture of hydrochloric and nitric acids, and evaporating the solution to dryness. This compound forms yellow crystals, which are very deliquescent, and its solution is reduced by ferrous salts, many vegetable and animal substances, oxalate of potassium, &c., the gold being precipitated as a purple powder. Gold chloride is soluble in alcohol and ether, and its solution forms a purple or brown precipitate with stannous chloride.

Gum Arabic is a vegetable substance, which exudes from the *acacia*, growing in Arabia. It forms transparent globules, usually having a yellowish tint, which are very soluble in water, and when mixed with dilute hydrochloric acid and alcohol it deposits a flocculent precipitate of *arabin*. When a solution of gum is added to a salt of zinc, copper, calcium, &c., a precipitate consisting of arabate of the metal is formed. This property is made use of in photo-lithography.

Iron perchloride, Fe_2Cl_6, is produced by dissolving iron in a mixture of three parts hydrochloric and one of nitric acid, and evaporating the solution to dryness. The salt is very deliquescent, and dissolves in water and alcohol. Its solution forms a dark blue precipitate with ferrocyanide of potassium, and with silver nitrate a white precipitate of silver chloride.

Iron oxalate, FeC_2O_4, otherwise known as ferrous oxalate, is precipitated when a solution of oxalic acid or potassium oxalate is added to ferrous sulphate. It forms a pale yellow powder which is almost insoluble in cold water, and only sparingly soluble in boiling water. Ferrous oxalate is readily soluble in a solution of potassium oxalate, with which it forms a double oxalate of potassium and iron, $K_2Fe(C_2O_4)_2$.

Iron protosulphate, $FeSO_4.7H_2O$, is obtained by dissolving iron or ferrous sulphide in dilute sulphuric acid, but on the large scale it is prepared, simultaneously with alum, by decomposing aluminous schists containing iron pyrites. Pure ferrous sulphate can be obtained by adding its aqueous solution to a large bulk of alcohol, when the salt is precipitated in the form of a bluish white powder. When the green crystals of ferrous sulphate are kept for some time, they gradually become covered with a brown powder consisting of basic ferric sulphate. A solution of ferrous sulphate forms, with silver nitrate, a grey precipitate of metallic silver, and with potassium ferrocyanide a light blue precipitate.

Kaolin is a porcelain clay, consisting for the most part of silicate of alumina. Its chief use is for decolourising the silver printing bath.

Mercury bichloride, $HgCl_2$, commonly known as *corrosive sublimate*, may be obtained by dissolving mercury in hydrochloric acid mixed with a small amount of nitric acid. On the large scale it is prepared by heating a mixture of mercuric sulphate, sodium chloride, and a trace of manganese dioxide, and collecting the resulting sublimate. When a solution of mercuric chloride is shaken with a small quantity of mercury, a white precipitate, calomel, is formed, which blackens on the addition of ammonia. Washed over a photographic negative it has the property of converting the reduced metallic silver into a white double chloride of silver and mercury, which is insoluble in water.

PHOTOGRAPHIC EXPERIENCES IN EGYPT.

An interesting account of an Eastern photographic expedition, in which Mr. Edward L. Wilson and others took part, appears in the *Philadelphia Photographer*. Mr. W. H. Rau, who writes the paper, is an old hand at photography far away from home, and our readers will not only be interested by his lucid descriptions, but also gather many practical ideas as regards photographic matters. He says:—

I first made out as complete a memorandum of everything that I could think would be required, and carried this in my pocket, together with a blank block of paper on which I jotted down at once every new thought that would help, or any article overlooked in the first memorandum. The first things ordered were the plates, of which we selected two rapidities, for instantaneous and groups, and for ordinary views, &c. The boxes for the 5 by 8 plates were made 5½ inches deep, 5½ by 8½ square; the corners were slotted to hold a triangular piece of cardboard, on which the plates were to rest, face down, in the box, each plate being thus placed by the use of a pneumatic plate-holder; four cardboard corners were inserted between the plates, so that no part of the face would be touched, excepting, of course, the corners which were outside the margin generally used. The boxes were lined with black canton flannel, nap side out; the lid was telescopic—that is, it closed over the box to the bottom—and handles were placed on the outside in such a position that the plates would always carry standing on edge. After the box was filled with plates, a soft pad of cotton batting and canton flannel was packed on top, the lid placed down snug, and a breast screw put in through the lid near the bottom into the box on each side, taking care to have the screws short enough not to penetrate to the inside. The first plate on the bottom rested on its corners on blocks a trifle above the bottom of the box. The boxes for the 8 by 10 plates were the same, only allowing an eighth of an inch above the size of the plate for margin. The wood was poplar, three-eighths thick, and the corners were dovetailed. Glue was not depended on, as experience in dry climates has demonstrated that it does not hold. After the boxes were filled, a tag with the number and rapidity of the plates enclosed was fastened on each strap handle, the boxes were numbered, and the bottom crack around the lid sealed with black "needle" paper, fastened or held on with ordinary negative varnish, as paste would not hold. Tin boxes were made large enough for two boxes in each, the wooden boxes placed therein; the lid was now hermetically sealed by placing a coat of rubber solution (thick) around the lid and an inch below it, then coating strips of rubber cloth long enough to go entirely around the box with the same rubber solution, applying it to the gum side of the cloth. After it had set, the tin lid was pressed down hard, and then the rubber strips were attached, taking care to press down every part, and lapping the ends so that no air could get in. Then the boxes were lettered with a prominent and large letter, so as to keep a record of every case or box as used, &c. Leather cases, made of good solo leather, with extra leather corners, riveted with copper rivets and sewed in every part, were made to carry two tin cases each of the 5 by 8 plates, or one tin case of 8 by 10 plates. These leather cases were also numbered. Around each tin box was wrapped a piece of ingrain carpet, which answered the double purpose of packing and giving an easy means of lifting them out of the leather case. Next in order came the cameras, tripods, lenses, &c. Our 8 by 10 camera is a model of strength and beauty, also the two stereoscopic cameras, all of which we had made with extra long bellows, and an extension bed that slips on and off very easily. The 8 by 10 camera will focus full 26 inches, and the 5 by 8 full 14 inches. The corners are all mounted with brass sheets, not strips. Although at first I objected to the cam motion, I have found since that it was very convenient, and not likely to get out of order. I will first give the points about the 8 by 10 camera. The front was made to slide higher than usual, and the back to swing a trifle more, although I have found that still a little more swing would have helped wonderfully in some of the narrow streets of Cairo and Alexandria. The plate-holders were made the actual size of the plate, a movable frame fitted in the back of the camera, on which the ground glass and plate-holders were in turn fitted, so that in making a vertical picture the whole of the movable frame was swung around. This not only made the holders more portable and lighter, but also gave the actual size of the picture, so that when focussing, all that was seen on the ground glass, which was 8 by 10 inches, was sure to come on the plate. The holders, of which we had three, of 8 by 10 size, were fitted in a box, but this was rather too weak, so we have a stronger one now, carrying the plates in a horizontal position, thus lessening the risk of the slides or partition slipping out. Every holder was numbered in a distinct manner over the slide, each slide having its own number. Several extra fronts were taken, besides those on which the lenses were mounted; also several extra slides for the holders, and extra ground glass, a duplicate set of screws for every part. Finally, the holders were made of mahogany well seasoned, no pine or soft wood being used in any part. (I have thought since that a box could be fitted in the space which is usually empty, viz., the inside of the camera; this box could carry extra lenses, screws, &c., and could be made so that it would not chafe or bear on the bellows.) Our stereoscopic cameras are mounted also with brass corners. The holders, of which we have 18, are all of mahogany and numbered. We have with us several extra stereo. divisions, in case of loss, &c., extra ground glass, extra screws, extra fronts, extra slides for plate-holders, and a bed-board for supporting the camera when making a vertical single 5 by 8 view.

In selecting tripods, I took only those that had the lower ends short enough to double up with the head or top on, as they could be folded without unshipping every time; also chose those that had the grain running straight, as a short grain will break very easily. Extra tops for each were taken, and had I had the time, should have taken the screws out and riveted the irons on the tripod tops that hold the legs—this should always be done, when possible. Of lenses we have the following:—a No. 2 Euryscope, for quick pictures, groups, &c.; a Hermagis, 10-inch, for general views, architecture, &c.; a Morrison 8-inch lens, and a Ross 5-inch symmetrical for very close quarters; all the above for 8 by 10 size. For stereoscopic, 1 pair Ross instantaneous carte-de-visite lenses, one pair Morrison $5\frac{1}{2}$-inch, 1 pair Darlot single view about 7-inch focus, 1 pair 3-inch Ross symmetrical. For the Morrison and Ross stereo. lenses we have exposing flaps or boxes, which are not only convenient, but protect the lenses from dust, &c. For the Darlot and carte lenses, we have flaps made that slip on over the front brass mounting, and have a thumb-screw on the right hand side for turning up the flap. Finally, an instantaneous drop for the Ross half-size lenses. After examining a number of instantaneous shutters, the old drop seemed the simplest and best, so we have such with us. I had the loose stops rivetted together for safety and convenience, and carry all the lenses in a light wooden box with ordinary lid. They are fitted in with padding, so that they will not jam, scratch, nor break, and strap the lid down, the strap making a convenient handle for carriage. For headcloth the black waterproof cloth (not rubber) is the best. I have tapes about 18 inches long sewed on the two corners, so that in windy weather it will not be blown away, and in carrying short or even long distances the cloth can be so tied around the camera that no dust, dirt, nor rain will damage them. This little trick is one of the best I have ever met with, very simple and quick. For the 8 by 10 lenses, where they varied very much in size, we have a flange made within a flange, so that small lenses could be screwed in a brass flange, which in turn fitted in the flange of the larger lenses; this saves carrying extra fronts, which at times do not pack very well. Another very important item for our journey was a dark tent, in which to change the plates in and out of the plate-holders, and perhaps for general use on the desert. It must necessarily be compact, strong, and not easily broken, and large enough to work in comfortably. After long deliberation and study I adopted the one I will now describe. A three-sided tent was made to fit inside or under the legs of our 8 by 10 tripod; the legs were spread about $4\frac{1}{2}$ feet apart at the bottom, in order to give plenty of floor space. The tent was made of rubber cloth (not gossamer) of the widest to be obtained; each side was a single piece. The inside was lined with a double thickness of Turkey red silesia; the bottom was enclosed same as the sides. One side was made rather full, and had an opening about 12 inches from the bottom large enough to admit the upper half of the body. Around this opening, which lapped over the body when the operator was inside, was a strong draw-cord, which could be drawn firm and taut and exclude all the light. On the left side, opposite the entrance, is a ruby silk window, about 9 by 10 inches; outside of this is a curtain to regulate the quantity of light; outside on the bottom, at each of the three corners, are three iron rings, in which the three points of the tripod legs fit; half way up, or where the tripod leg is riveted, are three wooden buckles fastened to the tent with strong tapes, one on each of the three sides; these buckles keep the tent from hanging down, as they fit in between the two top pieces of the tripod leg. Inside on top, or just in the point, is a triangular block about four inches each side; the cloth is drawn well over this and fastened with double-pointed tacks; on this board is screwed a brass nut by which the tent hangs fastened to the ordinary camera screw put down from the tripod top. This completes the tent. It is very strong, roomy, and can be packed almost anywhere, as it takes any shape. I found great difficulty in obtaining the proper colour and quality of silk for the window. Finally, I saw some very close-grained heavy white silk. In order to operate in this tent it is, of course, necessary to kneel down and enter only the upper part of the body. We have a number of pieces of rubber cloth and some rubber cement, in case a tear is made in the outside; also an extra piece of ruby silk for the window. As we wish to develop occasionally and see if everything was working well, a supply of chemicals sufficient was packed to take with us. Oxalate of potash in half-pound bottles; iron was powdered very fine and dried, also in half-pound bottles; a bottle of powdered alum; a four-ounce bottle of oxalic acid, saturated solution; in fact, I nearly filled the bottle with oxalic acid, and added water to fill up to the neck, and corked well. A four-ounce bottle of bromide of potassium solution, half a pound of the dry salt, and hyposulphite in half pound bottles. Litmus paper was folded in tin-foil and carried in a box. All the bottles were well corked, and a piece of pure rubber cloth tied over the corks, making them air-tight. Also about three extra six- and eight-ounce empty bottles and corks; one eight-ounce wide-mouthed bottle I marked on the outside for measuring taking the place of a graduate. Four rubber 8 by 10 developing dishes, a sponge, towel, and a folding negative rack completed the outfit for development. The following list of articles and necessities come next in order: lump of beeswax, a cake of opaque, small brush for same, two bottles of "Stratena," a bottle of rubber cement, two broad camels'-hair dusters (from which cut off the long handles), one good soft chamois skin, a good diamond, two balls of thin, strong twine, one pneumatic holder, one box rubber bands, a large number of record books, small bottle of parlour paste with brush, one dark lantern (ruby bull's eye), one box candles for same, three boxes of safety matches, twelve sheets needle paper, six heavy treasury blotters, a yard of canton flannel (brown), extra rubber cloth strips enough, cut ready for sealing, tin boxes for return voyage, several straps, and two shawl straps (very strong and long), one bottle of Pond's extract for wounds, two mouth-drinking filters for the desert, one thirty-three foot tape measure, a mariner's compass, a magnifying glass, a box of tools, which contained all of those most necessary to have in time of need, viz., hammer, plane, screw-driver, gimlet, file, pincers, scissors, metal shears, whetstone, saw, copper wire for repairs, one pill-box of small French nails, two boxes of brass screws, a paper of pins, box of assorted screw eyes and screw hooks, one paper double-pointed tacks, one Aiken's tool handle, several strips of sheet brass, and a paper of fine tacks. All the tools were small, and took up very little space. We also took six sheets of ruby paper, rolled on a round stick. A few small tags for marking we found quite handy. And since we might wish to photograph inside the pyramids and in some of the tombs, for underground work we took with us one pound of magnesium wire, made into small torches by twisting in some iron wire, which was hermetically sealed for the voyage. A stylographic pen for making the records in the books is a very good thing, as the mark is in ink, and will not rub like pencil. Everything was packed in leather cases, each case numbered, and an inventory taken of every case with its contents, so as to be able at any time to get any article that was wanted. Joseph paper was packed wherever anything soft and yielding was required, as it could be used in many ways afterwards. Each case had a printed label pasted in a prominent place, with name and destination, and cautionary words as to handling. As to personal luggage, a small valise each served us for all we needed.

Everything being ready, the lenses were taken aboard the steamship *Illinois*, safely stowed in a vacant room so that no shifting would take place, and we sailed for Egypt. During the voyage to Liverpool we made a few instantaneous exposures on deck, and while doing so, the crew were drilling in the life-boat service, so that we made several negatives of this very interesting scene. The waves were so very beautiful over the stern of the ship, covered as they were with foam, that we made several exposures in that direction, and, just as I was about to release the drop, a flock of sea-gulls came before the camera, one of them turning his body full, when I made the exposure. In due course of time we left Brindisi on the *Bangalore* for Alexandria. The cooks on board were lascars, many of the crew were from Goar, in India, some were Turks, some Egyptians; in fact, a more motley crew could scarcely be imagined. The captain requested a picture of them, so we mustered them all on deck on the top-gallant forecastle, and, with the ship for a background, a number of exposures were made. A few were instantaneous, several had two and three seconds' exposure. We passed several of the Ionian islands on the coast of Greece, on one of which is mount Saint Elias, which had its peak capped with snow. Of this we made a few exposures, and finally on the passengers of the vessel. Among them were two English amateur photographers, who were armed with an outfit of gelatine plates, of small size, to be used in India and Australia. Arriving in Alexandria on January 4th, we were surprised to find a gentleman who assisted very much in the custom-house, a Mr. Fervest, an Englishman, who was chief inspector, and who, fortunately, is also an amateur photographer. He understood our bulk of luggage, and passed it through at once. We arrived early in the morning at the hotel, about 9.30, and were out ready to work at 10 o'clock. We had with us a dragoman to show us the points of interest and act as interpreter. He was a fine old man, with full white beard, and, of course, wore his picturesque native costume. Our first point was the harbour, and, by climbing a stairway leading on top of a house, we obtained a grand view looking out seaward, and showing the lighthouse and the Khedive's palace. As there was a great deal of motion of vessels and figures in the foreground, it was necessary to make instantaneous exposures. Thence we drove around the bay as far as the arsenal, and from there obtained a fine view of the city, showing some shipping in front. A number of prisoners chained together in couplets were leaning aimlessly around the arsenal grounds; so, to make a picturesque foreground, we placed several in our picture, and afterwards, while Mr. Wilson was getting out money to pay *backsheesh*, they made a tumultuous rush towards me, tangling me up in their chains, and trampling and kicking the lens-box and some plate-holders in a most alarming manner. Our dragoman's stick being brought to bear well on them, they were soon driven away. I found that no damage had been done to any of our plate-holders or lenses; still, it taught us a lesson in taking care not to distribute the *backsheesh* until everything of ours was secure. Our next point was Pompey's Pillar, or the Column of Diocletian. On our way there our springs in the carriage gave out, and we were obliged to spend some time in a Moslem cemetery, where we secured some beautiful pictures, a high bluff surmounted with bright Oriental buildings forming a fine background. We were strictly cautioned not to step on any of the graves or tombs, and were refused permission to mount a tomb in order to get a better view. Men are always here on guard; whole families were encamped in the cemetery, moaning and crying. Another carriage arriving by this time, we soon arrived at Pompey's Pillar, which does not offer much of beauty for the camera, but its history is interesting. It stands entirely alone, nothing, not a palm, close by to break the sky or fill in the sides. Arabs are here innumerable; one wonders where they come from, so suddenly do they surround you. They are a very good-natured set, but extremely inquisitive, crowding close around you. In making the exposures it was necessary, in order to keep the place clear around the base of the column, to employ several policemen and our dragoman, after which they one and all demanded *backsheesh*, so that we soon found that the very least service had to be paid for with *backsheesh*. Just as we were leaving, we saw a very picturesque old woman, suckling a babe, carrying it astride her hips. After much coaxing and promise of *backsheesh* we made several exposures on her, with an Oriental doorway as a background.

Of mosques there are few fine ones, the better ones standing in the suburbs; they are odd-looking, and are surrounded generally with palm trees which frame them into beautiful pictures. We secured a very characteristic picture of a village of mud-houses (very much like our Pueblo Indian houses), the walls of which were covered with the droppings of cows and camels. This is their fuel, as wood is scarce in Egypt. A very beautiful part of Alexandria is the street in which the consuls live; fine large Oriental palaces line it for several blocks. The buildings are bright and nicely decorated, so that one is tempted to stop before each one with the camera. In the centre of the city is an open square, called the Place Mahomet Ali; in the centre is a large bronze equestrian statue of Mahomet Ali, the great general, great grandfather of the present Khedive. In making negatives of this statue, we had no sooner planted the camera than we were surrounded with hundreds of curious Arabs—in fact, the crowd was so dense that police officers were required to clear the street. Having done Alexandria, we took the train for Cairo, which we reached after six hours' ride. Our first day's mark we spent in the famous Boolak Museum, the most complete and largest collection of Egyptian antiquities in the world. Mr. Brugsch Bey, who was in charge of the museum, gave us much valuable assistance. He stood up and arranged several mummies of the old Egyptian Pharaohs, so that we were enabled to make large portrait heads of them. The camera certainly had some rich food spread before it. Here is a black basaltic statue of Cephum, the founder of one of the great pyramids; it is a difficult subject on account of its colour, but was in quite a good light. Again we have two mummy cases, ten feet high, made by wrapping one layer of linen over another, and fastening with pitch, until the thickness of several inches was reached. Another mummy case has the entire face covered with burnished gold, and the case as brilliantly coloured as when it was first applied. Several very perfect sphinxes of syenite granite adorn the grand vestibule, also a dark-green statue of Ramases II., the great Sesostris. Many cases of nicely-arranged bronze, terra cotta, and stone images of Egyptian gods and goddesses, of royal jewelry and gold work, of fruit, vegetables, furniture, &c., of hundreds of "Scarabees" stood crowded close together. Still, by using good judgment and skilful handling, we secured the most important objects. An especially interesting collection is gathered in the room, dating back to the ancient empire, six thousand years ago. In this room is a wooden statue of a man standing, which undoubtedly is the oldest piece of sculpture in the world; it dates before the great pyramids; also a painting in brilliant colours, one foot wide by six long, which is six thousand years old, and many other statues and stone sarcophagi used for holding the mummy cases. Mr. Brugsch, who is an amateur photographer, wished a few negatives for his own use of several very dark statues, which he was unable to get on account of their very black colour and the poor light on them. So we exposed with a Euryscope, smallest stop, twenty-five minutes, for 8 by 10, and with Morrison 5½ in full opening, twenty minutes for stereos. These negatives, on development, came up beautifully, and gave Mr. Brugsch intense pleasure. They were made on the brand A plates. Mr. Brugsch furnished us with a vacant room in an outhouse attached to his residence, in which were tap and water-sink for developing plates.

I was very anxious to see how the plates would come up, as they looked well and free from spots before development. My method of proceeding was as follows. I took with me the necessary chemicals, bottles, and dishes, first measured out fifteen ounces of water, then three ounces of oxalate, added to the water (cold), and shook until dissolved; it did not take more than a few minutes. In one dish I mixed some hyposulphite solution, and in a bottle a little saturated alum solution; to the oxalate solution I added a few drops of oxalic acid, tested with litmus paper for acidity, found it acid. Now for development. I poured five ounces of oxalate into the wide-mouthed bottle, measured out one hundred and twenty grains of powdered iron, added this dry to the oxalate, which took it up quite readily, shook a minute, then added ten drops of a sixty-grain solution bromide of potassium: finally added water to make up to eight ounces for the A plates, while had they been B plates, should have used it without adding any more water. The first plate developed was an 8 by 10 of a double statue of very dark colour, almost black; in a half minute it began to come, and developed up slowly and full of detail, showing the cut in hieroglyphics in the deepest shadows; the half-tones were soft, and the shadows clean—in fact, it was a perfect negative. The intensity was just right. I washed well under running water, and put it into the hypo-solution. Next I developed an 8 by 10 of a black sphinx, which was equally difficult, but, like the first, equally successful. After developing a few more with like result, I went back to those that were fixed, and washed well and flowed from the bottle a minute or more with alum solution, washed, and stood on rack. Mr. Brugsch expressed great surprise and extreme pleasure at the simplicity and beauty of working gelatine, and although he had almost decided to abandon photography on account of the bother it gave by the wet method to the amateur, he will now take fresh hold with gelatine plates. He requested to have some of the same make as ours to be sent him from America.

(*To be continued.*)

Correspondence.

PHOTOGRAPHY AT SEA.

Dear Sir,—By last mail I sent you a hasty sketch of my two forms of instantaneous shutter. I hope the description was intelligible, but I had not time to write it carefully.

It may interest some of your readers to hear how the ship was taken on the open ocean. She was sailing about six knots an hour, with a steady wind and slight swell broken by small cross waves. The sky was dull, but as we were getting out of the calm tropical regions, and towards the Cape of Good Hope, I thought it better not to wait for fine weather, so the captain launched his gig (a twenty-foot boat, horribly leaky), and in it descended four sailors, the captain, three passengers, and myself. The ship's yards were kept aback until we had rowed and sailed about a mile ahead, and then the captain waved a flag and she sailed up past us. I took two shots at her from the starboard side, then the same manœuvre was repeated, and I had three more tries from the port side. Only two of the plates were rapid enough to give a printable result.

Although the sea seemed fairly smooth when aboard the big vessel, we found the gig jumped about considerably. We were often hidden in the trough of the waves from the sight of those on board, and it was very difficult to stand steady while focussing. If it had not been for a little "finder" (made out of a toy lens and hollow two and-a-half inch cube of wood) that I had fixed on the top of the camera, I could never have got the ship into the field at all except by chance. As it was, I had only to watch her flitting up and down and in and out of the finder's ground glass, and easily saw the best opportunity. The shutter was held up by a piece of thin string passing over to the back of the camera, and held by a catch. There are many other ways in which this shutter could be "fired off," but I think the string is the simplest and handiest. A quick enough exposure for many moving objects can be got by taking off the india-rubber band, and simply pressing the shutter down with a finger. Two bands of velvet fastened one on each side of the shutter will keep it in position, and also prevent any light leaking in.

The two photographs of the bows were taken from the dolphin striker as the ship was running before the wind about fifteen miles an hour. I sat on a netting fixed in the angle of the stays, held the camera against my chest with one hand, and pulled the string of the "rotating shutter" with the other. The first view represents her plunging into, and the second rising out of, the water.

I did not like to risk my half-plate camera out there, so I used a quarter-plate one which I constructed on board by fixing a few extra fittings on to the half-plate extending front, with sciopticon dark slides and a walking-stick tripod; this front contrives "a double debt to pay" in a very satisfactory manner, but I had to give the tripod a greater splay, and otherwise strengthen it, before it was steady enough. With it, I hope to be able to get about in the interior of Japan without attracting much attention; but for places where any ordinary camera would be viewed with suspicion, I constructed during my spare time on the voyage a sort of detective camera, taking plates $2\frac{1}{6}$ by $1\frac{1}{2}$. The changing box holds eighteen plates in a very small compass, as the grooves were made by sticking slips of ferrotype iron into knife cuts in the sides. The sliding spring shutter serves for this too. I am a bad sailor, but it is wonderful how soon one gets used to the ship's motion in a few weeks; it was quite easy to do mechanical work as accurately in the heavily rolling ship as on shore. Development was not quite so easy, especially as the plates had to be carried in the dark from cabin to cabin to get them washed; my friends' basins having to be utilised for that purpose.

A good climber might get some very interesting photographs from the rigging, but it is difficult to find a safe place for the camera. I never got it up higher than the foretop, and it was not pleasant work lying down focussing there.

Land views taken from a ship seldom make good pictures, owing to the absence of foreground. I have coasted nearly all round New Zealand, and found hardly any really "takeable" subjects. The best view of Mount Egmont, however, is from the roadstead, and I spent two hours watching for a chance of taking it, and lost the opportunity through greediness. Not satisfied with having the mountain itself wonderfully clear, I waited for the sun on the town (Taranaki) in the foreground. Alas! when the sun came on the town, the clouds came on the mountain, thus adding one more to my list of interesting photographs *not* taken by an amateur. In the evening again it was most tantalizing; the brilliant snowy peak would occasionally clear for one or two hundred feet down, and then cover up again, till at last the sun set, the anchor was weighed, and Mount Egmont became to me one of the visions of the past.

I believe good views of Mount Cook might be got from the sea, and there is a very narrow channel, called the French Pass, which would make a good picture taken from the west side; but the steamers generally go through at night. Herbert Green.

Ohinemutu, N.Z.

FERROUS OXALATE REDIVIVUS.

Sir,—Being abroad I had not seen the article by Mr. W. T. Wilkinson, bearing the above title, till a day or two ago. Perhaps you will permit me to make a few brief remarks thereupon.

Mr. Wilkinson commences his paper by an imputation which is not argument, and by no means fair and courteous. He says that a return to ferrous oxalate is advocated especially by some manufacturers who find it impossible to make plates free from chemical fog. This assertion would be entirely beside the mark if it were true, which it is not, but it shows the animus with which Mr. Wilkinson starts out.

I have not a copy of my article which you did me the honour to extract for your journal quite without my knowledge, but in it I made certain claims on behalf of this method of development; I stated that it was employed in France by the very best men, both in Paris and the provinces, to the entire exclusion of pyrogallic. I made this statement on my own personal knowledge. I have had opportunities of seeing bromide plates developed in first-class Parisian studios, and having had some little experience in photographic work, I may take some credit for knowing a good negative when I see it, and I have seen negatives of the highest possible excellence developed in three or four minutes, full of detail and vigour, and of a quality not to be surpassed by any method of producing a negative.

Any one who will take the trouble to look at Reutlinger's studies of children—instantaneous pictures, as shown by the wonderful variety of expression on the faces, and the exquisite naturalness of pose—cannot but come to the conclusion that it is fine work; but nothing but ferrous oxalate is employed in his studio. Again, take the exhibits of Monsieur Walery, now a successor whose name I do not know; take the exhibits of Monsieur Liebert; we see nothing so fine in London, in my judgment; yet these are all on bromide plates developed with ferrous oxalate.

I will not take up time and space by giving names, but I have had hundreds of fine negatives through my hands, from all parts of France, from photographers whose names I do not know, and from many whose names I do know and recognize as princes of the profession, and I say that amongst these have been many of the highest technical excellence, and all developed with ferrous oxalate. The fact is, a Frenchman will not have anything to do with pyrogallic, and developing with ferrous oxalate has been worked out in France to a perfect system.

But what seems to have been the last straw on the camel's back to Mr. W. T. Wilkinson, was Mr. Alexander Campbell Swinton's letter in the News of July 14th. Now this gentleman put his statement in a perfectly straightforward and lucid way, but he has the misfortune to agree with the article in *Autotype Notes*. I have not the pleasure of Mr. Swinton's acquaintance, but felt the pleasure that one naturally does feel by a public expression of opinions agreeing with one's own. But Mr. Swinton has the advantage of Mr. Wilkinson, inasmuch as Mr. Swinton sends specimens of his work, which are characterized by the editor as "admirable out-door studies, fully detailed in the shaded parts, yet well gradated and vigorous." Perhaps these may be taken to balance Mr. Wilkinson's cricketer; but I must beg Mr. Swinton's pardon for the suggestion.

Now ferrous oxalate was introduced, I think, by Captain Abney; it was adopted exclusively by Dr. Von Monckhoven; it has been from time to time, and is in fact, being now, discussed by well known names; but yet it is left for Mr. Wilkinson to discover that it is defunct, and that certain manufacturers are, for their own purposes, striving to revive it.

If Mr. Wilkinson will turn to the advertisements of some of the best makers, he will find the statement that their plates can be developed either with pyrogallic or the ferrous oxalate developer; if he will set himself up with sample boxes of plates from the best makers, he will find in some of them formula for development with ferrous oxalate; if he will try some of the continental plates he will find them quite equal to any he has ever touched, and they give a ferrous oxalate formula exclusively. Permit me to detail the experiments that were made in my laboratory, and upon which I formed the opinions given in the article in *Autotype Notes*. Plates were purchased from every maker. I do not give names, as I object to making the pages of your journal a medium for praise or dispraise of any article offered commercially. Suffice it to say, there was no maker of any repute not represented. Two of each of these plates were exposed most carefully to a sensitometer scale, with a standard and constant source of light. One plate of each was developed by the exact pyrogallic formula given by the maker, the other with the ferrous oxalate formula as given by the maker, or, if he did not give one, then my own formula was employed. This experiment was carried through with all possible care, and the results were, that in some cases the ferrous oxalate had a slight advantage, in others the pyrogallic was quite equal, and in about two makes of plates the pyrogallic had an advantage: such was my experience.

There were about thirteen different makes of plates experimented upon, and these were the results obtained. The scales themselves are carefully preserved, but, not having access to them at present, I cannot give exact particulars. There is one thing, however, I should mention, that, whereas all the scales developed with pyrogallic were affected with the well-known yellow stain, the ferrous oxalate were entirely without it.

On behalf of the ferrous oxalate, I urge that it was introduced by a well-known chemist and scientific man in England, adopted exclusively by an equally well-known chemist and scientific man on the Continent, that it is used exclusively in France, and that the finest possible work is daily produced by its means; that it will develop a picture on any well-made dry plate as rapidly and as full of detail as alkaline pyrogallic, and with more vigour; that there is a total absence of yellow stain; that it is much more cleanly, and presents greater conveniences; that it is just as easy to control the picture by the addition of bromide as it is with pyrogallic. The ferrous-oxalate developer seems to me to present these advantages. I may be entirely mistaken. If Mr. Wilkinson is of a different opinion, he has the most perfect right to hold and to express it, but not to impugn the conduct of, and attribute unworthy motives to, those who may, perhaps, be as capable of forming an opinion upon this or any matter as Mr. Wilkinson himself.

THE AUTHOR OF THE ARTICLE ON FERROUS OXALATE IN "AUTOTYPE NOTES."

SIR,—Mr. Wilkinson's letter on "Ferrous-Oxalate Redivivus," in your issue of August 4, is so injurious to progress, and so opposed to facts known to all successful workers of this beautiful process, that I cannot help, with your permission, putting in a protest. The experiment tried on a cricketer—given without data as to lens, light, &c.—is almost useless; but I should say it probably was much over-exposed in three seconds (Swan's twenty-five times). About one second would have been nearer the proper time, and would have given a picture for which a development of about eight minutes would have sufficed; being so much over-exposed, it would be difficult to bring up to printing density.

The extraordinary statement that ferrous-oxalate negatives are harsh and dirty-looking—well, after that it seems wasting time to say more; but who, I may ask, has so found them, excepting some very bad workers indeed?

The statement that the only plates suitable for ferrous-oxalate development are those that are faulty in manufacture, is funny; at any rate, personally I much prefer the faulty plates. I should think several manufacturers would have a word to say on this subject.

I cannot pass over so quietly as Mr. Wilkinson the fact that the best Continental artists do use the ferrous oxalate; their doing so should at least be something in its favor. They are not in the habit of doing things in the wrong way.

Then comes the third point in Mr. Wilkinson's letter, which he thinks not worth arguing, but I think very important. I always use my old developer for starting and bringing out the image, and use it over and over again, not for three or four plates, but for all I develop. This statement of course requires some explanation; but I have worked out the process carefully, and have given it about two years' trial, so can claim to have some knowledge of the matter. I also gave a year before that to pyrogallic—and gave it up in disgust—for the ordinary work in studio and landscape. I will not say for very quick work pyrogallic may not be best; but I do say that in the ordinary way ferrous oxalate gives all that can be desired. Half-tone is perfection, and a general keeping in the picture which is most artistic. Can we say the same for any but the very best pyrogallic work?

I want to see ferrous oxalate taken up with half the care that pyrogallic has had bestowed upon it, and then we should hear that it, after all, did *not* give harsh and dirty results. I beg to enclose you a carte I took recently; I think you will say it is fairly good. This was one second ordinary light, Britannia plate, oxalate developer.—I am, yours sincerely, O. C. Smith.

[Our correspondent sends a charming little group picture of children.—Ed. P.N.]

Proceedings of Societies.

London and Provincial Photographic Association.

At the meeting held on August 10th, under the presidency of Mr. Collier, a paper was read by Mr. A. L. Henderson, on "Cold Emulsification with Uniformity" (see page 487).

The Chairman said that from the reports that had appeared in the photographic papers of the meeting on the 27th ult., he seemed to have been misunderstood as to the details of the method he had described of obtaining gelatine from parchment cuttings. What he actually did was not to add three quarts of water to half a pound of washed parchment cuttings, but to make up the quantity to three quarts in all. He claimed that by making emulsion directly with newly extracted gelatine, decomposition was avoided.

Messrs. G. Hare and G. Taylor were elected members.

Talk in the Studio.

Dry Plate Competition in Germany.—During the convention of German photographers at Eisenach, Saxe-Weimar, a dry plate competition will be held. All manufacturers and dealers may compete, but the latter must mention the name of the manufacturer in their sealed letter. Each competitor must send by the 20th August one dozen of each of the following sized plates, addressed to Herrn Photograph Remde, Eisenach, Germany (carriage paid), namely, 10 by 13 centimetres, 13 by 21 centimetres, 18 by 24 centimetres. Advice respecting the plates (for identification of package, &c.), with name of sender, manufacturer, &c., is absolutely necessary; but this must be contained in a sealed envelope, bearing outside a motto. The package of plates will also bear the same motto, but *no name*, together with the words "Concurrenz von Trockenplatten." Details respecting development of the plates, &c., should accompany each packet. A sum of thirty shillings should also accompany the packages, to meet expenses, but this sum may not all be spent. The result of the competition will be published in the *Deutsche Photographen Zeitung*. A silver medal may be awarded to the most deserving competitor, and a diploma to the next. The jury will consist of four persons, two chosen by the committee, and two by the convention. The president has the right to serve on the jury, and to give a casting vote.

Maritime Photography.—Messrs. G. West and Co., of Gosport, whose fine panoramic picture of Portsmouth Harbour will be remembered, send us some capital views of H.M.S. *Bacchante* with the Royal Middies on board, returning from their cruise round the world.

Photographic Society of Great Britain.—In consequence of the success of the technical meetings of this Society, it has been arranged that they shall be continued during the recess (August and September). They will now, therefore, take place on the fourth Tuesday of every month during the year. The next technical meeting will be held on Tuesday, August 22nd, at 8 p.m., at the Gallery, 5a, Pall Mall East.

Cetewayo's Photographs.—Upon Mr. Vaughan taking his seat at Bow Street on Tuesday, Mr. Crewes, of Cape Town, South Africa, stepped into the witness-box, and said that he was the proprietor of the original photograph of Cetewayo, taken at Oudo Moulen, South Africa. He had registered the copyright, but on his arrival in England, recently, was surprised to find that copies of the photograph he had taken could be purchased in the streets at 1d. each. He produced a copy, and stated that at the place he had purchased it he had been told that he could be supplied with large quantities. The object of the present application was to ascertain what steps he could take to uphold his right to the sole sale of the photographs through his agents in England, Messrs. Marion and Co., of 22, Soho Square, as he had been put to a considerable expense, and had sustained great damage by the sale of the copies complained of. Mr. Vaughan asked if the applicant knew who had published the prints. Applicant stated that he did not know definitely, but had been informed that it was a German. Mr. Vaughan said he could not do anything until the name of the publisher had been ascertained. If this were done, applicant could have a summons.

Return of Mr. Muybridge.—"Our old friend Mr. Muybridge of San Francisco, Cal.," says *Anthony's Bulletin*, "has returned from Europe laden with honours, having exhibited before the royalty of England and the *savans* of France. Meeting with universal success, and being the recipient of many honours hitherto seldom conferred on photographers in the old world, he proposes to gratify, during the coming season, the American public with an exhibition of his remarkable productions, of which we hope to give timely notice. Mr. Muybridge is, perhaps, the most indefatigable and adventurous photographer of the day, and his efforts in securing admirable photographic results have never been exceeded. Intensely devoted to his profession, he has braved many climatic perils on the western coast, in the Farrallones de los Frayles Islands, and among the coffee plantations of Panama; also on the coast of California and in the Yo Semite Valley and the Upper Sierras, where he succeeded in procuring immense views of the magnificent scenery of those vast elevations at untold risk of life and limb."

New Ferric Sulphates.—P. Marguerite-Delacharlonny.—The author enumerates 15 ferric sulphates. Six of them are soluble, and contain respectively 2, 3, 4, 5, 6, and 7 molecules of ferric oxide to 12 mols. sulphuric anhydride. The remaining 9 sulphates are insoluble, and contain, along with the same quantity of sulphuric acid, from 9 to 84, or rather $84+y$ mols. of ferric oxide. The author recognises 11 aluminium sub-sulphates—those with 2, 4, 6, 8, and 10 mols. aluminium sesquioxide to 12 mols. sulphuric anhydride being soluble, and the remaining insoluble with 12, 16, 18, 20, 24, and 30 mols. alumina to 12 mols. of acid. He finds that if alumina is added to a solution of ferric sulphate, the ferric sulphate may be entirely displaced, yielding a solution of aluminium sulphate perfectly free from ferric salts. —*Chemical News*.

The Hektograph.—This is the well-known copying process in which gelatine transfer pads are used. Contests were carried on for a long time after its invention, before the United States Patent Office, to determine who were the original and first inventors. A mass of testimony was taken; but the priority of invention was finally awarded to Vincenz Kwaysser and Rudolf Husak, of Austria, to whom Letters Patent were granted June 1, 1880. During the progress of the interference proceedings hundreds of dealers began to make and sell the article, and it was difficult for them to understand that, now a patent had been issued to the inventors, they must cease to manufacture or assume the liabilities of infringers. In some cases it became necessary for the Hektograph Manufacturing Company, the owners of the patent, to bring suit for damages. One of these suits has lately been brought to a conclusion, the patent being fully maintained by the United States Court.—*Scientific American*.

Acid-Proof Cement.—Make a concentrated solution of silicate of soda, and form a paste with powdered glass. It will be found invaluable in the operations of the laboratory where a luting is required to resist the action of acid fumes.

To Correspondents.

*** We cannot undertake to return rejected communications.

J. Byron.—Add a few drops of a solution of nitrate of silver; if a milky precipitate ensues, it contains salt. Most waters do contain it, but only in very slight quantity.

Colchester.—The "Studios of Europe" contains the most practical and latest formulæ about collotype; if you study the articles on Löwy, Albert, and Obernetter, you will be posted up in the most recent methods.

Albumen.—The process employed by Levy for his transparencies has not been published, and this is, we presume, the method you desire. Printing upon films of sensitized albumen upon glass is a difficult process, and great skill and experience are required to ensure success; but any practised photographer taking up the matter seriously should succeed. There is no difficulty about getting density with the collodio-chloride process, if you have recourse to fuming the film with ammonia before it is put into the pressure frame.

G. G.—Because it is a restrainer.

Cape Wrath.—1. We cannot recommend. 2. We can only say that we have employed sulpho-pyrogallol with success.

Nitrate.—So slight an impurity would not matter in a bath for sensitizing paper, although wo should not employ it for a dipping bath. Our lessons in photo-chemistry will teach you something on this subject.

Pyrogallol.—Thank you.

T. A.—1. Our Year-Book for 1882 has been advertised as out of print for some weeks past. 2. 2s. 3d.

Gelatine Amateur.—The percentage is, of course, *dry* albumen; in an egg, of course, this is not the case.

Collodion.—We advise a preliminary coating of albumen; see our Everyday Formulary.

B. B.—No, thank you.

Feed.—Do not employ your solution so strong; 3 per cent. strength is ample.

C. Green.—1. Chrome alum is far more energetic in its action than ordinary alum, and it is probable that 45 grains dissolved in about two ounces of water would be quite sufficient. 2. Tho third on your list.

F. Barrington.—1. It is quite easy to take a cast in plaster from the wet relief, but before trying to separate the cast, it is as well to dip the whole in water. 2. It is not much use telling you how many grains per ounce, as samples differ much as to the proportion of soluble matter. Break the bitumen in small pieces, and just cover it with benzole, after which adjust matters so that you get a solution having about tho consistence of thin syrup. One part of this and four of benzole will probable answer your purpose.

Max.—1. The starch granules swell, and finally burst. 2. Principally lactic acid. 3. Add oxide of silver until the solution is neutral. 4. No.

A Constant Subsciber.—We are sorry wo cannot give you any definite information. Mr. Notman's studio is at Montreal, as you state.

Student.—1. The City Guilds, at their Cowper Street laboratory, are, we believe, making arrangements to give instruction, theoretical and practical, in photography. 2. "Almost touching" is rather difficult to understand; your best plan will be to make a practical experiment, for it depends much on the nature of your lens.

G. Canald.—We think your spots must be due to defective filtration; see if anything is visible before development, holding plate against a ruby light. Your emulsion appears otherwise so good, that we cannot but believe it is a mechanical difficulty only that you are troubled with.

Enquirer.—Your best plan would be to look at tho Melbourne and Sydney Directory.

Eltham.—Wo have seen them in several of the wholesale fancy warehouses in Houndsditch and the immediate neighbourhood.

Sicah.—You will find it more convenient to make use of one combination of tho lens you already have. If you employ the back half, leaving the diaphragms in front of the lens, barrel-like distortion will occur; but if, on the other hand, you remove the back combination, the direction of tho distortion will be reversed. In ordinary cases the distort on is unimportant, providing there are no straight lines near the margin of the picture.

A. B. C.—1. For first trial you had better uncap and cover as quickly as practicable. 2. Often as short an exposure as one-thirtieth of a second.

PHOTOGRAPHS REGISTERED.

Mr. C. W. Smartt (Leamington)—Photograph of Shakespeare's Baptismal Register. Photograph of Shakespeare's Register of Death.

Mr. Eskett (Lindall, York)—Group of Females of Salvation Army. Three Photos. of Rev. D. Hill, and J. R. and E. Hill.

Messrs. Appleton and Co. (Bradford)—Two Groups of Prince and Princess of Wales, Mr. Titus Salt and Family.

THE EVERY-DAY FORMULARY.

The Gelatino-Bromide Process.

Emulsion.—A—Nit. silver 100 grains, dist. water 2 oz. B—Bromide potassium 85 grains, Nelson's No. 1 gelatine 20 grains, dist. water 1½ oz., a one per cent. mixture of hydrochloric acid and water 50 minims. C—Iodide potassium 8 grains, dist. water ½ oz. D—Hard gelatine 120 grains, water several oz. When the gelatine is thoroughly soaked, let all possible water be poured off D. A and B are now heated to about 120° Fahr., after which B is gradually added to A with constant agitation; C is then added. Heat in water bath for half an hour, and stir in D. After washing add ¾ oz. alcohol.

Pyro. Developer.—No. 1—Strong liqnid ammonia 1 oz., bromide potassium 160 grains, water 80 oz. No. 2—Pyro. 30 grains, water 10 oz. In case of an ordinary exposure mix equal vol.

Iron Developer.—Potassium oxalate sol. (1 and 4) 80 parts, ferrous sulphate sol. (1 and 4) 20 parts, dist. water 20 parts. To each 4 oz. of the mixed developer add from 5 to 30 drops ten per cent. sol. potassium bromide, and 30 drops sol. sodium hyposulphite (1 and 200).

Substratum or Preliminary Preparation.—Soluble silicate of soda 1 part, white of egg 5 parts water 60 parts. Beat to froth and filter.

Cowell's Clearing Solution.—Alum 2 parts, citric acid 1 part, water 10 parts. Edwards adds enough strong solution of perchloride of iron to give the preparation the colour of sherry when it is required to reduco intensity.

Eder's Method of Intensification.—The negative is whitened by being soaked in the usual saturated solution of mercuric chloride, and after thorough rinsing is immersed in potassium cyanide 10 parts, potassium iodide 5 parts, mercuric chloride 5 parts, water 2,000 parts. As the film becomes dark brown, the actinic opacity is enormously increased; but prolonged action causes the brown tint to become lighter, until at last the negative is no denser than previously to its treatment.

Fol's Backing Sheets.—A chromographic paste is prepared with gelatine 1 part, water 2 parts, glycerine 1 part, and a very small addition of Indian ink. Strong paper or shirting is coated, and the sheets are laid, face downward, on waxed glass to set. One of these pressed into optical contact with the back of the glass is an effectual preventive of halation.

The Wet Collodion Process.

The Nitrate Bath.—Water 14 oz., nit. silver 1 oz., nitric acid 1 drop. Before using coat a very small plate, and allow it to remain in the bath for about twenty minutes.

Cleaning Preparation for New Plates.—Alcohol 4 oz., Jeweller's rouge ¼-oz., liquid ammonia ½-oz.

Film-removing Pickle for Old Plates.—Water 1 pint, sulphuric acid 4 fluid oz., bichromate potassium 4 oz.

Substratum.—The whites of 2 eggs are well beaten up with 6 pints of water, and 1 dr. of liquid ammonia is added.

Negative Collodion for Iron Development.—Alcohol 1 pint, pyroxyline of suitable quality 250 grains, shake well and add ether 2 pints. *Iodize this by mixing with* one-third of its volume of alcohol ½ pint, iodide ammonium 80 grains, iodide cadmium 80 grains, bromide ammonium 40 grains.

Normal Iron Developer.—Water 10 oz., proto-sulphate iron ½ oz., glacial acetic acid ½ oz., alcohol ¾ oz. The amount of proto-sulphate iron may be diminished to ¼ oz. when it is desired to obtain full contrasts, or may be increased to 1 oz. when contrasts are likely to be unduly marked. When a new bath is used, the quantity of alcohol may be reduced to ¼ oz.; but when the bath is very old, it may be necessary to add rather more than recommended above.

Intensifying Solution, or Re-developer.—Water 6 oz., citric acid 75 grains, pyro. 30 grains When used, add a few drops of the silver bath solution to each ounce.

Eder's Lead Intensification.—After the negative has been well washed it is immersed in dist. water 100 parts, red prussiate potash 6 parts, and nit. lead 4 parts. When the negative has acquired a yellowish white appearance it is again well washed and immersed in liquid sulphide ammonium 1 part, water 4 parts.

Cyanide Fixing Solution.—Potassium cyanide 200 grains, water 10 oz.

Varnish.—Shellac 2 oz., sandarac 2 oz., Canada balsam 1 dr., oil of lavender 1 oz., alcohol 16 oz.

The Ferrotype Process.

Collodion.—Ammonium iodide 35 grains, cadmium iodide 25 grains, cadmium bromide 20 grains, pyroxyline 70 grains, alcohol 5 oz., ether 5 oz.

Bath.—Silver nitrate 1 oz., water 10 oz., nitric acid 1 drop.

Developer.—Ferrous sulphate 1 oz., glac. acetic acid 1 oz., water 16 oz.

Fixing Solution and Varnish.—Same as for the ordinary wet collodion process.

Printing Processes.

Albumen Mixture for Paper.—White of egg 18 oz., add 500 grs ammonium chloride dissolved in 2 oz. of water. Beat into a froth, allow the mixture to settle, and filter.

Sensitizing Solution.—Nit. silver 50 grs., water 1 oz., sodium carb. ½ gr.

Acetate Toning Bath.—Chloride gold 1 gr., acetate soda 20 grs., water 8 oz.

Lime Toning Bath.—Chloride gold 1 gr., whiting 30 grs., boiling water 8 oz., saturated solution chloride of lime 1 drop. Filter when cold.

Bicarbonate Toning Bath.—Chloride gold 1 gr., bicarbonate soda 3 grs., water 8 oz.

Fixing Bath.—Sodium hyposulphite 4 oz., water 1 pint, liquid ammonia 30 drops.

Reducing Bath for Over-Printed Proofs.—Cyanide potassium 5 grs., liquid ammonia 5 drops, water 1 pint.

Encaustic Paste.—Best white wax 1 oz., oil of turpentine 5 oz.

Sensitizing Bath for Carbon Tissue.—Bichromate potash 1¼ oz., water 30 oz., ammonia 1 dr., methylated spirit 4 oz.

Enamel Collodion.—Tough pyroxyline 120 grs., methylated alcohol 10 oz., ether 10 oz., castor oil 20 drops.

Mountant for Prints.—A freshly prepared solution of the very best white gum.

Collotypic Substratum.—Soluble glass 3 parts, white of egg 7 parts, water 10 parts.

Collotypic Sensitive Coating.—Bichromate potash ½ oz., gelatine 2½ oz., water 22 oz.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1251.—*August* 25, 1882.

CONTENTS.

THE BRITISH ASSOCIATION.

No better president could have been nominated to the British Association this year at Southampton than Dr. Siemens, who delivered the inaugural address on Wednesday evening. The past twelvemonth has been marked for the advancement of practical science, and singularly prolific in electrical discoveries and inventions; and as Dr. Siemens is one of our foremost authorities in this province, his advent to the chair of the Association was indeed fortunate.

It is impossible within the limits of our space to print *in extenso* the presidential address, but we may at least call our readers' attention to some of its more important points. Speaking on the subject of the general advance of scientific knowledge and the relation between theory and practice, Dr. Siemens said:—If the facilities brought home to our doors of acquiring scientific information have increased, the necessities for scientific inquiry have increased in a greater ratio. The time was when science was cultivated only by the few, who looked upon its application to the arts and manufactures as almost beneath their consideration; this they were content to leave in the hands of others, who, with only commercial aims in view, did not aspire to further the objects of science for its own sake, but thought only of benefiting by its teachings. The advance of the last fifty years has rendered theory and practice so interdependent that an intimate union between them is a necessity for our future progress. Take, for instance, the art of dyeing, and we find that the discovery of new colouring matters derived from waste products, such as coal-tar, completely changes its practice, and renders an intimate knowledge of the science of chemistry a matter of absolute necessity to the practitioner. In telegraphy, and in the new arts of applying electricity to lighting, to the transmission of power, and to metallurgical operations, problems arise at every turn, requiring for their solution not only an intimate acquaintance with, but a positive advance upon, electrical science, as established by purely theoretical research in the laboratory. Our increased knowledge of the nature of the mutual relations between the different forms of energy makes us see clearly what are the theoretical limits of effect; these, although beyond our absolute reach, may be looked upon as the asymptotes to be approached indefinitely by the hyperbolic course of practical progress.

Electrical progress was, as might be expected, treated of at considerable length, and with a thoroughness characteristic of the speaker. Dr. Siemens pointed out that although the ultimate nature of electricity, the youngest scientifically investigated form of energy, is yet wrapt in mystery, its laws are the most clearly established, and its measuring instruments (galvanometers, electrometers, and magnetometers) are among the most accurate in physical science. Nor could any branch of science or industry be named in which electrical phenomena do not occur, to exercise their direct and important influence. If, then, electricity stands foremost among the exact sciences, it follows that its unit measures should be determined with the utmost accuracy. Yet, twenty years ago, very little advance had been made towards the adoption of a rational system. In 1862, the Electric Unit Committee was appointed by the British Association, at the instance of Sir William Thomson, and it is to the long-continued activity of this Committee that the world is indebted for a consistent and practical system of measurement, which, after being modified in details, received universal sanction last year by the International Electrical Congress assembled at Paris.

Regarding the transmission of power to a distance, the electric current has now entered the lists in competition with compressed air, the hydraulic accumulator, and the quick running rope as used at Schaffhausen to utilize the power of the Rhine fall.

The deposition of metals from their solutions is perhaps the oldest of all useful applications of the electric current, but it is only in very recent times that the dynamo current has been practically applied to the refining of copper and other metals, as now practised at Birmingham and elsewhere, and upon an exceptionally large scale at Ocker, in Germany. The dynamo machine there employed was exhibited at the Paris Electrical Exhibition, its peculiar feature being that the conductors upon the rotating armature consisted of solid bars of copper thirty mm. square in section, which were found only just sufficient to transmit the large quantity of electricity of low tension necessary for this operation.

With respect to electric light, the President said:—Assuming the cost of electric light to be practically the same as gas, the preference will in each application be decided upon grounds of relative convenience, but gaslighting will hold its own as the poor man's friend. Gas is an institution of the utmost value to the artisan, requires hardly any attention, is supplied upon regulated terms, and gives with what should be a cheerful light a genial warmth. The time is not far distant when both rich and poor will resort to gas as the most convenient, cleanest, and cheapest of heating agents, and when raw coal will be seen only at the colliery or the gasworks.

The use of the mild steel as a constructive material was discussed at some length, and the conditions under which land and water communications might be made to cross each other without serious detraction from the usefulness of either highway was treated of at some length.

Dr. Siemens alluded to several other matters bearing on past and present scientific progress, and his discourse will long be remembered as a far-sighted and able exposition regarding the main foundations upon which modern progress rests.

IODIDE IN EMULSIONS—THE DRYING OF GELATINE PLATES.

Those who have had any experience in emulsion work will have read with special interest the communications on the subject of "Iodide in Emulsions," which have recently appeared in our columns from the pens of Captain Abney and Mr. A. L. Henderson.

We propose to say a few words as to the result of our experience in the use of iodide since the time when Captain Abney first published his investigations on the subject.

We do not propose to enter into the theoretical question of whether or not there is an actual chemical combination between the silver, the iodine, and the bromine, or merely a mechanical mixture of bromide of silver and iodide. We believe that there is no proof, either one way or the other, and that it is a question of mere assertion on one side and on the other.

There are two separate and distinct functions which iodide performs in emulsions: in the first place, it changes the position of maximum sensitiveness of the emulsion to the spectrum, and destroys entirely its sensitiveness to the rays of lower refrangibility. Besides this, it has a most decided action in making it possible to secure plates which will give transparent shadows. This action is quite apart from the mere fact that the emulsion containing iodide will be less affected by the light used in manipulation. We consider this last by far the most valuable property of the iodide. Doubtless it is useful to be able to work freely in a comparatively well-lighted room; but it is quite easy, especially to those who have not been demoralized by the luxurious light used in working collodion, to work pure bromide plates in what is a practically safe light.

Admitted an advantage in the use of iodide, the natural questions are, in what proportion should it be used, and how introduced? We have used all quantities, from 10 per cent. downwards; we have found the distinctive action of the iodide in giving a clear and vigorous plate to be evident even with very small quantities of the haloid. One per cent. gives a plate quite perceptibly differing from a pure bromide one, and 2 per cent. has a very considerable effect.

We have now settled down to the use of about three to four per cent., as giving as great clearness of shadow as is to be had, and as retarding the sensitizing process less than a larger quantity. We are now talking of percentage of the silver haloids. The quantity mentioned will be got by using from two to three grains of iodide of potassium to every hundred grains of nitrate of silver which is to be converted. We believe that the small quantity mentioned makes no great difference as to the light which may be used in manufacture and development. At any rate, it is best to err on the safe side. Too safe a light cannot be used in the manufacture of emulsion and coating of plates.

The iodide may be brought into contact with the bromide in any of three different ways. The two soluble haloids may be mixed, and the silver solutions may be added to them; the bromide and silver may be emulsified, and the iodide immediately added in a separate solution or a bromide; and an iodide emulsion may be made separately, and mixed in any desired proportion.

We much prefer the second method. If the first be adopted, the iodide of silver is very apt to be formed in a granular mass, and to go to the bottom of the vessel. If the last be used, the great advantage of the iodide as a fog preventive is lost. With the second method the iodide replaces the bromide already formed, and is always in a fine state of division.

Now as to the objections which are urged against iodide. There are only two that we know: the first is, that it gives less sensitive emulsions than those containing pure bromide; the second, that plates made by it will not keep.

With regard to the first of these we are decidedly of opinion that *with the same treatment* a bromo-iodide emulsion will be slower than a pure bromide one; but we are equally sure that whatever is the process used to secure sensitiveness, that process may be pushed to a greater length in the former than in the latter case, without the advent of fog; and that it may be pushed to such a length as will in all cases make the bromo-iodide emulsion as sensitive as it is possible to make the pure bromide one, and this with far less chance of fog. With the boiling process a bromo-iodide emulsion, if it be never allowed to be alkaline, may be boiled for hours without showing fog. As to the keeping qualities of bromo-iodide plates, we may say that we have ourselves kept them for a year and a half without their showing any signs of deterioration. Of course it is necessary to keep any gelatine plate in a moderately dry place.

We would call special attention to a remark made by Mr. Herbert Berkeley in a recent article as to the drying of plates. He is on the subject of green fog, and points out the fact that a frequent cause of it is the method used to dry the plates. He advises that a plentiful current of air at the ordinary atmospheric temperature be employed. We think that this is a point which cannot be too strongly urged. Green fog is by no means the only evil that results from using artificial heat and an insufficient current of air. It is inconceivable what different qualities of plates it is possible to get from the same emulsion by drying them in different ways. There is no need for artificial heat except in very cold and damp weather, and then a very little of it will do; but the current of unheated air must be ample. Plates will dry quicker with such a current than with an insufficient one heated to any temperature below that at which the gelatine will melt and run.

FLAMELESS COMBUSTION.

The exact physical nature of flame is a point upon which physicists and chemists are by no means agreed; but there is a general notion that the clearly visible portion of flame consists of solid matter heated to incandescence, and the nearly invisible portion—comparable to a hydrogen flame or that of a Bunsen burner—is merely highly-heated gaseous matter. Such a view is incompatible with many well-known phenomena, as, for example, the fact that metallic arsenic burns in oxygen with an extremely brilliant light; and it is well known that Professor Frankland has made careful investigations which throw considerable doubt on the popular view.

It is established that a given weight of fuel yields a definite and easily-estimated amount of heat when completely burned; but the intensity or heat-tension varies according to the rate at which the oxidation takes place, and the area over which the action is spread; hence the aim of those who wish to attain to high degrees of heat tension or temperature is to burn fuel with the utmost rapidity, and in such a manner as to produce as small a flame as possible. In the case of the usual blowpipe, these ends are partially attained by injecting air into an ordinary flame; while the most perfect exemplification of this principle is that form of the oxy-hydrogen blowpipe in which the mixed gases are burned at a jet. The insignificantly small and scarcely luminous flame thus obtained is intensely calorific, and when it is directed on to a cylinder of lime, the brilliant incandescent light known as the lime-light results.

Mr. Fletcher, of Warrington, whose improvements in gas furnaces and heating burners have been from time to time described and illustrated in our columns, has recently found that by increasing the air supply to a blast gas burner, which is being used to heat a solid body, a point is arrived at when the flame entirely disappears, and combustion without flame results. A vague something appears at the mouth of the burner and playing around the heated body, but it has no clear outline, and is certainly not flame in the ordinary sense of the word. When this condition of flameless combustion sets in, the intensity of the heat increases to an extraordinary extent, the temperature attainable being comparable to that of the oxy-hydrogen blow-pipe; and we may expect practical results of considerable value to result from the new method of burning gaseous fuel.

Mr. Fletcher, in a communication to the Institute of Mechanical Engineers, writes as follows:—

My efforts have been turned to the reduction of size of flames, as I had practical proofs that a higher duty was to be obtained from a small flame than from a large one burning the same quantity of gas. Carrying this idea out to as great an extent as possible, I found that under the most perfect conditions the flame would totally disappear, and this invariably happened when the conditions for perfect combustion were fully complied with. The whole matter is so new in its practical form that no great amount of experimenting has yet been done, but it is quite evident that flame and smoke have no connection with combustion, further than an accidental one. If we examine a flame from this point of view, we find that the visible part of it is nothing more nor less than solid matter, which is being heated up by the work done by that part of the fuel which is already burnt; it is made up of solid particles in a state of incandescence, and this incandescence is not combustion.

The part which flame plays is, under certain circumstances, an important and peculiar one, *i.e.*, to continue the combustion or chemical combination already commenced by supplying heated matter to make the combination continuous. This appears to be proved by the fact that flame can at any point be cooled down so as to totally stop combustion, simply by putting a cold substance in it, and the fact that flameless combustion instantly ceases on the removal of the heated solid body such as iron or fire clay, or on its temperature being sufficiently lowered. The flame, in fact, plays the mechanical part of the action in the absence of other heated solid matter, and no doubt it will be found that combustion is impossible except in the presence of heated solid matter of some kind; at all events it is so with those substances which only combine at a high temperature. Flame is, in fact, a fuel in an intermediate state between perfect combustion and smoke, and it may either go on to perfect combustion, or degenerate into smoke, according to the conditions present.

If we take gases which contain no solid matter or dust—for instance, pure oxygen and hydrogen—and burn them, we get a flame certainly, but so insignificant that it can be accounted for, probably, by the difference in the refraction of the heated space as compared with the outer air, added to the dust in the air drawn in, and, possibly, other accidental circumstances.

I have, as yet, made no experiments, except with gases or the vapour of petroleum; but there appears to be no doubt whatever that the same results can be obtained from solid fuel easily, ensuring not only the complete disappearance of the black smoke nuisance, but also perfect combustion of the whole of the fuel instead of the production of poisonous carbonic oxide, which at present appears to be the special aim of most of the smoke consumers now in use. I will show you the consumption of coal gas at the rate of about 70 or 80 cubic feet per hour in this ball of iron wire, and as you will see the iron will fuse easily, with a total absence of a trace of flame. Using this blowpipe will enable you to see the complete transition from a large and comparatively cold flame, which does very little towards heating the wire. As air is added in increasing proportion you will see the temperature gradually rise as the flame becomes smaller, until, by pinching the gas tube for an instant, the flame is extinguished. At the instant of extinction you will see the sudden glare of heat and the instantaneous fusion of the iron, the difference in temperature, with and without flame, being strongly marked, the conditions in other respects remaining precisely the same. I use, as you will see, a foot-blower, because it is desirable to show you an effective experiment quickly, and having no hot chimney stack at hand, a draught must be got by some other means, so as to obtain a high temperature.

Where a moderate heat is required, such as an ordinary domestic firegrate, it is quite possible that this system of combustion is to be obtained in practice without any forced draught, and we may yet come to a clean, flameless, and, of course, smokeless, incandescent fire in our houses.

I select iron wire, because it is easiest to show as a lecture experiment, as both the iron and the coal gas can be burned; but I will also do the same thing with lumps of fireclay, both with coal gas, and petroleum vapour. An examination of the results shows at once that the combustion takes place by simple contact of the gases with a surface sufficiently hot to cause combination, and that flame as flame has no existence. Since the first note on this subject was published, a friend, who is a large brewer, tells me that on drawing the fire from his coppers he has noticed the contents suddenly boil up furiously, and there is a visible glare of heat all over the hot lining of the firehole. This he never could account for until the hint gave him a clue to the fact that gases from the drawn fuel were burning without flame by simple contact with the red hot fire bricks.

A NEW PHOTOGRAPHIC GELATINE.—TESTING COMMERCIAL OXALATE OF POTASH.

BY DR. J. M. EDER.

The quality of the gelatine employed exercises a notable influence on the quality of an emulsion, and, although emulsion may be made with hard gelatine alone, especially in the summer, and when the ammonia method is employed, it is not unusual to add a certain proportion of soft gelatine, in order to ensure clearness of the film and rapid development. Makers of plates are, as is well known, often tormented with dull and generally round spots when hard gelatine is alone used; but this defect arises notably when the proper relation between gelatine, water, and silver bromide is not properly regulated—a point which has not been sufficiently considered up to the present time.

The gelatine factory of Winterthur, in Switzerland, which is under the direction of Mr. C. Simeons, is now sending out a soft quality of gelatine which has no tendency, even under unfavourable circumstances, to give rise to spots, and can be used alone for the preparation of emulsion. Such emulsion also gives uniform and satisfactory films when one-half of the soft gelatine is replaced by the hard quality of Winterthur gelatine, and the admixture of the two qualities is very convenient and satisfactory. The hard Winterthur gelatine is sold in packets having white labels, while the softer quality is sold in packets with green labels.

Testing of Potassium Oxalate.—Now-a-days the oxalate of potassium is manufactured in many factories, and can be purchased at a low price; but, unfortunately, we often find samples which have been carelessly and badly prepared. A strongly alkaline reaction is far more objectionable than a slight degree of acidity, and one does not often meet with a completely neutral preparation. The use of alkaline oxalate often leads to the production of a yellow fog or stain, especially if there does not happen to be any free acid in the iron sulphate employed, or no care has been taken to neutralise the stock solution of potassium oxalate.

The presence of a notable amount of potassium chloride is especially objectionable, as this salt is almost as powerful a restrainer as potassium bromide. For this reason many samples of oxalate (those containing chlorine) tend to give hard and glass-like negatives, while others give soft, well gradated, and satisfactory pictures. The above considerations indicate the propriety of testing all oxalate for chlorine before admitting it into stock; this being easily done by dissolving a few grains in distilled water, acidifying with a moderate excess of nitric acid, and adding a few drops of silver nitrate solution. If more than a slight turbidity arises, the sample of oxalate should be rejected.

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

By Fjord and Fjeld in Norway.

There are two ways of getting to Norway: you may go there by boat direct from Hull or Leith, and this is the cheapest and most direct way; or you may journey *viâ*

Copenhagen and Sweden, a picturesque route enough, and to be recommended especially to those who love the sea most from a dry-land point of view. If you go by water it is best to land at Bergen or Trondjem, on the western coast, for here are situated the grandest fjords; but coming from Christiania, there is the advantage that you traverse the rugged Fille Fjeld, as the southern part of the Scandinavians is termed.

We made the journey by Denmark and Sweden, and in this way not only got a glimpse of those countries, but were able to secure some photographic sketches of them into the bargain. In forty-eight hours, travelling by Cologne and Kiel, you are in Copenhagen, and thence a steamer brings you in a couple of hours to Malmœ, the most southern point of Sweden. Travelling by rail, if you do not go by express, is of a very free and easy kind, and during the journey to Christiania the periods of waiting are frequent and long. At Falkoping, where a rest of two hours is permitted, we sallied forth with our camera and secured a view of the wooden-built village, located, of all places in the world, in a wilderness of big rocks. We chose some of these massive boulders for a foreground, showing the pine dwellings beyond, and now that we look at our picture, we marvel still more at the natives taking up their abode in such an un-get-at-able spot. They would certainly be proof against any sudden rush of cavalry, but no other advantage is apparent from the situation.

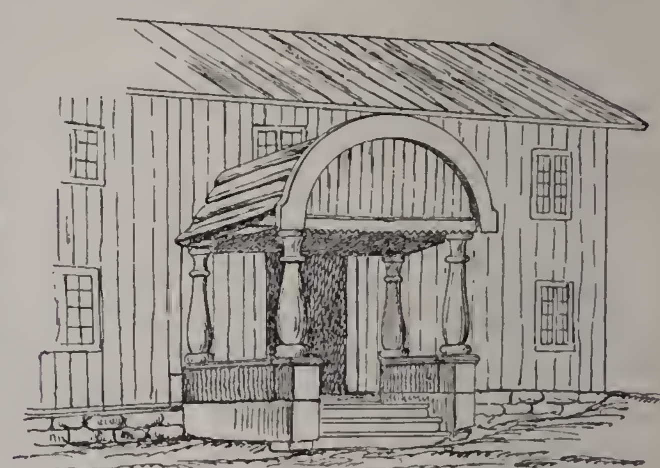
Of Svarta in Sweden we have another view, secured while the engineer leisurely repaired his locomotive and took in water; and of Amot lake, a placid water bordered by undulating forest land, and green hills, we have also a picture, albeit the wooden roof of a railway building—we set up our camera on the platform during a half-hour's wait—rather interferes with the foreground. You do not get into Norway until you are within a few miles of Christiania, the division of the twin-kingdoms being plainly marked by a broad belt of open land which has been cut through a dense forest of pines to indicate the boundary.

The cold granite buildings of Christiania remind one of towns in the north of Scotland. There is little of interest to depict in the camera, for the public buildings are square and modern, and the streets offer no characteristic feature. But the out-look towards the Christiania fjords makes a delightful picture; the craggy headlands of grey rock jutting out of the smooth water, and the forest-clad hills, their foliage in many parts sweeping down to the very edges of the fjord, constitute a scene especially Norwegian, and give one a foretaste of what Scandinavian scenery is likely to be. Perhaps the best view of the Christiania Fjord is obtained from the roof of the king's palace.

By rail and boat to Hamar, and thence we begin our journey to Bergen and the west coast. But a word on Norway-travelling before we start. When once in the interior, there are but two ways of locomotion, by foot or by carriole. The carriole only holds one—there are sometimes double conveyances to be found, but not frequently—so the passenger must drive himself. It is a little shell or cup, perched upon a couple of shafts, the recess being large enough for your body, while the feet rest upon supports like those of a "trotting" cart. The carriole is hired like the old post-chaise by the stage, so that if you are tired of walking at any time, or wish to get over your journey fast, the convenient little vehicle is at your disposal. So far, then, in respect to conveyances; now as to accommodation. There are no inns or hotels in Norway except in towns and large villages. In lieu, there are so-called "stations." The stations are generally good farm-houses appointed by government to receive travellers, and they are at convenient distances of about eight or ten miles on the road. There are comfortable reception rooms in some of them, and good sleeping accommodation, and here it is that you may hire your carriole. There are ordinary stations and "fast" stations, the difference not only being that the accommodation in the latter is much better, but that at the fast station the owner is bound to have horses ready for the traveller, while at the ordinary station you must wait till the steed has been caught on the hill-side, or brought home from the plough. Another thing should be noted in respect to these "stations": the traveller must remember he is not lord and master, as in an hotel; he is simply there on sufferance, and it is the owner of the farm-house to whom he is under an obligation. So he had best be upon his good behaviour. It is no good your rapping on the floor, or pulling the bell, when there is one; it is far better for you to go to the good people, wherever they may be, in the kitchen or in the store-room, and ask them politely for what you want.

But it must not be supposed for a moment that they are churlish or ill-natured—quite the reverse. They are always trying to please you, and sometimes, indeed, their kindness becomes embarrassing. They bring you your coffee and fladbröd to the bedside, and come and go through your sleeping apartment without the slightest hesitation. There are seldom locks on the doors, but if there are it makes no difference, for the worthy people knock away at the panel and wait outside until admitted.

Although it is so far north, Norway is not cold. Our first day's walk to a hamlet called Lien was one of the hottest walks we remember. Fortunately, the path lies through groves of monster firs, their stems rugged with mossy lichen. The air is pure and crisp to a degree, and, despite the warmth, the walk is most exhilarating. We should have done better, so we hear afterwards, to have stayed for the night at Musted, but, like all pedestrians on a first day's tramp, we are anxious to get well on the way. So, only stopping once on our journey to secure a reminiscence of Ransfjord, a sweet scene of wood and water, we decide on a few miles more, and halt at the station at Lien. We here give an outline sketch from a photograph we took



"Station" or Inn, at Lien. Norway. (from photo)

of the homely hostelry; built exclusively of wood, and with a portico supported by pillars that seem to have come out of a toy-box, the house looked as if it had been piled up from a child's box of bricks.

We only wish, by the way, we had made it a practice, in our wanderings as a tourist-photographer, to take a picture of every quaint inn at which we have tarried. One's pleasantest reminiscences of a tour are sometimes connected with the halting-places on the road, and, supposing the traveller is not passing through a land of modern hotels, his photographic sketches, in the end, of this kind, would be full of interest, and probably of some value from an artistic stand-point. We do not wish to point out our little inn at Lien as an artistic pile, but it is certainly a primitive one, and we doubt if a more simple house-of-call is to be found now-a-days except among the log-huts of the bush.

Our way lies through the Etnadal to Gravdalen. A photograph we secured of the valley of Etnadal, and another of a tearing white torrent in the midst of black pines in Gravdalen—taken on collodio-bromide plates—turn out particularly sharp and clear on development when we reach home, so that we have no difficulty in securing tolerable enlargements of them to the extent of five diameters.* We suspect the purity of the Norway atmosphere has something to do with the clear detail in the distance shown in the negatives, for although in many respects the plates leave much to be desired, this feature is decidedly a prominent one.

We need scarcely point out that once fairly started in Norway, the tourist photographer has only himself to rely on in respect to chemicals or apparatus. It is quite impossible for him to purchase even the most conventional of chemicals, supposing he wishes to develop a plate *en route*, or perform other simple operation. In the same way, if his apparatus requires to be augmented or modified, he must do it himself. Fortunately, in our case, there was a party of four, for besides the photographer's kit, other necessaries required to be carried. The weight of camera, dark slides, and stock of plates amounted to less than six pounds, and for tripod, three mountain staves of the party were fitted together. This remarkably solid tripod did other duty besides supporting the camera. A hook underneath permitted the attaching of a wire, whereon could be hung a *pot-au-feu* for cooking purposes (made, by the way, out of a stout biscuit-tin), for, truth to tell, living in Norway is generally of a most frugal kind. During a ramble of three weeks, our party only tasted fresh meat once (some reindeer steaks at Nysteun on the Fille Fjeld), and if tinned provisions are obtainable at a station, you may consider yourself decidedly fortunate. For this reason a supply of extract of meat, groats, condiments, &c., for the making of soup by the way-side, wherewith to make bread or biscuit palatable, is very requisite for a tour in Norway if you mean to rough it. The staple food, indeed, may be said to be fladbröd and butter, or smoer, as it is called. This fladbröd, with which travellers in Norway soon become on intimate terms, is an exceedingly thin rye or oat cake, prepared in disks some two or three feet in diameter, and so papery in consistence as to be capable of being folded into sheets like cardboard. It keeps good for weeks and months; to the taste it is not unpleasant, but the annoying part of the matter is that, if at all hungry, you become tired of eating long before the cravings of appetite are satisfied. Quire after quire may be consumed of this edible stationery, until the lips are parched and the jaws aweary, and yet one's hunger is unappeased.

There is a succession of charming lake scenery all the way to the Fille Fjeld; at Gravdalen it is a silent mere encircled by tall sombre pines; at Freydenlund a smiling blue lakelet, with islands of tufted foliage and undulating green hills, dotted here and there with white farm buildings. A big cloud above, as a background, puts Freydenlund lake half in shadow half in shine, as we photograph it, but we lack, unfortunately, the ability of an England or Bedford to make the most of our chance.

It is uphill all the way to the Fille Fjeld, and snow on the neighbouring mountains and a keener atmosphere tell us how rapidly we are ascending. The hills grow bare, foliage ceases, and only scrub and moss are met with. At Nysteuen the scenery is that of one of the high passes in the Alps, and in the photograph we secure from the station, snow is shown on every side, and it even covers the inhospitable shores of the lake that is here to be found on the summit of the ridge.

(*To be continued.*)

* Our readers may remember seeing these and others in 1877, when we showed them at the Photographic Society of Great Britain, in illustration of a paper on "Photography from a Holiday-maker's Point of View."

PHOTOGRAPHIC EXPERIENCES IN EGYPT.*

Our next day was to be spent at the great pyramids of Ghizeh; so early in the morning we started, crossed the beautiful Kasr-el-Nil bridge at Boolak, over the Nile, and after a drive under beautiful acacia and palm trees arrived at the foot of the great pyramid about 8·30. One is so filled with wonder and admiration that it takes a few minutes to bring one's self to work; however, we opened up our traps at once, and after being placed by Mr. Brugsch in charge of the Sheikh of the Arabs, who gave us eight men to assist iu carrying, we began work. It was, indeed, a full day's work with no idle moment. The pyramids are very deceptive in size, and do not look so large until one tries to focus, when he finds he had but part of the pyramid on the ground glass. The Sphinx I was rather disappointed in; I had my impression, from pictures which made it loom high up in the sky, that it was very much higher. Our best pictures of it were made with single lenses; thus for 8 by 10 the back lens of the euryscope was used, which doubled the size and gave better perspective; the time of exposure with the smallest stop is trebled, but the resulting image is very sharp and clear cut. For stereoscopic size, the back lenses of the Morrison stereo, five and a-half inches, gave a fine image; exposure, also, three times as much as ordinary combination. In making the close view of the entrance to the great pyramid, a lens of exceptionally wide angle must be used; so one five-inch Ross was put on, and found to embrace an angle of fully 90°. We made the circuit of all the pyramids on the Ghizeh platform, and made negatives of all of them; in one general view all were embraced; but our foreground was a vast desert, unbroken for hundreds of yards. To break this monotony, a group of Arabs, with their white turbans and striped cloaks, were carefully placed in the foreground. Many bits of the construction which were not beautiful nor picturesque, but would aid the student in architecture, &c., were taken, and special pains were taken to show the great pyramid in every part—looking up from the bottom, down from the top, along the long layers of stone, up the corner, &c., &c. A group climbing the pyramid was made to show how the Arabs assist. The ascent, although not so very tiresome at the time of climbing, tells in a day or two, when every bone in the body aches. On the top, the Arabs insist on cutting your name. Many famous persons have indulged in this fancy; among others is the name of Jenny Lind, in very large letters. The point or top is rather large and flat, about twenty feet square, in the centre of which stands a staff about forty feet high, placed there by General Stone Pasha for triangulation. Here we waved our American flags, emblems of the youngest nation, on the monuments of the oldest in the world. After all outside work was done, we prepared for the interior, which was much more tiresome than the ascent. We were given eight Arabs, two a-piece, as helpers in climbing, and four to carry our instruments. A supply of magnesium was also taken; and in we started, down an inclined, slippery opening, about four feet square. Notches were cut in the stone, which served as steps. Suddenly we are stopped by a huge stone; we turn to the right, climb hand over hand up the smooth, polished limestone, and find ourselves in a similar tunnel—only now we ascend, soon reaching the grand gallery, which is twenty-eight feet high, inclined at an angle of about 40°. Here we depended entirely on the Arabs pulling us up, as our shoes would slip and slide, so that it was impossible to stand; but the bare feet of the Arab clung fast, and, while one pulled and the other pushed, we soon reached a part where notches in the bottom served as a foothold. Suddenly one of the Arabs shouted "Look out!" cautioning us to lower our heads. We again entered a four-foot opening, and twenty feet further on entered the famous king's chamber, with its broken sarcophagus. The heat was intense, the darkness so thick you could feel it. After a hasty inspection, the cameras were pointed, the magnesium lighted, and exposure commenced. In focussing I used the candle, focussing on the light, and getting the size by first holding it on the one side, then on the other extreme of what was wanted in the picture. A general view can not be made, as there is nothing but the stone sarcophagus that would give relief; even this, like all else inside, is intensely black. For 8 by 10, the euryscope was used; for stereo, Morrison, full opening, both cameras exposing at one time. The exposure given was about five minutes. Sometimes there were six double tapers burning at once time. Great care was taken not to get the light immediately in front of the camera, or quite a spot or streak will result. After duplicating the exposures we

* Continued from page 493.

found the chamber so full of smoke that we were forced to leave. But during our stay in the king's chamber (which lasted an hour) our Arabs kept up much yelling and gesticulating, which in this close, pent-up place, under thousands of tons of masonry, gave one an idea of the nether regions. In returning nearer to the open air, we could not resist making an exposure in the grand gallery. This was more difficult; as the light did not reach far, and was necessarily in front of the camera, we were obliged to place the magnesium behind a figure; in this way the gallery was quite brightly lit up. We paid a visit to the queen's chamber, which contained nothing but a few bats flying about, after which we came out, having been inside about two hours.

We photographed the pyramids and sphinx and surroundings thoroughly, and needed changes of plates, so my dark tent came into use for the first time, and I confess I was more than pleased with its working. I had plenty of room inside.

And now back to Cairo, which offers much more that is picturesque and beautiful than Alexandria, many beautiful mosques, some of them very old, reaching their minarets high towards the sky. One of the oldest is that of Sultan Hassan, which is 535 years old; it is falling into decay, no one seeming to interest himself in its preservation. On entering, large straw slippers are put on our feet to cover the unholy dust of the Christian, and, after winding about several avenues or halls, we enter the large open court, facing which is the niche, which faces Mecca, where the Mahomedans pray to the east; finding a number of Moslems at prayer, we arranged them in positions and made several pictures of them, after which the inevitable *backsheesh* had to be paid, the men running after us as we left, begging for a piastre. Just as we were leaving, and had just entered our carriage, we saw coming down the narrow street a Moslem funeral; this we wished to have a picture of more than many others, and as they were already close on us we were hurried our utmost. The steps at the entrance of Mosque Sultan Hassan offered the only available elevated spot; to this we scrambled in all haste; one opened the tripod legs while the other brought out the holder; no time to adjust instantaneous drop; so focussing on our carriage, which was in line with the funeral when it reached the proper distance from us, the plate-holder was put on, and just in time, for the crowd of mourners had reached the spot, and the flap was thrown up, the plate-holder turned, camera moved on its pivot a trifle to gain on them as they moved, and another exposure made; the whole time occupied was not over three minutes. Where would a wet-plate worker have been? Here was a large funeral procession, such as one might not see again, and one that would make a good picture. We saw quite a number of smaller ones, but none so picturesque and impressive as this. Immediately opposite, across an open park, is the citadel; it affords a commanding view of Cairo, the Valley of the Nile, the distant pyramids, and the sand hills of the desert beyond.

The single lens of both 8 by 10 and others were used, as the distance was considerable, and required such treatment. A rail-iron fence interfered with the use of a tripod so much that we were obliged to make a stand of our leather cases. Within the limits of the citadel is the beautiful alabaster mosque of Mahomet Ali, with the tomb of this unscrupulous tyrant, who died in 1849. It was completed in 1857. It is certainly one of the noblest structures of the kind, and, being new, it is exceptionally clean and elegant. The minarets are of all proportions, being very slender and very high (280 feet). In making negatives of its exterior, the swing-back and sliding-front were used to their utmost limit; even then there was scarcely enough sky to make a well-balanced picture.

On trying to enter the mosque we were at first refused admission, but finally succeeded on promise of liberal *backsheesh*; large red slippers were put on our feet over the shoes, and we entered with our traps. We first enter a large open court with a magnificent fountain for ablution in the centre; immediately in front of the mosque, on one of the four sides, is a square tower with a French clock, presented to Mahomet Ali by Louis Philippe of France. As the sun shone obliquely into this open court, it made a truly fine picture; everything was pure white, dazzling alabaster; in fact, so bright is the glare, that on entering the mosque (which is quite dark) we were unable at first to distinguish anything. The interior, consisting of a single large quadrangle, the domes of which rest on four huge pieces of alabaster, presents an imposing appearance; the ceiling is effectively painted and gilded. At the south-east angle is the tomb of Mahomet Ali, enclosed by a handsome railing. We made negatives of the interior, but I am doubtful if the 8 by 10 will develop up enough detail, as we were obliged to leave after having given but half-an-hour, when at least one hour was necessary. The greatest charm of Cairo is the street life. It is as exciting, amusing, and bewildering as the Arabian nights' entertainments. It is a moving panorama of all nationalities, creeds, languages, and costumes, with a strong preponderance of the Oriental and semi-barbarous element. It is a perpetual carnival which defies description. The old houses are high and narrow, with upper stories projecting. The streets are covered in many places with rafters and matting, to keep out the glare of the sun, and are lined with open shops of every variety. They are alive with gaudily dressed and half-dressed men and veiled women, water carriers, peddlers of all kinds of wares, braying donkeys, camels, horses, and carriages—jostling against each other in endless confusion. In the mosque the crowd is so dense that it seems impossible to get through, and the noise is so loud that you cannot hear your own voice. The men as a rule wear the red fez or tarboush, with turbans of all colours. The women are imprisoned in long veils of silk or muslin, white, black, or blue, according to rank; the veil is divided about the forehead, and fastened to a pin or cylinder of brass, silver, or gold over the nose, so as to leave the dark, restless eyes free to satisfy curiosity. Many of the lower rank carry naked babes on their shoulders or in baskets, and the eyes of the poor children are in undisturbed possession of swarms of flies. The bazaars are simply impossible to describe; there are bazaars for gold and silver work—for silks—for shoes—for fez caps—tobacco and pipes—each thing in its own special place. Every carriage and aristocratic donkey is preceded by one or more fleet runners (seris) in short trousers, bare legs, Tunisian fez with very long tassel, and with a tall staff to clear the way. We had the good fortune to make the acquaintance of a young English lady, who wished us to make a picture of a fine Arab horse, white as milk; she had quite a garden attached to the house, and in this, with some shrubbery behind, and the seris, decked out in his best gold-embroidered costume, holding the bridle of Dervish, we had indeed a picture. Our plan of working was to take a carriage for the day, get a dragoman, an Arab who speaks enough English to explain and assist, then drive around through the crowded streets, and snatch anything or anyone that we wished to photograph.

Coming through one of the narrow lanes, not much wider than an alley-way, we found some rare old latticed windows—every style, every shape, and form seemed to be located close together—and in making negatives of them I sincerely wished for a front that would slide an inch or two more, and a swing-back that would go another inch. A person who has never seen Cairo can scarcely conceive how very narrow and winding the streets are. Occasionally, on making a short turn, one faces a beautiful high minaret, which seems to block the street, and even high up into the sky. We long to make a picture of it, but are almost powerless. Again, on planting the camera, we are at once surrounded with such a crowd that the passage is completely blocked, reminding me of the Centennial, where similar occurrences so often took place. Early one morning we drove over to the market on the Western bank of the Nile, just near the end of the Kasr-en-Nil bridge. Here we were at once assailed by the irrepressible donkey boys, at least ten of whom were shoving and fighting each other for our patronage. We, instead of hiring their donkeys to ride, grouped them, with a fine palm grove as a background, and photographed them, much to their delight, after which they had their usual fight over the *backsheesh*, which was given one of them to divide among the rest. In the market we grabbed many picturesque groups, all the more natural because they were captured with the instantaneous drop. One old fellow, holding two goats, especially interested us—his costume of striped goat's hair-cloth was simple yet graceful. An old woman seated on a high table, selling bread, was caught on the fly, just as she was reaching over some loaves to a little girl close by. Just beyond the market begins the noble avenue of acacia trees, which shade the drive to the great pyramids. We caught a picture of this avenue just at a happy time of the day; that is, when the sun was low and lit up under the trees.

On our return to the city we saw, on crossing the Kasr-el-Nil bridge, an unusual stream of passengers, donkeys (loaded and unloaded), and many camels loaded with immense piles of long grass. We could not resist the temptation to make a number of instantaneous exposures. By climbing up the trestling to the broad top a good solid stand was reached, which commanded a view of the entire length of the bridge, and as each group of camels, or donkeys, or carriages, would come in place, flash would go the drop. A police officer stood ready, when we clambered down, to receive his *backsheesh*. A few minutes' drive into the city brings us to a newly-erected dwelling-house that is a marvel of beauty and fine workmanship. It is indeed a palace—is surrounded by a magnificent garden, and is strictly Arabic and Moorish in architecture. The owner, Mons. St. Maurice, a wealthy French banker, has bought up, during fifteen years' residence in Egypt, every rare old bit of lattice-work, inlaid doors, floors, fine tiling, fountains, &c., that he could procure, stored them away, and finally built his palace, using all his gatherings to beautify and furnish it. We made several exterior views of it, taking each end separately, and, as usual, introducing a few Arab figures to locate it and assist in the composition. We could not gain admission, as the proprietor was in Europe. We wished to make a picture of an Arab woman, as we saw them every day riding on their donkeys. This was rather a delicate matter, as they are very shy, and besides, the men would scarcely allow it; but *backsheesh* will procure almost anything; so we sent our dragoman in search of a woman who would unveil and allow us to photograph her on a donkey, veiled and unveiled. He reported one afternoon that he had a wife for us (meaning woman), so he took us through many winding streets, where we saw many women; he bargained with a handsome girl that we picked out of the crowd, and after promise of an extra *backsheesh* if she behaved well, we went to work right there in the street, selected an arched door as background, and placed her on a donkey, and made several negatives of her in various positions illustrating the Oriental mode of conveyance for Arab women of the middle class. The crowd was simply awful—yelling, hooting, and many cries of *backsheesh*. We were kept busy calling Imshee! Imshee! (clear out) and driving them away. When ready to make an exposure, I'd cry out, Estana! Estana! (stand still) and then watch the opportunity.

Our last afternoon in Cairo, before going on the Nile voyage, was spent among the tombs of the Caliphs. On reaching them, the sky had clouded over and the wind sprung up, so that we did not make as many as we wished, but still caught enough to satisfy ourselves with in between the gusts of wind and when there was a little brightening up of the light. While climbing about among the ruins, an officer of some soldiers quartered there came and ordered us to leave, as we might set the place a-fire. The absurdity will be noticed from the fact that the buildings are all of stone. Doubtless he thought we had explosive chemicals, or that our cameras were a new army engine of destruction. In one of the old mosques built over a tomb we got some bits of old inlaid and Saracenic work that well repaid us for the trip out. One old mosque is kept in quite a good state of repair, and is the only one that is complete. Its dome and minaret are very high, and, like all mosques, it is built closely surrounded by other buildings, so that it was almost impossible to make a picture of it and not show bad lines. After packing up our traps for the return to the city we missed our dragoman, and in hunting him up we found him down on his knees before a niche in the wall of an old mosque, facing Mecca, his slippers lying beside him. We at once opened our camera and caught him in the act, just as he was posed in his praying position. In one of our strolls we saw a dwarf about the size and age of Tom Thumb. Of course we must have him in our list of subjects; he fought shy at first, knowing his worth, and bargaining how much *backsheesh* he was to get before standing for his picture. After a satisfactory bargain had been made, we stood him, with a bit of wall as background and his cane in hand, beside our dragoman, who stood about six feet four inches high: the contrast, of course, dwarfed the dwarf. We found afterwards that he was a favourite at the court of the Khedive, where he acted the part of clown and jester. We took with us in our trips through and about the city, one of our larger leather cases, in which our long box, containing the 5 by 8 plate-holders, the lens-box, and a few other small articles were carried; also the dark-tent, a case of 8 by 10 plates, a box with the 8 by 10 holders, 8 by 10 box, and small camera, which we always carried screwed on the tripod, the legs bent up and the head-cloth tied around with the tapes on the corners. We were very choice and careful of our instruments, always carrying the 8 by 10 wrapped in the large waterproof head-cloth, with a shawl-strap around it. On the bed of the 8 by 10 camera, near the back end, I fastened, with gum bands, a roll of Joseph paper, which saved the ground glass, and spring which held the ground-glass frame and holders.

On finding that our Hermagis lens was needed more than the others, we always carried it on the camera, turned in towards the ground glass. The single lens of our euryscope was not often needed, but, when wanted, only required the slipping on, without screwing of the extension bed of the camera, which then gave full length of focus, even for a tolerably close subject. In some of the narrow streets, and in making the mosques and other high buildings, we found the eight-inch Morrison lens to give a clear-cut, sharp image, embracing an angle of fully ninety degrees. For dark interiors, moving subjects, figures, &c., we invariably used the euryscope, as it will make a full-timed negative on a B plate in two to four seconds. The 8 by 10 plate-holders we carried in a box we had made in Cairo, so they would stand on their side, always handling them so; otherwise an accidental opening of the catch that holds in the division may allow plates and division to drop out. In exposing we began always on plate-holder No. 1, using them in consecutive order, excepting when we carried two rapidities of plates, when we filled six holders with B, or extra rapid, and the balance with A, or ordinary rapid, at the same time always putting them in the register in their regular order, beginning at No. 1. Immediately on making the exposure a record of it was made by Mr. Wilson in one of the Scovill Manufacturing Company's books, with the date, time of stop, remarks, and title of subject, before making another exposure, thus preventing possible mistakes. An operator using gelatine plates should always have his wits about him, and keep cool, especially where two rapidities of plates are used. Just before exposing, think a moment: first, which lens and stop you are using; second, which kind of plate—rapid, extra rapid, or instantaneous; third, the lighting of your subject; then expose, always for the shadows. The great trick in exposing, especially on a view or subject in which there is an occasional movement—unless the exposure is instantaneous—is to know just when to open the flap. Practice only can teach this, as your eyes soon learn to note the moment all is still, then open and expose. Don't allow any one standing near by to affect you in the least, but only expose when you see all is still and ready. In making instantaneous exposures, I could see what was before the camera and in the scope of the lens by looking over the top, from behind, through the holes in the drop, as it was drawn up ready for an exposure; in this manner being able to judge of the subjects moving before us, and thus having a choice. We found our 5½-inch Morrison lenses served for the majority of views, although we were many times forced, in narrow quarters, &c., to use the three-inch Ross. In making instantaneous single figures or groups we always used the half-size Ross portrait lenses, nearly always using the fourth stop, rarely the fifth; while the exposure was being made, or immediately afterwards, I dusted the slide on both sides with a camel's-hair brush, which I always carried in my pocket; also often brushed off the camera, as the soil and dust was gritty, and soon would grind varnish and polish away. I also always carried with me in my pockets a diamond, a screw-driver, several gum bands, a few brass screws (various sizes), and the loose stops of our lenses. I never parted with them, so they were never missing. We began at once to mark by system, and never deviated from it, as this, we found, would be the only safe method, travelling constantly as we were, and using dry plates in quantities, as we might otherwise expose the same plate more than once. We found a good plan to keep track of the holders was to carry them in regular order, beginning at one and with the slide up; then, as soon as a holder was used—both plates having been exposed—place it back in the box reversed, or slides down. In this way, if you are hurried, you are always sure of taking up the right holder.

As we carried eighteen 5 by 8 plate-holders, we generally had a sufficient number of plates for an ordinary day's work, and left the changing, packing, and re-filling of the holders until night. The method of marking was to take a whole sheet of ruby paper, pin it in the shape of a cylinder, fold over one end only, allowing a small vent for air, placing this over a candle around which stood a round box which prevented the light slanting down around the bottom of the ruby cylinder. The round box was afterwards used as a carrier for the pneumatic holder. The room being all ready, we opened out two plate boxes, one with unused plates and another for exposed plates, and at once adopted a uniform method of placing and arranging things, so I could find anything wanted at once. The boxes were opened in front of the light, with the fresh plates on the left and the packing box on the right, then the plate-holders were piled up on the left of the light, in the order they had been exposed and registered, so the plate in holder No. 1 went in first, &c.; as soon as a box was full of exposed plates, a note was made in the register, marking the number of the following box, so that no mistakes and blunders would occur; and, to insure safety, I detached the tag telling the contents from the box as soon as it was empty, and marked *negatives* plainly on it, in one corner, as soon as we began filling it with exposed plates.

As each plate was put into the box from the holder, with the pneumatic holder, four pasteboard corners were inserted, then another plate, &c. When a box was only partly filled, a board with a spring at each corner was placed in next to the plates, and the corners filled in to the top with triangular wooden blocks, of which we had varions thicknesses. In this way they always carried without shifting or rubbing their faces in the least.

(*To be continued.*)

Notes.

The present meeting of the British Association at Southampton is the fifty-second since its formation.

Our "Everyday Formulary" we propose to publish two or three times a month, keeping it under constant revision, so that it shall always be abreast of the times.

The setting properties of a gelatine is very materially influenced by the presence of salts. Dr. Vogel tells us he prepared an emulsion with nitrate of ammonia which refused to set at all, even when chilled with ice; but, curiously enough, on diluting it to three times its volume, the emulsion set rapidly.

The *Mittheilungen* contains, by way of illustration, a series of micro-photographs of the hair of various animals, a most interesting set of pictures, for few of us have imagined that hair is so different iu colour and shape that the student could name the beast if he but saw a single hair. In these photographs, of which the detail is of the most delicate nature, we see that some hairs are twenty times as thick as others, while iu construction and tint they vary as much as Indian grasses. Indeed, a perfectly new research is here opened up for the student of Natural History, in pursuit of which micro-photography renders material assistance.

One of the principals of a firm of "Photographers to the Queen" has just purchased an estate for £45,000. Evidently there are some who make money out of photography.

It was the little *Willem Barents*, the familiar schooner in which Mr. W. J. A. Grant has made so many photographic trips to the north, that found Mr. Leigh Smith and the missing crew of the *Eira* on the coast of Nova Zemlia, although the two relieving ships, the *Hope* and the *Kara*, were close at hand. The *Hope*, with Mr. Leigh Smith on board, reached Aberdeen on Sunday; but it will be some weeks yet before we can hear of Mr. Grant's return in his sailing yacht.

The Brattice stand recently introduced by Mr. George Smith, and already described in the News, has many points to recommend it over so-called alpenstock stands, as it is lighter and more rigid than any stand of the same weight which we have seen. Although five feet high, it only weighs one pound-and-a-half. Of course no one supposes that it is possible to employ a tripod for arduous climbing in the same fashion as a strong mountain-pole, but Mr. Smith's compound stock would help a lady up Montanbert.

Dr. Hermann Vogel, of Berlin, has just completed a work on "The Progress of Photography since 1828"—*Die Fortschritte der Photographie seit dem Jahre* 1828—which will be published in a few weeks. He is now engaged on a volume relating to the different modifications of bromide of silver.

The Egyptians are quite alive to the advantages of photography in the field, according to the *Morning Chronicle* of yesterday. Our outposts at Alexandria cleverly caught on Wednesday ten of the enemy who were sketching our advance works, and who had with them a photographic apparatus to aid them in the task. Our troops fortunately were able to appropriate the camera as well.

The Postal Photographic Society has sent us their first scrap-book for inspection. It naturally contains both good and bad photographs; but many of the latter are interesting as results, if not as pictures. Some of the prints are exceedingly good; to wit, an out-door portrait by Mr. Withall, and a sailing lugger by the same gentleman. We must also say a good word for the village scene (Wigmore) of Mr. Watkins. The chief fault of the faulty photographs is over-development, and hence flatness.

Some well-executed photo-enamels produced by M. Cacault, of Colombes, seem to have attracted attention in France. M. Cacault, we are told, takes his photographs upon the fine hard faience of Creil, and they are burnt upon enamel at a single heat, at a temperature about equal to that of boiling varnish. This is all we know about the enamels, except that we are informed they are very beautiful. If M. Cacault's process is indeed a simple and certain one, it will be warmly welcomed.

Schlegel recommends the addition to the developer of a solution of cyanide of silver in cyanide of potassium; he says that a few drops of it is exceedingly advantageous, and gives the negative all the character of a wet plate.

M. Marey is continuing his interesting experiments in photographing movement. M. Marey, as our readers know, works differently to Mr. Muybridge, although he aims at the same results. Mr. Muybridge employs a series of cameras, exposing them rapidly one after another. M. Marey has but one camera, the lens directed against a black background, or, rather, a dark cavern, which answers the same purpose. A man runs across the field of vision, and M. Marey's plate remains exposed until the end of the run; but, during the running, the lens is capped at intervals by a rotating wheel, which interferes between the object and the plate, something like one hundred times in a second. The consequence is that, when the film comes to be developed, it does not exhibit a long, blurred image of a man running, but a number of sharp images of the man, the images separated from one another by intervals of darkness.

The picture of the man running we reproduced in these columns a few weeks ago, and now M. Marey has applied his camera to recording other movements. Thus, the trajectory of bodies has engaged his attention; he has photographed a stone wrapped in white paper and thrown across the field of vision, and a stone whirled at the end of a string. The path of these objects has been accurately recorded in the photograph, and since the speed of the rotating wheel (which interferes between object and sensitive plate) is accurately regulated, as also the time that the plate is exposed during the whole experiment, M. Marey has been able to deduce from his photographs the velocities of the moving object at each instant of its flight, as also the trajectory curve taken in the air. Verily, Mr. Muybridge's experiments are bearing good fruit.

Mr. Muybridge, we hear, lectured on instantaneous photography, and what it has revealed, at Indianopolis, on the occasion of the meeting of the Photographers' Association of America, a fortnight ago. After being so well received in Paris and London, Mr. Muybridge is likely to command due attention in the United States.

Deaths from touching electric wires are unfortunately becoming common. A fortnight since we reported two casualties in Paris, at the Tuileries Gardens, and now it is said that on board the *Inflexible* two seamen have died through touching the electric connections employed for illuminating the ship. It is surely easy enough to employ for the most part covered wire—we see that a composition of asbestos has recently been proposed—and this ought always to be done, when possible. Indeed, if electric ighting becomes general, it is not unlikely that a law will be passed, making the use of covered wire compulsory.

Touching H.M.S. *Inflexible*, which has done most of the hard work of bombardment in Egypt, with her four stupendous eighty-ton guns, that hurl a mass of iron weighing three-quarters of a ton at every discharge, it may be mentioned that she is termed the *premier* battle ship of the British navy. This name has been given her simply because she happens to be the most heavily armed and armoured of our war craft; but the scientific illumination on board gives a further claim to the title. Not only is the *Inflexible* provided with powerful electric arc lights, to sweep the sea at night, to detect danger, whether this is breakers ahead, or a torpedo's launch meditating attack; but every cabin and bunk below, as well as the gloomy 'tween decks, are lighted up by Swan's beaming incandescent lamps.

To fit a thousand strange pack saddles upon a thousand strange animals, especially if those animals chance to be mules, is a task that would be difficult at any time; and when it has to be undertaken at a depôt alive with all the bustle of warlike preparations, and by soldiers who have never perhaps harnessed a horse in their lives, it is one most likely to be done badly and clumsily. Where this strap goes and that buckle fits, how the head fastenings are adjusted and the tail straps put on, are matters that might bewilder a hostler, let alone the men of a baggage train; and the worst of it is, that if everything is not in its place, the result, after a few days' travelling, is that the animals get sore backs, and break down. The difficulty is, however, solved by photography; two or three views of a mule properly harnessed sent with every score of saddles, demonstrate at once the method of adjusting every detail in the equipment.

CURE FOR BAD PERSPECTIVE, AND A NEW ADJUSTABLE DIAPHRAGM.

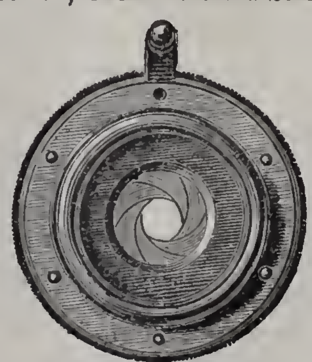
BY ARNOLD SPILLER.

Almost every photographer has experienced at one time or another the difficulty of photographing high buildings, such as churches, monuments, &c., especially when situated on high elevations or in confined situations. Again, there are several amateurs who have at one time or another taken photographs with somewhat imperfect apparatus; as, for instance, photographing St. Paul's Cathedral from Ludgate Hill with a camera not fitted with a swing-back or rising front, the only alternative being to tilt the apparatus, and of course spoiling the resulting negative from an artistic point of view.

Now, as far as I am aware, no method is known for correcting the bad perspective thus produced, but if our readers will try the following process, they will find that it is as simple as it is successful.

The defective negative when dry is placed in contact with a gelatino-bromide plate, exposed, and developed in the usual way, thus producing a positive: this is then placed, bottom upwards, in a copying frame, and the camera tilted to exactly the same extent as was necessary in taking the original negative. If the copying camera be provided with a swing-back it is preferable to tilt it, rather than the camera itself. A plate is then exposed in the ordinary way, and the resulting negative will be perfect as regards perspective.

Mr. Collins, of 157, Great Portland Street, is the maker



of an adjustable stop for microscopes, known as the "graduating diaphragm" (see fig.); and I feel certain that the same, if adapted to photographic lenses, would prove far more convenient than the designs now in use.

In the first place, there is no chance of losing the stop; secondly, one is not obliged to move from under the focussing cloth in order to try different sized stops, the aperture being adjusted by means of a pinion; the apparatus has advantages over the rotating diaphragm, as there is at one's disposal a large variety of sizes, and the aperture is diminished or enlarged without the usual interval of darkness.

In conclusion, I should advise that a scale be marked on the pinion, so that one can tell at once what the exact size of the aperture is.

RENDERING WEAK AND PARTIALLY FOGGED NEGATIVES VIGOROUS.

BY DR. J. M. EDER.

It occasionally happens that in the case of landscape photographs, those parts of the negative corresponding to the dense foliage and other deep shades are somewhat fogged or obscured. This may happen when too long an exposure has been given, or reflected light penetrates into the apparatus. Such pictures lack brilliancy, and the foliage portions are deficient as regards modelling, and the following is a useful method of treating such defective negatives.

The fixed negative is well washed, soaked in alum solution, and once more washed. After this it is placed in a sulpho-cyanate and gold toning bath, such as one would use for toning albumen pictures or glass dia-positives. The following may be given as an example of a suitable solution: Half an ounce of ammonium sulpho-cyanate, five ounces water, and thirty to fifty drops of gold chloride solution (1 to 50); or the double chloride of sodium and gold may be used.

While in the gold bath, the feeblest shades of the image first become acted on, becoming bluish in the first place, and indigo-blue afterwards; while the slight fog gradually clears. The deeper shadows preserve their brownish colour for an hour or more in this toning bath, so that, by removing the plate at the proper time, a virtual intensification is obtained, as those parts which have become blue have acquired considerable actinic transparency. As the bath acts very slowly, it is quite easy to watch the changes with great exactness.

It is desirable to place the plate in a new hyposulphite fixing-bath, in order to ensure permanency of the image. An old bath, which may contain traces of developer, should not be used.

These experiments were made with plates which had been developed with Berkeley's pyro-sulphite developer.

RECENT ADVANCES IN PHOTOGRAPHY.

BY CAPTAIN W. DE W. ABNEY, R.E. F.R.S.*

I finished my last lecture by showing you the effect that dyes had upon sensitive salts. In my previous lectures I have not touched on the method of producing sensitive surfaces, except by the calotype or paper process, or by the wet collodion process; but I should be remiss if I did not mention the subject of collodion emulsions, which have been in vogue now for seven or eight years, but which have been supplanted, to a large extent, by gelatine emulsions. Whether that be an improvement upon the collodion process, except for certain things, I hesitate to say; but certainly, in a collodion emulsion process, we have a process which is admirably adapted, at all events, for landscape work. The collodion emulsion was originated, I believe, in September, 1864, by Messrs. Bolton and Sayce, and a new era was opened out when they made their first emulsion.

Now, an emulsion is very simply formed, particularly a silver bromide or chloride emulsion: but, as far as I know, it has been rather a crux amongst photographers to make an emulsion with silver iodide. However, this is a very easy thing to do, and I propose roughly to show those who are initiated in emulsion-making how an emulsion can be made, and further, how iodide of silver can be made amenable to treatment. The point in emulsion-making seems to be to get the precipitate in as fine particles as possible, and it is said that this can only be obtained, except at very great cost of time and trouble, by first adding the soluble bromide or iodide to the collodion. If you take the trouble to add the silver to the collodion first of all, the aspect of emulsion making is entirely changed, and you can get any amount of fineness by adding the iodide or bromide to the silver contained in the collodion so long as you keep the silver nitrate in excess. In this bottle is some ether, and some gun-cotton which is not dissolved up. In this test tube I have some nitrate of silver dissolved in alcohol containing a very little water. I simply pour this solution into the mixture of ether and gun-cotton, shake it, and I find an emulsion of nitrate of silver in collodion, since the alcohol and ether dissolve up the cotton. In the old days, emulsion makers would have said there is something wrong in having an emulsion of silver nitrate, but I think I shall soon demonstrate to you that in reality it is all right. Now I will add an iodide to this silvered collodion. I pour a solution of potassium iodide into it, not drop by drop, but somewhat carelessly, and shake it up in the bottle at intervals, and as a result we get a very fine emulsion. You would find if you reversed the operation, and put the iodide into the collodion first, and then added silver nitrate, you would have precipitated the iodide of silver at the bottom of the bottle, and in a form which would not emulsify at all. My advice to those who wish to make collodion emulsion (and gelatine emulsion) is to add the silver to the collodion (or gelatine), and then add the haloid salts afterwards, and you will get as perfect an emulsion as you choose. This formation, in so simple a manner, of an iodide emulsion, is a practical lesson which I hope will not be thrown away. I would just remark that if you examine this newly-made emulsion, you will find the iodide is in most minute particles, and that by transmitted light it is perfectly orange.

I have already showed you the colours of different haloid salts of silver under different conditions. I showed you two bromides, two iodides, and two chlorides, one of each of which had been boiled in gelatine, and the other unmodified, and you saw the different colours they transmitted. To night I wish to show you a new form of emulsion, which is adapted to certain purposes, and which is sensitive to the red and the ultra-red rays of the spectrum. If I had time I could show you that green is the most likely colour to absorb all above the red, and it was for this reason that I worked till I obtained a green-blue colour for the purpose I had in view. [The colour of the new form of bromide was shown on the screen.] I propose to try and take a photograph with the dark rays of the spectrum which lie below the red. These rays, which were discovered by Sir W. Herschell, and whose properties were examined by Tyndall by means of the thermopile, we can now analyse by means of photography. I will first, however, show you how very sensitive this form of bromine is to the ultra-red rays. There is what looks a very uninteresting picture on the screen, but still it is sufficiently interesting for me to explain it to you. There are now, apparently, four black smudges, and these smudges were produced as follows:—A film of green bromide was prepared, and over it was put a card punctured with holes of the same shape as the smudges, one-eighth of an inch away from it. Above the card, and about half an inch away, was placed a kettle of hot water, having a blackened surface. After considerable exposure on development, I got the image of those holes in the card developed on the plate, and the result is the photograph on the screen. So you see that the dark rays of the kettle, or rather the energy of radiation from the kettle, was able to produce an image. This particular kind of bromide is very difficult to manipulate in a lecture, but I am going to be so bold as to make an experiment. I dare say some of you here who had the satisfaction of hearing Professor Graham Bell in his late visit, heard him discourse about the photophone; that is, as you know, an instrument which produces sounds in a telephone connected to a selenium cell acted on by light. In one form of this instrument the light is intercepted by a revolving disc with alternate opaque and transparent sectors, which is traversed by a beam of light impinging on the selenium. He found when he introduced between the source and the rotating disc a piece of ebonite, he still got the same effect, which was a matter of some interest. There were all kinds of explanations given about this remarkable fact. Some people supposed the ebonite took up the radiation and gave it out on the other side, but I hope to show you that ebonite is transparent to the dark rays of the spectrum. I have some of this green bromide as a film on a plate. In front of that I have a piece of moderately thick ebonite. I propose to let the image of the carbon points forming the electric arc fall on the plate through the ebonite by means of a lens. If the ebonite be permeable by the dark rays, we ought to get an image of the points on the bromide film when it is developed. As the rays have to penetrate through a mass of ebonite, I propose to give an exposure of about thirty seconds, and I dare say we shall then find we get the points fairly delineated. It would be impossible to develop this plate in this light, so I will give it to Sergeant Jackson, and ask him to place it in the developer, and by-and-bye I will throw it on the screen. [This was subsequently done.]

For the sake of those who are uninitiated, I will show how very easy it is to develop an ordinary collodion emulsion plate. I am going to develop it with ferrous oxalate by means of a brush.

* Continued from page 477.

Behind a negative is a plate coated with a collodio-bromide emulsion, and I will illuminate it by the magnesium wire. On taking it away from the negative, I place it in a little water, in order to make the developer flow, and then I brush the developer on the surface. It is rather a bold proceeding to manipulate a collodion film with a brush, but still I dare say it will answer. [The image was developed and shown.] The usual plan of developing these plates is to place them in a dish, and pour the developer over them. They can also be developed in the hand in the same way as a wet plate.

Now there is a great comfort in the collodio-bromide process, in that you are able to give local intensity to the image ; and I hold that, for real artistic work, the great object is to be able to give local intensity to any part which the manipulator may judge expedient, so as to give it that tone and that vigour which an artist may think necessary. I have often asserted this before, and I am glad of the opportunity of repeating it. I do not believe any process is perfect until that power is placed in the hands of the manipulator ; and the fact is that in the next process which I shall describe, you are at the mercy of your plate, and you must let come out what will.

The process which I refer to is the gelatine process, which may be described as silver bromide, held in suspension in gelatine, in the same way that it is in collodion. The origin of that, I believe I am correct in stating, was due to Dr. Maddox, who took the first picture on gelatine. I know there have been other claimants for the credit ; but I believe, after consideration of the subject, that Dr. Maddox was the first person who used the gelatine emulsion with success. But of all people to whom we are indebted, there is no doubt, first of all, we are indebted to Mr. Bennett for the very perfect way in which he brought the emulsion before the public Mr. Kennett laboured many years in improving gelatine emulsions. He, no doubt, bore the burden and heat of introducing this process commercially ; but for the extreme rapidity with which gelatine plates can at present be prepared, Mr. Bennett must be credited with the full honour. Mr. Bennett showed how a gelatine emulsion could be rendered very sensitive by keeping it at a comparatively speaking low temperature in a liquid condition for many days. Seven days were not too long a time to get full rapidity of a gelatine emulsion. Colonel Wortley afterwards claimed that he could get the same sensitiveness with heating up to 150° Fahr. for a short time, and then Mr. Mansfield capped it by showing that in a very few minutes you could get the same sensitiveness by boiling. Another method was then introduced of producing very sensitive gelatine emulsions, by Dr. Monckhoven, and that was by the introduction of ammonia with the bromide of silver. The ammonia process found many admirers, amongst whom was Dr. Eder, and no doubt the process which he has described lately, of adding a large quantity of ammonia, has given very sensitive plates, and at the same time has given very vigorous pictures when the sensitiveness was not too great. But I think I may say that in England, a gentleman who is well known amongst photographers, Mr. Cowan, has introduced an ammonia process which certainly beats that of Dr. Eder. He emulsifies his bromide in a very small quantity of gelatine with ammonia, and then adds sufficient gelatine when the emulsion is ripened. Dr. Eder's method was to add the full amount of gelatine with the ammonia, by which means, of course, he got a certain amount of rapidity. By Mr. Cowan's method, you certainly get greater rapidity, and greater certainty. I thought it necessary to enter into this, because it has been imagined that your lecturer has been always an opponent of the ammonia process. I am not ; but I honestly say I prefer what is called the boiling process in gelatine emulsion making ; and if anything would convert me to the ammonia process, it would be Mr. Cowan's method.

Now what is the reason of this sensitiveness in the gelatine emulsion, for pictures can be taken in a tenth of the time necessary for a wet plate, and perhaps a thousandth that necessary for an ordinary dry plate ? First of all, we have seen on the screen, in the last lecture, that it has a blue form. But you must not run away with the idea that because anything is blue, therefore the molecules composing that emulsion are blue. It may be an agglomeration of red molecules, agglomerated together in such a way, that when light is scattered by it, it gives you the effect of blue light ; and I believe I am right in stating that the most sensitive emulsion is that in which the agglomeration is in a red state, that is to say, the molecules themselves are red, and the agglomeration appears blue—the blue is there by accident, if I may say so. One reason why the gelatine emulsion appears so much more sensitive than the collodion emulsion is, that you can use a more powerful developer. If you separate bromide of silver which has been emulsified in gelatine, and which gives very rapid plates, from the gelatine—and there is an easy way of getting bromide of silver out of gelatine—and place it in collodion, the extreme rapidity will be found to be gone, simply because you cannot use as strong a developer as you can with the gelatine emulsion ; in fact, the property that gelatine possesses of acting as a physical restrainer comes into play ; each little particle, or aggregation of particles, is surrounded by gelatine, which prevents the developer acting rapidly on them.

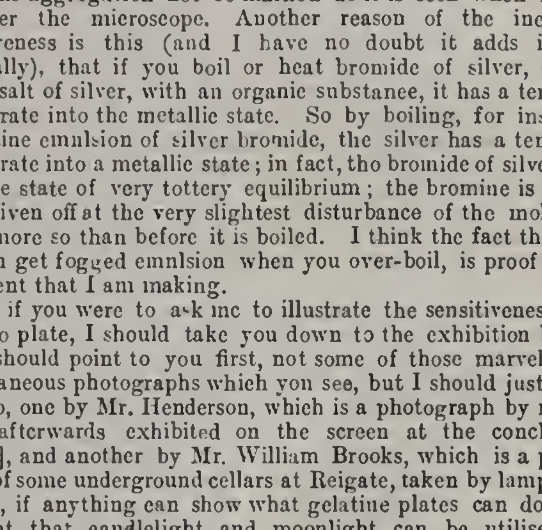
Again, the fact that by boiling, or by the ammonia process, you get a coarser deposit of bromide of silver, also points to increased sensitiveness, for the reason that I tried to give point to in my first lecture. For when sub-bromide of silver is acted on by the developer, you have bromine, the last atom of bromine being taken away from the silver ; and the moment you have freshly-reduced silver in the presence of bromide of silver, and in contact with it, the bromide of silver can no longer exist, and, therefore, you have fresh sub-bromide formed, thus :—

$$Ag_2+Ag_2Br_2=2Ag_2Br,$$

and this, in its turn, is reduced, and so on, until the whole of the bromide is reduced. The faintest action of light on one of these particles will therefore show itself, which it would not do were this aggregation not so marked as it is seen when looked at under the microscope. Another reason of the increased sensitiveness is this (and I have no doubt it adds it very materially), that if you boil or heat bromide of silver, or any haloid salt of silver, with an organic substance, it has a tendency to separate into the metallic state. So by boiling, for instance, a gelatine emulsion of silver bromide, the silver has a tendency to separate into a metallic state ; in fact, the bromide of silver then is in the state of very tottery equilibrium ; the bromine is ready to be given off at the very slightest disturbance of the molecule, much more so than before it is boiled. I think the fact that you so often get fogged emulsion when you over-boil, is proof of the statement that I am making.

Now if you were to ask me to illustrate the sensitiveness of a gelatine plate, I should take you down to the exhibition below, and I should point to you first, not some of those marvellously instantaneous photographs which you see, but I should just point out two, one by Mr. Henderson, which is a photograph by moonlight [afterwards exhibited on the screen at the concluding lecture], and another by Mr. William Brooks, which is a photograph of some underground cellars at Reigate, taken by lamplight. I think, if anything can show what gelatine plates can do, it is the fact that candlelight and moonlight can be utilised for impressing the gelatine surface with an image.

I have here another proof, perhaps, which will interest you, as showing you how rapidly a gelatine plate can act. I propose to take an image of a rotating disc, having alternate transparent and opaque sectors, when illuminated by the light of a single small spark. I have here an ordinary plate electric machine, and



six small Leyden jars, together with a discharging machine, the knobs of which are placed five millimetres apart. If the Leyden jars are charged to a certain point, the spark will leap across between these two knobs. The light from that feeble spark will illuminate the rapidly rotating disc which I hold in my hand, behind which is placed a gelatine plate. [The apparatus was charged, and the spark passed between the knobs, illuminating the disc. The plate was then developed and shown.] The image, you see, of the rotating disc is perfectly sharp. [The disc was apparently motionless.] I dare say it will interest you to know with what speed that photograph was taken. The duration of the electric spark, for a distance such as I have here, has been measured, and found to be 42-millionths of a second. You have now some idea of the immense velocity with which the spark travels, and the extreme sensitiveness of the plates which I employ. This recalls to my mind a very early experiment, made in the Daguerreotype days, where a piece of newspaper was placed on a rotating wheel, and by the light of a spark obtained from a battery of fifty largo Leyden jars, a photograph was taken of the rotating uewspaper. I believe the words were tolerably well defined. The time of passage of tho spark was greatly longer that that which I showed you first, and immensely thicker and more luminous. I should suppose the spark from the large battery at the Royal Institution would take not less thau a thousandth part of a second to travel, so that you see they were labouring under better circumstances than we are. I have taken a photograph of this rotatiug disc in the camera, with only a spark from one jar, but it was rather a ticklish thing, so I preferred to carry out the experiment in the way I have done, rather than to risk a failure. But you may take my word for it, that if you had fifty Leyden jars, you could take a portrait of our Chairman with the greatest ease, by a flash from the spark, in about a thousandth part of a second.

Dr. Vogel has recently introduced a new kind of emulsion, which is a sort of a mongrel between collodion and gelatine emulsion. It is made with acetic acid, gelatine, pyroxyline, and bromide of silver; but I will not coat a plate to-night with it, as the smell of acetic acid is very strong. It is a very good emulsion, very clean, and very fairly rapid. I pass on from this, merely saying that plates are more readily coated thau by gelatine emulsion, but less so than with collodion emulsion.

But we come now to a decided advance in photography, and that is the doing away with glass as a support for the emulsion. Anybody who has travelled, and had to make mountain ascents, will know perfectly well that glass is a serious drawback to the mountaineer; he would do anything to save himself the infliction of taking twelve whole plates up to the top of Mount Blanc. My friend Mr. Warnerke, who is generally to the fore in all matters of photography, was to the fore in doing away with glass for carrying collodion films, and is now to the fore in doing away with glass for gelatine films. He has perfected a process by which the photograph is taken on paper instead of on glass, and he has kindly brought me here some illustrations to show the method pursued. First of all, he has a sensitive tissue, which can be of any length. I do not know whether he has made it a mile long, but certainly a great many yards, and it can be rolled on a roller, and exposed in the dark slide. By simply turning another roller, a fresh surface is brought into the plane of the focussing screen. The sensitive tissue is developed in tho ordinary way with alkaline development. Here we have it in the developed state. The film can be either stripped off, or else transferred to glass. In the latter case, we come to another point, which is a distinct advance in photography. Mr. Warnerke has found that when you develop a gelatine plate with alkaline development—hat is to say, with pyrogallic acid and ammonia—the parts which have been acted upon by light, and which have been developed, become insoluble in hot water. He thus is able, after development, instead of using the hyposulphite bath to fix the print, to transfer it to glass, and wash away with hot water the parts of the film which have not been acted upon by light, and he gets a transparency such as I hold in my hand, and which no doubt you will examine with great interest by-and-bye. It should be noticed that, to do this, it is necessary that the back surface of the gelatine film should be exposed to the water, as in carbon printing, and this is secured by transfer to glass. Mr. Warnerke is not satisfied with doing away with glass for the camera, but he does away with glass for printing; and in order to accomplish this, he re-transfers the negative from the glass to a sheet of gelatine. I may say that the glass is freshly collodionised, which enables the film to strip off readily. In the picture before you we have an illustration of the gelatine film ready for printing, and here we have the print taken from negative. An advantage of these film negatives is, that you can print from either side, each one yielding sharp prints, which is a desideratum when using the single transfer carbon process, and other such processes where reversed negatives are required. I think that Mr. Warnerke has really made a very great advance by enabling us to do away with glass. I only hope the time will come, before very long, when not only he himself, but his friends and the public at large, will be able to avail themselves of this excellent invention, which he has now been cogitating for some time. I myself know he has been working at it for nearly two years. There is another part of his process which I shall have to speak about presently. But before leaving this part of the subject, I wish to call your attention to the "reason why" of the invention. I do not like taking anything on trust, and I do not liko seeing a thing and not knowing the reason of it. I hope that Mr. Warnerke will agree with me, when I say I think I have fonnd the explanation of the insolubility of the film which has been acted upon by alkaline development after exposure to light. If you take a gelatine plate and expose it from the back very strongly to the sun-light, behind a negative, and then put it in tepid water, you will find there is a tendency for the part which has not been blackened by light gradually to dissolve away, and to leave the black image formed by light undissolved. What is the meaning of that? It means this, that bromine is liberated from the silver bromide, and the bromine renders the gelatine insoluble. If you take bromine and brush it across a plate, and put it in hot water, you will find where the bromine has acted, there the film will refuse to wash away. Again, if you take bromine water, and act in the same way upon gelatine emulsion with which plates have been coated, you will find the gelatine emulsion becomes insoluble. I believe the rationale of Mr. Warnerke proves that bromine is liberated in the gelatino during the act of development. Now, you may say that the bromine is absorbed; so it is; but what becomes of it? If you add sulphite of soda, as in Berkeley's developer, I think Mr. Warnerke will bear me out in saying that there is no insolubility created by development. If you use a ferrous oxalate developer, there is no insolubility of the film created by such development. Why is that? Simply because the sulphite of soda is able to mop up the bromine, as is also the ferrous oxalate developer, as quickly as it is liberated, whereas the pyrogallic acid and ammonia is not able to do so. I have thrown this out as a hint for experimenters who wish to work further in this direction.

In the matter of gelatine films, we have Prof. Stebbing's, which are really workable. The gelatine emulsion is apparently flowed on an insoluble gelatine film on glass, which is then stripped. They are developed by placing them on glass. I have here examples of negatives taken on such films.

But I must now hurry on. The next point I am going to touch upon is the enlargement of negatives. Now, the question arises, how are you going to get an enlarged negative? Of conrse you will at once say, get a transparency by contact, and then enlarge it in the best way you can. The best way you can is, of conrse, to do it very perfectly indeed; but, unfortunately, by the wet process, an enlargement is very often sadly defective. The best way which I know of getting an enlargement of a negative is one which was brought forward a few years ago by Mr. Valentine Blanchard, and it is this. He takes the original negative which he wishes to enlarge, and places it in an enlarging camera. He then takes a transparency of the exact size which he wants his negative to be. He next takes a piece of common albumenised paper, and prints that transparency upon it, and by this means gets a very soft and beautiful negative. If you have a hard negative, it is almost impossible to get a soft transparency by the wet plate process, but by this artifice of "printing out" your transparency, and using that as a negative, you get a decidedly soft paper negative. If you trace the reason of this, it is as follows:—When the albumenized paper is acted upon by light, we know it blackens immediately, and, of course, light acts less violently on the underneath portions where it has been blackened. Thus, in printing from a transparency, the most transparent portions first blacken, then the next most transparent part blackens, before the first blackened part becomes too intense, and so on. So you see, by the shielding of the film by the blackening action, you are able to get a softness which you otherwise would uot get. I have here such a negative, which I prepared several years ago, by which you see we get some of this softness. Mr. Blanchard, I am sorry to say, has gone back from his old love, and recommends now that you should use a gelatine plate instead of the albumenised paper. A gelatine plate is a very good thing, but I think the albumenized paper negative beats it when you have to enlarge from a very small negative to a very large one. I think the grain of the paper, too, is an improvement in large photographs, and you get no grain in a gelatine negative. I will next show you how to obtain a paper negative by the ordinary lantern, but I must ask you to bear with me if I keep you rather long. I will make an enlarged negative from a transparency taken from one of my Egyptian negatives, developing it before you. This is ordinary paper to which a couple of washes of bromide of potassium were given, and which, when dried, was floated on silver nitrate. Half a minute's exposure to the light coming through the transparency will be sufficient. I shall use the developer which I recommended to your notice some time ago, the ferrous-citro-oxalate. [The negative was developed and shown to the audience.] So much, then, for paper enlargements. We now come to another great advantage of the gelatine process, which is, that by it you can get soft transparencies. I am aware that it is said there is a certain amount of blurring in gelatine transparencies, but I am not prepared to say that is necessary—in fact, I should say it ought not to be the case, as I think

I shall be able to show you in the next lecture. Therefore, if you have a hard negative by the common process, it is always possible, by the gelatine process, to get a soft negative from a gelatine transparency, in which case you can substitute for the paper such as I used just now, a gelatine plate, or a collodion plate, or a wet plate, whichever you prefer. The main point to aim at in getting enlarged negatives is to get thin, delicate transparencies, with every atom of detail present in them. If you get that, you can always get a decent enlarged negative from them. If the detail is blocked up you will not do so, unless you use a paper printing process, such as I showed you, with the albumenized paper negative.

After these preliminary remarks, I propose to show you one of the new applications of the gelatine emulsion process, and that is the development of a print on paper coated with gelatino-bromide. The paper is prepared by coating ordinary paper with gelatino-bromide (of the most sensitive kind if you like). Such paper can then be exposed to the image formed by an ordinary magic lantern; by that means you can get an enlarged print. The lantern before you is a triple-wick oil lamp, and I think you will be able to see that I shall get a very good print indeed from the negative, which is at present placed in front of the condenser. [The negative in the lantern was a view taken by the lecturer of one of the caves of Ellora, in Western India. An exposure of half a minute was given, and then it was developed by the brush with a ferrous oxalate developer.]

For my own part, I prefer gelatino-chloride paper, as it gives a very black image, which beats the bromide out of the field altogether. The reason why the tone is black is, that chloride of silver, when developed, is developed in two states, in a red or ruddy state, and also in a green state, and when you put red and green together, the result is not far from black. I think you will see, when this is developed, that we shall have the ruddy state first. I use the ferrous-citro-oxalate. It will not bear the ferrous oxalate at first, although it may be brought out more quickly with it. Now, if I turned up the light, you would see it in the pinky state; as it goes on, the pinky state gives place to the green, and the two together make up the black, and you will see afterwards that this black is of a most beautiful hue. I want particularly to call attention to the beautiful black tone it has. On the table there are some plates prepared with gelatino-chloride, to show the same black tone.

[An enlargement on gelatino-chloride paper was here made, and developed before the audience, the developer used being the ferrous-citro-oxalate.]

We may thus say that an advance has been made, when, by an ordinary magic-lantern, with a good negative, you can get a perfect enlarged paper print by development. Perhaps they will not have that lustre which albumenized prints have, but it is a matter of taste whether you like that gloss or not.

I have now to allude to Mr. Warnerke's invention again. He has found that he is able to mix with his gelatine emulsion colouring matter, and you will at once perceive the value of this. When you wash away the unaltered bromide of silver that is not acted upon by development, you get silver left behind, *plus* the colouring matter embodied in it. I have a developed print containing colouring matter, and, to save time, I have placed it on a transfer paper. The image was developed with alkaline pyrogallic acid, and was placed in contact with gelatinized paper rendered insoluble by chrome alum. I propose to wash away the soluble gelatine containing the bromide of silver and the pigment, to show what a power this discovery places in our hands. I first place it in hot water, and, as soon as it has soaked a little, the outside paper on which it was developed will peel off, leaving the gelatine film on what we may call the transfer paper. The subject is one of Mr. England's statue subjects, of which he was kind enough to give me the negative. Stripping away the paper on which the print was developed, the picture remains on the transfer paper, and we have the image waiting to be freed from the soluble matter. The print before you was taken in my laboratory with the electric light, and had a very short exposure. The soluble matter is now gradually washing away, and the whites are gradually coming out, and we get a picture in the colour of alizarine. You can get almost any variety of colour, but it is not every colour the operator can use, because some would destroy the sensitiveness of the gelatino-bromide; but most colours he can use. I can hardly thank Mr. Warnerke enough for the trouble he has taken in illustrating this part of my lecture for me. He has furnished me with pictures showing a variety of tints, from sepia and photographic purple to almost any colour. This I may claim as a great advance in photographic printing.

PHOTOGRAPHY WITH THE MICROSCOPE.*

There are two kinds of micro-photography, viz., that in which an enlarged photograph of a minute object is produced by the agency of the microscope, and that in which the conditions are altogether reversed, and a very minute photograph is produced by the same agency. The former of these may fittingly be designated as a "megatype," the latter as a "microtype," the one being the direct antithesis of the other, and both terms, it is well known, belong to the Greek language. To an ex-President of the Royal Microscopic Society of England the world owes the former term, and probably the second also.

The microtype has its own special uses, but they are social rather than scientific. The production of an enlarged photograph of an object which may in many instances be quite invisible to the naked eye possesses a high degree of scientific and educational value.

The mode of producing an enlarged photograph of a microscopic object is simple. It is only necessary to remove from an ordinary camera the lens, and insert in the aperture in front the eye-piece end of a microscope, the body of which has been adjusted to a horizontal position.

It frequently happens that an image which is focussed so as to be exceedingly sharp on the ground glass screen of the camera is not quite so sharp in the negative. This arises from the object glasses of microscopes having to be a little "over-corrected" for colour; in order to compensate for the correction of photographic lenses, the visual and chemical foci have to be brought into coincidence; in the microscope all that is aimed at is to have a visual image of the most perfect nature possible, no attention being paid to the chemical rays. Hence, in consequence of this, the blue or chemical rays are projected beyond the yellow or visual rays. The distance between the foci of these groups of rays is not great, but it is sufficiently so to interfere with securing sharpness of the highest order.

This may be obviated in several ways. A common way is to find by experiment with each object glass the amount of difference, and shifting the sensitive plate away from the microscope to that extent. A better way is to remove the object glass a little distance away from the object, and this distance must be regulated by the fine adjustment of the microscope, bearing in mind that the lower the magnifying power of the object glass the greater will be the distance which it will be necessary to move it. With the high powers, such as a one-fifth and upwards, the difference is practically nothing with the majority of objects.

The kind of adjustment we have found most convenient is the insertion of a simple crown glass lens at the upper end of the objective. Of these we possess half a dozen, any of which can be screwed into the objective, and all of which vary in foci. They are composed of ordinary spectacle glasses, which are found to answer this purpose quite as well as lenses specially ground. The manner of using these is as follows. Any one of them having been screwed in the place of the upper diaphragm of the objective, a trial is made, and if the effect has been to bring the chemical sharpness to coincide, well and good; if not, another is substituted, a trial again made, and when the result is entirely satisfactory, a memorandum is made to the effect that such or such an object glass requires a No. 3 (or other) correcting glass when being used for photography.

Concerning the light to be employed, the sun's rays are to be preferred, especially when using very high powers and photographing difficult subjects; but for these subjects requiring only the lower powers, of which an insect like a flea may be assumed as a type, a kerosene lamp answers the purpose in a satisfactory manner, and enables a good negative to be taken on a four-inch gelatine plate with an exposure of from one minute to three or more minutes, according to the colour and density of the object.

Occasions sometimes arise in which it is necessary that the camera be pointed upward or downward to a much greater degree than is possible by the usual method of pulling out one of the legs a little way. This sloping of the camera is useful when one desires to photograph anything situated at an angle of considerable altitude, such as a cloud of the upper portion of a high building. It is useful when one has the camera at a high elevation, and desires to secure a picture of something at a much lower level, such as a very steep ravine taken from above.

Seeing that by the usual method of adjusting the camera for such requirements—that is, by the legs—there is so much danger of the camera "toppling over," expedients of various kinds and devices have been had recourse to, with a view to enabling the

* Condensed from *Philadelphia Photographer*.

camera to be tilted to a considerable extent without endangering the stability of the stand, which depends upon the relation of the centre of gravity to the base. It is unfortunate that all such expedients prove inimical to portability, as they increase the bulk of the tripod head.

While conversing a few years ago on this subject with an ingenious English amateur, Sir Thomas Parkyns, and showing him a new device which had just then been introduced for the purpose of tilting the camera upward, that gentleman showed us a means he had hit upon some time before for securing the same end without any special appliances, or, indeed, any addition whatever to the ordinary camera stand.

Let a camera be mounted upon an ordinary tripod stand in the usual way, the legs being well spread out to insure stability. The camera will then be level and quite rigid. Now, grasp one of the legs of the camera stand, any of them, and pull it right through between the two which stand opposite, as far as it will go. The effect of this is to place the moved limb in a diametrically opposite position, as regards the remaining two, to what it previously occupied, to retain the camera on as firm and secure a basis as before, and to impart such a slope to the top of the tripod head that the camera shall possess either a high or low angular elevation, as the case may be.

This plan is so simple and so excellent as to insure its meeting with the warm plaudits of those who try it for the first time. To the clever amateur who introduced this method of crossing the legs of the camera stand in order to secure the effect of tilting, much credit is due.

FERROUS-OXALATE DEVELOPER FOR GELATINE PLATES.

BY JOHN CARBUTT.*

In the old wet collodion process, photographers, when asked what strength of developer they used, would reply : " Oh, a twelve, fifteen, or twenty-grain iron solution, as the case may be." Ask a gelatine dry-plate photographer the strength of his iron developer, and I question if there are many who could answer as to the number of grains of iron to the ounce of developer he was using. My experience teaches me that to be successful in working gelatine plates, it is important to know the strength of your developer best suited to the plate and subject in hand, a knowledge not at all difficult to acquire. The first to use ferrous-oxalate developer recommended saturated solutions of the oxalate of potash and sulphate of iron. The writer early saw that a solution under saturation would be preferable, so as to maintain the same strength under varying temperatures.

The simplicity of preparation and use of the ferrous-oxalate developer has made it a general favourite, and the object of this article is to give a few notes from the writer's experience in making and using this developer.

First, in the preparation of the oxalate solution : the neutral oxalate of potash sold as such will be generally found slightly alkaline; this should have added to it sufficient oxalic or citric acid (the writer prefers the latter) to give a decided acid reaction to blue litmus paper ; we take then to make our stock solution of oxalate of potash—

Neutral oxalate of potash ...	... 16 ounces
Clear water	... 64 „
Citric acid	... ½ ounce

When dissolved, and at a temperature of 60°, test with the actino-hydrometer ; if it tests over 80, add a little water, well mixing with bulk, until the hydrometer just stands at 80 grains to the ounce.

If it is thought best to make the oxalate solution from the raw material, proceed as follows :

Carbonate of potash (sal-tartar)	... 16 ounces
Dissolve in warm water... ...	... 50 „

In an earthen or glass vessel capable of holding at least twice the quantity, add by degrees oxalic acid, 14 ounces ; when dissolved, test with litmus ; if it remains blue, add of a strong solution of citric acid sufficient to redden it, then add water until it tests 80 of the actino-hydrometer ; the bulk will be a little larger than that made from 16 ounces of oxalate of potash, but not much ; do not suppose that, because you use 30 ounces of dry material, you will get, if it were evaporated, 30 ounces of oxalate of potash, for much passes off as carbonic acid ; nor take 2 pounds of oxalate of potash to replace 1 pound each of carbonate of potash and oxalic acid, as was recommended by a writer some time ago in one of our journals.

The above strength of oxalate solution we have found a very useful one.

Stock iron solution we make of a strength of 100 grains to the fluid ounce. Select clear, light-green, and fresh crystals of sulphate of iron, 8 ounces ; dissolve in hot water, 28 ounces ; then add water to exactly measure 35 fluid ounces ; add sulphuric acid, 30 drops ; filter into a clean bottle, and cork for use. Bromide solution of 10 per cent. ; potassium bromide, 1 ounce ; dissolve in water sufficient to make 10 fluid ounces ; add of this 1 drachm for each 6 ounces of oxalate solution. Now as to the strength of the iron to the oxalate, I am guided by the character of the plate I am using, slow, rapid, or of the instantaneous kind, and also subject, light, and exposure ; for general use, a mixture of 1 part of iron solution to 5 of oxalate will be found to work well on a 5 to 6 times wet-plate rapidity ; for a landscape, I would add 2 or 3 ounces of water, and ½ drachm more bromide solution, with a view to slow development, passing it into the stronger developer if found to require it from under-exposure ; where a developer of greater energy is required, as for on and off exposures in the studio, and instantaneous out-door views, the iron can be added to the oxalate solution in a dry state, as recommended some time ago by Mr. H. J. Newton, of New York.

Pulverize fresh and clear crystals of sulphate of iron, and keep in a closely corked wide-mouthed bottle ; to form a developer of great energy, add twenty grains of powdered iron to each ounce of oxalate solution, stir with a strip of glass, and use at once.

Our experience, both with wet and dry-plate photography, leads us to the conclusion that a very close similarity exists as to the number of grains of iron required to the ounce of fluid developer in the wet and the dry. Therefore I use for landscape time exposures, using A plates, a developer composed of—

Oxalate solution	... 5 ounces
Water	... 2 „
Iron solution	... 1 ounce

which makes about 12 to 13 grains of iron to the ounce of developer ; when using B plates omit the water, and the developer will contain about 15 grains of iron to the ounce. I prefer the image to be 20 to 30 seconds before putting in an appearance. Where it is desired to obtain a thin, clear negative for solar printing, omit any use of bromide, and in place, as a restrainer, add to each ounce of developer one drop of sulphuric acid. Finally, we find a general expression of opinion by those using ferrous oxalate, that a developer fresh mixed for every six or eight plates is the better plan.

* *Philadelphia Photographer.*

EXAMINE YOUR CAMERAS.

BY DAVID ROBERTSON.*

I wish to call the attention of amateurs (and professionals also, for that matter), of whom there are, no doubt, many starting out on a summer's tour with camera and dry plates, to the necessity of carefully examining their apparatus before concluding that everything is all right, and, perhaps, returning with a batch of plates more or less fogged, or, in other words, lacking " wet-plate brilliancy," of which we hear so much against the dry plate. I refer to light that reaches the plate without coming through the lens.

Noticing that some of this season's negatives, compared with last year's, lacked " something " shown by the latter, I took my camera out into the bright sun to examine for leaks, suspecting that as the cause of the fog. I capped the lens, inserted the smallest stop, removed the ground glass, put my head into the camera, drawing the focussing-cloth well about me to exclude all light, and saw nothing but perfect darkness. I then shut my eyes, and waited in this position for a few minutes, and opened them. Beautiful streams of pure white light greeted my sight, coming from around the edges of the square front piece, from under the sliding front (when well up), and from the top (when well down) ; also through the stop-slot. I tried other lenses with rotating stops, and found one of a celebrated English maker (made in wet plate days) that let in enough light for me to read the numbers of the stop-opening by. The quantity of light coming in at all these points was something considerable, and if one-quarter of the amount had reached my plates in the dark-room, when coating, I should have considered them spoiled. How, then, about every plate going through such an ordeal? I had examined for such before, as no doubt many others have done, and noticed nothing wrong; but one must take a long look until his eyes are accustomed to the darkness. Loose woodwork will shrink and sometimes warp.

I need not say more; but take my advice, and look into these matters before you take it for granted that everything is all right with your camera and lenses. The result may cause you to feel more friendly towards the dry-plate maker, and be the means of your producing what some think cannot be, viz., brilliancy on a dry plate.

PS.—I might add that I have three first-class makes of cameras, and that only two of them leaked.

Correspondence.

NORTH WALES.

Sir,—If there should be any amateur photographers carrying the camera in this charming neighbourhood, I would earnestly recommend them to make a call on Mr. James Leach, photographer, Dolgelly, whom I have found most obliging in placing his dark-room and its contents at my disposal. There are some fine glens and waterfalls to be secured for the camera near Dolgelly, if you are careful to give a long enough exposure.—Yours obediently,

J. D. Leader, F.S.A.

THE USE OF CAMERAS BY PAINTERS.

Sir,—My attention has been called to a paragraph in a number of your paper published June 16th, in which you state that I and some other painters whom you name are expert photographers, and use photography extensively in obtaining studies and subjects for our pictures. Will you allow me to say that so far as I am concerned you have been entirely misinformed? In the early days of photography I amused myself as an amateur, and have always admired the art as practised by some of its professors; but I have never copied a photograph, or relied upon one to furnish me with incident for my pictures. My "instantaneous views of passing craft" are done direct from nature with pencil or brush as the case may be.

May I add that I have not taken a photograph for twenty-five years, and am quite innocent of the development of dry plates? I am obliged to ask you to publish this disclaimer, as I find other papers have copied, and in one the quotation is inexact.—I am, your obedient servant,

Henry Moore.

Yacht "Dawn," off Poole, Dorset, Aug. 22.

[We regret to hear that Mr. Moore has of late given up practising photography, for he would have found the modern dry plates much more easy of employment than collodion films.—Ed. P.N.]

Proceedings of Societies.

Bury Photographic and Arts' Club.

The members of the above Club held their second out-door meeting at Bolton Abbey, on Thursday, the 27th of July. The morning being fine, there was a good muster of members, who proceeded by the 6·8 train to Skipton, where breakfast was awaiting them at the Devonshire Hotel. The members afterwards went per waggonette to Bolton Abbey, where a portion of the members proceeded to photograph the ruins from various points of interest, whilst the rest proceeded up the river to the strid, taking numerous views. The weather, unfortunately, changed early in the afternoon, the rain beginning to fall rather heavily. The members then returned to Skipton, and left for home by the 8·15 train. We understand the results of the day's work were some beautiful negatives. The vice-president, Mr. E. Eccles, secured a good group of the members.

Talk in the Studio.

The Precipitation of Alum by Sodium Carbonate.—Some interesting points regarding the precipitation of alum by sodium carbonate have been noted by Mills and Barr, a considerable addition of carbonate being necessary before the alumina is precipitated at all; but afterwards the amount precipitated proceeds according to laws which have been formulated by the investigators in question.

The Atomic Weight of Carbon.—This important chemical constant has been carefully re-determined by Professor Roscoe, and he used Cape diamonds, which possess the peculiarity of containing no trace of hydrogen. An allowance was made for the ash or mineral constituents present, and the mean of six experiments gave the number 11·97, oxygen being taken as 15·96.

Oxidation of Pyrogallol in Presence of Free Acid. By P. da Clermont and P. Chautard (*Compt. Rend.*, 94, 1,189-1,192).—When pyrogallol is oxidized in presence of free acid, by silver nitrate, chromic acid, or potassium permanganate, the reaction is complex, purpurogallin being the principal product. When the oxidizing agent was potassium permanganate mixed with sulphuric acid, the authors were able to isolate, in addition to purpurogallin, pyrogallo-quinone, and a third substance, the composition of which has not been determined, but which forms small needles and transparent prismatic tables with a silvery lustre. Analysis of carefully purified purpurogallin, of the barium and sodium salts, and of its acetyl-, ethyl-, bromo-, and nitro-derivatives, proves that its true formula is $C_{20}H_{16}O_9$, as found by Gerard, and not $C_{18}H_{14}O_9$, as found by Wichelhaus. Heated with hydriodic acid in sealed tubes, purpurogallin yields a hydrocarbon containing C_{10}, and probably higher homologues containing C_{10n}.—*Journal of the Chemical Society.*

Memoir on Hydrocellulose and its Derivatives. By Aimé Girard.—Under the influence of acids, both mineral and vegetable, both dilute and concentrated, and in variable conditions of temperature and time, cellulose, $C_{12}H_{10}O_{10}$, before becoming saccharified, and even before taking the state of soluble cellulose, is transformed into a new compound, $C_{12}H_{11}O_{11}$, exceedingly friable, but retaining many of the properties of normal cellulose. The conversion is most easily effected by immersion for twelve hours in sulphuric acid at sp. gr. 1·420. The author remarks that Mercerised fibres present the same physical state as those treated with acids. Hydrocellulose possesses special tinctorial aptitudes. It takes up readily colours which can only be fixed upon normal cellulose with great difficulty.—*Chemical News.*

The British Association.—The sections and their presidents are to be as follows:—Mathematical and Physical Science, Professor Lord Rayleigh; Chemical Science, Professor G. D. Liveing; Geology, Mr. R. Etheridge; Biology, Professor A. Gamgee; Department of Anatomy and Physiology, Professor A. Gamgee; Department of Zoology and Botany, Professor M. A. Lawson; Department of Anthropology, Professor W. Boyd Dawkins; Geography, Sir R. Temple, Bart.; Economic Science and Statistics, Right Hon. G. Sclater-Booth, M.P.; Mechanical Science, John Fowler, C.E., F.G.S.

Electricity in Breweries.—A curious instance of electrical development by friction has been observed in a Berlin brewery, though not without causing a good deal of alarm among the workmen. The building is constructed of stone and iron, the floor being laid in asphalte. In the upper storey of the malt-house was a malt-cleaning machine from which the malt was taken through an iron shoot to waggons below for distribution through the works. It was found that if this machine remained in operation for a length of time, electricity was developed by the friction of the malt with the shoot, and in the most isolated portions of it the tension of the electricity was such as to cause a continuous stream of sparks. The malt itself crackled, while the sparks flew from it to the hands of those standing by, who looked upon the manifestation as one of demoniacal origin. An expert was called in to examine the phenomenon, and the subject was brought before the Electrical Technical Union. Dr. Werner Siemens showed how, through the influence of the asphalte floor, the malt room was so insulated from the other portions of the building as to become a large Leyden jar.

Nitrite Solution of Potassium Iodide and Starch Mixture.—The author has examined this mixture as regards its behaviour with acid liquids. He used a very dilute potassium iodide starch paste, to which he added so much potassium nitrite that the liquid was coloured deeply blue by a few drops of acetic acid. It was coloured a deep blue by dropping in moderately dilute solutions of most inorganic and organic acids and acid salts, while weak and sparingly soluble acids, such as the carbonic, boracic, arsenious, uric, carbolic, tannic, had no action.—*A. Vogel.*

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News*" *Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed* "*Union Bank, Photographic News Co. Account.*"

⁂ We cannot undertake to return rejected communications.

E. S. K.—It is an article of commerce, and can be obtained from any large glass merchant.

A Retoucher.—The only work on the subject is Piquepe's "Enamelling and Retouching," price 2s. 8d. by post from our Publishers.

H. Spink.—The case is a somewhat difficult one, but it is probable that by considerably increasing the amount of bromide used, matters may be partially mended.

Leodiensis.—The return motion is generally a disadvantage, as unless great care is taken, some motion of the camera results. but there is a notable advantage as regards prolonged exposure of the foreground; and judging from what you say, your mechanical arrangements are calculated to overcome the first difficulty. Will you let us have a drawing and short description of the shutter?

3988.—Ventilate by two large ∩ shaped wooden pipes passing through the partition, one low down in the room, and the other high up. If you *thoroughly blacken* the inside of the pipes, and select suitable positions, these ventilators will be quite safe.

A Gleaner.—1. Write to the Secretary of the City and Guilds Institute, Gresham College, London, E.C. 2. Yes. 3. Add excess of hydrochloric acid, and it will be deposited as chloride; but you should perform the operation out of doors, and be careful to avoid the fumes of the hydrocyanic or prussic acid.

Bromo.—Test it with litmus paper. Blue litmus becomes red when exposed to the action of an acid, and red litmus becomes blue when treated with an alkali. See also Dr. Eder's article in our present number.

Glasgow.—We are inclined to attribute the spots to contact with some foreign body—perhaps the fingers or packing paper.

H. K.—1. Certainly not. 2. Each part is 2s. 6d. post free (by P.O.O.) and can be had from Wilhelm Knap, Halle, Germany. (See advertisement).

T. Howard.—Both equally. 2. Sometimes, but the addition is not desirable. 3. No. 4. Not so well as the wire. 5. A one-twentieth part is sufficient.

C. Glassford.—1. It is generally true of ferrous salts, but ferric salts have quite a contrary action. 2. Fine hard bank-post paper. 3. Excess of ammonia will do no harm. 4. It should be dry in about two hours. 4. The addition of a silver salt is altogether unnecessary.

A Beginner.—They are merely thin tin plates, coated with a bituminous varnish; but you will find it much more convenient to purchase them ready for use.

R. T. Kennedy.—Either your lens does not work to focus, or the position of the focussing screen does not correspond with that of the sensitive plate. Expose with full aperture on the middle card of a long series arranged at different distances from the camera, and notice which is defined best in the picture. Now alter the position of the focussing screen in its frame, until that card which was sharpest in the photograph is clearly depicted on the surface of the ground glass. Care must be taken not to shift the camera while doing this, and it must be understood that the adjustment only holds good for the camera and lens when used together.

M. McArthur.—No. 2 is much better when looked at from a theoretical point of view; but the greater simplicity of No. 1 renders it a much more useful instrument for every-day use.

M. M. (Widnes).—Keep it from the action of light, and your trouble will cease.

J. Bell.—In all probability the "cyanide" consists almost entirely of carbonate. Try another sample.

Printer.—1. When the sensitizing bath is weak, it often happens that the albumen coating is dissolved instead of being coagulated. This not only renders the paper unfit for use, but also deteriorates the solution. 2. Undesirable unless a moderate excess of acid is present.

James Fullwell.—Ultramarine is the pigment most ordinarily used for the purpose, but you must not forget that weak acids, even if considerably diluted, discharge the colour.

A. G. B.—1. Because it rapidly absorbs oxygen from the air. 2. Methylated spirit answers admirably. 3. Excess of alkali is very prejudicial.

THE EVERY-DAY FORMULARY.

The Gelatino-Bromide Process.

Emulsion.—A—Nit. silver 100 grains, dist. water 2 oz. B—Bromide potassium 85 grains, Nelson's No. 1 gelatine 20 grains, dist. water 1½ oz., a one per cent. mixture of hydrochloric acid and water 50 minims. C—Iodide potassium 8 grains, dist. water ½ oz. D—Hard gelatine 120 grains, water several oz. When the gelatine is thoroughly soaked, let all possible water be poured off D. A and B are now heated to about 120° Fahr., after which B is gradually added to A with constant agitation; C is then added. Heat in water bath for half an hour, and stir in D. After washing add ¾ oz. alcohol.

Pyro. Developer.—No. 1—Strong liq. ammonia 1¼ oz., bromide potassium 240 grains, water 80 oz. No. 2—Pyro. 30 grains, water 10 oz. In case of an ordinary exposure mix equal vol.

Iron Developer.—Potassium oxalate sol. (1 and 4) 80 parts, ferrous sulphate sol. (1 and 4) 20 parts, dist. water 20 parts. To each 4 oz. of the mixed developer add from 5 to 30 drops ten per cent. sol. potassium bromide, and 30 drops sol. sodium hyposulphite (1 and 200).

Substratum or Preliminary Preparation.—Soluble silicate of soda 1 part, white of egg 5 parts, water 60 parts. Beat to froth and filter.

Fixing.—Sat. sol. of sod. hypo. 1 pint, sat. sol. of alum 2 pints, mixed.

Cowell's Clearing Solution.—Alum 2 parts, citric acid 1 part, water 10 parts. Edwards makes this sherry coloured with perchloride iron.

Eder's Method of Intensification.—The negative is whitened by soaking in sat. sol. of mercuric chloride, and after thorough rinsing immersed in potass. cyan. 10 parts, potass. iod. 5 parts, mercuric chloride 5 parts, water 2,000 parts. As film becomes dark brown, the actinic opacity is increased; but prolonged action causes brown tint to become lighter, until at last the negative is no denser than at first.

Fol's Backing Sheets.—A chromographic paste is prepared with gelatine 1 part, water 2 parts, glycerine 1 part, and a very small addition of Indian ink. Strong paper or shirting is coated, and the sheets are laid, face downward, on waxed glass to set. Press to back of glass plate.

The Wet Collodion Process.

The Nitrate Bath.—Water 14 oz., nit. silver 1 oz., nitric acid 1 drop. Before using coat a small plate, and immerse it for 20 minutes.

Cleaning Preparation for New Plates.—Alcohol 4 oz., Jeweller's rouge ¼-oz., liquid ammonia ½-oz.

Film-removing Pickle for Old Plates.—Water 1 pint, sulphuric acid 4 fluid oz., bichromate potassium 4 oz.

Substratum.—Whites of 2 eggs well beaten, 6 pints of water, and 1 dr. liq. ammon.

Negative Collodion for Iron Development.—Alcohol 1 pint, pyroxyline of suitable quality 250 grains, shake well and add ether 2 pints. *Iodize this by mixing with* one-third of its volume of alcohol ½ pint, iod. ammon. 80 grains, iod. cadm. 80 grains, brom. ammon. 40 grains.

Normal Iron Developer.—Water 10 oz., proto-sulphate iron ½ oz., glacial acetic acid ½ oz., alcohol ¾ oz. The amount of proto-sulphate iron may be diminished to ¼ oz. when full contrasts are desired, or increased to 1 oz. when contrasts are unduly marked. With new bath quantity of alcohol may be reduced to ¼ oz.; but when bath is old more is wanted.

Intensifying Solution.—Water 6 oz., citric acid 75 grains, pyro. 30 grains. When used, add a few drops of the silver bath to each ounce.

Lead Intensification.—After neg. washing, immerse in dist. water 100 parts, red pruss. potash 6 parts, and nit. lead 4 parts. When it is yellowish white wash and immerse in liquid sulph. ammon. 1 part, water 4 parts.

Fixing Solution.—1. Potass. cyanide 200 grains, water 10 oz. 2. Sat. sol. of sod. hypo.

Varnish.—Shellac 2 oz., sandarac 2 oz., Canada balsam 1 dr., oil of lavender 1 oz., alcohol 16 oz.

The Ferrotype Process.

Collodion.—Ammonium iodide 35 grains, cadmium iodide 25 grains, cadmium bromide 20 grains, pyroxyline 70 grains, alcohol 5 oz., ether 5 oz.

Bath.—Silver nitrate 1 oz., water 10 oz., nitric acid 1 drop.

Developer.—Ferrous sulphate 1 oz., glac. acetic acid 1 oz., water 16 oz.

Fixing and Varnish.—Same as wet collodion process.

Printing Processes.

Albumen Mixture for Paper.—White of egg 18 oz., 500 grs. ammon. chlor. in 2 oz. of water. Beat to a froth, stand, and filter.

Sensitizing Solution.—Nit. silver 50 grs., water 1 oz., sod. carb. ½ gr.

Acetate Toning Bath.—Chlor. gold 1 gr., acet. soda 20 grs., water 8 oz.

Lime do.—Chl. gold 1 gr., whiting 30 grs., boiling water 8 oz., sat. sol. chl. lime 1 drop. Filter cold.

Bicarbonate do.—Chl. gold 1 gr., bicarb. soda 3 grs., water 8 oz.

Fixing Bath.—Sodium hypo. 4 oz., water 1 pint, liq. ammon. 30 drops.

Reducer for Deep Prints.—Cyan. potass. 5 grs., liq. ammon. 5 drops, water 1 pint.

Encaustic Paste.—Best white wax 1 oz., oil of turpentine 5 oz.

Sensitizing Bath for Carbon Tissue.—Bichromate potash 1¼ oz., water 30 oz., ammonia 1 dr., methylated spirit 4 oz.

Enamel Collodion.—Tough pyroxyline 120 grs., methylated alcohol 10 oz., ether 10 oz., castor oil 20 drops.

Mountant.—1. Fresh solution of best white gum. 2. Fresh starch.

Collotypic Substratum.—Soluble glass 3 parts, white of egg 7 parts, water 10 parts.

Collotypic Sensitive Coating.—Bichromate potash ½ oz., gelatine 2½ oz., water 22 oz.

Collotypic Etching Fluid.—Glycerine 150 parts, ammonia 50 parts, saltpetre 5 parts, water 25 parts.

Printing on Silk.—Remove all dressing from the fabric by boiling in water containing a little potash, dry, and albumenize with ammonium chloride 2 grammes, water 250 cubic cents., and the white of 2 eggs, all being well beaten together. A 70-grain silver bath is used, and the remaining operations are as for paper.

Cyanotype Printing.—Water 1 oz., red prussiate of potash (ferricyanide) 1 dr., ammonio citrate of iron 1 dr. Prepare and preserve in the dark. Float the paper and dry. Fixation by mere soaking in water.

Various.

Luckardt's Retouching Varnish.—Alcohol 300 parts, sandarac 50 parts, camphor 5 parts, castor oil 10 parts, Venice turpentine 5 parts.

Matt Varnish.—Sandarac 18 parts, mastic 4 parts, ether 200 parts, benzole 80 to 100 parts.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1252.—*September* 1, 1882.

CONTENTS.

THE BRITISH ASSOCIATION.

The session just concluded, although the papers brought forward have possessed quite as much intrinsic importance as is ordinarily the case, was characterised by an element of dullness which is a little unusual. Possibly this may be due to local circumstances, or from the failure of the Southampton townspeople to display much activity and energy in making arrangements for the comfort and convenience of the members of the Association.

A series of visits to the Ordnance Survey Offices were organised by Major General Cooke, the General Director; and an unexpectedly large proportion of the members availed themselves of the opportunity thus afforded of inspecting the various methods employed for map reproductions—photo-lithography and photo-zincography taking an important part among these.

The Mathematical and Physical section was perhaps rather more practical as regards its programme than usual, but few recondite or highly theoretical papers being communicated. Some considerable interest centred round a communication by Professor G. Forbes, in which he detailed experiments which convinced him that different rays of light travel with varying velocities.

A preliminary account of results obtained by Professor Schuster and Captain Abney during the late total eclipse in Egypt was given by Professor Schuster, who exhibited three admirable photographs obtained of the corona. In these photographs the comet seen close to the sun is visible, and so great was its motion that on comparing the first and third photographs it is seen to have changed its position. In the protuberances, calcium lines were more prominent than hydrogen lines, and variations in the temperature of the corona were detected. Some unknown lines appear in the photograph.

Professor Schuster also read a paper on some of the results arrived at by recent studies of solar physics.

Mr. W. H. Preece brought under the notice of the section a form of hand dynamo machine worked by two men. Mr. Preece showed a small arc light, and produced a good light with three Edison lamps. The success of the experiments was testified to by the general applause of the audience. The electromotive force of the machine at full speed was 70 volts. The resistance of the field magnet was 4 ohms, and the resistance of the armature was 4 ohms. One capital Swan light would be produced if only one man worked the machine. The price of the dynamo itself, without the mechanical gearing, was only £15. He strongly recommended the machine for its usefulness in home work or in the demonstrations of the lecture-hall. The results obtained were, however, unsatisfactory in comparison with those obtainable with the modified Paccinotti machine which we recently described.

Captain Abney read an interesting paper on the light of the sky at high altitudes, based upon observations made in the Alps, on the Riffel, at a height of 8,500 feet. His investigations proved that in high altitudes the light of the sky diminishes very much, so as to make photography difficult; and that it is only a tenth or a twentieth of that which is found on the surface of the earth. There was a remarkable absence of the rain-band spectrum. On the Riffel he only saw it once, and that was during a shower. The solar spectrum was the same on the Riffel as in London. He did not believe that aqueous vapour was present in the upper regions, at all events in the form in which it exists below. In the red part of the spectrum he found that the benzine and alcohol which had been found to exist in the atmosphere actually increased in strength in the higher regions, and he could only suppose that benzine and alcohol are not of terrestrial formation, but come to us from space.

Professor S. P. Langley, of the United States, in a paper on the distribution of energy in the solar spectrum, stated that he had investigated the infra-red spectrum at a height of 13,000 feet in a very dry region, and found that it extends very much further than had been mapped heretofore. The wave lengths of the visible part of the red end of the spectrum are only one-fourth of those in the infra-spectrum, so that three-fourths of the energy were invisible. His observations proved the existence of great gaps in the spectrum, and he was inclined to support Abney's conclusions on the existence of benzine and alcohol in space.

The Chemical section was well attended, but the absence of several familiar faces could not fail to be noticed.

Professor Liveing, in his address, remarked that if he were asked in what direction chemical science had of late been making the most important advances, he should reply that it was in the attempt to place the dynamics of chemistry on a satisfactory basis, to render an account of the various phenomena of chemical action on the same mechanical principles as are acknowledged to be true in other branches of physics. He could not say that chemistry could yet be reckoned among what are called the exact sciences, that the result of bringing together given matters under given circumstances could yet be deduced in more than a few special cases by mere mathematical processes from mechanical principles, but that some noteworthy advances have in recent years been made, which seem to bring such a solution of chemical problems more nearly within our reach.

Professor Abel communicated an interesting account of the legal flashing test for petroleum, and described the various tests which had from time to time been employed to ascertain the temperature at which petroleum and the mineral oils of this country gave off an inflammable vapour.

The present test, legalized in 1879, which was regarded as extremely accurate, required some modification to regulate it according to the varying conditions of barometric pressure. At his suggestion Mr. Redwood visited Switzerland for the purpose of experiment, and discovered that the variation of the flashing point was two degrees Fahrenheit for one inch of the barometer.

The report of the committee on the photographing of the ultra-violet spark spectra emitted by metallic elements and their combinations was presented by Professor Huntington. It stated that the chief objects to be gained from a knowledge of the character of the spark spectra of metallic elements were the means of readily identifying the metals by photographs of their line spectra; a knowledge of the alterations producible in the spectra of metallic salts by the presence of various non-metallic elements; a knowledge of the alterations in spectra caused by the dilution of metallic solutions; the possible means of performing rapid quantitative determinations of metallic substances by the aid of photography, and obtaining permanent records of the results.

In a paper on the reversal of metallic lines as seen in over-exposed photographs of spectra presented to the Royal Society, Professor Stokes said an under-exposed plate was likewise difficult to develop, and was liable to cause the strong lines to appear reversed. Any strong lines might be reversed by over-exposure without materially altering the appearance of the rest of the spectrum. The reversal took place in the centre of the line, and was where the radiation was most active and subject to reversal by over-exposure. The subject was one well deserving the attention of those who were engaged in the study of solar physics. Comparative exposures should be methodically employed to confirm the accuracy of the observations made entirely by the aid of photographic representation and of spectra. Professor Hartley had stated that some fourteen years' practice in photography had convinced him that when a plate was properly exposed the development of the image was the simplest of all operations. In order to simplify spectroscopic work he had carefully ascertained the time of exposure required to produce the spectra under various conditions, such as intensity of spark and conductivity of the electrodes. He preferred a general period of half a minute. It was a remarkable fact that at the present time they knew little or nothing of the sensitiveness of the spectrum under certain various conditions, notwithstanding that such knowledge was absolutely necessary for the purpose of giving stability to numerous theories and arguments which were based on spectrum observations.

The president of the Mechanical section, Mr. John Fowler, discussed at some length the unnecessary waste of mechanical energy in various industrial operations, and, making special reference to the dynamics of a railway train, said that on the Metropolitan Railway, no sooner has a train acquired a reasonable speed, than the brakes have to be sharply applied to pull it up again. Sixty per cent. of the whole power exerted by the engine is absorbed by the brakes. In other words, with a consumption of 30 lb. of coal per train mile, no less than 18 lb. are expended in grinding away the brake blocks, and only the remaining 12 lb. in doing the useful work of overcoming frictional and atmospheric resistances. Comparatively high speed and economy of working might be attained on a railway with stations at half-mile intervals if it were possible to arrange the gradients so that each station should be on the summit of a hill. An ideal railway would have gradients of about one in twenty, falling each way from the stations, with a piece of horizontal connecting them. With such gradients gravity alone would give an accelerating velocity to the departing train at the rate of one mile per hour for every second; that is to say, in half a minute the train would have acquired a velocity of thirty miles an hour, while the speed of the approaching train would be correspondingly retarded, without the grinding away of brake blocks. Could such an undulating railway be carried out, the consumption of fuel would probably not exceed one-half of that on a dead-level railway, while the mean speed would be one-half greater.

Arrangements have been made to hold the next meeting at Southport, under the presidency of Professor Cayley; and the proposal to hold the following meeting at Montreal is well received.

THE UTILISATION OF THE SOLAR HEAT.

Although the sun is the main source of that physical energy which is available for the use of mankind, it is remarkable that the direct use of the solar rays is rather the exception than the rule. It is true that the photographer is especially interested in the immediate utilization of the solar radiations; but the dynamic equivalent of the rays absorbed by the sensitive preparations used in photography is extremely small, and may be disregarded as a factor in estimating the energic magnitude of the solar radiations. Only a small proportion of those solar rays which reach the earth serve to enable plants to store up force through the agency of the carbon and hydrogen which they separate from water and carbon dioxide; but it must be remembered that small as this proportion is, it nevertheless has been the means of accumulating or storing up that force which we are now freely using through the agency of steam, gas, and hot air motors.

Few can form a just notion of the enormous dynamical energy of the full solar radiations as now expended in heating large expanses, where the heat is, at any rate as regards immediate use, practically wasted. Although up to the present time few attempts have been made to directly utilise the immediate radiations of the sun as a source of motive power, an experiment recently carried out in the gardens of the Tuileries at Paris, by M. Abel Pifre, affords abundant proof that in latitudes where sunshine is intense and tolerably constant, considerable use might be made of the solar radiations as a source of heat for industrial purposes.

A parabolic reflector about eleven feet in diameter was mounted with a small boiler placed axially, and the steam generated in this served to actuate a motor, this in its turn driving a small printing press, which, between one o'clock and half past five, struck off copies of the "Solar Journal" at the rate of five hundred copies an hour.

Such experiments as that of M. Pifre, although perhaps not likely to lead to immediate results of industrial value, possess great importance, insomuch as they call prominent attention to vast stores of force which are ready to yield to the controlling hand of man.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Photography and Tricycles—The Hoeschotype Process—Photographing the Sea.

Photography and Tricycles.—The stock of the photographic dealer is continually increasing in variety. It will not be long before he will be called upon to keep the photographer's tricycle; that is to say, when tricyclists have decided amongst themselves which is the best, by no means an easy matter, as it is rare to find in one tricycle all advantages combined. Passing through Guildford the other day, we came upon a couple of photographers, each with his tricycle, and each tricycle bearing its load in the way of impedimenta. To see cyclism—if we may coin a word for this mechanical science, yet in its infancy—in conjunction with photography was quite sufficient to make us stop and pick up a wrinkle or two. The photographers, we found, were professionals, and, therefore, their tricycles were likely to be well and truly tried. They had come from Farnham that morning, had executed their commission at Guildford, and were going back with their exposed plates to Farnham—in all, a distance of over twenty miles. Cameras, lenses, plate-boxes, and plates weighed about a hundred pounds, and this baggage was divided into two portions, so that each tricycle carried, besides the rider, fifty pounds—altogether no light weight. As we ourselves had had some experience on an Excelsior tricycle, we naturally had some curiosity as to the effect of the extra weight. "It makes very little difference, we find," said the photographers, "save in going up a hill. If the hill is a long one, it is better to get off and push the machine; but with short hills this is not necessary." The tricycle used by these gentlemen was the Rapid, fitted with a hill-climbing gear, which, they said, answered very well, and with the baggage disposed on a light iron frame placed at the rear of the seat. This frame was, of course, made specially and fitted, as there is no tricycle in the market which could be used by the photographer as it is bought. "We have had these tricycles a little over six months, and we are quite sure we have paid the cost in the extra work which we have been able to do," said they. Now, this is valuable experience. It is certain that, in country districts, where houses lie at long distances from railway stations, the tricycle will be found of immense service. It is not every photographer who can afford to keep a horse; but a tricycle does not entail an enormous outlay, and, in many cases, can be purchased on very easy terms. The only question is, which is the best kind?

The Hoeschotype Process.—The attempts to combine photography with a mechanical printing process have been endless in numbers; to many of these attempts must be ascribed a fair amount of success. Most of these processes are confined to reproduction of line subjects, and so far a practical and easy method of reproducing tints has been wanting. Photo-lithographic and photo-zincographic processes are now worked commercially, but only in monochrome, and hitherto little has been done in the way of printing pictures in two or more colours. This problem has, however, now been boldly attacked, if we may judge from the admirable specimens of what are termed Hoeschotypes, which last week we had the pleasure of inspecting at Messrs. Gladwell Brothers, 21, Gracechurch Street. The Hoeschotype is the invention of Herr F. C. Hoesch, of Nuremberg, who has spent the last three years in bringing his process to perfection. The method by which Herr Hoesch works is at once simple and rapid. A photograph is first taken of the picture. From the negative six gelatine prints on glass are made, and a colour plan having been made on one, on each of the other five a separate colour scheme is worked out corresponding to the particular tint desired, all the portions not required being painted out. The colours used are the three primaries, a neutral grey, and a brown, and with these five tints any combination can be produced. The gelatine is made insoluble with bichromate of potash, and thus can be printed from in an ordinary lithographic press. The advantage which Herr Hoesch claims is that where a chromo-lithograph of an extended scale of tints may require from a dozen to twenty printings, the Hoeschotype may be produced in five printings. The various stages of the colour printing by which the finished print is built up are exceedingly interesting. The print we examined was the portrait of a girl. Plate No. 1 showed only the yellow tint graduating from the deep points of colour in the hat to the light tints in the hair. The outline of the features was only just discernible, while the cheeks were left white. In the next printing the colour was red. Here, where necessary, the red mingled with the yellow, producing orange. No 3 was blue, and the greens and purples made their appearance in their proper places. No. 4 was a neutral tint of grey, which toned down the crudeness of the three primaries. Finally came the brown, which gave a mellowness and warmth to the shadows, and completed the picture. For the result we have nothing but praise; and if examples like the ones we saw at Messrs. Gladwell's can be produced rapidly and at a small cost, chromo-lithography will be almost superseded. It is evident that some artistic skill in manipulating the gelatine plate is absolutely necessary, for herein lies the power of being able to produce graduated tints at one working; but whether the gelatine is worked upon before or after being bichromatised we are unable to say. So far as the artistic element is concerned, we understand that Herr Hoesch is certain that any South Kensington student of average skill could, with three months' practice, acquire proficiency. If this be so, there is no insuperable difficulty for the artist. We believe that no attempt has been made in connection with enlargements of portraits from life, but we saw several Hoeschtypes of vases from the objects themselves, which left nothing to be desired. Of course it is not necessary to use five tints in every case, and in the reproductions of the vases three only were employed. To ensure absolute accuracy in the matching of tints, the inventor has prepared a scale in which every combination of the five colours in certain proportions is shown. Herr Hoesch divides his five colours into fifths, and having thus twenty-five portions to ring the changes upon, he gets 1,600 tints, each of which has a number attached to it which shows on reference to a table that it is composed of so many fifths of one colour and so many fifths of another, as the case may be. The equality of the prints may therefore be depended upon. So far as we could see from the results shown by Messrs. Gladwell, there is hope that the Hoeschotype may take its place before long as one of the recognised art processes of the day.

Photographing the Sea.—Photographs of the bed of the sea some time ago caused a little sensation. There was the usual nine days' wonder, and then they went the way of all wonders. To those who may be desirous of repeating the experiment, it will be interesting to learn something of the distance to which light can penetrate water. A series of observations has been lately made on the subject by MM. Secchi, Pourtalis, and Bougner, who have found that the depth to which light can make its way in sea water is between forty-three and fifty fathoms. These observations have, however, not been made by means of photography, but by examination of the fauna. The deep sea fauna are beings of darkness, and these are first met with, according to another naturalist, Herr Frichs, at about fifty fathoms. In some places, where the light limit is higher, the deep sea fauna extend higher, and in fresh water lakes, where the light penetrates to greater depths, the shore fauna reach further down. Again, many deep sea animals have either uncommonly large eyes, like nocturnal animals, or are quite blind. It is quite possible that by means of photography the distance of this penetration of light could be ascertained with absolute accuracy.

FRENCH CORRESPONDENCE.

Scarcity of Photographic News—Captain Biny's Researches—Numerous Gelatine Processes—Ferrous Oxalate Developer—Boca's Chronometric Shutter—Necessity for a Chronometric Shutter—Portability of Apparatus—Paris Exhibition—Bibliography.

Scarcity of Photographic News.—We have now arrived at the time of year when one finds a dearth of news in photography. The photographic societies have suspended their meetings, professional photographers have neither more nor less to do than at other seasons, while amateurs are travelling with their apparatus of more or less portable form and gelatino-bromide plates or pellicles.

Captain Biny's Researches.—Several good workers, however, still continue their researches at home, and among them Captain Biny, from whom we hear of such interesting experiments. We cannot recommend too highly his last work relating to the means of preparing emulsion in open daylight, of which we have spoken in our last letter (page 481). After relating his experiments of adding hyposulphite of soda to the ferrous oxalate developer, and thereby increasing its properties, he has stated that this powerful agent should be used in the developing bath when working instantaneously.

Numerous Gelatine Processes.—For some time past every meeting has given itself up to the subject of the gelatino-bromide process, and it is certain that of all the different methods, one will be found excelling all others, and be universally preferred. Each moment brings forth a new way of mixing the emulsion, or a new developer. Being often obliged, professionally, to answer questions —for it is supposed that we ought to know the best —we often find ourselves greatly embarrassed. We wish to indicate the last improvement, and no sooner is it produced than it is replaced by another which seems superior. Notwithstanding all these improvements, there are no essential formulæ, and we continue to recommend the use of the ferrous oxalate developer, composed of three parts of saturated solution of neutral oxalate of potash and one part of sulphate of iron, to which add one or two drops of sulphuric acid per litre. With certain plates—Von Monckhoven's among others (the most used in France)—it is useless to add bromide of ammonium to the mixture unless when certain of having over-exposed; but with other plates liable to fog it is advisable, and often necessary, to add to the developer a few drops of a solution of bromide of ammonium. With regard to the ferrous oxalate bath, care must be taken to keep in a special vessel in open daylight, and to mix a few grammes per cent. of tartaric acid, as we have already stated, as indicated by M. Audra. By this means the developer will last until exhausted, particularly when kept in a brilliantly lighted place. To our mind this seems the most economical and cleanest process of development. The pyrogallic developer also offers advantages, but it appears unquestionable that in the majority of cases it is preferable to employ the ferrous oxalate.

Boca's Chronometric Shutter.—With Monckhoven's plates and diaphragm of 20 m.m. we have worked instantaneously, exposing for one-hundredth of a second. The focal length was 23 c.m. Boca's chronometric shutter was used to measure the length of exposure. This shutter would be excellent if it did not cause the camera to vibrate, resulting in a notable loss of sharpness. We had obtained very good pictures with an aplanatic lens by M. Hermagis, using a large diaphragm; but, after fitting on the shutter in question, the results were not nearly so good. The cause of this failure we have put down to the vibration of the apparatus. A shutter so perfect in other respects ought not by any means to shake the camera during its use. We can only greatly regret that M. Rédier, maker of Boca's apparatus, has not yet been able to arrive at a method for suppressing all vibration. Assuredly this desired improvement will not be long in forthcoming, and the instrument will then be perfect. It is so useful to be able to measure the length of the action of light, and so difficult to know what one is doing without having at disposal something of this kind. How may fractions of seconds varying from $\frac{1}{10}$ to $\frac{1}{100}$ be judged approximately? It is difficult, but, at the same time, necessary, to be able to expose with precision for such short spaces of time. For instance, we have an aplanatic lens, with a diaphragm of 20 m.m., requiring an exposure, in full daylight, of $\frac{1}{50}$ of a second; but, with dull illumination, it may be lengthened to $\frac{1}{10}$ or even $\frac{1}{5}$ of a second, but beyond this it passes into destructive over-exposure. To work with successful utility it is, therefore, indispensable to employ a precise shutter such as Boca's, which marks with accuracy the length of exposures from $\frac{1}{100}$ up to five seconds. Beyond this limit recourse may be had to the seconds hand of a watch without fear of erring

Difficulty of Solving the Problem of Portability of Apparatus.—The question of portability has not made visible progress. It is, however, one of the most important questions of the moment. M. Enjalbert's photo-revolver does not seem to offer a sufficient solution on account of the minute dimensions of the plates. One cannot, unless accustomed to delicate manipulations, work properly upon such a small surface; we therefore require the size to be extended to 6 by 5 c.m., in order to obtain useful pictures. It is, unfortunately, essential to produce an apparatus which can be used while held in the hand, for which a considerable rapidity is necessary, as at least $\frac{1}{100}$ of a second, and this can only be obtained with a lens of short focal length and a large aperture. These small pictures being, as a rule, intended for enlargement, they cannot be too sharp and rich in detail. This problem is less easy to solve, as with such rapidity it is necessary to work with full aperture, sacrificing some of the detail because the instrument vibrates so much when in the hand, and this movement is added to those of the object to be reproduced. Hence, it is only upon rare occasions that a really good negative is obtainable, and perfect results may not be counted upon when employing apparatus of this kind. The question is one still meriting a long research.

Paris Exhibition.—The Paris exhibition (photographic section) has taken a long time to establish itself; it is now nearly ready, and we hope soon to be able to give a detailed account.

Bibliography.—A fourth edition of the "First Lessons on Photography," by M. Perrot de Chaumier, has just been published at Gauthier Villars' library. This treatise is excellent, but, unfortunately, has for its aim the wet collodion process, which tends more and more to disappear; it would be useful if the author felt inspired to publish a similar treatise on the use of gelatino-bromide, as this is the only process employed now by amateurs, with very few exceptions. LEON VIDAL.

By-the-Bye.

CONTINENTAL RAMBLES WITH A CAMERA.

By Fjord and Fjeld in Norway.*

We have now crossed the highest portion of the Fille Fjeld on our way to the west coast of Norway. Snow and ice is no longer seen by the wayside, but the scenery is still very wild and grand. You must not be deceived by well-sounding names or well-marked localities on the map. We travelled by Waligorski's, and we cannot recommend it; for paths are marked of which we found no sign, and empty huts only were discovered where dwellings were supposed to exist; thus Kogstadt, notwithstanding its town-like name, consists of but three log huts. We take a photograph of the little plank erections, standing high upon a dark rocky eminence, with a big mountain side flecked with snow for a background; and Halne, which we reach later on, being marked by a little circle on the map, is but a wooden shed, six feet square and about four feet high.

But we are still on the highway as yet, where good "stations" abound. At Bergund we secure a picture—a very bad one, it turns out, unfortunately—of a famous old church that is reported to have stood here for many centuries past. Built of oak, its beams are as black as ebony, and, although we knew of its whereabouts, its tint harmonized so thoroughly with the sombre landscape, that there was some difficulty in finding it. We give a sketch taken from our photograph of this quaint edifice, whose outline is well known to archæological students.

At Leirdalsoeren we reach the Sogne Fjord, and here a steamer may be taken to visit the wonderful coast, and to reach Bergen if necessary. The scenery on the Sogne Fjord goes beyond the magnificent—it is appalling.

* Concluded from page 501.

Mighty rocks tower up like giant walls out of the green water, appearing, as one looks up at them from the little steamer below, to reach right into the heavens. Your boat is dwarfed to insignificance as it creeps along the narrow channels under shadow of these mighty cliffs, that assume the most fantastic shapes as they rise skywards.

You understand now why people come all this way to get a peep at the fjords, for nowhere else are there such rocky chasms, such wild defiles, such bright green waters to be seen. Now you sail into a dark inland lake surrounded apparently by nature's stern walls; now you pass the opening of a smiling valley, all green fields and verdant pasturade; now you approach a gigantic cascade that comes tumbling out of a black cleft in the rocks, the white foam rippling the placid water as it falls.

We do not go to Bergen, but land at Gudvangen. Before bidding adieu to the Sogne we take a photograph of our landing-place, where the cliffs rise higher than ever at the water's edge. Then we pursue our way through the sweet green valley of the Naerodal to visit another not less famous fjord—the Hardanger. Vossewangen is the only good "station" between the two fjords, those at Vinge and Twinge being mere squalid hovels at which only milk and fladbröd are obtainable; but at Vassewangen there is good brown bread to be had, and tinned meat. We attended service here, and the marvellous costumes of the peasants, gathered from many quarters, are most picturesque. The clergyman, a grave Lutheran priest in a long black robe and white frill, is himself a relic of the past; of his congregation, the men wear, for the most part, knee breeches, bright green vests, and red night-caps, while the women have the shortest of skirts and whitest of stockings. In some cases the women's dresses had waists coming right up to the armpits, like those worn in this country at the beginning of the century; others had gaily-stitched corsets, meeting high up the neck, with smart embroidered aprons, and white head-dresses, and full white sleeves. Blue eyes and straight flaxen hair are everywhere to be seen, and certainly Scandinavian features are more like our own than are those of any foreign people.

In fact, you soon get "at home" with the simple Norwegians. To pledge a glass of beer to "Gamle Norge" will make their friendship at once, for as we say Old England, so they say Old Norway. When they are especially pleased, they shake you by the hand or pat you gently on the arm. Shaking hands, indeed, is a universal sign of gratitude. If you give your carriole boy a few skillings, he at once shakes hands, or if you hold out a bit of fladbröd to a beggar, he employs the same token of friendship.

There is, however, one drawback the tourist photographer experiences in Norway, at any rate in the summer time; that is, the absence of darkness in which to change his plates in safety. It was very strange the first time we became aware of this. We waited patiently hour after hour on our arrival at Christiania for the light to fade. We sat chatting together, talking over our plans, but still the daylight lingered; presently, looking at the time, we found it was one in the morning. Then the truth came very strongly upon us, and we at once saw that our old plan of leisurely changing plates under cover of the night could no longer be practised. It was no easy matter to get a cupboard that did not admit light, and on several occasions it was necessary to drape a bed all round with thick hangings and get underneath, to pack and unpack in safety.

Eide, on the Hardanger, is a convenient spot to take boat to visit the Fjord and the mammoth waterfall, the Vöring Foss that is near at hand. The steamer calls but rarely, but a row-boat may be hired, with three or four men, for a reasonable sum. The shores of the Hardanger are less rugged than the Sogne, but not less attractive on that account; in truth, there are few things pleasanter than being propelled along over the sea-green waters of these glorious fjords watching the fine panorama of mountain and lake glide past you. Now a flock of wild geese fly straight over your head in two lines, foring an acute angle; now something splashes into the fjord from a low rock just ahead of the boat, and the men turn quickly to see if they can catch a glimpse of the seal that has dived into the translucent water; now you start some screaching wild fowl as the boat sharply rounds a headland.

Presently the boatmen begin to sing. What is that well-known part song they are trolling? Listen; how familiar it is! They all join in chorus, and so could we, if we only remembered the name of the song. Hurrah! we have it:

> "The hardy Norseman's home of yore,
> Was by the stormy sea."

The boatmen are delighted at their passengers joining chorus; they check their oars for a moment and wave their hands. "Gamle Norge," our party shout in return, and then we all laugh and shake hands. Presently the boatmen start another song; this is also familiar, and we join once more:

> "O, who will o'er the downs so free—
> O, who will with me ride?"

And so the time passes pleasantly upon the Hardanger Fjord; you row on and on through the live-long day, and it is only when you arrive at Vik at the head of the loch, and find the people at the little inn are fast asleep in bed and want rousing up, that you begin to realise it is two o'clock in the morning.

The Vöring Foss, called the lion of Norway—is a good walk from Vik—beware of the charges here, by-the-bye, for they incline to be extortionate—and the way is so steep at times, that it is difficult work even for a horse; there is no such thing as a carriole to be secured. The best way, therefore, is to foot it, and so our party mean to make way across the Scandinavians, by the Hallingdal Valley, and the borders of Tellemarken, to the lower Christiania road. We fill up with provisions before starting. And we may at once say that although our maps showed a path all the way, we found it in the end a trackless waste, over the wildest country, and a distance at the least of ninety miles.

A short walk to the Saebo lake, over which you are ferried, and then up a very wall of a mountain, that leads you, like Jack's beanstalk, into another world apparently, a vast table-land. You follow to where a cloud of mist spray hangs over the plain, to be observed miles away. The fall, or Voss itself, is not seen until you approach close to the fissure or chasm in the rock, in which the torrent foams and chafes in its headlong career. A fierce tearing rapid, broken up into hissing foam, dashes over a yawning abyss with desperate force, and, falling into space, disappears out of sight in a halo of spray and vapour. What becomes of the torrent after its terrific leap, you know not; but the deafening thunder of the water below, and the cloud of mist that rises to the brim of the awful cauldron, conveys to the shuddering senses some idea of the strife below.

Of course we get out our camera. The stand cannot be used from this point, for in order to see as much as possible of the fall—the Voss can be viewed at full length lower down, but it is then further from the spectator—you must approach the precipice on your stomach and crane your head. To secure a proper focus, we regard the opposite shore, for we cannot put our head where we mean to put the camera; as it is, our position is a dizzy one, the stormy blast of the fall, the terrible thunder, and the wet foam rising from the vast abyss, all combining to attack the senses. A sudden gust comes that bids fair to blow camera and lens into the foaming water; we seize it as we lay there at full length, but at the cost of our wide-awake, which goes flying over the black precipice, never more to be seen by mortals.

We do not advise any of our readers to follow in our footsteps further across the Hardanger Fjeld unless provided with a good guide, and perhaps a pack-horse, with food and camping equipage. We travelled by map and compass only; within a few miles of the Vöring Foss, the map left us in the lurch, or rather our track did, while the glaciers, fierce mountain streams, and broad waters, prevented one from travelling in anything like a straight line. In these circumstances it took us three days' hard walking to reach the nearest hamlet—Tufto—at the head of the Hallingdal Valley. After you have passed Maursaet, there are only half-a-dozen little wooden huts between you and civilisation; these are so much the colour of the big grey boulders strewn in all directions that they are difficult to find, and when found they are sometimes without inhabitants. A good-natured farmer whom we providentially met, the first day (the only individual we did meet on our three days' tramp), directed us to one of these huts, writing a line of recommendation on our note-book: "These are Englishmen; they are not vagabonds," a passport that was several times of value to us in the district.

But the scenery of the Hardanger Fjeld is well worth many hardships. One of the most charming natural effects in Norway is the midnight sunshine glowing upon the interminable wastes of snow and rugged grey peaks. In these districts, in midsummer, the sun merely dips down out of sight for half-an-hour or so, and during this period you may observe the most lovely effects of sunset or sunrise, whichever it may be called, for the same phenomenon answers both purposes. To see the cold white landscape gradually become tinged with rose colour and purple as the lurid rays of the sun strike aslant the snowy regions is a sight that will never escape the traveller's memory. You watch from some eminence the gorgeous colours as they change and modify, the white snow-fields and distant glaciers now shining like burnished gold, now bathed in the violet haze of sundown. The orb of day has been lost to view for some time, but presently the colours, instead of growing fainter, become vivid again. It must be the moon, we think, that is coming up to take the place of the sun during its brief retirement from the scene. The tints brighten perceptibly, and the gilding upon the mountain-tops shines out as brilliantly as ever as the luminary rises. But it is not the moon; it is the fiery sun again that proclaims another day has come, and that the night is over before it has begun.

Fortunately the mountain air is so crisp and exhilarating that no such thing as fatigue comes over the traveller. Perhaps the excitement of travelling on one's own responsibility has also something to do with it; but although the second night is passed in a lonely hut, with but little food and a half-hearted fire—for the juniper bushes afford the only fuel to be got—our party keeps up its energy and spirits. In front stretches an endless moorland covered here and there with broad fields of white, the higher valleys filled with congealed snow or glacier. To the north is seen the mountain peaks of the Fille Fjeld and Northern Scandinavians, some of them grey and craggy, others with snowy hoods and closely drawn mantles of white, with broad glaciers streaming down their sides like white lava.

It is only when at last your journey is done, and you see the smiling fir-clad Hallingdal Valley at your feet, and behold the white farmhouses at Tufto, that fatigue creeps over your frame. There is no "station" at Tufto, but, fortunately, hospitality is a marked feature of the Norwegians. Rest and food we are welcome to, and ten miles further on—a weary trudge—Sundre is reached, which is a "station," if only a slow one. The lower Christiania road is now not far off, and this being reached, we face for home.

A RAPID-VIEW INSTRUMENT FOR MOMENTARY ATTITUDES.

BY FRANCIS GALTON.*

The wonderful photographs by Muybridge of the horse in motion, and those by Maret of the bird on the wing, induced me to attempt the construction of apparatus by which the otherwise unassisted eye could verify their results, and catch other transient phases of rapid gesture. Its execution has proved unexpectedly easy, and the result is that even the rudest of the instruments I have used is sufficient for the former purpose; it will even show the wheel of a bicycle at full speed as a well-defined and apparently stationary object. This little apparatus may prove to be an important instrument of research in the hands of observers of beasts, birds, and insects, and of physicists who investigate such subjects as the behaviour of fluids in motion.

My object was (1) to transmit a brief glimpse of a moving body, (2) to transmit two or more such glimpses separated by very short intervals, and to cause the successive images to appear as simultaneous pictures in separate compartments in the same field of view.

The power of the eye to be impressed by a glimpse of very brief duration has not, I think, been duly recognized. Its sensitivity is vastly superior to that of a (so-called) "instantaneous" photographic plate when exposed in a camera, but it is of a different quality, because the impression induced at each instant of time upon the eye lasts barely for the tenth of a second, whereas that upon a photographic plate is accumulative. There is a continual and rapid leakage of the effect of light upon the eye that wastes the continual supply of stimulus, so that the brightness of the sensorial image at any moment is no more than the sum of a series of infinitesimally short impressions received during the past (say) tenth of a second, of which the most recent is the brightest, the earliest is the faintest, and the intermediate ones have intermediate degrees of strength according to some law which an apparatus I shall describe gives us means of investigating. After the lapse of one-tenth of a second the capacity of the eye to receive a stronger impression has become saturated, and, though the gaze may be indefinitely prolonged, the image will become no brighter unless the illumination is increased.

This being premised, let us compare the sensitivity of the eye with that of the rapid plate in the photographic camera, under conditions in which the eye is just capable of obtaining a clear view, let us say during an overcast day in a sitting-room whose window does not occupy more than one-thirtieth of the total area of wall and ceiling, which is the light under which most of us habitually write and read. A glimpse under these circumstances of one-tenth of a second in duration suffices, as we have just seen, to give a clear view; but the sensitive photographic plates sold in the shops as "instantaneous" will not give a portrait in that light under thirty seconds' exposure. In other words, the sensitivity of the eye is fully 300 times as great as that of the plate. Of course, I am aware that more sensitive plates than these have been made, and I have seen a rapidly-revolving wheel photographed under the momentary illumination of an electric spark; but I never heard of that being done

* *Nature.*

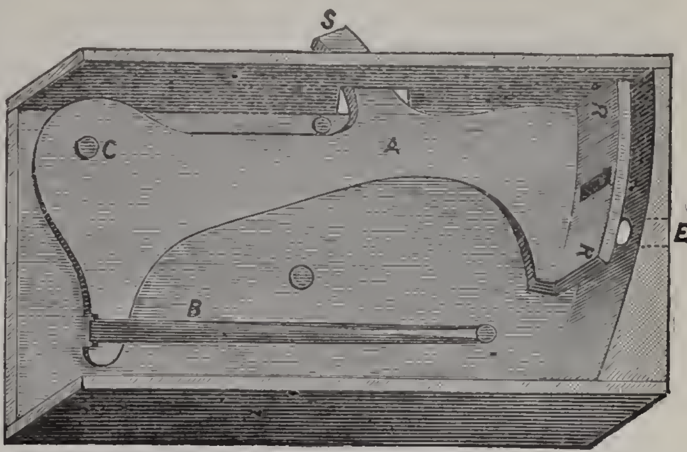
when, at the same time, the revolving wheel was not perfectly distinct to the eye.

The range of ordinary illumination is very great. The photographer who requires thirty seconds in a dim window-light would photograph clouds in some minute fraction of a second, showing that the illumination of the latter is fully one thousand-fold greater. If, then, the eye has been shaded and adapted to a dim light, an object in bright sunshine may require no more than the thousandth part of the tenth of a second to be visible, and, in saying this, I am confident that I am under-estimating what could be done. Consider what even this means: a cannon ball of ten inches diameter, in its mid career, travels with a velocity of little more than 1,000 feet in a second; in one ten thousandth of a second it would shift its place through only one-tenth of its diameter, and would present to the eye, if it could be viewed under the above-mentioned conditions, the appearance of an almost circular disc elongated before and behind by only a slight blur.

It may be said, how is it possible to give such brief exposures as the above? I see no difficulty at all in the matter. Let us take two examples, (1) of quick movement, and (2) of very quick, but by no means the quickest possible, movement. As regards the former, I can flip with my forefinger, and with the greatest ease, a light weight—such as a very small stone—nine feet up in the air; now the maximum velocity of the tip of my forefinger is that of the initial velocity of the stone, which is calculated at once by the usual formula, $v = \sqrt{2 f s}$, or taking $2 f = 64$, which it is very nearly, $v = 8 \sqrt{s}$, the units being in feet and seconds. The velocity in question is therefore 24 feet, or 288 inches, per second. As regards a very rapid movement, we may take that of the wing of a bird, which can undoubtedly be rivalled mechanically. A pigeon is by no means the swiftest of birds, but it can fly easily at the rate of 35 miles an hour, and the part of the wing by which it is chiefly propelled, and which cannot be its extreme tip, must move much more rapidly than this; let us say, very moderately, at 70 miles an hour, or 1,232 inches per second.

Now, the duration of an exposure depends on three data, namely, the rapidity with which the screen moves past the eye, the width of the slit through which the momentary glimpse is obtained, and the diameter of the available portion of the pupil of the eye. I prefer not to limit the pupil by using a small eyehole, which is a source of much trouble in actual work, but to have as large an eyehole as is in any way desirable. I find the width of the pupil of my eye in an indoor light, as measured by holding a scale beside it, and reading off in the looking-glass, to be about 0·1 inch, and I use a slit of the same diameter. The exposure begins when the advancing edge of the slit is in front of the near edge of the pupil, and it ceases when these conditions are reversed; in other words, it lasts during the time that the screen is occupied in moving through one-fifth of an inch. In the cases just taken of velocities of 288 and 1,232 inches per second, the duration of the exposure would be the 1,440th and the 6,160th part of a second respectively. There is therefore no difficulty, either theoretical or practical, about shortness of exposure and sufficiency of illumination. The power exists, and can be utilized, of seeing bodies in motion by a rapid-view instrument, showing them in apparent stillness, and leaving a sharply-defined image on the eye, that can be drawn from visual memory, which, in some persons, is very accurate and tenacious.

I find on trial that great rapidity of exposure is in nowise essential for analysing the attitudes of a galloping horse or a flying crow. The instrument I commonly carry with me is a very rude one, but convenient for the pocket, and is shown below. The duration of the exposure given by it under the action of its spring is the 360th part of a second, but the beginning and end of the exposure ought not to count, so little light passing through the edges of the pupil at those times that what is then seen is relatively faint and is disregarded. I estimate its practical duration at about one 500th of a second, and it is rather less when the finger acts with a sharp tap in opposition to the spring. The instrument is shown in the figure, without its sliding lid, which protects it from injury in the pocket. A is an arm which turns through a small angle round C, its motion being limited by two pins. Its free end carries a vertical screen, R R, which is a cylindrical (or better, a conical sheet) described round an axis passing through C perpendicular to the arm. As the arm travels to and fro, this screen passes closely in front of the end of the box, which is cut into a hollow cylinder (or cone) to correspond. There is a slit in the middle of the screen, and an eyehole in the centre of the end of the box. When the slit passes in front of the eyehole E, and the instrument is held sideways, a view is obtained. A stud, S, projects upwards from the arm, and an india-rubber band, B, passing round a fixed pin and a descending spoke of the arm, acts as a spring in causing the stud S to rise through a



hole in the side of the box, where the finger can press it like the stop of a *cornet-a-piston*. Nothing is then visible, but on pressing or tapping the stud the slit passes rapidly in front of the eyehole and the view is obtained.

After this, the stud is released and the arm springs backwards, when a second view can be obtained, or the eye may be purposely closed for the moment.

I measured the velocity of the instrument by filing a nick on the stud and laying a light weight (a small bent nail) upon it, after having temporarily put in a peg that checked the arm in its recoil when the slit was opposite the eyehole. Then, holding the instrument firmly against the wall with the projecting end of the stud as vertical as might be, I drew back the arm and released it, and noted the height to which the weight was tossed. It was three inches. This gave the velocity of the stud in the central portion of the arm, and from this datum the velocity of the more distant screen was easily calculated. I have made more elaborate instruments with multiple levers and with revolving discs, but am not as yet prepared to recommend any of them in particular. Different sorts would be probably be wanted by different persons. For instance, it might in some cases be convenient that the trigger should be pulled at the right moment by a bystander, the eye of the observer being in the meantime kept closely shaded from the surrounding light. Again, there are periodic movements which would be best analysed by a slit in a rotating disc whose period of rotation was a little slower than that of the movement, so that each exposure should show a phase one step in advance of the previous ones; or, again, the rapidity of the periods or that of the motion may be such as to make it necessary to expose only at each second, third, or longer periodic interval. This would be effected by the use of two discs rotating at different velocities. Suppose, for example, one to revolve three times while the other revolved twice, then two slits would be in accord in front of the eyehole only once in three revolutions.

In order to present the images formed by two successive glimpses as simultaneous pictures seen side by side in the field of view, I took a prismatic eyeglass of the sort sold by spectacle-makers to correct want of parallelism in the optic axes. I cut it in two pieces, and placed these in opposite ways in front of two horizontal slits, lying one above the other in a shutter that fell vertically between slides. When the first slit came in front of the eye, the image it transmitted was deflected four degrees to the left; and when the second slit followed it, its image was deflected four degrees to the right, and two apparently simultaneous pictures were produced. Also, by crossing the prisms I found it would be easy to construct an apparatus with four successive slits showing four images; 1, up to the left; 2, up to the right; 3, down to the left, and 4, down to the right. I doubt, however, whether this would be often found a useful development of the instrument, owing to the difficulty of watching more than a small area with attention.

I noticed an important optical effect, namely that the image first seen was always considerably fainter than the others, showing that its brightness had faded in the brief interval that elapsed before comparison began. It would appear that the law of the rate of fading could be investigated by this apparatus. I have not now the opportunity of doing so myself, but if I had, I should mount two prisms below radial slits in a disc that was revolving steadily at a known velocity, and I should watch a circular wafer through them. The width of the slits would be adjustable, and so would the angular distance of the prisms, and I should measure under various circumstances the width of the second slit that was necessary to tone down its image to an equal brightness with that seen through the first. Or the investigation might be made without prisms, by using two wafers and watching them with the same eye through slits at different radial distances, separated by various angular intervals, the adjustments being such that only the outside wafer should be seen through the outer slit, and the inside wafer through the inner one.

Notes.

A commercial treaty between France and Switzerland specifies photographic pictures as works of art. In a word, they are classified with paintings and engravings. Recognition by government in this way is an important gain to photographers.

Incandescent electric lighting is on its trial in the press-telegram room of the General Post Office, where no less than 1,200 persons are employed. Fifty-nine Edison lamps serve to illuminate the apartment, and satisfactory accounts are given as to the diminished heat of the atmosphere, and the personal comfort of the staff.

In the United States a considerable saving can frequently be effected by the use of electric lighting instead of gas, as this latter illuminant is charged from seven shillings to sixteen shillings per 1,000 feet; but in this country, where gas averages about one-third the American prices, things are more evenly balanced.

At the Liverpool Street station of the Great Eastern Railway, where everything is favourable for electric lighting, the cost of each method has proved about the same—viz., £600 to £700 per annum.

Many of the high-class Paris photographers, having no means of exhibiting specimens at their semi-private residences, rent a show-case or shop-front in some fashionable thoroughfare. There is no attendant, and no business is carried on there; it is a display of pictures for passers-by to look at, and nothing more. A lamp-lighter, who does not need to enter, lights up the place at dusk, and puts out the lamps late at night. Thus, an attractive little exhibition is provided, early and late, at the expense only of the rental of a shop front or window.

The recent experiments of M. Demarçay on the easy volatility of metals *in vacuo* possess interest as calling prominent attention to the previously published researches made by Mr. Parry, of Ebbw Vale, regarding this matter; and although M. Demarçay makes no mention of Parry's work, most photographers will remember his curious experiments on the volatilization of iron at a low temperature. Mr. Parry is now engaged on a new and remarkable series of photo-spectrographic investigations.

A work on "Natural History" illustrated by photography is announced in France. If this book is well executed, it will be the first time boys and girls have been presented with true illustrations of the animal kingdom. Early impressions of lions, tigers, crocodiles, &c., are always very wide of the mark, simply because our educational works are full of exaggerated pictures of these creatures.

The United States Engineers recently photographed the explosion of a wreck, which was blown to pieces by submarine charges of dynamite, to ascertain, among other things, how long the spectacle really lasted. The result was exceedingly interesting. There were six cameras employed, and the instant of the explosion, as also the several instants when the exposures were made by shutter, were electrically timed by a chronograph.

A photograph taken $\frac{1}{10}$ of a second after the explosion showed the vessel broken, and a column of water 70 feet high; a photograph secured 1·5 second after the instant of explosion showed a column of water 160 feet high; a third photograph, taken 2·3 seconds after, showed the column at its full height of 180 feet, while fragments of wreckage were in the air, but none had fallen to disturb the surface of the water; a fourth picture, taken 3·3 seconds after, showed the column falling, and the surface of the water disturbed; while a fifth photograph, secured 4·3 seconds after, showed that all was over.

Of course these times would be slightly modified by the nature of the submarine charge and the depth at which it is exploded; but still the experiment is warning enough to the photographer never to be in a hurry when securing pictures of this kind. A simple drop shutter worked by hand is all that is necessary, together with a little coolness and patience. He need only watch till his eye tells him the full effect is before him—in the above instance he would have leisurely waited two seconds before exposing—and then press the bulb in his hand. M. Charpentier has just told us we can repeat a signal within thirteen hundredths of a second of seeing it, so that very little time is lost when the moment for action comes.

Our readers may like to know something of the chronograph employed for timing the exposures, especially when we tell them that such an instrument is capable of recording intervals of one-millionth of a second. From each camera shutter, as also from the submarine charge itself, leads an electric wire to the chronograph. This may be best imagined if you think of a wheel spinning round at a high speed, but at a speed that is well known, say ten feet per second. There are several wheels in reality, but one is enough for our purpose. The margin of the wheel is of metal covered with a fine deposit of soot, so that an electric spark passing on to it makes a bright pin point, the electricity flicking away the soot. The ends of the wires leading from the shutters are close to this revolving wheel, and as the shutters act one after the other, they send an electric current, which is recorded by a pin-point upon the moving wheel. At the end of the experiment the wheel is stopped, and the distance between the points is then measured; as it is known that every ten feet means one second, it is easy enough to convert any distance into time; and, as we have said, a millionth part of a second may be recorded in this way.

Printed matter on the back of a sheet of paper often interferes very seriously with the work of the copyist; but those who are troubled by ghost-like images of the reverse side should try the simple expedient of blacking the whole of the back. If this is undesirable, the sheet can be fastened up over a black ground.

The interesting discovery that light shining upon selenium alters its resistance to an electric current—a fact made use of, as our readers know very well, by M. Vidal in his photometer, as well as in other photo-electric apparatus—has caused an increased demand for this substance, which a short time ago was very rare, and consequently very costly. One thousand francs per lb. (£40) was the price quoted for the element a few years back, notwithstanding the circumstance that there was no useful or scientific application of value for it, the greatest call being for museums and collections in the form of specimens. But now, selenium having been diligently sought for on every hand, and with considerable success, its price has rapidly gone down, and you may purchase it at forty francs a pound. Should a steady demand for the material arise, a still further reduction is likely, for an ore has been found in La Plata, containing no less than 30 per cent. of selenium. So that photometers in selenium need not cost very much on account of their material.

Even at the present time the highest praise which can be bestowed on a gelatino-bromide picture is to say it is "like a wet plate"; this probably explains why wet plate work holds its own when rapidity or convenience in working are not primary considerations.

Out-door photographers may be glad of a hint as to preserving matches and vesuvians from damp. Left in a dark-tent or in packages in the open air, matches become useless in twenty-four hours, and all attempts fail to strike a light with them. If, however, they are varnished—ordinary photographic varnish will do—they will resist the dampest weather, and may be always depended upon. The heavy sea fogs encountered in the Polar seas are especially mischievous to fire-making appliances, and a film of varnish has been found effectively to shield them from injury.

We have recently seen several examples of fog in gelatine plates, due, without doubt, to the admission of light into the camera through the Waterhouse diaphragm. Our readers will remember that in our "At Home" with Mr. H. P. Robinson, we stated that gentleman had unfortunately met with the phenomenon repeatedly, and accordingly he now always secures his dark-cloth round the lens with an elastic band. In the case of very rapid exposures there is little danger, but when a small stop is employed and an exposure of some seconds, sufficient light may get into the camera by the diaphragm slit to spoil a plate. A searching examination—keeping the head under the dark cloth some minutes with the lens capped, while an assistant alternately covers and uncovers the diaphragm with his hand—will soon show if a camera admits light or not.

The extemporisation of a non-actinic lantern by the following method may often be of advantage to the continental traveller. A small drinking glass is placed inside a larger one, and the interspace filled with red wine. A small night-light or taper is burned inside; and a metal funnel, so placed as to allow a sufficient circulation of air, completes the arrangement.

Patent Intelligence.

Application for Letters Patent.

4071. William Chancellor Haigh, of the city of Manchester, Artist, for an invention of "Improvements in apparatus for printing.—Dated 25th August, 1882.

Allowance of Provisional Protection.

3329. William Patrick Bruce, of Kinleith Currie, Midlothian, for an invention of "A new process for the reproduction of designs applicable to the illustration of books and the like."—Dated 13th July, 1882. Notice to proceed also given.

Patents Sealed, August 25, 1882.

1166. Joseph Julius Sachs, of Sunbury, in the county of Middlesex, for an invention of "Improvements in the production of surfaces for printing, stamping, and embossing."—Dated 10th March, 1882.

Patents Void through Non-payment of Duties.

3336. Thomas Salkeld Borradaile, of 7, Union Court, Old Broad Street, in the city of London, Gentleman, for an invention of "Improvements in the construction of autographic printing apparatus."—A communication to him from abroad by Michael Flürscheim, of Gaggenau, in the empire of Germany.—Dated 19th August, 1879.

Patents Granted in France.

147,376. Lacroix, for "Photographic paper for obtaining proofs in black lines on a white ground."—Dated 15th February, 1882. Class 17.

147,377. Lacroix, for "Photographic paper for obtaining proofs in white lines on a brownish-black ground."—Dated 15th February, 1882. Class 17.

147,398. Roze and Maurel, for "Obtaining photographic stained windows."—Dated 16th February, 1882. Class 17.

147,399. Roze and Maurel, for "Heliographic stained windows."—Dated 16th February, 1882. Class 13.

147,504. Dewe, for "Means of and apparatus for exhibiting framed photographs."—Dated 23rd February, 1882. Class 17.

147,506. Day, for "Flexible negatives for artists, lithographers, designers, &c."—Dated 23rd February, 1882. Class 17.

147,546. Renet, for "Reproducing drawings in black lines on white ground."—Dated 24th February, 1882. Class 17.

147,600. Osterneth, for "A photo-electrotype and photo-electroplastic process."—Dated 28th February, 1882. Class 17.

Specifications issued during the Week.

395. Richard Schroer, of Vienna—"An improved proceeding to prepare photographical copies on the surface of all matters."

This invention consists in the production of photographic images on wood, leather, paper, india-rubber, tissues, porcelain, stoneware, metals, and other materials by applying to their surface a sensitive coating containing tanned glue, and developing the image after exposure in the following manner. I dissolve one part of alum in 300 parts of water, and add 16 parts of glue best quality, or of isinglass, leaving it in the solution about twenty-four hours, during which time the liquid is frequently stirred. Subsequently I pour out the solution of alum, wash the glue well with water, and allow it to dry. By this process the glue is tanned, and obtains a very high melting point. I then dissolve in a bottle 2 parts of potassic iodide, 1 part of potassic bromide, 1 part of sodic chloride, 16 parts of the tanned glue with 200 parts of water, and at the same time in another bottle 6·5 parts of argentic nitrate with 50 parts of water; both solutions are then heated to 35° centigrade, and mixed together. This mixture is kept in a water bath of 30—38° centigrade for about twenty-four hours, and frequently agitated. Afterwards I add 20 drops of ammonia, agitate again, and filter the mixture through fine muslin. The proportion of chlorine, iodine, and bromine salts may, however, be varied to suit certain requirements, and replaced by other compounds of iodine, chlorine, and bromine. Non-metallic but compact materials, such as glazed porcelain and stoneware, to which the photographic image is to be applied, are first slightly heated, after which the sensitive mixture is poured over their surface, and left to dry. Metallic surfaces are first coated with a dull white lac or other dull lac; after the coating is dry, it is cautiously polished, and the sensitive coating applied. Porous materials, such as wood and paper, are first coated with a solution of tanned glue (one part of glue in 15 parts of water), after which the sensitive coating is applied. The photographic image is then prepared on the sensitive surface by an exposure of two to five seconds to diffused daylight or electric light, and subsequently developed by a mixture of the following solutions:—(*a*) 1 part of pyrogallic acid, 2 parts of citric acid, 1 part of alum, 300 parts of water; (*b*) 5 parts of argentic nitrate, 6 parts of citric acid, and 100 parts of water, six parts of the solution (*a*) being mixed with one part of the solution (*b*). After the image has been slowly developed by applying to the surface the above mixture, it is washed with water, and fixed by a solution of 1 part of sodic thiosulphate in 8 parts of water. Finally it is treated for five to twenty minutes with a solution of alum, and again washed. (*Provisional protection only*).

TWELVE ELEMENTARY LESSONS IN PHOTOGRAPHIC CHEMISTRY.

No. V.—Photographic Chemicals.

Platinum dichloride, $PtCl_2$, may be obtained by dissolving platinum in nitro-hydrochloric acid, and, after evaporating to dryness, the platinic chloride is gradually heated to 400° F., when chlorine is given off, and the platinous salt remains as a brown residue. A simpler method of preparing the salt is to treat a solution of platinic chloride with sulphurous acid, when the platinous chloride will separate out in the form of a yellow crystalline mass. It is insoluble in water or nitric acid, but is readily soluble in a solution of potassium chloride, with which it forms a double salt, known as *chloro-platinite of potassium*, $PtCl_2{\cdot}2KCl$, which is the compound used in the platinotype process.

Potassium bichromate, $K_2Cr_2O_7$, is obtained by heating chrome-iron ore with chalk, and constantly stirring the mass. After about twelve hours the compound is mixed with water and filtered, sulphuric acid being added till the solution is distinctly acid; it is then agitated with chalk to precipitate the sulphate of iron, and, after allowing the liquid to stand, potassium carbonate is thrown into it, and the bichromate of potassium is crystallized out. The salt forms orange-coloured crystals, which dissolve in about ten parts of cold water and in about five parts of boiling water. A solution of potassium bichromate produces a red-brown precipitate with silver nitrate, and the characteristic odour of aldehyde, when heated with alcohol and sulphuric acid.

Potassium bromide, KBr, is prepared by adding bromine to a solution of caustic potash; when a certain amount of bromate is simultaneously produced, the liquid is evaporated to dryness, and the residue heated to fusion; this converts the bromate into bromide, and the salt is finally purified by crystallization. The salt forms white cubical crystals which are very soluble in water, but only sparingly so in alcohol. The commercial salt generally contains iodide of potassium as an impurity; it may be detected by adding one drop of a very dilute solution of silver nitrate (one grain to the ounce) to about ten grains of the sample to be tested dissolved in half an ounce of water. If the ordinary cream-coloured precipitate of silver bromide is produced the salt is free from iodides, but should a bright yellow precipitate of silver iodide be formed, the above impurity is present.

Potassium cyanide, KCN, is prepared by igniting the ferrocyanide; in this way it is decomposed into carbide of iron, nitrogen, and potassium cyanide, the latter being purified by crystallizing either from an aqueous or alcoholic solution. Cyanide of potassium is very soluble in water, and slightly so in alcohol containing a small proportion of water; the salt is deliquescent, and is decomposed by the carbonic acid of the atmosphere in the presence of moisture, thus accounting for its odour of hydrocyanic acid (prussic acid). Commercial potassium cyanide is very impure, containing a large quantity of potassium carbonate; both the pure and impure samples are very poisonous, from the presence of prussic acid, the best antidote being a mixture of protosulphate and perchloride of iron in solution.

Potassium ferrocyanide, $K_4Fe(CN)_6$, otherwise known as *yellow prussiate of potash*, is manufactured on the large scale by heating together animal matter, such as horn, dried blood, and leather, with iron filings, and potassium carbonate; the fused mass is then treated with water, and the potassium ferrocyanide crystallized by evaporation. With ferrous salts potassium ferrocyanide produces a pale blue precipitate; while with ferric salts a dark blue precipitate of Prussian blue is formed.

Potassium ferricyanide, $K_3Fe(CN)_6$, otherwise termed *red prussiate of potash*, is obtained by passing chlorine through a solution of potassium ferrocyanide, and purifying the salt by crystallization. Potassium ferricyanide forms beautiful red crystals which are converted by light into the yellow potassium ferrocyanide; the solution produces a dark blue precipitate with ferrous salts, and a brown colour with ferric salts.

Potassium iodide, KI, is prepared by adding iodine to a solution of caustic potash, and, after evaporating the solution, the residue is gently heated to decompose the iodate formed in connection with the iodide. Potassium iodide forms white cubical crystals, which are very soluble in water and alcohol; the solution produces a bright yellow precipitate with silver nitrate, and liberates iodine with the production of a brown colour when added to chlorine water. The only impurities that are likely to be present are potassium iodate and carbonate; the former will give a slight brown tint if hydrochloric acid is added to the solution, while the latter impurity produces an effervescence when the acid is added.

Potassium oxalate, $K_2C_2O_4,H_2O$, or *neutral oxalate of potash*, is obtained by neutralising a solution of potassium carbonate with oxalic acid. The salt is moderately soluble in water, and, when pure, it is neutral to test-papers; but it generally exhibits a slightly alkaline reaction from the presence of potassium carbonate. A solution of potassium oxalate forms a white precipitate with chloride of calcium, which is soluble in hydrochloric acid.

Pyroxyline, $C_{18}H_{22}(NO_2)_8O_{15}$, or *nitro-cellulose*, is prepared in a similar manner to gun-cotton, but with the addition of a small quantity of water. Several kinds of soluble cotton are prepared to suit different requirements. One method is to make a mixture of three parts nitric acid, two parts water, and nine parts sulphuric acid; the mixture is kept at a temperature of 140° F., and tufts of cotton-wool are placed in it for about five or ten minutes; the cotton is then thoroughly washed for some hours in running water, and finally dried by exposure to the sun's heat. Pyroxyline, when pure, is perfectly soluble in a mixture of equal parts of alcohol and ether, forming the liquid known as collodion; the cotton is also soluble in methylic alcohol (wood spirit); but it should be totally insoluble in ethylic alcohol.

Silver bromide, AgBr, may be prepared either by acting upon silver with bromide, or by precipitating silver nitrate with a soluble bromide. The compound is a cream-coloured powder slightly soluble in ammonia, and when acted upon by iodine water it forms the bright yellow silver iodide, and liberates bromine. If absolutely dry chlorine is passed over dry silver bromide, bromine is set free, and silver chloride is formed.

Silver chloride, AgCl, is prepared in a similar manner to silver bromide, substituting chlorine and a soluble chloride for bromine and a soluble bromide. Silver chloride forms a white powder, very soluble in ammonia, potassium cyanide, and sodium hyposulphite. When acted upon by moist iodide or bromine, silver chloride is converted into iodide or bromide of silver; but dry iodine or bromine has no action on dry silver chloride.

Silver iodide, AgI, may be obtained in a like manner to the two preceding compounds; it is a bright yellow substance, insoluble in water, but moderately soluble in sodium hyposulphite and potassium cyanide. Silver iodide is unacted upon by moist bromine or chlorine; but dry chlorine or bromine converts dry silver iodide into silver chloride or bromide. If a solution of silver nitrate be percipitated with a mixture of potassium, iodide, bromide, and chloride, silver iodide will be first formed, then the bromide, and finally the chloride.

Silver nitrate, $AgNO_3$, is prepared by dissolving silver in nitric acid, and evaporating the solution to dryness. The salt is moderately soluble in water, and slightly so in alcohol. The solution produces a white precipitate with sodium chloride, which is soluble in ammonia, but re-precipitated on the addition of nitric acid.

Sodium chloride, NaCl, or *common salt*, is the principal salt in sea water, and also rock salt. It is—as, of course, every one knows—very soluble in water, but practically insoluble in alcohol. A saturated aqueous solution precipitates soap and several dyes when dissolved in water. When sodium chloride is acted upon by strong sulphuric acid, hydrochloric acid gas is given off, and may be recognized by its pungent odour and the white fumes produced when ammonia gas is mixed with it.

Sodium hyposulphite, $Na_2S_2O_3$—or, more correctly speaking, *sodium thiosulphate*—is prepared by boiling sulphur in a solution of caustic soda, and then passing sulphurous acid into the liquid till it is decolourized. The crystals contain four molecules of water, and, when heated, the salt dissolves in its own water of crystallization. Sodium hyposulphite dissolves the silver haloids—*i.e.*, bromine, chlorine, and iodine—forming silver hyposulphite and the haloid of sodium.

Tannin or tannic acid, $C_{27}H_{22}O_{17}$, is a vegetable product contained in the bark and other parts of several plants. Tannin is the astringent principle of gall-nuts, from which it may be extracted by water, as in the preparation of ink. Its chief use is for tanning leather, the gelatinous membrane forming an insoluble substance with the tannin.

Uranium nitrate, $U_2N_2O_8 6H_2O$, is produced by dissolving uranium or either of its oxides in nitric acid. The salt forms bright yellow crystals, which are extremely soluble in water and alcohol. The solution forms a brown precipitate with ferrocyanide of potassium. When acted upon by light, in the presence of organic matter, uranic nitrate is reduced to uranous oxide.

A PHOTOGRAPHIC EXCURSION ALONG THE VALLEY OF THE WYE.

A correspondent, who writes under the easily recognizable initials "H. T. W.," sends us the following interesting notes about this charming and romantic part of the country.

The district round the Wye is ground well-trodden by the photographer, but perhaps you may be willing to receive notes of some experience gathered in an excursion down the river from Ross to Chepstow.

You lately had an account of how a party of photographers were withstood by a sexton, who sought to protect his church from the attack of other lenses than those of his employer; but as a set-off to this, let me give due credit to the clerk of Ross church, who received with enthusiasm the suggestion that the view from the tower ought to be photographed. Not till I had carefully adjusted the camera upon the edge of the parapet did he come up to inform me that this very identical spot had been hallowed by the camera of the great Bedford. "There, sir," said this excellent servant of the church, in awe-struck tones, "there was where Mr. Bedford took his views." This was the first time I crossed this gentleman's trail, but during the remainder of my little tour I found myself continually following him. Let me say that whether from the pleasant impression left by his behaviour, or from some other cause unknown, the photographer is well received just now in the valley of the Wye. Perhaps the inhabitants think we are all as clever as Mr. Bedford. At all events, I shall be careful not to undeceive them by sending any of my own pictures into the country.

Those of my successors who decline to clamber up the narrow (very narrow) staircase of the tower will probably take the south-west view of the church, a view which, it is hardly needful to remark, will best be taken in the afternoon. If they like interiors, they will find excellent subjects within the church, notably the monuments of the Rudhalls. I felt that my excellent friend the clerk was a little disappointed because I could not spare a plate for them, so I hope some reader of this will make up for my remissness. The market-house (two hundred years old) is curious, if not specially beautiful, and there are other bits in the town capable of being made into pictures; but the hurried photographer will probably reserve his plates for the country outside. From the meadows just below the town several good views can be taken. So well recognized a fact is this, that the old boatman whom I engaged to convey me and my traps about seemed almost hurt when I told him the points to which I wished to go. He gave me to understand that he knew the proper places, and that he was of course going to take me there. The ruins of Wilton Castle are just out of the town, and the best view of them appears to be from the other side of the river, and here the morning light would be required.

The time-honoured way to see the Wye is by boat, but the railway which has been open for some few years has greatly lessened the number of travellers by water. This same railway, too, has by no means increased the beauties of the scenery, for, except when it disappears into a tunnel, or cuts off a corner, it seems to follow the river all the way. I went from Ross to Monmouth one day, and from Monmouth to Chepstow the next, by river all the way, but I am not sure that I should recommend anyone who is anxious to secure many views of the river to adopt this plan for the second half of the journey. The Wye, before reaching Tintern, becomes a tidal river, and during most of the second day's journey it is not easy to get ashore with the camera; still there is much beautiful scenery that would be missed by rail, and I should be inclined to try the road.

The two principal objects of interest during the tour are Goodrich Castle and Tintern Abbey. The former is easily accessible by river, rail, or road from Ross, the latter from Monmouth or Chepstow. Either ruin might well occupy a photographer for a day, and would justify the expenditure of as many plates as his carriers will hold. I managed to re-charge my dark-slides at the little inn of Lydbrook (between Ross and Monmouth), and it was with fear and trembling that I developed two of those thus treated; but changing plates in a small cupboard in what is darkness to the eyes, but may be light enough to fog, is unsatisfactory work. I was sorry I had not provided myself with some sort of changing box or bag, which could, of course, easily have been conveyed in the boat.

Monmouth Castle, and the curious old bridge with a gate on it, should not be neglected, and a fine view of the town may be got by crossing the Monnow river into the "Castle Fields." This view is from the N.E. Chepstow Castle also, as you approach it from the river, deserves a plate. By spending a day at Monmouth, Raglan Castle may be visited, but as I did not go there I cannot say much about it.

It will be evident to the meanest comprehension that the above notes are the result of nothing more than a hurried scamper through the country, but perhaps they may induce others to thoroughly go over the same district.

RECENT ADVANCES IN PHOTOGRAPHY.

BY CAPTAIN W. DE W. ABNEY, R.E. F.R.S.*

I have already shown you the example of a production of a positive from a negative, having previously to that demonstrated the production of a negative from a positive. I wish to commence this evening by showing you the productiou of a positive picture from a positive picture; not that there is anything essentially novel in it, but it points to a moral to which I shall preseutly have to draw your attention. What I propose to do is, to take some sensitive iodide paper, expose it to light, and then soak it in a weak solution of potassium bromide, and next expose it behind a positive on glass. On developing, I think, the probabilities are that we shall get a positive picture. It is perfectly immaterial, as I am going to expose it to light, whether the paper sees the light now or not, and the small modicum of light we have here will make very little differeuce to this comparatively insensitive paper. [The paper was shown to the audience.] I now burn a small quantity of magnesium wire, in order to fully expose the sensitive surface. If I were to put a developer on that paper as it is now, it would at once blacken. Instead of applying the developer, I will place it in the solutiou of potassium bromide, then expose it under a transparency, and subsequently develop it. I will give it rather a prolonged exposure, for this paper is not very sensitive, aud, of eourse, the time in which this positive is produced depeuds on the sensitiveness. [A lantern image was thrown ou the paper.] Half a minute with this light would be sufficient, but, for safety's sake, I will give twenty seconds longer. I will now develop the picture with ferrous oxalate, and a positive instead of a negative appears, as it would do in the ordinary way. In other words, the lights are reversed.

Before I draw any conclusion as to this, I will show what part of the spectrum produced this positive picture, because this is an important item in the deductiou I shall have to draw. I will take another similar piece of paper, and throw the spectrum upou it. You will recollect that we applied a solution of bromide of potassium to an exposed piece of paper, aud that it was theu exposed to the image. I will, therefore, expose this second piece of paper to the light from the magnesium wire, as before, and immerse it in a dish in which there is a solution of potassium bromide, and place it in the spectrum. I leave it to be acted upou for about half-a-minute. This I propose to develop on the screen, so that you may see absolutely the part of the spectrum which affects the paper. If everything goes right, there ought to be a bleaching action in the blue rays, and the red rays also will exert a bleaching action if the exposure is continued for some time. I am not going to enter into that part of the subject during my lecture, as it will carry me into too much theory; I simply want to show you the practical result of bromide of potassium on an exposed paper. On developing, you see we have the bleaching action caused by that portion of the spectrum which I mentioned.

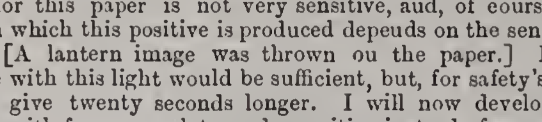


Fig. 1.

Now, if you will allow me, I will point the moral. These may seem paltry experiments to bring before an audience; but those of the audience who aro interested in gelatine plates—and I believe there are a great many here who are—will now, perhaps, be able to draw an inference equally well with myself. All gelatine plates, without exception, I believe, are prepared with an excess of soluble bromide, and I will now ask you to consider what happens, supposing any bromide is left in the film. While the light is acting on the film, the bromide of silver is decomposed and, at the same time, the bromide of potassium (or ammonium) is also being decomposed, and undoing the work that the light has done upon the bromide of silver; so that you see that the sensitiveness really got by gelatine plates with an excess of soluble bromide is only the difference between the effect of the light on the silver bromide, and on the bromide of potassium (or ammonium). I think those two experiments ought definitely to settle that gelatine plate makers have not, as yet, obtained the highest sensitiveness possible, simply because they prepare their emulsions with an excess of soluble bromide. I may say, with reference to this, that Dr. Eder has recently shown that on immersing gelatine plates in a weak solution of silver nitrate (in which there is a little citric acid), though stroug enough to neutralize any soluble bromide which may be left behind, an increase of sensitiveness—two or three-fold—is produced. The problem to be solved by gelatine plate makers is this: how to get rid of any possible excess of soluble bromide in their gelatine films. When they do that, no doubt they will get more rapid plates even than they have done at present. I hope the effect on the minds of the audience of these two experiments will not be thrown away, as now you have seen that the same rays which act upon the silver bromide act upon the potassium bromide. I will now show on the screen those interested in the chemistry of the subject the formula which represents the action which takes place:—

$$(1)\quad 2Ag_2I + 2KI + H_2O + O = 4AgI + 2KHO$$
$$(2)\quad 2Ag_2Br + 2KBr + H_2O + O = AgBr + 2KHO$$

In the first equation (1) we have silver iodide, but a similar formula (2) applies to bromide of potassium and bromide of silver. In 1 there is sub-iodide of silver, iodide of potassium, water, and oxygen, and that forms iodide of silver, potash, and iodate of potassium. When you have more iodine or bromine liberated, we get—

$$(3)\quad 6I + 6RHO = 5KI + KIO_3 + 3H_2O$$

or the iodine aud potash combine, and form fresh potassium iodide, water, and iodate of potash. When this reaction is finished, we have to go back to the equation (1), and the samo decomposition is repeated. The oxygen, of course, is a crux; where does it come from? It comes from the air. It will find its way through the gelatine. Gelatine is not impervious to the air. Dr. Eder has very recently found that this reaction does not take place when there is no oxygen present. So that you see, in order for this reaction to take place, there must be oxygen obtainable from some external source. If you prepare your emulsiou with hydrochloric acid, as some do, you have nitric acid left in the film, and that will supply the necessary oxygen for this formula to take effect. I need not enter into details of what takes place with the nitric acid; it is sufficient to say that the nitric acid will supply the oxygen.

This leads me next to consider what causes the destruction of the photographic image. You may destroy the image on a photographic plate, or photographic paper, by any substance which will readily part with oxygen. You can destroy it, for instance, by bichromate of potash; you can destroy it by any of the ferric salts; or you can destroy it by oxygen-yielding substances, like permanganate of potash; ozone, per-oxide of hydrogen, or hydroxyl; in fact, there is hardly any substance which will part with oxygen which will not destroy the developable image; the photographic image remains behind, as a rule, though not always, but these reagents prevent it becoming developable. Here is paper prepared with bromide of silver, which has been already exposed behiud a negative. After immersion in water, I propose to apply to it some of theso destructive agents which I have already mentioned. First, I will give it a streak of bichromate, next ferric oxalate, and next permanganate of potash. If everything goes right, on those parts to which these solutions have beeu applied the image will be destroyed, or almost destroyed, and a little longer application of the solution would entirely destroy it. I now develop; part of the image appears, and you see those parts which have been brushed over with the above solutions entirely refuse to appear. This demonstrates, then, that oxidising agents will destroy the developable image.

Now, I do not wish to detract from any developer, but this shows you the care you should take in seeing that your ferrous oxalate developer is tolerably fresh, for if you have a large pro-

* Continued from page 509.

portion of *ferric* oxalate present with it, it will be very liable to "slow" your plates, and those who are photographers will know what that means. If you take your pyrogallic acid which has been fully oxidised you will find that it will play you the same trick as this ferric oxalate does, so that neither the ordinary alkaline developer nor the ferrous oxalate developer is certain to give you the best results unless it is fresh. Photographers! take warning, and when using a ferrous oxalate developer, use it fresh. If you use the ferrous-citro-oxalate which I have introduced so often to your notice, you get the same result; it has the same bad qualities that the ferrous oxalate has.

I now come to the one other destructive agent of the photographic image, and that is bromine; and while I am on the subject, I should like to show you a neat way of exposing a transparency. It is not mine, and, therefore, I can praise it. Through Mr. Bolas's kindness I have here a phosphorescent plate made with calcium sulphide, which I propose to expose to light, then to use it as a source of illumination for obtaining a transparency. I now expose the phosphorescent plate to the light from magnesium wire, and then, placing it over a negative behind which is a sensitive plate, expose for 30 seconds. I next take a little bromine water, and brush it across the exposed sensitive plate; I rinse with water, and develop with ferrous oxalate. As I showed you in a former lecture, the ferrous oxalate is a very fair medium for cutting off the radiations which affect a bromide plate, and so I can develop it before you. The image begins to appear, and by degrees we have the image pretty perfect, except that, where the bromine has acted, there the image is totally destroyed, or very nearly so. This is a very simple experiment, but I did it for the purpose of leading you to another important point with regard to gelatine plates. Most of you are aware that when you have a pure bromide plate it is very easily reversed, as they call it; that is to say, instead of a negative there is a tendency for it to become a positive. The reason of that, I think, will be found in a measure in the experiment which I have just showed you. When you expose a bromide plate to the effects of light, anybody who has at all a keen sense of smell will perfectly well know there is some substance liberated which is somewhat pungent, and it will be found that it has a smell of bromine. If, therefore, you expose a plate for a considerable period—longer than it should be, that is to say—to light, what is the first effect? The first effect is for the bromide to be decomposed at the surface, and bromine to be liberated in a gaseous state, part of it ascending into the atmosphere, and part of it having a tendency to go down into the film. As the light penetrates still further, the energy of the radiation will split up the bromide below into bromine and sub-bromide, and so on, and the part beneath the first part will be passed over by bromine liberated from the molecules immediately below; so that, by a continuation of this emission of bromine, you get, first, the top practically saturated, as it were, with the bromine from the lower particles, and, as we have just seen, when you have bromine applied to a plate that has been acted upon by light, it destroys its developable powers—in other words, it forms fresh bromide of silver. If such is the case, you ought to have a reversal of the image at the top at the plate, and non-reversal, probably, at the bottom. I think I can show you this in the lantern. I exposed two gelatine films, such as are prepared by Mr. Stebbing, behind a plate which is prepared with squares of different thicknesses of coloured gelatine; that is to say, it allows different gradations of light to pass through. On these graduated thicknesses of gelatine are painted opaque numbers. No. 1 shows the thinnest amount of gelatine, and No. 25 shows the thickest amount of gelatine. With a moderate exposure to light of a gelatine plate behind such a screen, the whole of these opaque numbers ought to appear transparent on a more or less opaque background plate, when developed and fixed.

Now I will show you an experiment demonstrating what over-exposure will do. Two of Stebbing's films were placed face to face, and exposed for a considerable time to light behind a graduated screen. The results are before you. On the film nearest the graduated screen, the whole of the numbers as far as 20 are reversed; that is, appear opaque on a transparent background. On the bottom film, except No. 1, the whole of the gradations are perfect; that is to say, there is not a reversed image at all. Thus you see that a reversal takes place in the top part of the film, and not at the bottom. That is the point I wish to bring before you. No doubt this reversing action is partly due to the bromine which passes over the molecules which lie immediately below it. Not only that, however, but, if you enter into the chemistry of the thing, you will find that gelatine will take up the bromine, as it is liberated, though slowly; and that, when bromine combines with gelatine, one of two things happen—it either replaces and liberates hydrogen, or else a molecule which has the properties of hydroxal. Either of these will combine with bromine to form hydrobromic acid, or yet another compound of bromine, which is equally ready to destroy the photographic image as bromine itself, or as any oxidising agent such as I showed you just now.

Now, before I quit the subject of oxidising agents, I should like to introduce to your notice a very remarkable utilisation of this oxidising process of photography which was proposed, and not only proposed, but carried out—there is a great distinction between the two, for we often hear propositions made by men who perhaps never have the pluck to carry them out—by Mr. Bolas. He, first of all, took an ordinary gelatine negative with proper gradations of light and shade. Then he wanted to reproduce it, so he took a gelatine plate, and immersed it in bichromate of potash, allowed the film to dry, and then exposed it to light behind the negative to be reproduced. You will see that in this exposure to light he had an oxidising agent present in his film, and that the oxidised parts were acted upon by light, leaving the other part intact, and by that means he got a reversed image. Now, he was aided by the fact that the gelatine is rendered insoluble to a large extent by bichromate of potash, but still that is not everything. On the screen is the original negative, and also the reproduced negative. These I had the pleasure of seeing manipulated at the Photographic Society. In regard to this process, we have a curious case of re-invention. We have lately had in the papers devoted to photography letters from France, in which a certain Captain Biny has been supposed to have invented this process. Across the Channel they have not the same facility for reading English, I am afraid, that we have for reading French. However, the discovery of Captain Biny's is nothing more nor less than Mr. Bolas's discovery, and I hope Mr. Bolas will put in a claim for it.

Another use of oxidising agents is to enable us to get rid of fog. If you have a gelatine plate which has been exposed to light, and so has been fogged, you can get rid of that fog by immersing it in bichromate of potash, I have here a fogged emulsion plate of which the upper half has been immersed in bichromate of potash, the bottom half being completely veiled; but you will notice how beautifully clear the top half is, where the plate has been immersed in the bichromate.

(*To be continued.*)

THE FIRST PHOTOGRAPHIC PORTRAIT.

The *Field Naturalist* contains an article, by Mr. Dudley Armytage, in which the question who took the first photographic portrait is answered in the following way.

The discovery of Daguerre was made known in France in 1839, but the first sun pictures were of inanimate objects only, and its application to portraiture was regarded as somewhat chimerical. When the news of the new discovery reached America, Dr. John William Draper, putting an ordinary spectacle lens in a cigar box, began to experiment, and succeeded easily in obtaining views from the east windows of the New York University Chapel. One day he determined to try the experiment of taking the human face, which it was said Daguerre had not yet succeeded in doing, although M. Arago had stated that he was hoping soon to overcome the difficulties.

In October or November, 1839, having covered his assistant's face with white powder, and taught him to sit still for a long while, Dr. Draper managed to get a likeness. That was the first ever obtained by the Daguerre process. In April, 1839, Professor Morse and Dr. Draper opened a primitive gallery on the top of the University Buildings. Professor Morse was at that time teacher of painting and the fine arts, and Dr. Draper was professor of chemistry in the University of New York. Thus Morse supplied the artistic element, whilst Draper attended to the scientific manipulation. The gallery was not a very elegant one—an old room was used for a workshop, and a hastily constructed shed, with a glass roof, served for an operating room—but nevertheless it was a grand success.

During the summer vacation the firm had all the business they could possibly attend to at £1 a picture. All the best known people of the city sat for their portraits. Among others, a very good picture was taken of Mr. Frelinghuysen, then candidate for vice-president. The main drawback to the business was in the fact that it was only on very bright sunshiny days that they could succeed in getting anything like a satisfactory Daguerreotype. On dark days they used to teach the art to would-be photographers, who came from all parts of the country to learn it.

Dr. Draper recorded his success in the *Philosophical Magazine* for September, 1840. This account is reprinted, with an historical note, in his "Scientific Memoirs." (London, 1878, p. 215.) From these sources and from the *New York Herald* of January 5th, 1881, we have derived the above statements.

Dr. Draper soon found that it was a mistake to suppose that no impression could result unless the face of the sitter was dusted with a white powder. Daguerre required from twenty to twenty-five minutes to take a landscape, but under the brilliant sky of New York, on a bright day, and with a sensitive plate, Dr. Draper was able to take a portrait in the course of five or seven minutes. "The chair," he says, "in which the sitter is placed has a staff at its back, terminating in an iron ring, which supports the head, so arranged as to have motions in any directions to suit any stature and any attitude. By simply resting the back or side of the head against this ring, it may be kept sufficiently still to allow the minutest marks on the face to be copied."

HYPOSULPHITE.

BY J. E. BEEBE.*

Recent experiments have convinced me that the addition of hyposulphite of soda to the oxalate developer is all that is needed to make it the most perfect and desirable developer before the profession.

Every claim made by the most enthusiastic worker of the alkaline pyrogallic developer is met with this new assistant. Softness, roundness, firmness of deposit, quickness of development, rapidity of exposure, rapid cutting, are all included in the list of its virtues.

If any of the sceptical users of dry plates will make the experiment of using the oxalate developer with the addition of this powerful accelerator, they will be compelled to admit that the dry plate can give effects that the most exacting wet-plate man will be forced to admire.

Further experimenting may change my views, or modify the formula, but at present it is as follows :—

Water	10 ounces
Hyposulphite of soda	20 grains

Try a negative with (say) one-half the time usually given to whatever dry plate you are using, and develop carefully ; then make another negative with the ordinary developer, leaving out the hyposulphite, and compare carefully shadow with shadow, and decide for yourself which has the best effect.

* *Philadelphia Photographer.*

Correspondence.

FERROUS OXALATE *V.* PYROGALLOL.

Dear Sir,—In reply to the author of the article upon ferrous oxalate in the *Autotype Notes*, his assertion of animus upon my part is absurd in the extreme. I have no object further than writing against the revival of a developer which under no circumstances will give the best possible results when good plates are used ; that it has its uses when inferior plates are in hand, I do not dispute.

The "Author of the Article" cites the work of continental photographers as being so very good, and being developed with ferrous oxalate. I would remind him that the work of English photographers is better. Let him compare continental and English work in any of the shop windows in London where pictures of celebrities are sold. Compare the work of Van Bosch with that of Bassano or the St. James Studio ; the work of one is hard compared with the other, and I know Mr. Bassano would sooner give up gelatine plates altogether than go back to ferrous oxalate.

Of course, I am aware that some people cannot see the slightest merit in English work, simply because it is English ; whilst all foreign work is good, because, being foreign, it must be so.

That I am not alone in my opinion (and experience) Mr. Burton's admirable and exhaustive article is ample evidence, and he is of opinion that ferrous oxalate cannot hold a candle to pyrogallol.

In reply to the courteous notes of Mr. Swinton and Mr. O. C. Smith, I would ask them to carefully read Mr. Burton's article, and then try ferrous oxalate side by side with, say sulph. pyrogallol, using either Wratten's, Edward's, Swan's, or the Paget plates, and I am confident the verdict will be entirely in favour of pyrogallol.

In this discussion it must not be forgotten that three or four years ago ferrous oxalate developer was almost universal in England, and a perusal of the journals of that time will give a good idea of the dissatisfaction prevalent amongst photographers with the quality of their work. A want of sparkle and difficulty in getting uniformity of results being the principal faults, that time was prolific with its suggestions for various forms of intensifying mercurial and with silver ; but until the ferrous oxalate was shelved, the days of collodion were looked back to with regret. Now all is changed : sparkle and uniform density are easily acquired, and when a negative is stored away, it is put away with confidence, and the assurance that even if not required for years it will not be spoit, like the majority of ferrous oxalate and mercurial negatives, as many photographers know to their cost.

As in England, on the first introduction of gelatine plates, pyro was the developer to be replaced with ferrous oxalate, which, after trying, was found wanting, and had to give way to pyrogallol. I have no doubt but the continental photographers will undergo the same transition, and by another year pyro will be universal, as it deserves to be.

In conclusion, I would wish to be allowed to state that the makers I name above are not the only good ones whose plates are in the market. There are at least a dozen others whose plates are first-class, and will work with pyrogallol, but for obvious reasons could not be listed.

W. T. Wilkinson.

INTENSIFYING GELATINE NEGATIVES.

Sir,—In intensifying weak gelatine negatives with mercury bichloride and potassium bromide, if the solution is used in a dish over and over again, I find when it has been used some little time it causes irregular markings, which print ; but by re-dipping a plate so marked in the hyposulphite solution such marks disappear, and after well washing, the negative can be re-intensified, and there is no trace of the previous marks. Can anyone inform me if these marks are caused by chemical action due to imperfect washing of the negative, or arise simply from weakness of the mercurial solution?—I am, sir, your obedient servant,

H. Spink.

Proceedings of Societies.

London and Provincial Photographic Association.

A meeting of the above Association was held on Thursday, the 24th ult., Mr. A. Cowan occupying the chair.

Mr. W. E. Debenham said it had recently been stated in the photographic press that prints on opal glass were likely to be much more permanent than paper prints ; but he produced a tinted opal picture taken about three years ago, and which was much discoloured (not faded) as though with dirt ; the parts most stained were those covered with the mount ; in consequence of this he now varnished every opal picture he issued.

Mr. Harrison exhibited his bijou camera, to which he had added an instantaneous shutter and a finder. The shutter was a roller one with an elongated opening, and released by a rachet and spring ; the finder consisted of small mirrors placed at an angle of 45°, so that when the eye of the operator was placed to a hole in a small piece of metal fixed in the side of the camera, the objects in the field of the lens were reflected on the mirror ; this finder was considered by those present to be a great advantage in taking instantaneous pictures of moving groups, &c., for which this ingenious little camera is designed, as it enabled the operator to appear to be looking away from the scene he wished to perpetuate.

The question was then discussed why rain drops falling on a gelatine negative destroy the intensity (in fact, act as a local reducer); and various experiments were suggested with a view of testing if this property belonged to rain water only, and, if so, under what conditions.

The Convention of German Photographers.

The eleventh Convention was held at Eisenach, commencing on the 23rd and closing on the 25th August. About eighty members of the Society assembled on the opening day, the chair being taken by the President, Mr. K. Schwier, of Weimar, who gave a very satisfactory report of the general position of the Society.

The ballot for council then took place, when the following gentlemen were elected:—

Chairman.—K. Schwier, Weimar.

Vice-President.—T. Müller, Munich.

Sec.—E. T. Rothe, Cassel. *Treasurer.*—K. Festge, Erfurt.

Council.—Carl Wunder, Hanover, and C. Kiuderman, Hamburg.

Six gentlemen were also nominated by the exhibitors out of twelve elected by the Assembly, as jurors, and these added three more to their number to complete the nine jurors for the general exhibition, whose functions further included the award of the annual prize given by Mr. Festge, of Erfurt, this prize consisting of a gold medal of the Society.

Then the exhibition of photograms contributed by about forty-five members was examined by the members and ladies, and at half-past one o'clock the festival dinner began, which lasted, with the usual toasts, until half-past three o'clock.

The projected excursion to the Wartburg was joined in by all the members, in spite of the rain, so that all again found themselves at the Restaurant of the Wartburg. At seven o'clock it seemed as if the weather would clear up a little, and an attempt was made to take the annual group picture of the "Wanderversammlung," but the endeavour failed owing to the bad light.

A concert at the Tantani kept the members together till after ten o'clock.

Next morning the annual balance sheet was read by Mr. Festge, and a discussion, with ultimate adoption of rules, for the Central Nach-weisungs Bureau (or Employment Register) began the day's work.

About midday a successful picture was taken at the Tivoli, and the afternoon was devoted to a walk which included the Marienthal, Landgrafenschlucht, Drachenstien, and back by way of Drachenschlucht, Annathal, taking a short refreshment at the Lophinau, and in the evening the gentlemen of the party held the Festkneipe at the Tivoli, which was the "Stammsitz" of all the meetings.

A lottery of objects* presented for the benefit of the Wandermapper was first taken in hand next morning, which brought in a pretty good amount to defray expenses for this purpose, and then the awards of the different juries were published, of which the results were as follows:—

(1). A gold medal, given by Mr. G. Brokesch, of Leipzig, for the best collection on emulsion plates, to Mr. Henry Schüren, of Hamburg; to which the jury added, as second prize, a silver medal of the Society placed at their disposal by the council, to Mr. Tiedemann, of Bremen.

(2). A painted background and balustrade to represent sandstone, given by Messrs. Mapmann and Finck, of Frankfort, for the best collection of direct cabinet pictures, to Mr. H. Natmann, and the jury also awarded here a second prize in the shape of a silver medal of the Society to the firm of Laura Lasinzky, of Düsseldorf.

(3). An elaborately-carved album, presented by Mr. Buslar, of Berlin, for the best collection of landscapes in cabinet size, to Mr. H. Astmann.

These prizes were awarded by three separate juries specially elected for each prize.

In the general competition, which included the golden medal annually given by Mr. K. Festge, of Erfurt, the awards were:—

Gold Medal.—Mr. L. D. Grienwaldt, Bremen.

Silver Medals.—Messrs. H. Astmann; Henry Schüren, and D. Wettern, Hamburg; Laura Lasinzky, Dusseldorf; W. Hoffmann, Dresden; and Edm. Gaillard, Berlin, for collotype.

Bronze Medals.—Messrs. Heenreich Fritz, Jun., Greiz; Flottwell, Magdeburg; Louis Held, Weimar; Emil Seelig, Cassel (amateur); Sissmann, for printing of photograms.

Diplomas.—K. Festge, of Erfurt; E. Queck, Weimar; Tellqmann, Mühlhausen; E. F. Rothe, Cassel; C. Remde, Eisenach; Tietschmann, Tauger, and Uhlemann, Dresden, for mounts; C. H. Harbus Leipzig, for photographic papers.

An excursion by carriage was attended by most of the party and brought a very pleasant and successful meeting to a close.

* Photographs are collected in maps, especially all those which obtain prizes at the annual meeting, and circulated afterwards amongst the members who wish to see them.

Talk in the Studio.

The Electric Light in Deal.—We are glad to see that photographers are availing themselves of the electric light for the display of their pictures at night. On Monday last, the evening of the Regatta, we saw the electric light in Mr. Mayland's studio—Mr. Mayland, the photographer to Her Royal Highness the Princess of Wales, has recently opened a branch establishment in Deal—the light in question taking the form of two Swan lamps, which gave a bright, yet very soft illumination. A picture of the fine transport the *Orient*, which conveyed H.R.H. the Duke of Connaught and the Guards to Egypt, was the subject under illumination, and Mr. Mayland is to be congratulated equally upon the excellence of his work, and upon the elegant manner of exhibiting it. We believe, by the way, that this is the first time Deal has seen the electric light.

The Crystal Palace.—Mr. G. Reay-Mackey, late assistant-paymaster, Royal Navy, and secretary to Admiral Rice and Admiral Luard, at Malta, has been appointed manager of the Crystal Palace; and Mr. G. G. Cleather, manager of the Scarborough Aquarium, and late secretary of the Whitby and Scarborough Railway, has been appointed assistant manager. Major Flood Page will leave for Australia in the Orient steamship *Austral* on September 7.—*Times.*

Photography in New Zealand: Prize Awards at the Christchurch Exhibition.—*Photography. First order of merit, certificates of gold medals.*—Lindt, Melbourne; Burton Bros., Dunedin. *Second order of merit, silver medals.*—Tuttle and Co., Melbourne; P. Schoureep, Christchurch; Hart, Campbell, and Co., Invercargill; J. C. Morris, Dunedin; Frith and Co., Reigate, England; Hemus and Hanna, Auckland. *Third order of merit, bronze medals.*—Frith and Co., Reigate, England; Frost, Dunedin; Caire, Melbourne; J. W. Bottomley. *Certificates of merit.*—H. William; F. G. Hawkins, West Coast; J. King, Greymouth; H. Coxhead, Timaru.

An Autographic Printing Method.—A method of reproducing an artist's drawings, which should be as effective and not so expensive as the process of wood engraving, has long been a desideratum. Mr. Crocker, of Tasmania, has invented a process that certainly promises to be successful. The *Southland Times* gives the following interesting description of the invention:—The basis of operations is common window glass—a most unlikely but perfectly reliable material to withstand the rumble and roll of modern printing machines. A solid ink, composed of beeswax, resin, and lampblack is made in proportions about which there is no secret. The drawing medium is a common steel pen, with this important adjunct, that it is constantly subjected to the action of a very tiny jet of gas, or an electric spark, which keeps the pen hot. It is inserted in the stick of ink, and its heat at once dissolves a "dip." The artist now proceeds to sketch on the glass, the fluid ink running as freely as necessary, but the instant it leaves the pen it again becomes solid, and adheres to the glass without blurring or running. As a consequence, shading of any intensity may be executed without risk of forming one big blot. The plate is now ready for an "engraver," whose hand is more potent and swift than that of any of his predecessors. This is hydrofluoric acid, a chemical well known as being about the only "eater" of glass known in practical chemistry. A small portion of this is poured over the face of the glass, and in a very short space of time eats its way downwards. The ink, however, defies the acid, and the glass below the sketch therefore remains intact. All that now remains to be done is to mount the slip of glass on a metal block of the same height as printer's type, where it is secured with a little shellac, and the engraving is ready for the printing press.

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. PIPER & CARTER, "*Photographic News" Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. PIPER & CARTER, *and crossed "Union Bank, Photographic News Co. Account."*

*** We cannot undertake to return rejected communications.

S. W. B.—You will find full directions in Mr. Ashman's paper, which was published in our issue of August 11th last.

T. BLAGROVE.—Your view of the case is certainly ingenious, but if you take the trouble to replace the initial w by the letter h, you will read the note as we intended it should be read.

AMATEUR.—1. Such a camera would prove very inconvenient and cumbersome in the field, and it would be better for you to obtain a light bellows camera. 2. The lens will answer fairly well for views, but it is extremely large and heavy when compared with modern instruments.

PRINTER.—The difficulties of the process are so considerable that but few firms practise it regularly; but success is tolerably certain to an intelligent person who is alive to the importance of apparently trivial circumstances.

BUMBLEHEAD.—There is no such compound known; perhaps nitrate of barium is intended.

CHARLES COTON.—They appear to us as if they had been exposed to fumes of sulphuretted hydrogen. Look to your drains.

DANIEL MANN.—You do not say whether you mean the so-called enamelling on paper, or the production of photographs in vitrified pigments. If the former, see p. 97 of our last volume; and if the latter, p. 241 of the present volume.

A. DRESSER.—Thanks for the pictures. That of the storm would have been very successful were not the foam parts of the negative dotted over with black specks, which of course show as clear white on the print. There are also some streaks of a similar nature, and as these defects happen to be abundant just where the spray is fine and wool-like, the picture will be valueless unless you can find some means of removing them. Possibly you might touch them out on a print, and then re-photograph this.

F. N. HAMILTON.—Leave rather more wax on the plate than you have been accustomed to do; but when a plate has been in use for some time, a very small trace of wax is sufficient.

HALL AND SON.—Purely a matter of business, and the price depends on quality. No doubt you could obtain them for half or double the price you name, and yet obtain equally good value for your money in either case.

ANXIOUS.—The picture must be taken with a light background; and after the print has been sufficiently exposed under the negative, all you have to do is to mask the required portion with a reversed vignetting glass (opaque centre), and expose until the required depth of tint is produced.

B. J. G.—Hard water is decidedly better for the purpose, as the lime salts held in solution tend to counteract the effect of heat to some extent.

SAMUEL ALLMAN.—There must be some mistake, as the salt is nearly insoluble, a pint of water dissolving no more than three grains.

AN OLD SUBSCRIBER.—1. It will answer well provided that a little care is taken to shade the plate as far as practicable. 2. A solution of india-rubber in chloroform. 3. Not so convenient as the first-mentioned process. 4. Certainly amusing, but of but little real importance. 5. It has been out of print for some weeks.

D. G. S.—Rather strive to attach exaggerated importance to each detail than to attempt to simplify the process at the present stage of your experience. It will be time enough to do this when you have worked the method with uniform success for some months.

BELTHAL.—1. Nitrate of silver is partially decomposed by fusion, even if considerable care is exercised, traces of nitrite being formed. 2. Purchase the pure potassium iodide, as the commercial salt almost invariably contains an excess of alkali. The pure salt becomes brown, from the liberation of iodine, on exposure to light and air; but the commercial salt remains white, as the excess of alkali balances the tendency towards the liberation of iodine.

C. BERTRAND.—1. It would be an extremely dangerous experiment to try, as the highly explosive chloride of nitrogen would probably be formed. 2. Hot sulphuric acid decomposes it rapidly, hydrofluric acid being evolved.

C. TEAN.—1. Not more than one-sixtieth of a second. 2. Yes, unless the bath is nearly neutral. 3. Probably not. 4. See the Formulary. 5. Add sufficient carbonate of soda to make the solution slightly alkaline, and expose to the light. Before use, a trace of nitric acid should be added.

L. PERRIN.—Write again when you have tried the experiment referred to.

ANGLE OF VIEW.

A few weeks ago, whilst writing on the subject of the "Enjalbert" camera, we gave it as our opinion that the abuse of the power given to photographers by the excellence of modern wide angle lenses has tended to the production of inartistic photographic pictures.

The subject is one of so great importance that we now propose to treat it somewhat more fully.

We may premise our remarks by stating that, if a picture be in correct perspective, and if it be viewed from a certain point, each line or part of the picture will take the exact position on the retina of the eye that the real object took on the eye of the artist; but that this is true for one point of view only. Further, we may state that, except for the very trifling curvature of lines given by certain lenses, a photograph *is always in absolutely correct perspective.* The only reason for the appearance of want of perspective in photographs is that the point from which it is necessary to view the picture is one which no observer would by inclination choose, and is frequently one from which it is impossible to see the whole of the picture.

It is a rule with painters—not an absolute rule, for art knows none such, but very nearly so—that the angle of view included in a picture should never be greater than that which the eye is able to embrace without movement.

At first sight this appears to be almost a truism, and its application to photography seems evident; but the case is a little more complicated than it looks at a glance.

The process whereby we *see* a picture in nature is by no means a simple one. The area which the eye is able to perceive with absolute sharpness is extremely small, and even the angle through which it is possible to distinguish from at all is far smaller than is generally supposed. If we place a printed page before our eyes at a distance of about a foot, and fix our attention on one word, it will be found that without moving the eyes it is impossible to distinguish even the one next to it. The angle of absolutely sharp definition is only about one or two degrees. The angle through which we are able to distinguish form with any accuracy at all is only thirty or forty degrees, and it is this latter which limits the amount of picture which the eye is able to take in without motion. But, as a matter of fact, the eye does move whilst a landscape is being observed. Unconsciously the observer causes it to flit from one object to another, each for the moment forming the centre of a picture, and at first sight it is not evident why the same process should not be put in practice with regard to a picture including a very large angle. In other words, it appears at first sight a question why the effect of glancing from one part to another of a picture, including an angle much larger than that which the eye is capable of taking in at one time, should not be similar to that produced by glancing from one part of the landscape to another.

The reason is this. When the eye, in looking at a landscape, passes from one object to another, the plane of the picture changes, and is always perpendicular to the axis of the eye. In the case of a picture it is not so. To satisfy the conditions, it would be necessary to make a picture in which the vanishing point would change with the eye of the observer. This would occur with a photograph taken on a spherical surface, but is impossible on a plane surface.

It is necessary, therefore, that a picture may give a correct idea of the object represented, that it should take in no wider angle than that which the eye can perceive without motion, and, theoretically, it is necessary that the eye should occupy a certain fixed point, and should be directed at a certain point of the picture. Under no other circumstances will the image on the retina exactly coincide with that which the object itself would produce. Practically, of course, there is considerable latitude; but the principal object in a picture should not be so far from the point indicated—in the case of a photograph that through which the axis of the lens passes—as to cause the attention to be drawn much from it.

The practical lesson to be drawn from this is, that lenses giving a comparatively limited angle of view should be used whenever it is possible. Of course it is not necessary that a lens *incapable* of giving a large angle should be employed; but if such be used, it should never, except in very exceptional circumstances, be made to cover the largest plate which it is capable of covering.

The angle of view given by lenses is entirely governed by the equivalent focal length of the lens and the diagonal of the plate covered. It is more common, however, to take the length of the plate as the base of the triangle, and certainly it is more convenient. When a certain angle of view is talked of, a horizontal line is generally taken as the one which subtends it. The angle given by a lens of focal length equal to one-and-a-half times the length of the plate used gives an angle quite as large as the eye is able to perceive with any degree of distinctness. This is a little less than the maximum angle given by the older form of single lenses, but is much less than that which can be got with almost all modern instruments; it is, however, the greatest which should be, as a rule, included. This gives, as a focal length of lens, for a 10 by 8 plate, 15 inches; for a 12 by 10 plate, 18 inches.

So far, we have been referring entirely to landscape work; but the same rule holds good with regard to portraiture. In fact, the limitation of angle is here even more necessary than in a landscape, for the reason that, if it be exceeded, the effect is more evidently incorrect in a portrait than in a view. For portraits, the rule which, we believe, emanates from Mr. Dallmeyer, is excellent. It is to the effect that the focal length of a lens should be at least twice the length of the plate used. It must, however, be recollected that, in photographing near objects, the focal length of a lens is perceptibly increased, so that, for example, a lens which is about 16 inches focal length for a distant object, may be used for a whole plate standing figure, or for a head and shoulders on a 10 by 8 plate.

MR. PLENER'S SENSITOMETRICAL INVESTIGATIONS.

The more recent papers of Mr. Plener divide sensitometers into two groups, the first comprehending those instruments in which a constant relation (λ) exists between the amount of light transmitted by two contiguous divisions, while the second group includes those sensitometers in which a constant difference or step takes the place of the uniform relation between successive divisions.

The light-screen of Warnerke belongs to the first group, and Mr. Plener arrives at the conclusion that such an instrument always gives the same number of gradations for plates of the same character, the general conditions being of course similar, and all properly exposed plates of good quality will indicate the same number. Mr. Plener appears to regard a proper regulation of exposure and developer as a function of the quality of a plate, and a plate which is capable of depicting all gradations of tint may be called a "good plate" for our present purpose. It is therefore rendered obvious that if a plate is capable of depicting the following four tints, it must be able to depict in just gradation all intermediate tints.

1. Absolute blackness (absence of light, and therefore absence of deposit on the negative).
2. Perfect whiteness.
3. A tint infinitely near to absolute blackness.
4. A tint infinitely near to absolute whiteness.

The case is somewhat different when sensitometers of the second group are concerned, the number of gradations being variable, as it depends on the magnitude of the grades corresponding to the faintest tints.

If the constant λ of any one such sensitometer be known, together with the number of gradations given by the ideal good plate, the corresponding constant of any other sensitometer may be calculated if the number of gradations given by a similar plate is known. This will render it possible to compare the results obtained by constant relation sensitometers, whether made of sulphur, tinted gelatine paper, or any other material; and in order to save the labour of calculation, tables might be so constructed to give the required comparison without trouble.

The practical difficulties centre principally in the construction of the first sensitometer in a thoroughly satisfactory manner; and it is probable that the most accurate results will be obtained by carrying out the principle adopted by Mr. Mucklow, but slits being made use of instead of holes, as it would be easy to regulate the length of these; and by the adoption of slits several collateral sources of error would be avoided. This preliminary work once carried through, the photographer would be put to but little trouble as regards sensitometrical work; and, moreover, the total error of observation and construction should be notably less than those of most other photographic operations.

Mr. Plener further contends that with the photometer now proposed, whatever kind of light is used as a standard, the numbers expressive of relative sensitiveness remain the same, while in the case of sensitometers belonging to the first group it would be necessary to calculate special numbers for each kind of light. Notwithstanding this, the results would not vary with the character of the sensitive compound; similar ratios being obtainable with (let us say as an example) bromide or bromo-iodide plates; it being of course understood that plates of the same kind are compared together.

When plates of a different kind are compared, the case is somewhat different; but if we expose the unlike plates in question simultaneously to daylight and to a special or standard light, and then divide the respective sensitiveness obtained with the special or standard light by that indicated by daylight, we shall obtain a ratio expressive of their relative sensitiveness, which we may express by the sign a. Now a should be constant for any two kinds of plates; and after having determined the relative sensitiveness of two corresponding plates with a standard or special light, we have only to multiply these results by a. The ratio a may be regarded as composed to two factors, one of which varies with the quality of the light, and the other with the chemical nature of the light. Of course it must be borne in mind that this latter characteristic is directly related to the nature of the plates used, and to some special light taken as unity.

By-the-Bye.

PHOTOGRAPHERS BY DIPLOMA.

We have on several occasions compared the position and status of the photographer with that of a painter or author—in a word, with those who receive just that rank and pay to which their individual efforts entitle them. A painter who is simply a painter because he chooses to call himself one, has no claim to consideration any more than he who fills a few sheets of paper with scribble, and dubs himself author. It is only when one or other has produced work of intrinsic value that he begins to assume a certain position, and this position is a high one or a low one, according as the work produced is great or small. So, we contend, it is with the photographer. A man may purchase a camera and dry plates, but does not thereby have any claim to position; he has still this to win, and, what is more, he must do it all, as cricketers say, "off his own bat."

So that he is differently placed from most professional men. There is no serving one's articles, studying for a course, passing through a curriculum, or undergoing an examination. Anybody may become a "special correspondent," Mr. Archibald Forbes tells us, who can buy a bottle of ink and a pen; and anybody may become a photographer, if he can only get the tools to work with. Unfortunately, in neither case, is the aspirant very much "forarder" when he has got them. The master-work has still to be performed, if he is to make any sign, and his outfit has scarcely helped him one jot.

But if this is the case with the photographer who is his own master, it does not altogether hold good with the assistant. The photographer's aim in life is to satisfy the public, that of the assistant is to satisfy his principal; and for this reason the assistant, or operator, as he is most frequently ill-named, may well seek to secure a diploma, in order to help him on his way through life. No doubt the best diploma an assistant can produce is a good picture, but all assistants cannot do this. With time and opportunity at their disposal, they succeed after a while in showing good work, and with this most principals are satisfied; but if in the meantime they could exhibit certificates proving the possession of chemical knowledge and art training, their claims would secure still more attention. In large establishments, especially, is theoretical as well as practical knowledge essential, for it is only by thorough economy, and by keeping an intelligent eye upon improvement in manipulation, that photographic operations can be conducted with profit.

This leads us to the point we wish here briefly to discuss. Of late there have been examinations held in this country under the auspices of the Society of Arts and the

City Guilds Institute. These have been productive of much good, there cannot be a doubt; but we trust they are the pioneers only of more extended operations. The examinations are instituted by bodies having no relations with photographers in general, and are, indeed, organised for the purpose of testing knowledge in photography as a science, without any reference to the photographic profession. But in France, or rather in Paris, although we believe the system is not yet in actual working order, steps have been taken by professional photographers themselves to institute examinations having special reference to a photographer's daily work. The Syndicate of Photography in Paris is anxious that the assistant should at no very distant date be an individual possessing a diploma, this diploma being proof of intelligence in general, and a knowledge of photographic operations in particular. The examination is to be both theoretical and practical, and it has very rightly been decided that unless the candidate shows theoretical knowledge in the first place, he shall not undergo a practical examination at all.

The Syndicate proposes to grant to all who pass its examinations a "brevet de capacité," those holding it being qualified assistants. The "brevets" will be of various kinds—those which are comprehensive and denote that the assistant has proved himself capable in all branches of photography, and those given for special subjects, such as carbon printing, collotype, enamel-photography, photogravure, &c. When a candidate passes, his name is to be published in all the French photographic journals; while those abroad will also be invited to note the name, so that the assistant may be known when applying for a post outside his native country.

The "brevets" or certificates are to be of three classes, according to the manner in which the candidate has passed. Thus:—

300 to 350 marks will entitle the candidate to "fair."
350 to 450 " " " "good."
450 and above " " "very good."

But he must earn 200 marks in his theoretical examination, or he cannot proceed; the theoretical questions having reference to (1) photographic chemistry, (2) applied photograpy, and (3) photographic physics.
