CONTENTS.

THE NEW YEAR.

THE year which has just commenced should be one of noteworthy progress, if we read the signs of the times aright; as never since the Daguerrean era has the popular interest in photographic matters been so widespread and real. As an illustration of this may be mentioned the fact that popular lectures on photography have formed a prominent feature in the programmes of many institutions of a semi-scientific character, and we hear that arrangements are being made in several directions for providing elementary instruction in photography.

During the past year but few processes or methods of a decidedly novel character have been brought before the photographic world, but this circumstance has been more than compensated for by the thorough and earnest way in which details have been studied and processes improved.

The progress made in photo-mechanical printing methods last year is satisfactory, and one may fairly hope that during the coming year much may be done towards the extensive utilisation of some of these methods by publishers and others who may require large numbers of permanent photographic impressions. The issue of a practical treatise on Woodburytype printing by Leon Vidal cannot fail to cause many to attempt the practical working of this beautiful method of producing pictures which are so similar to ordinary silver prints as to be readily confounded with them by casual observers; and the circumstance that Mr. Woodbury's new method of working without the expensive and cumbersome hydraulic press is subject to no patent rights in this country will further facilitate the operations of experimenters in this direction. As regards collotypic work, which we are inclined to consider one of the most promising methods of the future, our description of certain practical details as carried out in the most important German establishments cannot fail to be of considerable value to those who are working in this country. We sincerely hope that during the year 1882 there may be a considerable advance made in the practical and commercial working of the collotypic methods; and it is to be hoped that the advantages to be gained by the use of the collotypic machine, rather than the hand-press, may be turned to account by those concerned. The fact of block or typographic printing not having made much progress during 1881 is noteworthy, but we hope that the method of casting from phototypic reliefs with the so-called Spence metal, originally proposed by us, may have an important bearing on block methods, especially as it is easy to obtain extremely sharp and perfect casts in plaster, or squeezes in wax, from the Spence metal; the former being suitable for use in the casting of type metal blocks, and the latter as moulds for receiving a deposit of electrolytic copper.

A good illustration of what can be done in the present day in the direction of plate printing is afforded by the portrait of Mungo Ponton issued with our YEAR-BOOK, this fine engraving having been produced in a very short space of time by Klic, of Vienna. During the past year we have seen a few specimens of work by Major Waterhouse's new method, the details being exquisitely fine, but the shadows somewhat wanting in vigour and pluck. The friend who showed us one of these informed us that it was deposited in about six hours by the current derived from a Gramme machine driven by a small gas engine. Here is a notable advance as regards electro-deposition, as the plate was over one-sixteenth of an inch thick, and the metal was extremely tough and good. To deposit such a plate with the old-fashioned appliances would have taken at least a week. The two examples of photo-engraving which we have presented to our readers during the past year speak for themselves.

With respect to gelatino-bromide work, we hope that during the year many modes of working which are at present but little employed may be so far improved as to come into general use. Among these may be mentioned the use of gelatino-bromide in the film form, or spread upon some such support as celluloid or fine paper; and the Warnerke process, in which a picture that has been developed with pyrogallic acid, but not fixed, is subjected to the action of warm water. Under these circumstances those parts of the film which contain unaltered bromide of silver wash away, while those containing reduced silver refuse to dissolve. As in carbon printing, the hot water should act on that side of the film which was farthest from the light when exposure took place: so a transfer of the film will be necessary in ordinary cases. The analogy between the gelatino-bromide film and sensitive bichromated gelatine goes even further, as the exposed and developed emulsion surface may be damped and inked so as to give a collotypic image. As a working process, however, this does not look practicable at present; but we hope to see useful results follow the experiments of Captain Pizzighelli, who, by treating a developed gelatino-bromide plate with bichromate, and exposing at the back, obtains a collotypic printing surface capable of yielding numerous good impressions. As details of this process have already appeared in the PHOTOGRAPHIC NEWS, it is unnecessary to now mention those precautions which must be taken in order to insure success. We hope that our readers will experiment with this process during the year; and we strongly recommend them to try the velvet roller in conjunction with Captain Pizzighelli's method.

It is much to be desired that during the year 1882 some convenient standard of light for photographic purposes should be arrived at, and that photographers may agree to the use of some screen for sensitometrical purposes which is constructed on scientific principles, and can be reproduced without any direct comparison with another standard. The principles on which such a standard screen can be made were clearly indicated in a leading article which appeared in the Photographic News during the first month of the present year; and we have every reason to think that the standard which we recommended, or something strictly analogous, will be ultimately adopted. As regards a standard light, more difficulty steps in; but we have found that when magnesium wire is burnt with suitable precautions, that much more uniform results are attainable than by the use of the ordinary standard candle; and, moreover, the bright light of burning magnesium is well adapted for use in conjunction with the standard light screen constructed on the principles which we enunciated in the article referred to.

Electric lighting for studio and for photo-mechanical work is likely to be largely adopted in the immediate future, and the secondary battery of Planté will probably be found of value as a means of storing up the current from a small battery which the photographer may keep in constant action. It is a pity that in the Electrical Exhibition at the Crystal Palace, exhibits bearing on photography are excluded, although the application of electricity to the various branches of photographic work formed a noteworthy and characteristic feature of the recent exhibition at Paris.

Considering everything, we enter on a new year with the brightest prospects, not only as regards scientific and technical progress, but also with respect to the commercial prosperity of those engaged in the numerous industries affiliated to the photographic art.

COLOUR BLINDNESS.

Intimately related as photography is with the colours of natural objects, it becomes a matter of some importance that photographers should be able to appreciate properly the colours of objects which are to be photographed. Yet it is probable that no two persons are exactly alike in their appreciation of colour, since that appreciation depends upon the physical constitution of the eye, an organ which is liable to all the imperfections of optical lenses, and which, even if naturally perfect, is under the control of that most uncontrollable portion of our bodies—the nervous system. Nervous derangement may produce temporary colour-blindness in every one. In many cases it has been proved that after prolonged nervous excitement the retinal apparatus for the reception of waves of light of medium wave-length is liable to become temporarily deranged, thus producing green colour-blindness. But whether we ascribe the defect to any structural imperfection in the eye itself, or whether it depends upon the temporary condition of the nerves, the fact remains the same, viz., that a comparatively large percentage of mankind are colour-blind to a certain degree, and that in very many cases the colour impression conveyed to the senses is altogether incorrect.

It is well known that a large number of candidates for employment on the railways are rejected on this account. Thus when, in 1876, Prof. Holmgren examined, on behalf of the Swedish Government, 266 engine drivers and other railway officials, he found eighteen of them totally unfit for railway service on this account alone.

The symptoms of colour blindness are so various that any classification of them seems almost hopeless; but a few of the more common mistakes often made by colour-blind people are as follows:—

Blue and yellow are nearly always perfectly distinguished, even in their lighter or darker tones, and are seldom confounded with each other.

Only these two colours are seen in the solar spectrum, the blue corresponding to the more, and the yellow to the less, refrangible rays. The red space is seen as yellow.

Red, although frequently identified in certain cases, is often confounded with black, white, or grey, with orange, with yellow, with green, with brown, with blue, and with violet.

Green is a colour most perplexing to the colour-blind, who generally cannot be said to manifest any definite sensation about it. It is confounded not only with red, but also with black, white, or grey, with orange, yellow, blue, violet, and brown.

Orange is confounded with yellow.

Violet is confounded with black, grey, or blue.

The cause of this variety of symptoms has been well explained. Sir J. Herschel has called the defect of colour-blindness dichromic vision, since the really colour-blind only have a sensation of two colours (yellow and blue), although they see white and black and pure grey precisely as others do.

Green, when unmixed with any other colour, would consequently be invisible to the colour-blind, and would have the appearance of grey; but the green of nature being generally mixed with yellow, they see the yellow only, darkened by the invisible-green element. In the same way, when the green is mixed with blue, they see the blue only. Violet being a compound of blue and red, would appear only as a blue darkened by the invisible red; and when the violet contains much red, this darkening may occur to such an extent as to cause a sensation of black or grey.

In the same way, all the above various symptoms may be explained by the composite character of most natural colours. We may take it as a fact that very many photographers have, in a greater or less degree, this defect of dichromic vision; and, without doubt, many mistakes are made in length of exposure by a want of proper appreciation of colour.

To see violet as grey, to confound green with yellow, and red with violet, would, in any case, tend to spoil a picture, the quality of which so much depends upon proper length of exposure. Fortunately, however, although a large number of persons have this defect in some form or another, comparatively few have it in the most severe form.

One practical truth is seen from a study of the colour-sensations experienced by the colour-blind—viz., the want of purity in natural colours; and it is the discrimination of such impurities, and the determination of actual shades of colour, in which there is such a wide-spread difference amongst different persons.

Unfortunately, many are not aware of the fact that they are colour-blind; nor is such a defect easily brought to notice without the aid of well-arranged experiments. But if photographers are liable to this defect, what must be the result if the artist also is colour-blind? Even the most scrupulous care will not improve the colour-discriminating power of the eye, if there is any physical defect in that organ with respect to any particular shades of colour. When we examine the statistics furnished by medical reports, and think of the wide-spread defectiveness in the colour sense amongst all classes of the community, we cannot but conclude that not a few, both of photographers and artists, are colour-blind. Sharp as the photographer is to detect the imperfections of his objective lenses, should he not also test the accuracy of the subjective lens—his eye?

PHOTOGRAPHING ON WOOD.

There are various known processes by means of which photographic impressions may be obtained upon wood blocks for the use of the engraver.

Wood blocks are sold of all sizes ready for use. They are quite flat and true on the surface to be engraved, and must so remain during all the operations to which they are subjected. In the event of a block getting warped it becomes useless for press-work. This is a point which photographers must bear in mind. In transferring to, or printing a photograph on the block, the wood should be uniformly wet all over, if water is used in the operation. It should also be set to dry on end, not on its back or face, otherwise it is almost certain to dry unequally and warp. The block as it comes from the maker has a very smooth surface, and, when used for drawing, must be dealt with by the draughtsman to render fit for work. It must be carefully prepared to receive the picture, in a manner which does not interfere with the engraver's work, while it facilitates the drawing.

This is done by making a paste of whiting and pumice powder. This paste is reduced to the consistency of cream, spread on the block, rubbed into the pores of the wood with the palm of the hand, and allowed to dry, so as to supply a white ground to sketch upon, and a tooth for the pencil.

As the pencil frequently requires to be used after a photograph has been printed on the block, the white gritty surface should not be dispensed with, as the conditions upon which success depends are the same whether the picture be a photograph or drawing. It is also necessary to note that there must be no film on the face of the block, either of collodion or gelatine—that is, no film that will flake off or interfere with the graver in cutting the finest lines.

The carbon process has been tried with only partial success, although we have seen some fine work cut through a carbon print. When carbon is employed, it must be in a very fine state of division, and the film charged with the smallest percentage of gelatine. Special tissue requires, indeed, to be prepared for the purpose.

The "dusting-on" or "powder" process has been used successfully; but it is difficult and uncertain in a climate so variable as ours. The best and simplest method, so far as we know, is transferring a collodion positive to wood. It has manifold advantages, and by one operation a positive of the exact dimensions required may be taken from the negative.

The collodion employed should form a tough film on the glass, and the glass plate, upon coating, should be either waxed or rubbed over with French-chalk, as recommended in the ordinary collodion-transfer process. After the transparency has been fixed and washed, it must be toned with a neutral solution of chloride of gold, strong enough to blacken the image through the glass. When the transparency is dry, it may be removed from its glass support, and transferred to the block. A weak solution of dextrine or (in preference) gelatine should be brushed over the block, and allowed to dry. The glass plate should be plunged into a trough of water rendered acid by sulphuric acid, and the film floated off the plate into the water. The film must now be turned over, the block placed in the water, and the film floated into position on the block.

The block is then withdrawn from the trough, and the superfluous water brushed away from beneath the film with a broad camel-hair brush; this secures perfect contact, and gets rid of air-bubbles. The water has swollen the gelatine up out of the pores of the wood, and brought it into contact with the film. It will be understood that, by reversing the film, the collodion side is presented outermost on the block. The block must now be dried without the application of heat by raising it up on blotting-paper edgeways. When dry, the impression should show up in black-and-white boldly on the block; but it will have a smooth, hard, glazed surface, which must be got rid of. This is done by dissolving off the collodion in a solution of ether two parts, alcohol one part.

In following out this process, no doubt technical difficulties will arise, and will have to be overcome by the operator; but the method is one with which we have ourselves succeeded in preparing blocks for the use of the engraver.

FREE SILVER NITRATE IN THE EMULSION.

BY DR. J. M. EDER.

In the number of the PHOTOGRAPHIC NEWS for the 23rd of December last (page 605), Mr. A. J. Brown describes his very interesting experiments on the behaviour of free silver nitrate in the gelatine emulsion, and he alludes to the investigations of this subject by Captain Toth and myself. Mr. Brown is correct in his supposition that the amount of free bromide present in the emulsion has an important influence on the result, my own researches under this head having a very interesting bearing on the question.

If the plate contains free bromide—that is, if the emulsion be insufficiently washed — steeping it in a weak solution of silver nitrate has very little effect, because the solution will be wholly or in part decomposed, so that no, or, at least, very little, free nitrate is present. Generally, it will be found useful to dip it in a mixture of 100 parts alcohol with ½ part of a solution of citrate of silver.* When the plates contain much gelatine, or when they are thickly coated, the silver baths must be dilute, or fog will be produced; on the other hand, thinly-coated plates, or those prepared with an emulsion containing less gelatine, must be treated with stronger baths. It is, therefore, necessary to test the degree of concentration of the silver baths before dipping the plates in them.

After the publication of my method, many complaints have been made to me from those who had tried it. Some were troubled with fog—these had used too highly concentrated baths; others found that no action at all was produced by the silver bath—in those cases the bath was too weak. A few trials will soon show when the proper degree of concentration has been reached. Favourable results are also obtained with thoroughly washed plates.

I feel convinced that free nitrate of silver acts as a sensitizer of the bromide—at least, to some extent—even though a part of the action may be due to the fact that the developer also intensifies the image.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

DISCUSSIONS AT PHOTOGRAPHIC SOCIETIES — CRIMINAL PHOTOGRAPHS—A NEW USE OF THE SOLAR SPECTRUM—FAMILY PHOTOGRAPHIC REGISTERS.

Discussions at Photographic Societies.—The papers read at the Photographic Society, and the discussions which follow, are of great value, but it may be questioned whether they would not be of more benefit if the papers were printed beforehand, and slips distributed to the members. In the case of an abstruse subject (such, for instance, as "Halation," introduced at the last meeting by Captain Abney) it is almost impossible to follow the speaker with any definite ideas when you are plunged without any warning into the middle of an elaborate subject; it is evident that the chances of being able to offer an opinion either one way or another are very small. Those who have had experience in societies will have noticed that in nine cases out of ten the discussion is more interesting than the paper, and it seems to us that facilities for discussion should be always kept in view by the introducers of subjects. To listen to a long, wordy paper is one of the most distressing things possible, especially when, as it often happens, the reader has not a good delivery. The result in most instances is a very incomplete presentment of the subject, and fogginess on the part of the audience. Much of this would be avoided if, as we have have suggested, the members were previously presented with slips. They would then come to the meeting with something like a clear notion of the subject, and would certainly enjoy the paper much more. This plan is adopted by the Institute of Chemistry, and with advantage, because in many cases it is not necessary to read the

* Citric acid	10 parts
Silver nitrate	10 ,,
Water	100 ,,

paper, and so much more time can be given to the discussion.

Criminals' Photographs.—It would be interesting to know what principle is adopted at Seotland Yard for the arrangement of the photographs of eriminals. In Paris the number of these photographs has grown to be so large that the authorities have found themselves overwhelmed with their own ereations. It is obvious that the whole utility of sueh photographs is bound up in the possibility of being able to identify a eertain prisoner with a photograph, and thus produee evidence of re-eonvietion. But what offieial, no matter how retentive his memory may be, ean retain 60,000 portraits in his mind, for during the six years sinee the rule has been in foree, the photographs have inereased to this number. The ordinary method of storing in albums certainly does not answer here, and the waste of time in searehing for likenesses or supposed likenesses is, we are assured, enormous. The *Annals de Demographie* has, however, come to the rescue of the police authorities, and suggests a classification of these portraits aeeording to those charaeteristies which may be said to remain constant. Thus, the first division would be the criminal's height, and all the portraits of men five feet being placed together, those of five feet two inehes in the same way, and so on up to six feet. Then might follow subdivisions, sueh as the colour of the eyes, the length of the foot, the shape of the head, and so forth, by which means some eertain clue would be afforded by each eriminal to be identified, which would reduee the present labour of search to a eomparatively trifling matter. In addition to this method, we would suggest whether it might not be possible to turn Mr. F. Galton's process of composite portraiture to practieal account? If it be true, as his experiments seem to show, that criminals are referrible to distinct types, the portraits of twenty or more criminals might be represented by one amalgamated portrait, whieh would possess suffieient resemblanee to any one of the twenty which has contributed to form the eomposite to make identifieation an easy task. These composite portraits are really more applieable to criminals than to any other class of society, and for this reason the faees are photographed under the same eonditions. We mean by this that in each case the ehin is elose shaved and the hair cropped, so that a eertain degree of uniformity is instituted before the work of combining the negatives is begun.

A New Use of the Solar Spectrum.—The solar speetrum has recently been made use of to show that the lower animals have the powers of vision. These experiments are very curious. Some almost mieroseopie erustaceans, common in fresh water (for instance, the daphnia or "braneh-horned water flea"), were plaeed in a well-darkened glass. A luminous speetrum was then introdueed, and as soon as the eolours appeared they beeame mueh agitated, and gathered together in the bright rays. By holding a sereen before the spectrum they were again dispersed. It seemed as if all the colours were attraetive, but they rushed the most quiekly to the yellow and green. If a rapid change were made to a violet they went away for an instant. Whilst the erowd was in the yellow a sufficiently large number appeared in the red, fewer in the blue, growing less and less in the violet. The most luminous portion of the spectrum was chosen by the daphnia, just as we ourselves should do, so that it may be fairly concluded that animals receive relatively the same impressions on the retina as more highly organised beings.

Family Photographic Registers.—If Mr. Francis Galton's suggestion, eontained in the *Fortnightly Review*, were earried out, a great impetus would be given to photographic portraiture, for whieh the profession generally would be very grateful. He remarks that the old-fashioned family Bible, which once served as a register of births, illnesses, marriages, and deaths, has disappeared, and nothing has taken its plaee. Photography, however, seems peculiarly adapted to supply what may be termed a "life history," and Mr. Galton aeeordingly advoeates the "establishment of a new form of family register, that shall contain all those notices that were formerly entered in the family Bible, and mueh more besides—namely, a series of photographie studies of the features from ehildhood onwards, together with faets that shall afford as complete a life history as is consistent with brevity. What is desired is something of this sort. In eaeh substantial family we should find a thin quarto volume solidly bound, having leaves of stout paper on whieh photographs may be mounted. Eaeh pair of opposite pages would be headed by the name of some member of the family. A double row of photographs would run down the side of eaeh page, eaeh about half as large again as a postage stamp, the one eontaining a medallion of the full faee, and the other one of the profile. Opposite to eaeh of these the events of the eorresponding period would be ehronieled. Every opening of the book would contain the photographs and events of about ten periods, five to each page, and would inelude from ten to twenty years of life history." To be of real use, however, it is obvious that the portraits should be permanent prints.

At Home.

HERR J. C. SCHAARWÄCHTER IN THE FRIEDRICHSSTRASSE, BERLIN.

A neat little office, with counter and show-cases around the room, forms the ante-ehamber of Herr Schaarwächter's studio. Herr Schaarwächter enjoys a high reputation as a portraitist—perhaps the highest in Berlin. His work, whether it is a soft vignette, or a deep and vigorously-printed study, betokens the care and assiduity of a man who loves his calling, and strives his every nerve for success. Like Luckardt, Herr Sehaarwächter poses every model himself, and employs plate after plate on a difficult subject until the sun deelines, and the model grows aweary. The photographer himself, however, seems never to tire; the interest he takes in his work keeps up his unflagging spirit. Herr Schwaarwächter's hour for ending his labours in the glass-room is two o'cloek; but it was five ere he regretfully gave baek his sitter—a tiny, blonde-haired English miss, of four or five—into the charge of her parents.

Before we leave the offiee, there is one praetical feature about it that may be reeorded, since it demonstrates what may be done in a small space towards the exhibition of pictures. There is against one of the walls a eabinet, on the inside of which are attaehed photographs of various kinds. The inside wall, you see, is not, however, the actual baek of the eabinet, for you may seize and open it—it is on hinges—and behind is displayed another show of pictures. This second back opens in like manner, and displays a third and fourth, so that the eabinet holds a large eollection whieh, while readily displayed, are within a very small compass. But the best of the arrangement is its exceeding simplicity. The false baeks, or walls, that open one after another, are all on the same hinge—or, rather,

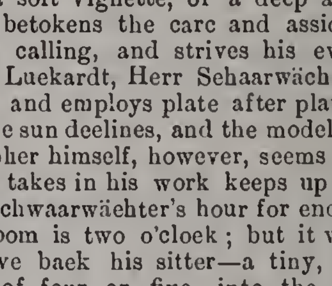

Fig. 1.

turn on the same pivot. As shown in our sketch, it is only necessary to lengthen the arm of every sueeessive hinge, in order to make one back fold over the other. Thus the outer back or flap of the cabinet, which folds over all the rest, is made fast to hinge *a*, while the next in order is fixed to *b*, until we come to the inside flap of all, which is carried by hinge *e*. With this economical means of exhibiting pictures, the customer need go no further than the little counting-house to select the kind of portrait he desires.

A handsome *salon*, the furniture covered with green velvet, serves as waiting-room, but there are few portraits to be seen here, as the visitor is supposed to have made his selection ere he penetrates thus far.

In the glass room there are several points to note. In the first place, Herr Schaarwächter has no lines or cords for the moving of his blinds or curtains. These, of blue linen, hang in very loose festoons from the roof. Brass wires run the whole length of the glass roof; they are parallel, and perhaps two feet apart. They are kept taut (this is very necessary) in the same way, pretty well, as our wire-fencing—that is, each end of wire passes over a roller, *a*, and then round a reel furnished with a cog'

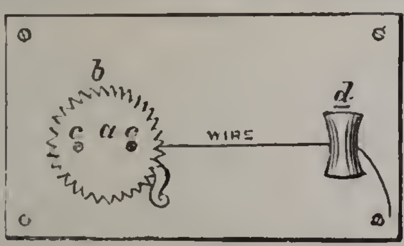

Fig. 2.

b. On the face of the cog-wheel are two holes, *c*, into which a key or winch fits, for the purpose of keeping the wire taut. The arrangement can easily be understood from our cut (fig. 2).

It is necessary that brass wire be employed, and not iron, for the latter rusts, and then loses its smoothness; and unless the wires are smooth, the curtain rings will not run upon them with ease and facility, for, as we have said, the curtains are quite loose and baggy. Here is a transverse section of the roof (fig. 3), showing how the wires

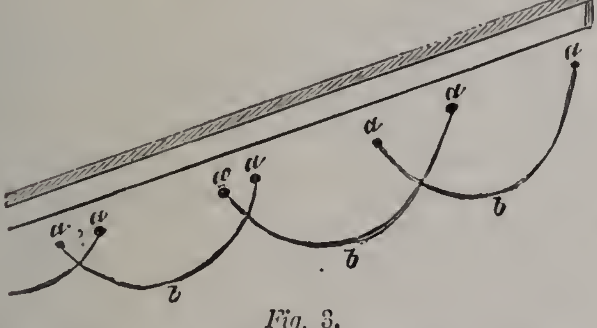

Fig. 3.

are fitted, and how the curtains are arranged. *a*, *a*, *a*, *a*, are sections of wires, and *b*, *b*, *b*, the curtains, which are so hung as to overlap one another. Herr Schaarwächter simply uses a light bamboo pole to manipulate his curtains. He pushes the curtain away at this part of the roof, or makes them cover that part. The rings on the stretched brass wire move with exceeding facility, and a more simple plan of manipulating curtains to effect light and shade cannot be conceived. "One of its advantages is that it never gets out of order," says Herr Schaarwächter, moving the blinds backwards and forwards with his pole, to show how easily they work.

The backgrounds, of which half-a-dozen hang one behind another, are drawn out for use with the same ease. The bottom of the background does not touch the floor, for the screen is suspended from above; the top is attached to two reels, which run upon a stout wire, and may thus be brought out at the back of the sitter, or pushed in again, with a motion of the hand (see fig. 4). A light and narrow skirting board is put down to cover the small pace between floor and background; or if it is an out-door scene, the join is covered by a fringe of grass, or something of the sort attached to a suitable foreground. The stretched backgrounds move out

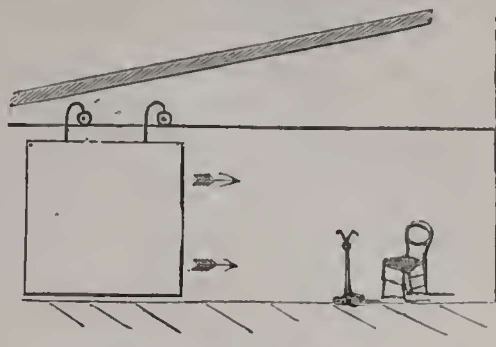

Fig. 4.

and in so easily that it is no trouble at all to change them. Most of the backgrounds are Seavey's, but one of home manufacture, representing a piece of faded tapestry, is marvellously good. Its subject was not only in keeping with many portraits we saw, but its faded neutral aspect afforded a striking contrast to the vigour and modelling of the sitter. The studio is protected from direct sunlight on the outside by an upright canvas screen about ten feet high; "but I always remove it in the winter time," says Herr Schaarwächter.

We walk into the laboratory. During the past winter Herr Schaarwächter employed nothing but gelatine plates with oxalate development; but for summer work he still prefers wet collodion, except for children. Here is an assistant washing plates and albumenising them; each sheet of glass is held under the tap, rapidly rubbed with a rag, rinsed again, and then albumenised, the solution being poured first upon one angle of the plate and drained, and then applied a second time from the opposite angle. Two whites of eggs beaten up and mixed with 8 lb. of water, to which a few drops of ammonia are added, serves for the preliminary coating of the plates.

"But I do not give up gelatine plates altogether in summer," says Herr Schaarwächter, leading us into his enlarging room. "All my diapositives are made with gelatino-bromide. A collodion positive is not only not so delicate, but it frequently exhibits a halo round the blacks, which gelatine never shows. Moreover, as enlargements all tend to hardness, while gelatine invariably tends to softness, the latter is a good counterpoise."

Herr Schaarwächter, however, although he produces small diapositives, does not make them in the ordinary way by placing negative and gelatine plate in contact in a printing-frame. He thinks you cannot control the exposure so well. He prefers making his transparency with the gelatine plate in a camera in the same way as the enlargement is afterwards made, giving a tolerably long exposure, and having recourse to leisurely development. A more satisfactory transparency is thus secured, he contends, for enlarging purposes, where it is very importpant that the utmost uniformity should exist. Herr Schaarwächter employs an enlarging apartment very similar to that we have described in our "At Home" at Messrs. Window and Grove, and elsewhere. He is wise enough to use also a horizontal bath, swinging on a pivot, for sensitizing plates, which permits of the draining of the plate so thoroughly; indeed, on the score of economy, little waste of solution, and cleanliness, this so-called Burton bath is exceedingly effective.

The printing room is an apartment fitted on one side with glass, towards which the printing-frames are turned. The frames are in tiers upon tall sloping stands, that much resemble flower-stands. The glass is not shaded, but in case the light is too strong, the stands are simply moved back—they are on a sort of tramway—two or three feet according to the judgment of the printer. The printing is said to proceed more rapidly than when a screen of tissue paper or dull glass is employed.

Herr Schaarwächter packs every negative in paper, putting half a hundred together in one pigeon-hole. Each negative is simply numbered consecutively, and a ledger describes them. If a negative is too large for the pigeon-hole, the searcher for it finds a piece of cardboard in place of the plate, and this cardboard tells the locality of the particular cliché. "I shall never throw away any of my negatives. I was thinking only the other day of clearing out the bottom row of old clichés, when I received an order for forty thalers (£6) from two or three of the portraits. As that sum represents a hundredweight or so of glass, I can look upon this old part of my stock as paid for."

Herr Schaarwächter had but just returned from a holiday on the shores of the North Sea, and he was good enough to show us a practical little outfit, made by a well-known hand —Stegemann, of Berlin—that had served him to bring back some reminiscences of his stay. To a spirit level upon his tourist camera, he attached considerable importance, for he found it one of the readiest means of levelling his camera, a point of some importance with tourists, whose small pictures have sometimes to be trimmed rather considerably to make them square. A changing box by Stegemann to hold a dozen plates, Herr Schaarwächter also pronounced to be very practical.

Just now Herr Schaarwächter is making a speciality of the Boudoir portrait; a single example of this is delivered to the customer for fifteen marks, or fifteen shillings. If he desires more afterwards, he may have a dozen for eighty marks. This plan of supplying single copies of the more expensive form of portrait might possibly be adopted in this country with advantage.

The "By-the-Bye" next week will be "On Finishing Carte Portraits." The following "At Home" will be "The Atelier Adèle in Vienna."

Notes.

We regret to hear that the conferring of the Legion of Honour upon Dr. Warren de la Rue finds that gentleman in a poor state of health. The distinction is given in connection with the recent Electrical Exhibition at Paris, but it recognises Dr. de la Rue's general claims to science, that of being an astronomical photographer being by no means the least among them.

It is likely that a professorship of photography will shortly be established in London, in connection with the City Guilds and South Kensington.

In view of the approaching marriage of the Duke of Albany, the Queen commanded Mr. Jabez Hughes to execute a series of portraits of His Royal Highness. The short, dull days of December are not conducive to good photography, but we hear that Mr. Hughes has, as usual, been eminently successful in carrying out the duty entrusted to him. Mr. Hughes evidently employed gelatine plates, for the local journal tells us the portraits were "taken by the most recent modern appliances, which permit photography to be exercised under conditions which till recently would be otherwise impossible." The sentence is little involved towards the end, but we think it must mean gelatine.

An old collodion worker writes as follows:—"In dealing with difficult subjects, I have entirely overcome halation by taking the negative on ruby glass, the flashed side next the film. Why should not gelatine workers do the same, as I am told that several satisfactory methods of stripping gelatine negatives are known?"

Accidents will happen in the best regulated journals. The illustrated newspapers have been frantic in their efforts to obtain sketches of the recent catastrophe in Vienna, and pictures of the Ring Theatre have been at a premium. One of the Paris papers succeeded in obtaining a photograph, and, setting to work, executed a wonderful woodcut showing the building, the excited crowd, the flames and all. Only, unfortunately, it was a photograph of the Stadt Theatre, and not of the Ring Theatre at all, and the Vienna public, who seem to be fastidious about such things, have been making quite a fuss over the little mishap.

But photographs of the burning Ring Theatre are also selling in Vienna, it appears, depicting the scene with great circumstance, and consequently finding a ready sale among those who have heard the wonders extolled of modern dry plates. It is needless to say they are not pure photographs; they are rather a *tour de force* of the retoucher than the photographer, being pictures of the building taken before the accident, and elaborated to meet a popular demand.

Photography has many valuable attributes, but it has also its drawbacks; and one of the latter is, that it is sadly unromantic at times. When it depicts a lovely lake scene, with some grand castle in the foreground, it will show us the chimney pots; or if a rustic maiden with her milk-pail is put before us, we notice at once that one of her boots is down at the heel.

That is the worst of photography—it won't make allowances. We have a friend who used to talk a good deal about his yacht, and beseech us to run down to Gravesend to have a cruise in it from Saturday to Monday. He doesn't beseech us any more, and for this reason. One day, in an unguarded moment, he showed a photograph of the craft; it was the picture of a mean-looking row-boat, with an extemporised mast and sail. He told us the photograph did not do justice to the little vessel, and we were quite ready to believe it, seeing the way in which the camera serves other romantic ideas; but, as we have said, he never afterwards asked us to go on a cruise.

The photographs of the Polar regions brought back by the *Alert* and *Discovery* are another instance of our art robbing a thing of its romance, for the dull stretches of half-thawed snow, and the bleak desolate foreshores that follow one another in the pictures, are simply typical of despair. One of the last examples is the series of bull-fighting scenes which instantaneous photography has recently given us. The pictures might have been better, but still the half-filled amphitheatre, the scanty performers in the area standing at a respectful distance from their foe, the clumsy-looking bull itself, though real enough in all conscience, convey no idea of the excitement and gorgeous pageantry usually connected with such displays.

In Germany they are paying attention to the chemical action of light upon liquors contained in glass bottles. It appears that whereas liquors contained in bottles of brown and green glass remain practically unchanged, even if exposed to direct sunlight, those kept in transparent bottles are materially affected by light, acquiring a disagreeable taste, and thus depreciating in quality, and therefore in value. Wine and liquor merchants are, on this account, advised to employ red, orange, yellow, green, or opaque glass bottles, and to discard colourless blue and violet ones, so as to avoid any photographic action.

"You know her?" a lady remarks in astonishment to an actress in *A Lesson*, for they are speaking of some very fashionable beauty, indeed! "Oh yes, very well," is the cool reply; "we often meet face to face, with perhaps a bishop or prime minister between us—in the photographer's window."

The camera is likely to be considered an indispensable article of outfit in the case of future exploring parties. An expedition just returned from the Spanish river in the province of Ontario reports the good news that it has discovered vast forests of pine, the trees being of wonderful growth; in some quarters the discovery appears to be treated with incredulity, but this would scarcely be the case if the exploring party had been able to confirm their story by a series of photographs.

Topics of the Day.

HOW TO MAKE A CAMERA STAND.

BY COSMO I. BURTON.

My old camera stand, which had served me faithfully for years, having finally broken down, I determined to obtain a new one. I say obtain, for on pricing them I found that I could not get such a one as I wanted under about twenty-five or thirty shillings. Not being willing to expend this sum without good reason, I resolved to make one, and I succeeded in doing this with a good deal of labour, but at a total cost of a little under half-a-crown. As I have used the stand for some time, and find it work exceedingly well, it may possibly be useful to some of the readers of the News to hear exactly how it was made.

To begin, then, at the beginning. The wood which is best for the purpose is English ash; it is not very heavy, is extremely tough, and, at the same time, tolerably easy to work, besides being pretty to look at. I do not know of any other wood which fulfils all these requirements so well as ash. Birch, for instance, is hard and tough, and when smoothly planed looks very well, but it is heavy, and also the worst wood to work that I ever came across, the grain usually running in about five different directions in any three feet of the wood; and here a word of caution: be sure that you get *English* ash—that is, not American—for though they differ very little in appearance, American ash is little better than fir wood in the all-important consideration of strength, and is much softer and easier to work than the English variety; for this reason it is very often used by carpenters instead, but it is a very poor substitute. Obtain, if possible, a piece of wood from near the root of the tree, as this is, at least, generally said to be the toughest part. The piece of wood I got was in the form of a plank about an inch and a quarter thick, and three feet long, and I ripped this up myself—a great deal of labour very much lost, for had I taken it to a sawmill they would have cut it to size in a few minutes for little or no charge, whereas cutting it with a hand-saw took several hours of very hard work. The stand I made was about four feet nine inches high; this is a little above the usual height of camera stands. Each leg was in three pieces, a lower thick one, whose dimensions were $\frac{7}{8}$-inch by $1\frac{1}{8}$-inch, and two upper thin pieces placed at each side of the lower one; their dimensions were $\frac{7}{8}$ by $\frac{1}{2}$-inch. Having sawn these nine pieces out of my plank, I planed them all carefully, then rounded the corners a little, and sand-papered them; this made them more comfortable to hold and carry in the hand, besides much improving their appearance. Then both ends of all the thin pieces and one end of each thick piece had to be rounded, and then came what I think was the most troublesome part of the whole process—that is, binding the ends of each piece with brass; it has to be done, or they would split away where the spikes of the triangle are inserted.

After a considerable number of unsuccessful attempts, I found that the following is the best way to do this:—Take a piece of thin spring brass sheet of the breadth of the end of the piece of wood to be bound—that is in this case half an inch for the small, and $1\frac{1}{8}$ inch for the large pieces, and about four inches long. Drill a hole near each end of the piece of brass, then open the jaws of a vice till they will just clear the wood without the brass; lay the brass across the opening of the jaws, and hammer the piece of wood down upon it until it closes upon the wood, then bore holes through those drilled in the brass, and screw it firmly on. If this operation is performed successfully, it should be quite tight, and the wood will never split from the end. When this is done, you have all the pieces ready to put together, which I did in the following manner, making each leg, as before described, of one thick and two thin pieces; bore a hole at one end of each piece, and another about eight inches from the same end, then take some hard brass wire one eighth of an inch diameter, or rather more, and make of it three small bolts. This can be easily done as follows: to make the head, take a small square piece of brass (a blank washer filed square does very well), drill in that a hole in which a piece of the thick wire will just fit tight; then solder it in with a spirit lamp or Bunsen burner (if the solder is good the head will never come off); then screw about half-an-inch of the bolt at the other end, and make a nut in the same way as you made the head, but screwing it, of course, instead of soldering it on. Then, to build up the legs, take the two thin pieces and one thick one, place them so that the holes at the ends of the thin pieces are opposite the hole in the thick piece, put the bolt through, and screw it up; then you have the leg in a state in which it will fold upon the slightest provocation; to prevent which another pin is put through the other set of holes, which are at the end of the thick piece, and eight inches from the ends of the thin pieces; this one may be a simple pin of thick wire; a bolt would be unnecessary.

When the three legs are built up in this way, all that is needed to complete the stand is the triangle at the top. This is best made of brass, but that is both troublesome and rather expensive, as it is necessary first to make a pattern of wood, which is a difficult bit of joiner's work, and then send it to a brass founder, and have it cast in brass. Accordingly, I made the triangle for my stand of wood, and it does very well. The wood I used was birch one inch thick, and the method of making it was thus. First make an equilateral triangle of about nine inches in the side, then cut off about two inches of each angle, and cut out the sides of the triangle in the form of the arc of a circle. The effect of this is to have what we might call three ends, to which it is easy to fix the camera legs. Bore a hole through each of these in such a way that when the triangle is laid flat the holes may be horizontal; through each hole drive a thick wire, leaving about half-an-inch projecting at each end. In order to fix the legs to this triangle, bore holes in the free ends of the two thin pieces, and fit them on to the projecting bits of wire above mentioned; then the two pieces of the leg must be pulled together a little below the triangle, and fixed there. The simplest way to do this is by means of a small hook and eye, or, instead of the hook, a screw nail, with the head projecting a little, does quite well.

Now we have the stand complete, except for the points of the legs, which must be made by a blacksmith, in the form of cones of sheet-iron to be screwed on to the legs. I have myself made such a cone of sheet-brass; but it was difficult, and not so good as a smith will make of iron for a very small charge. In speaking of the binding of the ends of the legs with brass, I recommended the use of spring brass, because for the same thickness it is much harder and stronger than common brass. The wire that is used should be of the same material. If a stand is made carefully, and following the above instructions, it should last quite as well as the best professional-made stands, and should bear a weight of more than 100 pounds. I can sit on the one I made myself, without its yielding perceptibly.

THE CHEMICAL ACTION OF LIGHT.

BY DR. J. M. EDER.*

Light promotes the oxidation of many of the resins. Guiacum resin darkens in colour under the influence of light. Powdered guiacum, or a piece of white paper stained yellow with an alcoholic solution of the resin, if exposed to the more refrangible rays of the spectrum, oxidises and becomes of a fine blue or greenish blue colour. In the red rays it is reduced, and the pale yellow colour is restored (Wollaston and Herschel). According to Becquerel, this change of yellow to blue takes place in that part of the spectrum lying between the lines H and P, the maximum of action being at M. Mastic, sandarac, and animé turn pale in the light, while gum ammoniac, gamboge, and other resins acquire a darker tint. Thin scales of asphalt are, by the action of light, rendered insoluble in a mixture of naphtha and oil of lavender, or in one of naphtha and benzine, or in oil of turpentine, or in benzole, or in petroleum ether. That part of the asphalt which originally was soluble in ether is, after the light has acted on it, rendered insoluble in the same menstruum.

This insolubility is caused by oxidation, since it does not occur either in a vacuum (Chevreul) in an atmosphere of hydrogen, or in nitrogen (Niépce), or under a closely-adhering film of collodion (Schrank). Kayser maintains that the change is unaccompanied by any increase in weight, and also that asphalt, rendered insoluble by the action of light, becomes again soluble by melting: for these reasons he concludes that the alteration is to be explained by polymerism. According to the same author, the constituent part of asphalt, which is insoluble in ether, but soluble in chloroform, is that which is most sensitive to light. Draper has shown that the whole of the visible solar spectrum acts upon asphalt. If a thin film of that portion of coal-tar which is soluble in benzine is exposed to the sun's rays, it becomes insoluble in that substance, as well as in a mixture of benzine and oil of turpentine.

According to Swan, caoutchouc is rendered insoluble in benzole and oil of turpentine by the action of light, but becomes soluble in alcohol. Caoutchouc also, dissolved in benzine, and exposed for a considerable time to the action of light and of the atmosphere, is oxidised, and the larger part of it becomes insoluble in alcohol or alcoholic ether; Eder and Toth found that this reaction took place much more slowly in the dark. The vulcanisation of rubber is effected by light in the same way as it is by heat.

To this class of reactions belongs the bleaching of many of the organic dye-stuffs, and on them depend the bleaching processes like those of wax and linen. Chevreul investigated the behaviour of various dyed fabrics under the influence of light, of the air, and of damp. He found that some of the dye-stuffs, such as indigo, archil, and safflower, in the absence of oxygen, withstand the action of light; while indigo, sulphindylic acid, turmeric, and annatto fade in the light quicker in a moist than in a dry atmosphere. The quality of the fabric—wool, cotton, or silk—is also a factor in the question of the permanence of the colour with which it is dyed. Turmeric, according to Chastaing, takes up oxygen, and bleaches under the violet or green rays, but not under the red; and A. Vogel finds that after a short exposure to light, turmeric paper is not visibly altered, but that lime water does not then produce the brown discolouration. Litmus bleaches most in the violet rays, less in the red, and scarcely at all in the dark. A change of colour is produced by light in the colouring matter of Campeachy and Brazil woods, weld (Gay-Lussac and Thénard), and barberry root; the latter substance discolours in oxygen much more rapidly than in nitrogen (Swindern). Berberin, and fabrics dyed with it, very soon bleach in the light, even when mordanted with tin; if tannin be used as the mordant, greater permanence is secured. A. Vogel found that alcoholic tinctures of violets, red carnations, poppies, and saffron, lose their colour sooner by being kept in blue glasses than in red. According to Herschel, nearly all the rays of the spectrum act upon vegetable colours, either destroying them altogether, or leaving a fainter tint produced by a second more permanent colouring material. Papers stained with colours obtained from different flowers fade soonest in the rays of the spectrum which are complementary in colour to that of the particular flower; thus yellow dyes of this kind are especially liable to fade in the blue rays, violet dyes in the green rays, and blue dyes in the orange rays. Sir J. Herschel, Mrs. Sommerville, and Mr. R. Hunt have investigated the action of the different rays of the spectrum on the dyestuffs from flowers, and Schübler and Frank their sensitiveness to white light. Dry substances dyed with vegetable colours are bleached by the action of dry chlorine gas much more rapidly in the light than in the dark (Wilson). Field and Bow have made some very complete experiments on the behaviour of the lakes and other painters' colours under the influence of light; yellow lakes, like that of Persian berries, are soon faded by the action of the atmosphere and of light—quercitron being, perhaps, the most permanent—and carmine is quickly destroyed by the light.

Chlorophyll, the green colouring matter of leaves, and its solutions, are bleached in the light, the solution in alcohol and benzol very quickly, that in ether more slowly, and that in olive oil most slowly; the rays of the spectrum absorbed by the solution act most energetically. The yellow and red colouring principles of leaves also fade in the light, and phyloxanthin especially in the blue rays.

Coal-tar colours are highly sensitive, and fade very rapidly in the light. Anilin red and chrysoidin are, as Eder and Toth have shown, especially affected by the blue and violet rays, hardly at all by the red. Abney's experiments prove that cyanin is particularly sensitive to the yellow rays, and that these rays are also the most powerfully absorbed by that substance. Hoffman's blue on starch paper fades very rapidly, but not so quickly on gelatine or albumen paper; fuchsin, anilin-green, and picric acid behave in the same way, and Bismarck brown is very sensitive. Solutions of fuchsin and alkanet red, and an alkaline solution of carmine, fade more slowly than the fabrics dyed with the same colours. H. W. Vogel has shown that a weak alkaline solution of purpurin is very sensitive to light. Anthracene blue is bleached by the sunlight three times as quickly as indigo.

According to Caprounier, the colours of a butterfly's wing fade soonest in white or violet light.

* Continued from page 609, vol. xxv.

ELECTRIC LIGHT IN PHOTOGRAPHY.

BY J. W. SWAN.

Last year I spoke of the probability of electric light coming into general use in homes and shops, and suggested that then photographers might, with very small cost, make use of it in their studios.

I have no doubt the anticipated change will come, and soon; but in the meantime it may not be without use to point out to those of your readers not to wait; that much of the trouble of producing electric light by means of the usual Bunsen cells may be avoided by using a secondary battery of forty elements, which can be coupled as one element in charging, and used in series in discharging. In this way the forty cells may be charged by two of Bunsen's cells.

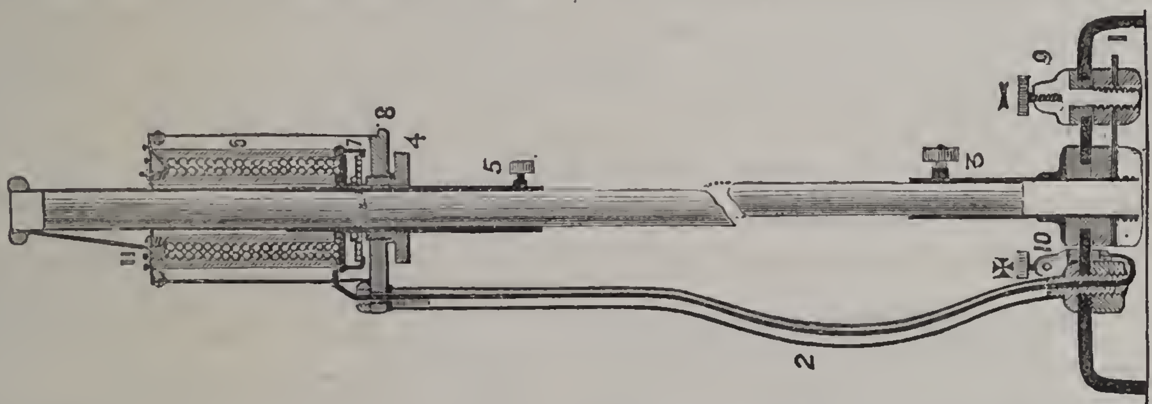
Should this plan be adopted, an electric lamp of some kind will be required, as the time during which the light acts is very short. The lamp may be of the simplest description. Two sockets to hold the two carbons, one fixed and the other to slide or screw in a tube, so that by hand the two carbons may be brought together or separate, is all that is absolutely necessary for photographic work.

For portraiture, where everything ought to go as quickly and smoothly as possible, it is an advantage to have a lamp with a simple automatic action for instantly distancing the carbons when the current is turned on by the switch.

The upper carbon should be large, and the lower one smaller and pointed. The two should not be in the same axial line; the point of lower carbon should abut against the front edge of the upper carbon, so as to produce the excavation on its point edge indicated in the sketch. The object of this arrangement is to have the whole light of the incandescent crater which forms in the positive carbon, and which is the chief source of the light thrown forward. The upper carbon is, of course, supposed to be the positive carbon.

With a lamp of this kind, the light need not be turned on until it is wanted. The turning on of the light should be effected by a strong and massive switch. In the distancing mechanism I have adopted the click action of the Brush lamp.

The following is a description of the lamp and its action.



1. Cast-iron stand.
2. Pillar supporting upper carbon mechanism, made of brass tube bent, as shown, to avoid heat of arc; the lower end is secured on to the base by means of brass bolt, screwed inside tube, and nut on the other side of base. The upper end holds the platform 4, and is fastened to it in the same manner as the base connection. A hole, large enough to admit the insulated wire, passes through the bolts at top and bottom of standard.
3. Lower carbon holder, made of brass tube, the exact size of carbon, with screw to secure it. A brass angle piece is soldered on to the lower part of holder, and insulating material—ebonite, vulcanite, or asbestos card of the shape shown—is introduced between holder and stand. The two binding screws, 9 and 10, are also insulated from the base in like manner, and connection is made between 9 and 3 by a copper plate screwed under both.
4. Brass platform, supporting electro-magnet and upper carbon holder. The brass case, covering electro-magnet, is soldered on to the platform on all sides, except where pillar is fastened. The lid of case is fastened to case with three screws, and the electro-magnet is screwed on to the lid.
5. The upper carbon holder, with set screw and ebonite top, slides freely through the regulating screw and the top of case, and is guided thereby.
6. The electro-magnet, of the type known as a cylinder magnet. The outer pole is screwed on to the inner one at the top, and two layers of insulated copper wire are wound inside.
7. The magnet-keeper is a washer of soft iron, guided by a tube soldered to it, and working upon the carbon holder. There are two brass fingers screwed on to the keeper opposite to each other, a layer of paper separating magnet and keeper.
8. Clutch is a washer with raised edge inside, split through the centre and hinged on each side of carbon holder; it is just large enough to allow the carbon holder to slide easily through it when the halves are in one plane, but the moment it is raised by the fingers on each side it grips the carbon holder. The regulating screw alters the lift given to the upper carbon; it forms a table for the clutch to rest on.
9. Binding screw, insulated from the stand, and connected with lower carbon holder by copper strap underneath stand.
10. Binding screw, insulated from stand, and connected with upper carbon holder by copper wire, with one end screwed underneath nut of binding screw; the other end of wire passing up the column to electro-magnet.
11. The flexible cord. The top end of the electro-magnet is pierced to allow of the insulated wire passing through, and one end of a piece of flexible cord, composed of a great number of small copper wires, is soldered to the wire from the electro-magnet, which projects above the cover; the other end of the flexible cord is soldered to the top of the carbon holder.

The action of the lamp is as follows:—

The current, passing up the column and through the electro-magnet to carbon holders, at once causes the electro-magnet to attract the keeper, which in its turn lifts the clutch at each side, and causes it to raise the carbon holder and carbon, the arc is established, and the current passes through the lower carbon-holder to the negative binding screw and through the battery.

The moment the arc becomes too long the electro-magnet is weakened, and the keeper, clutch, and carbon, drop, to be at once snatched up again by the re-invigorated magnet, and the arc is again formed.

When the current ceases, the keeper, clutch, and carbon drop; the keeper rests on the small shelf which is highest on the clutch, the clutch rests on the regulating screw, and the upper carbon on the lower one. It will be noticed that the lower carbon is slightly in advance of the upper one, in order that the glowing crater formed by the arc may be in front.

Both carbon-holders are open at top and bottom to allow of any length of carbon being used. The lamp is strong, and, having little mechanism, is not liable to get out of order, and it can be easily taken to pieces.

The binding screws are shown in the engraving, for the sake of clearness in explanation, out of their proper places; they should be opposite one another at right angles to a line drawn between the column and lower carbon-holder.

There is no regular feed in this lamp, as the regulations of the arc will be few, and it is not likely that one would occur during the time the lamp was used for the photograph, and even if a regulation did occur, it would be so quick as to be almost inappreciable.

CASH PAYMENTS, HOW I GET THEM.

On this subject, a lady sends us the following little drama:

SCENE—*The Reception Room of a Photographic Gallery. Assistant discovered putting pictures, &c., in order; after which she seats herself at desk.*

Assistant.—Now I wonder how this new scheme of ours of getting payment in advance will act! Pretty well, so far, certainly. In the week since the change was made only three people have objected; but that is almost too good to last, especially as we have for so many years worked on the old credit system. And a nice lot of debts we have to show for it! A customer—one of the oldest on our books, too *He* will object to paying before sitting, I'm sure. Now for the tug of war (*rises and goes forward to meet customer as he enters*). Good morning, Sir.

Customer.—Good morning. Fine day for a portrait—eh? and as several of my friends want my photograph, I thought I had better drop in on my way to the City.

Assistant.—Will you sit to-day, or have some copies from the last negative?

Customer.—That was taken six years ago.

Assistant.—Rather more than that, Sir; you've had a great many duplicates from time to time.

Customer.—Well, I think it is time I sat again. Unfair to cheat my friends by giving them a picture taken six or seven years ago—don't you think so?

Assistant.—Many of our customers are of a different opinion.

Customer.—Oh, let 'em, if they can believe anyone is deceived.

Assistant.—What style of picture did you think of having, Sir?

Customer.—Cabinet; can hardly do better, I think—eh?

Assistant.—Well, no; perhaps not, sir. You have seen the new styles, which are very popular—the Promenade and the Malvern?

Customer.—They are the long upright pictures for standing figures, aren't they?

Assistant.—They are best adapted to the full length, certainly.

Customer.—Now, if they'd introduced them ten years ago, I should have been glad; but it scarcely suits my figure *now*. I'll send my girls, though; just the thing to suit them.

Assistant.—Thank you, Sir. Then you will have cabinets —a dozen, I suppose?

Customer.—I shall probably want more, but I will see about that when I see proofs.

Assistant.—Certainly. Shall I give you a receipt, Sir?

Customer.—Receipt—for what?

Assistant (*aside*).—Now for the explosion; sit still, my heart! (*aloud*) We have made an alteration in our mode of business, Sir. You may have observed the notice.

Customer.—No, I didn't. Oh! I see (*reads*): "*We beg respectfully to intimate to our customers that we cannot in future keep open accounts. All pictures must therefore be paid for at the time of sitting.*" But what is the reason for this change?

Assistant.—Several, Sir. The principal is that we ourselves have to pay cash for chemicals and labour. Then the work of keeping accounts is very large in proportion to the sums booked. There are heavy working and post expenses incurred in sending, as we often have to do, several invoices for a trifling account. Then, again, we generally have to wait a long time for payment, and sometimes we lose altogether—perhaps not large amounts taken separately, but in total, since we have been in business, a handsome fortune.

Customer.—That must be your own fault. I am a business man, and never heard of such a thing in the City.

Assistant.—Your City businesses are different, Sir, and your customers are also different, to ours; yours keep books, ours do not; yours file accounts received, ours put them in the fire very often; yours forward the amount of account, or at least have a certain day set aside when the collector may call and get the amount.

Customer.—That may explain some, but hardly the large sum you speak of.

Assistant.—We lately kept a collector, but he found it almost impossible to collect as much money as would pay his expenses. When he went to a house, the lady or gentleman would be in the Park or visiting, or on the Continent. If at home, most probably "engaged." It is not that our customers generally had any wish to withhold the money, but, from the peculiarity of their position, it is difficult to think of it at the right moment, or for us to catch them when disengaged.

Customer.—Yes, granted all that: but why should I pay before I get the article I purchase?

Assistant.—There must be a certain amount of trust on one side or the other, Sir. We have tried giving it, and the experiment was a costly one. Now we are old and well-established photographers, and in this place all the year round we are to be found. We guarantee satisfaction with our pictures—that is, if you do not like one proof, we will give another sitting, and so on until you are satisfied: where then, the objection to pay at the time of sitting?

Customer.—But let us take my own case. I am an old customer, well known in the City, and with a tolerably big dwelling house in South Kensington. What objection can there be to trusting me? Is it worth your while to risk losing the orders of a large family by insisting on my paying money down?

Assistant.—Apart from the money loss, we should grieve to lose an old customer.

Customer.—Very well, then. Is your new rule likely to prove advantageous to you?

Assistant.—I have stated several reasons for its *necessity*, Sir. I think I might also give you another reason which may convince *you*.

Customer.—I should be glad to hear it.

Assistant.—Last year our collector called six times at your house for an account of £4 14s. 6d.

Customer.—But I was in America on business.

Assistant.—Certainly, but we did not get the money; no one had authority to pay it.

Customer (*aside*).—Had me there! (*aloud*). Well, I think I had better go and sit down. Give me a pen, and I will write you a cheque for that amount and for two dozen cabinets.

Assistant.—Thank you, Sir.

Customer.—But I don't acknowledge your argument sound, mind!

SOME EMULSION NOTES.

BY ARCHER CLARKE.

FIRST, when *liquid ammonia* is added to nitrate silver previous to mixing the same with gelatine and bromide, there does not appear the necessity to use the same degree of care as in the ordinary English plan, in order to obtain the nitrate silver in that fine state of subdivision that a spray-producer or a funnel drawn to a point gives. It is sufficient if one solution be poured into the other, and in this case equally good results follow, whether the bromide be poured into the silver, or the reverse, so long as the solutions are well stirred as the bromide of silver is formed.

Second, the supposed necessity to settle emulsion in a flat open dish is now, to a great measure, exploded. If left to set in any cylindrical vessel, either opaque or otherwise, as a salt-jar or glass beaker (even one up to five or six inches in diameter), both answer remarkably well; when thoroughly set, if some cold water be run on the top of the emulsion, and with the forefinger just loosen the edge all round, it will turn out in one piece, just like a *blanc mange*, and is then ready for breaking up and washing. To do this, the adaptation of the brawn presser, as shown by the writer at last technical meeting of the South London Photographic Society, is one of the readiest means, and a description of the same may be interesting to those who were unable to attend that meeting.

To an ordinary presser solder a fine *copper* wire gauze (sixteen to the linear inch inside the presser at the bottom), then solder a tin ring about three-quarters to an inch wide over the wire mesh, so that in looking through the presser a similar appearance is presented as in the diagram; then

to the outside fasten two metal handles, to support it over the wooden box the emulsion is washed in. If desired, a piece of fine canvas can be placed on the box before inserting the presser, and the emulsion squeezed into that; then, if a hole has been previously bored near the bottom of the box, the same will form a washing trough as well.

Third, I am inclined to modify my opinion that prolonged or excessive washing causes a thin but more sensitive plate, and put down the increased sensitiveness to the extra time the emulsion has to be left, in order to give the longer washing.

NOTES ON DEVELOPING-ROOMS, ETC.

BY SAMUEL FRY.

The persistence of error was never more abundantly exemplified than in the difficulty found in inducing photographers to work in a light room instead of a dark one. In the large majority, so dim is the illumination, that on entering from a studio or the open air, some time is required to sufficiently accustom the eyes to the gloom to discover any of its surroundings. Now the reverse should be the case. The most rapid plates made for use may safely be developed or changed in a room of which all details can be seen readily on entering, and in which the columns of a newspaper could be easily read. The counsel given to photographers, even down to the present time, by writers is seldom good. I will briefly describe what may be looked upon as a suitable developing-room for rapid dry plates. One must, of course, be guided by the construction of the room, but do not fear the window being too large. Mine is 4 ft. 6 in. high and 9 feet long, and none of it shut off. Avoid ruby glass. If it is reliable, it is so dark that, unless a very large amount is used, a dull day stops your work.

I recommend two systems, both carefully tested and known to be good—one with thin yellow tissue paper fastened up just clear of the glass, and an inner cover of Turkey-red twill. The latter can have a portion made to raise on a roller if needed. During the brightest weather in June I used the saloon of a screw steamer to change and develop in, and not in a single instance was there wanting the clear glass round the edges and in the shadows which always indicates that the light is safe. I really was very anxious till I ascertained by development that all was well, for the room was brilliantly illuminated. During a voyage on the Thames, when large numbers of most rapid plates were exposed, no sign of fog was ever found. Some people—many, in fact—paint their developing rooms black, which indicates their ignorance of one of the first principles, viz., that the reflection from a white surface, coming in through a properly-coloured window, cannot possibly acquire actinic power. The black walls make it like an undertaker's place. This yellow tissue and Turkey-red twill are capital for covering over lanterns for artificial light. All should have the means of turning on, at any moment, such a light; in dull weather, and towards evening, it is always better.

The second plan is by the means I have before described in these columns, viz., the well-known orange paper, stained by an alcoholic solution of magenta, and rendered translucent by boiled oil. This takes a capital colour, does not fade, and two thicknesses are sufficient; but the first plan is so simple, nothing more is required.

Now, with regard to developing dishes. Buy a few sheets of stout tin-plate at the ironmonger's, and have them made into dishes three-quarters of an inch deep. For 2s. 6d. I got a 12 by 10, two half-plates, and two quarter ones made. The solutions do not affect them. All the papier-maché dishes, ebonite, or gutta-percha, have a short life.

Now, with regard to developing, it is clearly shown by the closest observation that double or treble the usual quantity of bromide is a great advantage, and does not, as supposed, require longer exposure; one has also the benefit of much clearer shadows and half-tones. The longer glycerine developer is used, the more it will be liked. The action of the glycerine is to prevent deposit on shadows, and it effects a very important economy of pyrogallic acid; the additional quantity of bromide also does this. I am inclined to think that by the use of 150 grains of bromide of potassium in 6 ounces of water, with 1 ounce of ammonia, ·880 instead of 60, advantage all round is got, and great economy.

Correspondence.

HALATION.

Sir,—I beg to offer the following suggestion to prevent or diminish halation in dry or wet plates.

Place some broken pieces of common glue in a saucer or suitable vessel with sufficient water to cover it; let it remain in a warm room, protected from dust, until the glue has absorbed as much water as it will; then add to it as much glycerine (common) as water used; next heat until all is dissolved and mixed. Waxed or oiled paper may be used for a mould, turning up the edges of the paper half an inch or so all round; the mould being warmed, and the mixture poured into it while hot, it must be allowed to set and cool on a level surface. It may be coloured by the addition of dyes, &c., at the time of heating; this to be cut to the size, and used as the backing for plates during exposure. It is clean, and the same piece will serve for many plates. Being very cool, it may serve for preventing wet plates from drying too rapidly in the camera.

This preparation, *minus* the colouring matter, serves for taking numerous copies, using Judson's violet dye to write with, as in the multiplex.

Will some dry plate workers kindly try this simple backing, and state their experience? J. J. Morgan.

Proceedings of Societies.

Thursday Evenings for Photographers.

At the meeting held on Thursday, the 29th ult., Mr. Warnerke occupied the chair.

On the subject of stripping gelatine negatives from the glass without distortion or tearing, and by preference, a process that did not require plates expressly prepared, Mr. Henderson said he found a solution of alum and hydrochloric acid, if used persistently, would loosen the film sufficiently to allow of its being stripped off, but that it caused the film to be somewhat enlarged. He found that if a loosened film was immersed in a solution of bichloride of mercury and alum, it would shrink considerably.

The Chairman had found that unless the plates were prepared expressly, there was no certainty of success; he prepared the plates by rubbing them with talc or purified ox-gall, the latter by preference, and said it was not necessary to rub it on the glass, but that it might be added to the emulsion. The ox-gall he used was a purified form supplied by chemists, and not that obtainable at artist's colourmen.

Mr. HENDERSON had mixed ox-gall and alcohol, the result being a clear solution with a flocculent deposit.

With regard to the best means of cleaning off old gelatine negatives, so as to render the glass fit for re-coating,

Mr. COWAN said he used boiling water and soda.

Mr. HADDON suggested coating the faces of two plates with strong sulphuric acid, and then placing them together until all the gelatine was loosened.

Mr. HENDERSON produced a sheet of glass covered with Balmain's paint, which he proposed to use as a reflector in the dark-room, the light from a ruby lamp being allowed to fall upon the phosphorescent surface, and this reflected light to be used to work by, the lamp itself being screened.

Mr. W. E. DEBENHAM found that in a red light, paper which was of a deep red colour, such as is used for covering pill boxes, appeared to reflect nearly as much light as white, and he therefore suggested it would be safer to use, working by reflected light, a material of this colour as the reflecting surface.

The CHAIRMAN used reflected light from a red surface, and found it so safe that with half-an-hour's exposure to it he obtained no image. He used a lantern with cylindrical sides and a conical top suspended from the ceiling; the inside was painted red and the bottom glazed with ruby glass; a paraffin lamp was placed in the upper part of the lantern, and a ruby saucer was attached just under the flame to prevent any direct rays from it passing through the bottom of the lantern.

Mr. AYRES disputed the assertion made at a previous meeting that when several exposures were to be given upon a collodion plate it was necessary to expose each successive image for a considerably longer time than those preceding it.

The CHAIRMAN said that in the studio of Mr. Levitzky, in St. Petersburg, where the electric light and collodion were employed, it was found that if the light was turned on for one second, and then intermitted and another three seconds given, although only four seconds' exposure was given, the subject was as well exposed as if twelve seconds' continuous exposure had been given.

Mr. HENDERSON exhibited a camera for use when making several images on one plate; the dark slide was made to run from side to side completely through the camera, and was kept always in true register by rubber-covered wheels working behind them.

Talk in the Studio.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next meeting of this Society will take place on Tuesday next, January 10th, at the Gallery, 5A, Pall Mall East, when matters of interest will be brought forward.

PHOTOGRAPHIC MAP-PRODUCTIONS ON NOTE PAPER.—Several communications on this subject will be sufficiently answered by the following remarks. An area of the map representing about a circular mile should be reduced to a diameter of about an inch and a-half, and the negative should be intensified by the lead process of Eder and Toth. The next step is to prepare a photo-lithographic transfer and put it down on a stone; but the general photographer will find it advisable to get the operation performed by a regular photo-lithographer, several of whom may be found in London. When an order for the map-paper is received from any customer residing within the circle, the stone should be sent to a lithographic printer, who will transfer an impression from it to a fresh stone, and mark thereon the position of the customer's house; any verbal address which may be required being then inscribed.

THE PREPARATION OF OXYGEN FOR LANTERN USES.—Several complaints have been made of an impure chlorate of potassium now in the market, and the use of which is likely to lead to serious accidents, as when it is heated to the decomposing point the oxygen is liberated with almost explosive violence. This impure article not only contains notable traces of chloride of calcium, but a considerable percentage of potassium chloride and some nitre, this latter being doubtless an intentional adulteration. The oxygen obtained by heating this impure chlorate is always so far contaminated by nitrogen and oxides of nitrogen as to be ill-fitted for the production of a lime light, as under ordinary circumstances a loss of over one-fourth of the light is the result. The price at which the impure article is sold is about half what one would pay for a good commercial article. When chlorate of potassium is crystallised in well-defined and perfectly dry prismatic tables, it may generally be relied on. All chlorate in powder, or any sample which becomes damp on exposure to the air, should be rejected. Chemically pure chlorate, such as is used in fabricating certain explosive mixtures, is not necessary for the preparation of oxygen, as this costs about twice as much as a good commercial article. The following may be taken as approximate prices:—

Bad and very impure samples	...	6d. per lb.
Good commercial chlorate ...	...	1s. ,,
Chemically pure ,, ...	...	2s. ,,

To Correspondents.

OTTO PFENNINGER.—The circumstance of the spots having made their appearance even when you used other samples of gelatine leads us to suspect that the muslin used for filtering is the source of the mischief. It is an excellent plan to boil the muslin with weak carbonate of soda solution before using, taking care to thoroughly wash it afterwards in clean water.

W. J. B.—1. Very well suited for the work, provided that a moderately small stop be used, and that you do not try to cover so large an area as to show the falling off of the light at the edges of the field. 2 and 3. No.

A. HONEY.—Any general advertising agent—as, for example, Messrs. Willing and Co.—will arrange the matter for you. 2. Probably about the same as in an English newspaper.

GEORGE B. SYMONDS.—It is principally a question of manipulative skill, and short instructions would be of no value. We will devote a leader to the subject at an early date.

L. B. BUSS.—1. Write to the Secretary of the Society, at John Street, Adelphi, W.C. 2. Next week.

SAMUEL ——.—1. It is a matter of taste, and hardly admits of such a view as you seem to take. 2. Very thin and soft iron wire. 3. Not unless the most extreme care be taken. 4. We have forwarded your letter.

INTERESTED.—1. At a temperature of about 1000° centigrade. 2. You had better perform the calculation for yourself. Multiply by 9, divide by 5, and add 32.

GALVANIC.—1. One cell of Leclanche's battery will suffice, if your receiving apparatus is well constructed and carefully adjusted. 2. We think it was in the year 1856.

THOMAS PATTERSON.—In such a case it is important that all traces of lead should be absent, but the presence of a small proportion of a zinc salt would do no mischief.

B. LAMB.—A 10 per cent. solution of a hard gelatine, such as that of Coignet.

MONTANS SOILLEUX.—We would recommend you to apply to the following houses: J. Atkinson, 33, Manchester Street, Liverpool; Marion, 22, Soho Square; and Oborne, Red Lion Square.

YOUNG FERRO.—1. Two ounces of the bleached shellac is the quantity of spirit you mention. 2. Gum dammar, 50 grains; benzole, 1 ounce.

JOHN NEWBURN.—There must be some mistake. The stamps have been returned.

A. LLOYD.—A portrait lens is not very well suited for the work, as the edges of the field receive much less light than the central portions. Under any circumstances you should use a small stop. Your lens may not be a genuine "Sheppard."

LIGHT.—No light is perfectly actinic, as you seem to imagine; and all visible rays, even those of the extreme red end of the spectrum, exert a certain action on such plates as you have been working with.

C. T. GALL.—The only way to succeed is to take extreme care as regards the purity of the bath solution, to avoid dirty or dusty supports, and to drain your plates thoroughly.

M. C. R.—A microscopical investigation of the question might throw considerable light on the matter.

CORNISH LAD.—It is probable that it is the result of an insufficient washing of the prints; or possibly you may be in the habit of working the fixing bath too hard.

ELECTRIC.—The conducting power of the solution may be considerably increased by saturating it with sulphate of soda; and we have fancied that deposits of copper obtained from such a solution are tougher and better than when the sulphate of soda has not been used.

PHOTO-LITHO.—It is very little use attempting to obtain a transfer from such a negative as you send us. Not only are the lines unsharp and badly defined, but the density is so unequal that some parts of the ground are less veiled than those lines which are on the denser portions.

ONE IN A DIFFICULTY.—1. We have examined the sample of blotting-paper, and found it to contain a considerable quantity of sodium hyposulphite. 2. Boiling water partially decomposes it. 3. Write directly to the gentleman you mention.

ERRATA.—In the report of the Thursday Evenings last week, page 624, line 20 of report, for "positive," read "protective;" and in line 21, for "spirit," read "ether."

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1219.—*January* 13, 1882.

CONTENTS.

TESTING THE RAPIDITY OF PLATES.

An interesting discussion arose at the Photographic Club a short time ago, as to the effect of various conditions on the sensitiveness of gelatine plates.

The principal questions were whether any actual difference of sensitiveness arises from the use of hard or soft gelatines, and also whether any considerable slowing effect is produced by leaving an appreciable amount of free soluble bromide in the film of a gelatine plate.

The most remarkable divergence of opinion was found to exist on each of these points, and evidently in the minds of a few there was some confusion between increase in the time taken to develop, and reduction of sensitiveness.

It is one of the most curious facts in connection with emulsion work, that different experimenters working under apparently precisely similar conditions produce entirely different results. It would almost appear as if the same physical causes could produce different effects. Certain it is, at any rate, that because one person has got a particular result, it does not follow that the same result will be got by a different person following the instructions of the first as closely as he can, and probably this is the true reason for a great part of the divergence of opinion; but we believe that there is a different reason, and a more easily explained one, than this: it is the different methods used to test the sensitiveness of plates of different kinds.

The most usual method is by the use of a sensitometer of one form or another. The one which has gained most popularity is that invented by Mr. L. Warnerke, and in which a tablet divided into squares of graduated density is interposed between a standard light and the sensitive plate for a certain length of time, and the result observed after development, but before fixing. The graduated tablet may be produced in various ways. We ourselves suggested not long ago the use of sulphur in various thicknesses.

At a recent meeting of the Photographic Society of Great Britain a new sensitometer was described, wherein light, either direct or reflected, is allowed to act upon the sensitive film after passing through a series of graduated holes, no medium being interposed between the light and the sensitive film. In this actinometer one of the factors of error is possibly done away with; but it was pointed out at the meeting above referred to, that it leaves the most serious ones—namely, the difficulty of obtaining a standard light, or a standard surface of reflection—still unsolved.

It has been pointed out at various times that the indications of sensitiveness given by the sensitometer seemed to be at variance with those given by actually taking negatives, and upon the reason of this variance, which certainly does exist, we should wish to say a few words.

We shall suppose that anyone of the forms of sensitometer above mentioned be used, and that all the defects of a standard light, &c., have been overcome, we have still the fact to take into consideration that this standard light is not at all likely to be of exactly the same colour as daylight, but that it will probably contain a greater or less proportion of that colour of light, which has the maximum effect upon the films tested, than daylight has. This will be most noted if films containing iodide and those that do not be compared first by gas or candle light, and then by the luminous tablet or by daylight. It will be found that if all three have the same sensitiveness by candle light, the bromo-iodide plate will have the advantage by daylight, and still more by the luminous tablet.

It is not, however, to this that we wish to draw attention, as the subject has been often discussed before; but it is to a far greater source of error.

In reading a plate which has been exposed under the sensitometer, the only thing which is taken into account is the last figure which is visible; that is to say, the only thing which is indicated by the test is *what is the minimum amount of light which has an appreciable effect upon the plate which has been tested.* This is no doubt one of the factors which decides the sensitiveness of a plate, but it is by no means the only one. When we hold up a negative to the light to judge whether it has been sufficiently exposed, it is not merely the last limit of detail, the most poorly-lighted object which has been able to impress itself on the plate, that we judge by; it is by the whole gradation of the picture from the high lights to the deep shadows.

Let us take an example to prove what we mean. Let us take two plates, one prepared by the slow digestion method, the other by the ammonia nitrate, and test them under the sensitometer. We shall suppose that the same figure appears in each case, and that a high one, and that the development is continued until the density of the first square which represents the high light of a negative is the same.

Now, according to the usual practice, these two plates would be put down as of the same sensitiveness; but let us look a little further into the matter. Let us fix the two plates. Probably in the case of the ammonia nitrate plate it will be found that after fixing, the same figures are to be seen as before, or possibly one or two figures will be lost. With the other, however, it will probably be found that three or four figures are due.

It may be said that if this is all, it is only necessary to read the plate after, instead of before, fixing; but there is more than this. On examining the plates closely, it will be seen that in the ammonia nitrate plate the shades of density run up with comparative quickness; that in the case of the last few squares which have made their appearance, each one is considerably more dense than the one immediately following it; whilst with the other it will be found that the rise is very slow, and that several of the squares are almost imperceptible. Now it will be quite evident that these two plates, which would probably pass as being of the same sensitiveness when tested with the sensitometer, will produce widely different negatives with the same exposure. The ammonia nitrate negative would appear more exposed than the other one. Probably something nearer fair judgment of the relative sensitiveness would be got by taking a silver print from each of the plates which had been exposed under the sensitometer, and judging from the general effect produced.

Very possibly what we have just considered accounts for the fact that so many consider that they have failed to gain sensitiveness by the ammonia-nitrate method, whilst others claim to have got greater sensitiveness by it than by any other. It also possibly accounts for the divergence of opinion which, as we mentioned, exists with regard to the effect of hard and soft gelatines, and of free bromide in the film.

It may be asked, what we propose to substitute for the sensitometer? We have no substitute to offer. We would only say, use the sensitometer with discretion; remember that it is not infallible; and check your results by camera exposures. The sensitometer is invaluable and correct enough for all practical purposes for comparing plates prepared by the same formula.

Dr. Eder exposes plates for various lengths of time in the camera (the subject being a draped bust), varying the time of exposure till results as nearly as possible the same are got on plates of different makes; and undoubtedly this is an excellent plan, although it has the objection that it wastes a great number of plates; and, further, that it must give a considerable margin in the results, as, when plates of the same sensitiveness are used, exposures varying a good deal may be given, without producing negatives which are appreciably different to the eye.

PRINTING-IN SKIES AND BACKGROUNDS.

Under any circumstances double printing is an operation requiring not only artistic taste and discrimination, but also no small amount of manipulatory skill and dexterity. To follow the outline of a sky or a figure in a portrait is by no means an easy task, and even if done successfully with the cutter or the brush, the result is generally a hard-outlined production, which a casual observer cannot look on without at once perceiving that something is wrong.

Some of the best combination pictures which we have seen were made by using one silver print as a ground, and attaching portions of the other prints which may be required to build up the picture; after any required retouching has been performed, the whole is photographed in the ordinary way. An expert manipulator and skilful copyist may produce admirable results by this process; but in the hands of the average photographer it might be expected to yield unsatisfactory results.

In many instances a necessity arises for printing-in a new background to a negative, or a fresh sky to a landscape, when the above-mentioned complex method would involve too great an expenditure of time and labour, even if one were sure that the quality of the picture would not notably suffer. In such a case the vignetting method of M. Lambert may be followed with advantage, as it is rapid, and well suited for work either in carbon or silver. It involves no process involving any probability of deteriorating the general character of the pictures.

The printing frame which is to be used is placed on a retouching desk, and the lower right-hand corner is marked, after which the negative is placed in the frame in an inverted position, and pushed well home into the marked corner. Over the negative is placed a sheet of plain glass, and on this the background is carefully stopped out by means of any opaque varnish. The glass is then removed and another substituted, and on this the figure is stopped out instead of the background. Two screens are thus obtained, and if both are superimposed and pushed up into the register corner of the printing frame, no light will pass. One of the screens, let us say, that which stops out the background, is now put into the frame, and over it the negative, care being taken that both are well seated in the marked corner; after this the sensitive surface, whether dry plate, silver paper, or carbon tissue; this being also well up in the corner. The required exposure having been given, the second or figure screen is placed in position, and over it the cloud or background negative, and next the sensitive surface; all (except, perhaps, the cloud or background negative) being well up in the register corner. The second exposure is now given, and if the operation has been successful, a delicately-vignetted edge, having an extremely near resemblance to a natural outline, will be the result, as in each case a thickness of glass intervenes between the cut-off of the light and the sensitive surface.

According to the skill of the manipulator more or less parallel light may be used for printing, the frame being placed fairly out of doors, or a little inside a window.

Surpassingly perfect results have been obtained by this simple and rapid method, and we have seen a fresh sky printed into a seascape so perfectly that even a close inspection of the rigging of the vessels would hardly betray the secret, even to an expert.

HINTS ON BUSINESS—EMPLOYMENT OF TIME.

At the present time, when the art of photography may be considered as settled into the quietude of middle age, as opposed to the mad rush and unrest of its youth, following its most brilliant and promising infancy, it must often be an anxious thought to the head of a business to know in what manner he may best employ his time for the furtherance of his business—a business which depends more than most others on the judgment, taste, and ability of its promoter.

It must obviously be impossible to lay down any rule for the guidance of any one on this point, as so much must depend on the idiosyncracy of the individual himself.

Many persons have splendid ability in the management of customers, or the power of pushing business into fresh channels; some are competent book-keepers, others, again, have the artistic feeling strong within them, or the scientific knowledge of chemistry invaluable in the mechanical work of photography. So many more examples of special ability for certain work must arise to each reader's mind, that it is unnecessary to indicate any more examples here, and each one must decide for himself to what department of his business he is most adapted, and to which he should devote his talent and energy.

All of us must have felt, and most regretted, how little can be accomplished by any one person in the hours that comprise our working day; and it is therefore a necessity, if we would accomplish anything satisfactory to ourselves or progressive in our business, that we should devote our time and ability to some practical purpose, in whatever department of our business we may have decided on as most fitting. What man can hope to excel in everything in business? And to acquire complete mastery over one branch is better than frittering away time in a vain endeavour to do everything, or see everything that is done.

Frequently persons the most anxious to use their time advantageously accomplish the least, as they go from one thing to another, leaving each incomplete in their well-intentioned but abortive efforts to do everything, and their determination not to let the most trivial matter pass without their personal supervision. Those who fall into this error *may* make good servants, but never successful men of business on their own account, for not only do they accomplish little themselves, but they obstruct others in the performance of their duty, and really retard work instead of assisting and forwarding it.

What Dr. Watts has said of ideas may not be out of place here in regard to business:—"There are some persons who never arrive at any deep, solid, or valuable knowledge in any science, or any business of life, because they are perpetually fluttering over the surface of things in a curious and wandering search of infinite variety; ever hearing, reading, or asking after something new, but impatient of any labour to lay up and preserve the ideas they have gained. Their souls may be compared to a looking-glass, that wheresoever you turn it, it receives the images of all objects, but retains none."

The head of a business should be content to be the lever moving the business machine, and not strive to be every crank, and pulley of it at the same time.

Not less to be avoided is the indifference and carelessness that others display in their business relations—the men who leave everything to others, not discriminating between the painstaking and careless workers, prefering ease at the present moment to prospective benefit, and when their business is going on well relax in their personal application to it—which may have been originally the mainspring of their success—and think they have fairly earned a right to live in ease, and trouble themselves no more. The machine may be working well, but the motive power must not be withdrawn, or a collapse must sooner or later follow.

Some examples of this nature must recur to the minds of most photographers of long standing—of clever men brought to ruin commercially by this laxity in personal application to business.

The indifference of the master is frequently followed by inattention in the subordinates, although there are many whose probity and industry are not to be affected, and whose sense of duty is strong enough to keep them through all temptations. Still it is not well to trust entirely to the chance of this fortunate combination of good qualities. Successful men of business are frequently—generally, even—not so much remarkable for great ability as for knowing exactly in what that ability consists, using it to its fullest extent, and being able to discern and make use of the capabilities of others.

To the photographer especially it is desirable, having determined which department of his business is most to his taste and ability, that while keeping supervision over every part, he should in practice confine himself to that selected.

PHOTOGRAPHERS' ASSISTANTS IN FRANCE.

As our readers are aware,* the *Chambre Syndicale de la Photographie* has recently instituted in Paris an official examination for photographers' assistants, and as the regulations for the conduct of this examination cannot fail to be of interest, we take this opportunity of making them known in England.

Every candidate for the diploma of "Photographic Operator" must apply to the President of the Society for admission to the examination, stating his Christian and surname, his birthplace either in France or abroad, the establishments where he has learned and practised photography, and his titles or degrees (if any). He must also submit at least two copies of each of the works he may have published, accompanied by a certificate of character and conduct, and he must indicate the special branches of his profession in which he desires to obtain a diploma. In reply he will be informed of the days and hours when the examinations, both theoretical and practical, will be held. The examination fee, which will be returned to those who fail to get a diploma, will be 25 francs (£1).

The theoretical examinations will be held publicly in the building of the Society, and only those candidates who obtain a certain number of marks will be admitted to the practical examinations.

* See Photographic News for 30th December, 1881, p. 614.

The maximum number of marks for each subject will be 20, divided according to the following scale:—

0—Nil.
1, 2—Very bad.
3, 4, 5—Bad.
6, 7, 8—Indifferent.
9, 10, 11—Tolerable.
12, 13, 14—Fair.
15, 16, 17—Good.
18, 19—Very good.
20—Perfect.

The subjects of the exercises for the theoretical examination will be fixed by the examining board in private before the examination commences, and will be placed in sealed envelopes. Before commencing, the candidates will draw by lot the order in which they are to be examined, and then they will ballot for the exercises. When a candidate has been examined in a subject, each of the examiners will fill up a report of the manner in which the candidate has acquitted himself, and will enter on it the number and description of the exercise, together with the marks he awards on the scale indicated above. The report, having been signed by the examiner, will be placed in a sealed envelope bearing on the outside also the number and description of the exercise. At the close of the examination the reports will be opened by the examining board.

In order that a candidate can be admitted to the practical examination, he must have obtained at least 200 marks in the theoretical examination. The number of marks obtained for the exercises in chemistry and physics will be multiplied by a factor 4, and that for the exercise in the application of photography by a higher facter (say 8), and these products added together will give the whole number of marks to the credit of the candidate. No candidate will be admitted to the practical examination unless he has obtained at least six marks in each of the exercises in chemistry and physics, and at least twelve marks in that of photographing proper.

The programme of the examinations will be as follows:—

I.—For the Certificate of Ability in the General Knowledge of Photography.

1. *Theoretical Examination.*—General principles of photography. Elements of chemistry and physics as applied to this special branch of science. Different negative and positive processes.

The examining board for this examination will consist of three members, of whom one will examine the candidate in photographic chemistry, another in photographic physics, and the third in the application of these sciences to the various negative and positive processes.

2. *Practical Examination.*—The exercises for this examination will be worked by the candidates who have been permitted to compete, in the presence of the same examining board, with the addition of members specially qualified to judge of practical work in photographic printing processes, such as phototypie, Woodburytype, photographic typography both in relief and in engraving, photographic enamelling, and other special processes.

Reports will be made on the various exercises with separate marks for each, viz.—A. Negative processes on collodion, both wet and dry, and gelatine, and all the details of the different operations. (Value: 10).—B. Positive printing process in silver chloride, and all its details. (Value: 10).—C. Manufacturing processes. (Value: 6).—Each member of the board will adjudge marks separately in the exercises A, B, and C, and a total of 300 marks in this examination will gain the certificate.

Each member of the board will make a separate report on each exercise of a candidate whom he has examined, and will hand it to the chairman marked with the different letters A, B, C, and the number of marks he has awarded.

II.—For the Certificate of Ability in a Special Application of Photography.

1. *Theoretical Examination.*—The programme will be the same as that of the theoretical examination in 1, the only difference being that a minimum of 150 marks will be necessary to admit the candidate to the further examination. The number of marks to gain the certificate in any separate speciality must be at least 15 (that is to say, "Good").

2. *Practical Examination.*—The exercises in this examination will bear on the special applications selected by the candidate. In this case the diploma will indicate the speciality in which the candidate has passed.

Diplomas.

The diplomas or certificates of ability will be of different kinds; there will be certificates of ability in the general knowledge of practical and theoretical photography, as well as of particular processes. These diplomas will be signed by the members of the examining board, and countersigned by the president and secretary of the *Chambre Syndicale.* They will contain the name and birthplace of the candidate, the nature of the examination he has passed, and, if there is room, the names of the instructors of the institutions where he has learned his profession.

A total of from—

300 to 350 marks will carry the qualification	—	*Fairly Good.*
350 to 450	,,	*Good.*
450 to 500 and above	,,	*Very Good.*

This qualification will be stated on the candidate's admission letter. A list of the diplomas granted will be published and issued to all the photographic societies at home and and abroad for insertion in the technical journals.

The Society will fix the time of the examinations, and will nominate the examining boards for each examination. These boards may be composed either entirely of Fellows of the Society, or of other persons selected by the Society for their special knowledge and qualifications, or of foreigners of distinction well known in the photographic world passing through Paris; the latter will only assist the examiners in the character of experts. The president of each board will be elected by the members of that board, but he must in every case be a fellow of the *Chambre Syndicale.* It will be his duty to regulate the proceedings at the examination, and to transmit the results to the president of the Society.

The questions of the general programme of the theoretical examination will be divided among the three examiners as follows:—

Chemistry	Nos. 1 to 10
Physics	Nos. 11 to 20
Photographic applications	Nos. 20 to 30

A syllabus of the subjects on which these questions will bear will be shortly published.

The practical examinations may include any or all the different processes at the pleasure of the examiners, but the exercises will be directed to one entire process—positive and negative. In any special process, such as Phototypie, Woodburytype, or Photo-engraving, the examiner may set any exercises he pleases, and there will be no syllabus of the questions that may be asked. Candidates may work with their own chemicals and apparatus.

Any special artistic qualification in the candidate, such as a certain knowledge of drawing and painting, will enable him to obtain 50 marks extra.

The *Chambre Syndicale* reserves the right of making any alterations in the above regulations which the progress of photographic and applied science may render necessary.

Applications of candidates for the diplomas may at once be addressed to M. Lévy, president of the *Chambre Syndicale*, 113, *Boulevard de Sebastopol, Paris.*

THE GREAT ELECTRICAL EXHIBITION AT THE CRYSTAL PALACE.

FROM OUR SPECIAL CORRESPONDENT.

When acting as a Special Correspondent for the Photographic News at the Paris Electrical Exhibition, I was informed that the directors of the Crystal Palace contemplated opening an extensive exhibition of electrical appliances towards the end of the year. At the time this information gave me pleasure, although it certainly appeared difficult to imagine how the big bazaar at Sydenham could be sufficiently cleared of the nick-knack stalls, peep-shows, and other fantasies which are so familiar to us, as to make room for the heavy plant, the motive machinery for producing the thousands of horse-power force which are absolutely essential, the ranges of shafting, and the various bulky articles which must be got together in order to in the least measure represent the present advance in electric science as applied to modern industry.

Assuming that the Palace Company could not move the stalls and other trivialities aside, so as to make room for the proposed exhibition, one might think that the only possible course would be to erect a suitable temporary building in the grounds, and leave the Palace proper in the hands of its old tenants.

Although the exhibition was to have been opened in December, I heard strangely little about it; but an article which appeared in the *Daily Chronicle* on Wednesday week announced the exhibition to be actually open; and on inspecting the advertisements of the Palace Company a day or so after, I found there could be no doubt of the fact, as a notice headed "International Electric Exhibition" finished with the note—"No extra charge to the Exhibition."

Accordingly, on Tuesday last I went to see it, but after a preliminary walk round the Palace had revealed no evidence even of any preparation for the Exhibition, I began to enquire, Where is it? A policeman, who looked more intelligent than the average, was first appealed to, and he pointed to a few electric lamps at the northern extremity of the central avenue, and laconically observed, "They will be lighted up between five and seven this evening." But where is the Electrical Exhibition? "There," he curtly said, as he again pointed to the lamps, and turned aside to admit some people into a passage which may have led to a concert hall or a peep-show. "Is that, then, the only set of lights which will be in action to-night?" I again enquired. "Rather," he answered; "but those will burn for two hours, as I told you before."

The next thing was to find the general manager's office, and to make enquiries. "Mr. Grist can tell you all about it," they said; "he is in there." Mr. Grist was, however, not in there, but someone who did occupy the office told me that Mr. Grist was busy with the catalogue, and that the Electrical Exhibition occupied the great central avenue and the galleries. A careful inspection followed. Where are the motors, where are the dynamo machines, the shafting, and the belts? As the policeman had pointed to the north end of the avenue, the first microscopic examination was directed in this quarter, and then, amidst the fancy stalls, the thin end of the great Electrical Exhibition was found. A real galvanizing machine, nearly as good as any which one can see in the New Cut on Saturday night, and having a large signboard over it announcing that "Electricity is Life," was only rivalled in magnificence by a few of Messrs. Willing's well-known electric signs, in which the words are studded over with small mirrors, these being kept in motion by a contact breaker arrangement, similar to that of the ordinary electric bell. One of these was actually in action, blinking out the word exhibition. Further search revealed a stall with a variety of telegraphic instruments lent by the South Eastern Railway Company, this being of some little interest, as including objects of historical note. Magnetic clothing and pads to be worn against various parts of the body next came under my notice; these appliances, like the *Pilules Electriques* which are sold in Paris, being calculated to cure most diseases. There is, however, one noteworthy distinction: the *Pilules Electriques* were *not admitted* to the Paris exhibition, but the magnetic appliances *are admitted* to the Crystal Palace show.

Long walks among pictures, pigeons, handkerchiefs, gloves, and fancy articles lead one at last to islands where electricity has at least some indirect bearing, there being no less than three exhibits of lightning rod tops, these being moulded and bent to every imaginable form, it being evidently thought that the more fantastic the design of the top, so much greater the efficiency of the conductor.

At this stage of the proceedings an official "Day Programme" of the Crystal Palace Company is obtained, and, as it gives a list of the exhibitors to the number of fifty-seven, it becomes possible to view the articles systematically. The Rustless Iron Company show iron pipes and other fittings, which are certainly of indirect interest to telegraphic and electrical engineers; while another firm shows a case of small hand-tools, including about a dozen pairs of pincers of ordinary design, all very useful to the practical electrician, no doubt. The United Asbestos Co., the Phosphor Bronze Co., and about half-a-dozen other firms show exhibits having a somewhat remote bearing on electric science.

One of the most extraordinary features of the exhibition is the absence, as far as my own observations go, of any form of dynamo machine; this apparatus being, as is well known, the keystone of modern electric progress. There must, however, be one somewhere for working the few lights which are placed, but perhaps it is put out of sight. The dynamo machines shown in the Paris Exhibition numbered over three thousand, and almost every stage in the experimental development of this remarkable engine of progress was well illustrated. Perhaps the reason may not be difficult to find, for if your readers will refer to page 599 of your issue of December 16th last, a letter will be found which leads one to suppose that the management regard a dynamo machine as some kind of photographic apparatus; and photographic apparatus is not admitted. Even the balloon photographic arraugement exhibited in connection with the name of Mr. Woodbury appears to be a mere dummy; the balloon being hung by a string, and the portion representing a camera being apparently far too heavy for the balloon, even if this had been inflated with gas. On the table underneath were other articles, possibly the real camera; but a stout cover, securely nailed all over the top of the table, rendered it impossible for me to ascertain.

One matter of interest—a magic lantern with about twenty slides arranged on a kind of wheel so that they can be exhibited in rapid succession—is shown by Messrs. Webster and Williams, of St. John's Wood.

Although the exhibition is open, it must be understood that it is not yet as complete as the management intends to make it.

By-the-Bye.

ON FINISHING CARTE PORTRAITS.

It is not only on the subject of finishing carte portraits that we are going to speak, although we have just said as much; but on the finishing of all kinds of portraits of small size, whether they are called cartes, cabinets, promenades, Malverns, boudoirs, makarts, &c., &c. The fact that we have now so many different sizes shows plainly enough the effort made on all sides to import novelty, chic, fashion, or other attractive quality to their wares, and if only this indispensable item to a prosperous portrait business were more thoroughly understood or recognized, it would be well indeed for photographers in general. By all means let our young photographers—and old ones, too, for that matter—study and practise the principles of art, for only under these circumstances can they win a name for themselves, and secure for photography a place among the fine arts. But there is a difference, we contend, between the small portrait that is issued by dozens, and the study or genre photograph of larger dimensions. The small portrait should possess art qualities, but in the nature of things it should possess something else too; and it is this something which, on the one hand, many photographers hold to be beneath their notice, and others do not sufficiently understand.

In the carte—by which we mean all other small portraits as well, that are issued by the dozen or half-dozen—it is not sufficient to have a graceful pose, a well-lit face, vigorous contrast, and soft harmonious colouring. All these proclaim the artist, and these, if present in perfection, may sell the picture, of course, no matter how slovenly it is mounted, how devoid of neatness and elegance may be the surroundings. Unfortunately, ninety-nine photographers out of a hundred do not produce—they cannot give the time, even if they have the qualifications—carte portraits which are to be valued on the score of art alone; and there is the consideration, moreover, that their customers in the main require something beyond. Hence it is that the finishing of small portraits is a matter of so much importance.

The finished carte is, as we have before maintained in these columns, something of an object of *vertu* or *article de Paris*. We would give an English name, if we could find any so expressive. The purchaser, nine times out of ten, is not the same, as he asks for a carbon enlargement on opal, or a large study finished in chalk or pigments. In the latter case it is art alone that carries the day; in the former the customer wants some bright presentable little objects for giving away. Many people have their portraits taken once or twice a year; while they are staying at a fashionable watering-place, or are up in town for the season, they call at a studio, in which they have seen some novel and attractive little portraits, and put down their guinea or half-guinea for a dozen. If they are not regular customers of the photographer, they may argue, "Well, I meant to have my portrait taken this year, and I shall get some done like those new ones in Oxford Street:" or, again, "My last portraits are so antiquated, I really shall be taken like Matilda, upon nice black cards with gold borders," &c. In a word, the "finish" of a picture secures new customers, and this is why it is so important.

We need not insist upon such a quality as neatness in the finishing of a picture; nor need we point to the importance of making the best of a photograph, although the latter never seems to receive the attention it deserves; a defective portrait, as everybody knows can be made presentable, and a good one considerably improved, by tact and judgment in printing and mounting; yet at some studios the same hard-and-fast rule prevails as to vignetting and trimming, whatever the negative may be like. The white card mount, thank goodness! is now very seldom seen—at any rate, without a tinted or Indian border—and hence the high lights of a photograph are not made to suffer as was formerly the case. The cream-coloured mount that now almost invariably takes the place of white gives a chance to photographs with degraded lights, while the reason of black mounts being so popular is very evident: they permit the use of deep rich shadows without these appearing unusually heavy.

Much favour has been bestowed upon the large three-quarter portraits on shining ebony cards and gilt bevelled edges. Novelty has much to do with this predilection; the thick card, the handsome gold bevel, and the exquisite finish are all attractive. The portrait itself presents nothing new, and is such as any good photographer might produce; yet there cannot be a doubt that a considerable impetus has been given in portrait photography by this new style of mounting—an impetus that has nothing to do with the art of photography itself.

While, then, art must be the basis of all good photography, art alone will not make the ordinary photographer busy. He must believe also in fashion, style, elegance, chic, or by whatever term he choses to call that quality which attracts the public. The other day we called attention to some Christmas cards by Mr. W. England; the ensemble was delightful, and yet it would be difficult to say that they contained anything absolutely novel. We are all conversant with photographs upon an ivory-like basis, such as Mr. England employs, and yet the semi-transparent opaline material in his cards appeared new. There was a comparatively large surface of it, and the tasteful gilt edging contrasted possibly with its translucent character. Then, again, the pigments of the little coloured photographs seemed to acquire transparency too, although the result was obtained by simply attaching a paper print to the gelatine surface. The finished picture, besides its pretensions towards art, was chaste, elegant, and attractive; and we feel certain that if Mr. England can only supply his charming little miniatures fast enough, there will be a considerable sale of them.

Reutlinger, of Paris, was one of the first to thoroughly understand the importance of studying fashion in the matter of small portraits. He it was who was so successful in the preparation of glazed and medallion pictures, and in the printing of fancy borders around the portrait, so that the high lights did not suffer by juxtaposition with the mount. Reutlinger was in the zenith of his fame just before the Franco-German war, and this, unfortunately, brought to a precipitate standstill, a most brilliant business. Reutlinger understood posing and retouching to the letter, but he understood how to finish a portrait still better, and this enabled him to distance his Paris colleagues.

Other continental photographers have been hardly less successful than Reutlinger in introducing changes of style and finish, and one of the last modifications—for it involves no actual photographic change—is that recently described by Fritz Luckardt in the YEAR-BOOK, which is so simple that it wants but a word or two to describe it. And here we may point out a singular circumstance. While to foreign photographers we owe most of the changes in respect to "finish" of carte pictures, it is to photographers in this country that changes in their size and form—no less an element of fashion, elegance, and chic—are due. The cabinet portrait, the promenade or panel, and the Malvern all date from this country, and although there are formats with other names, none are so popular as these.

In conclusion, then, we would say that photographers would do well to look upon carte portraits not only from an art point of view, but also in the light of *articles de vertu*, or bright little knicknacks upon which taste and fashion exercise an influence. It is, we assure our readers, because the photographers of foreign capitals pay more attention to this point, and not because they produce better photographs, that they secure the favour of so many of our travelling countrymen.

The "At Home" next week will be "The Atelier Adèle in Vienna"; the following "By-the-Bye" will be, "The Photographer's Elixir Vitæ."

Notes.

The Photographic Society of Great Britain has awarded the silver progress medal for 1882 to M. Leon Warnerke.

A grand art exhibition, in which photography has a share, was opened this week in Lisbon. The King and Queen of Spain were present with the Court of Portugal at its inauguration.

Some discussion took place on Tuesday evening at the meeting of the Photographic Society, on the subject of drying gelatine plates, when M. Warnerke gave it as his opinion that films dried in an hour were less sensitive than those dried in four hours. The last-named period he preferred to any other.

Still, it is well to bear in mind that, however skilfully a gelatine film is dried, its sensitive properties may be afterwards impaired by faulty storage or packing. Gelatine is one of the most hygroscopic of substances, and speedily absorbs moisture again from the atmosphere if it gets the chance.

Last year we chronicled a remark of Mr. Robert Faulkner's, to the effect that he thought artificial light might well be employed in the studio during dull murky days, for the purpose of strengthening the high lights. This is precisely what M. Levitsky does in his electric studio at St. Petersburg. He takes portraits by means of the electric light during the daytime. The high lights are those illuminated by electricity, while the shadows are portions of the model lit by daylight alone.

The Royal Polytechnic closes finally on the 21st inst. We paid it a visit on Saturday, and were well rewarded for our pains. It is a pity that just as photographic transparencies are taking the place of the old coarsely-painted slides, the best place in London for exhibiting them should be closed to the public. A tour through the Isle of Wight is illustrated by lantern photographs at the Polytechnic, and the vivid truth of the scenes called up before the spectator—Sandown Bay, Ventnor, the Needles, &c.—invoked the enthusiasm of the audience again and again.

But it is the photographer himself who appreciates a lantern picture best. He really does not know what he has in his negative until it is thus amplified and illuminated. The wonders of photography then stand out indeed, provided the transparency has been skilfully produced. In another lecture on ballooning by Mr. Hepworth, a cheap and effective mode of producing diagrams was shown to be that of photographing wood-cuts, and projecting these on the screen with a lantern. Photographs of maps are especially successful; it is surprising how clear and bright the stupendous continents appear which originally came from some school atlas. This application of the camera opens up a wide field for the instruction of youth.

A friend of ours returned in great glee last week from a visit to one of the principal workers of gelatine plates in London. "I went right through every room, where they mix the emulsion, coat the glass, dry the plates, and pack them. He showed me everything, sir, everything!" Here was a lucky man, and we at once proceeded to congratulate him; he would now be able to set about plate-making on his own account. "Oh, you can't see anything, don't you know, because it is so dark; but he described everything to me as I went along!"

When Madame Albani quitted Berlin on Monday, the Emperor of Germany gave her a photograph of himself, and the Empress an autograph letter. The Empress of Germany, we hear, is the only crowned head who refuses to give away a portrait, and, so rumour affirms, she has only once been photographed.

The Newcastle-on-Tyne and Northern Counties Photographic Association celebrated its first anniversary on Tuesday. The success of this, the newest of our societies, seems never to have been in jeopardy for a moment, and the Honorary Secretary—for upon him it usually depends whether the society shall be an active or passive one—may be pardoned when he proudly boasts that the twenty-five promises of membership, twelve months ago, have developed into sixty-seven members and two non-members at the present moment.

At the same time it cannot be denied that Newcastle enjoys unusual advantages to foster a photographic association. The distinguished president is Mr. J. W. Swan, F.C.S., and among the Council is the honoured name of Professor Herschel, M.A. Mr. J. B. Payne, F.R.M.S., is the hon. secretary, Mr. P. M. Laws the treasurer; while among its active supporters are Professor Marreco, M.A., Dr. Berwick, Messrs. Mendelssohn, J. Downey, and E. Sawyer—all men of known ability.

There was a time when shellac was considered a necessary constituent of sealing-wax; but its assistance is dispensed with now-a-days, it seems, in the manufacture of the ordinary article. Here is one receipt: Common resin, 12 parts; yellow beeswax, 1 part; lampblack, 2 parts. You melt the resin and beeswax, and then stir in the black. If red wax is wanted, Venetian red is substituted for lampblack.

The Admiralty has been trying experiments with a view to get at the best way of reflecting the electric light without loss, a problem that is likely to concern the photographer very closely ere long. Most of our battle-ships carry the electric light for the purpose of sweeping the seas in search of torpedo-boats contemplating a night attack. It would be the aim, of course, of the torpedo launch to destroy the light apparatus as soon as it could, and for this and other motives the swift little craft is armed with small but powerful guns. The battle-ship, on the other hand, is seeking to protect its source of light behind armour, and then to bend the rays in the proper direction by some suitable apparatus.

Both lenses and reflectors have been tried on board the *Sultan* at Portsmouth, and her captain has come to the conclusion that a dioptric lens is by far the best apparatus to employ. A reflector made of Chance's glass, and carefully silvered, proved tolerably serviceable, but the bright light travelled a much greater distance when aided by the lens. The smoke and steam of a torpedo launch can be plainly seen a mile off, for the rays strike against the vapour as it would against a solid screen.

One hundred and eighty pounds is usually quoted as the highest price paid for any negative—the sum given by Messrs. Marion and Co. to Mr. Watkins for a photograph of the Prince of Wales in Masonic dress. But negatives ten times as valuable have been in existence, which have been simply too costly to sell. A recent example of a valuable cliché is that of "You Dirty Boy." This well-known statuette is by Giovanni Forcadi, the same sculptor who produced "I'm First, Sir," two ragged newspaper boys touting for customers. The right to photograph this last was sold for ten pounds, and the sculptor would willingly have parted with the right of "You Dirty Boy" for twice that sum, before the work was exhibited at the Paris Exhibition.

But after its exhibition matters were different; the statuette began to attract, and when the sculptor was asked a second time to sell the right of photographing it, he demanded one hundred pounds. Nevertheless, the would-be purchaser had foresight enough to pay the money, and the sum he realised by selling photographs of "You Dirty Boy" passes the wildest imagination. Some say that the profits were no less than ten thousand pounds; but be this as it may, the lucky speculator gained sufficient on this single work to ensure him comfortable retirement. Subsequently £1,600 were paid for the exclusive right of employing "You Dirty Boy" as a trade mark, of which the possessors are the well-known soap makers, Messrs. Pears and Co.

Topics of the Day.

NOTES ON DARK-ROOMS.

BY COSMO I. BURTON.

Within the last few years—in fact, since the introduction of gelatine emulsion—the construction of either permanent or temporary dark rooms has become a very different problem from what it used to be. I was going to have said in the days of collodion; but, to be cautious, I will say before the days of gelatine.

I think we may classify dark rooms under five heads, according to what we might call their degrees of darkness.

1. Under this head come rooms for working processes less sensitive than the ordinary silver printing process, such as the copying of tracings and the like. About this quality of dark room there is not much to be said, because generally one thickness of ordinary yellow blind cotton is a sufficient protection against any but summer sunlight, for which two thicknesses are advisable or even necessary.

2. To pass on, then, to the second head, which includes all the ordinary printing processes, ranging in sensitiveness from the common silver printing up to the slowest dry collodion. These, again, require very little remark, except that, I think, for amateurs, unless they work very large sizes, a special room for printing is quite unnecessary. I have always found it most convenient to use a pantry with water laid on, and to tone at night by lamplight. Here a word of warning to the inexperienced: it is necessary always to use the same kind of light for toning by, or you will be sure to have your prints irregular in colour. I have always used a paraffin lamp, because I had no gas, and having got accustomed to it find it does very well; but I believe a whiter light would have been better, as, for instance, a colza lamp; but, as I have begun with the paraffin, it is best to keep to it.

3. The third class of dark rooms includes those intended for the collodion process in any of its multitudinous forms. Perhaps it would have been more correct to have divided dark rooms into only three heads, because it is here that it begins to be really necessary to exclude light, except that of the proper colour, which ought to be yellow. Red light is very dangerous when working with iodide of silver in in any form; and a red light which appears to the eye not to be so strong as a yellow light will yet produce more fog on a wet collodion plate, as I know from bitter experience; yet, notwithstanding this fact, it is strange what an amount of white light one may have in a collodion room, supposing that you have an opaque bath, and the light all comes from one direction, so that you may turn your back to it in developing. For the window of such a room, I decidedly prefer yellow glass or oiled yellow paper to blind cotton, as the former lets through more light, and that of a purer yellow colour than the latter; however, this is a matter of taste, and of no real importance. I therefore hurry on to class—

4. Dark rooms for working ordinary gelatine emulsion in. Here the real difficulty of dark rooms may be said to begin. The first object is to exclude all light whatever. When I first made a dark room for working gelatine emulsion in, I chose a large press, about ten feet by six: went inside, and shut the door; then began to congratulate myself on having got a room perfectly light tight, except under the door; this was easily corrected by means of a piece of old carpet laid on the floor so as to cover the crack. Then I was about to proceed with my self-congratulation, when I saw light coming from a crack at one corner, then from along the angle of the roof and one of the walls, then from another corner, and so on; in fact, when I had been in that place for a quarter of an hour, I could see light streaming in at every corner, the very walls seeming transparent; so there was half a day's work pasting up brown paper before that room, which I at first supposed perfect, before it could be considered safe to work a sensitive plate in. And here I would remark how extraordinarily difficult, it sometimes is to see where light is coming from; you may see a spot of light on the wall of a room, but to see where it has come in is sometimes by no means simple, especially if the light has been once reflected off a mirror or a piece of glass. I remember once noticing a bright spot of light on the roof of an ordinary room; it was obviously produced by the reflection of the sun from somewhere, but where the reflecting surface might be I could not for the life of me make out. However, my curiosity being excited by the matter, I at last climbed up, and got between the window and the spot of light on the roof, and then observed that it was reflected off the edge of a crack in one of the panes of glass in the window. I give this merely as an instance of how difficult it may be to find out at once where light is coming from.

The press which I utilized as a dark room had no window, otherwise the difficulty of making it dark would have been somewhat increased, though not very much, I think, because it is comparatively easy to shut out light like that from a window where there is no doubt about it. What is really difficult is to make all the cracks and crevices of a room light-tight; but though it is easy to permanently darken a window, it is by no means easy to do so temporaily, if the room, for instance, be required for other purposes than photography. I have seen this very neatly done, in the case of a skylight, by placing a piece of carpet over the window, which could be pulled up and down by means of two strings. The arrangement, when I saw it, did not work well, but I think that the construction was to blame, and that the theory was good; but this arrangement was not sufficient to make the room completely dark; it was necessary to have a shutter besides, which, in the case I am describing, was made of a very light wooden frame covered with paper, and painted black. This was supported in the window by means of two light springs of ash wood, which were fixed on to the frame, so that they could be turned round and made to grip on the sides of the window. I recommend this method to all who have such a window to darken; of course, the shutter would work equally well in almost any window.

And now I pass from methods of keeping out light to methods of admitting it—that is, to the much-discussed problem of a light for the dark room. The most conflicting opinions are constantly expressed on this subject by different writers; one saying that you must work with no more light than one candle behind two thicknesses of the deepest ruby glass; another affirming, with equal confidence, that it is quite safe to work with daylight and one thickness of yellow or orange glass. I do not admit the truth of either of these statements, and in my own case try to hit the happy medium, always keeping on the safe side, and having too little rather than too much light; and as convenient a way of working as any, I think, is to put the plate in the slide in darkness, and do not have any light at all till after the plate is in the developer, when a little white light will do no harm, and it is much easier to see how the development is going by white than by red light. At different times I have used many different kinds of light; the one I have used oftenest is simply a candle inside a ruby funnel; but this light is very feeble, and white light escapes by the top of the funnel, unless it is covered in some way; also the funnels are expensive, and break very easily. The reason for this I believe to be that they are not properly annealed after being flashed or covered with a thin coating of red glass to give them their colour. In constructing a permanent dark room in a friend's house, I made a very convenient and safe light by taking a brick out of the partition between his laboratory and workshop, covering the space with one or two thicknesses of ruby paper, and placing a gaslight at the other side. This arrangement did exceedingly well, and it is easier to take a brick out of an ordinary partition than most people suppose.

5. The fifth and darkest class of dark rooms are those used for preparing and working emulsions for special purposes, such as the photographing of the spectrum, as in the case of Abney's researches into the photography of the red and ultra-red portion of the spectrum. The light he used was a candle placed behind ruby glass at a distance of twenty feet from his working table, and even that light was not safe for some of the processes in the preparation of the emulsion. But as I have never worked in a dark room of this kind, I have no more to say on the subject.

ON PHOTOGRAPHIC ADVERTISEMENTS.

BY CLIFTON CLIFF.

There are a good many people about who hold with the doctrine that a business of any kind cannot be made to pay without liberal advertisements. It is reported, and I believe truly, that one patent medicine vendor spends no less a sum than £50,000 per year in advertisements, and it is argued therefrom that the more we advertise, the more business we get. This is to a certain extent true, the main point being, however, not in the quantity of advertisements, but in their quality and genuineness. The gentlemen in question has, without doubt, realised an immense fortune; but the question that arises in thinking minds is, whether it was the advertisements, or the quality of the goods advertised, that helped him to do so. In my opinion, neither the one nor the other, taken separately, would have had the desired effect; it has been the combination of the two that has led to the happy result. Had the medicine been advertised as better than everybody else's, and able to cure every disease, and upon trial have turned out useless, I do not think all the advertising in the world would have made the sale for it that it now has. This is a point we should seriously consider before we spend our capital on advertising.

I recently had a photographer's circular put into my hand, in which the firm sending it out, stated that their studio was the finest in London—that their portraits were the best in England—that they were more highly finished than elsewhere, and wound up by stating that their price was 3s. 6d. per dozen.

Now, I would ask, is this kind of advertisement likely to make the fortune of its originator? Most people now-a-days are endowed with at least a modicum of common sense, and such being the case, they cannot fail to see that the advertisement is, on the face of it, mere bombast. They would naturally ask themselves, "How is it that if this man takes the best photographs in England for 3s. 6d. per dozen, there are people who go to other studios and pay double, treble—aye, and quadruple—for portraits which are inferior?" An advertisement of this kind is likely to bring an influx of business at the moment of issue; but are the people likely to come again or to recommend their friends? The margin left after deducting cost of materials and rent would necessarily be very small indeed, and the operator who could turn out the "best photographs in England" would not be very likely to accept the salary that the advertiser would be able to afford to give. Then, again, come the gentlemen who advertise that they are using a process that nobody else is allowed to use, and turn out, in consequence, superior photographs to all others. This is just as bad as the other sample. A few people may be cajolled into sitting, but they do not find such a very vast difference in the resulting proofs, and they don't try a second time.

One advertisement recently shown me in a provincial paper was unique; it specially requested mothers not to bring their leather-lunged and squalling brats to a certain studio, as they would not be taken, and also requested gentlemen from the country not to bring so many samples of different earths and clay on their boots and leave them on the reception room carpet. It wound up by requesting visitors not to be misled by another photographer who had hired "a second-hand stable" as a studio. This I conceive to be a sample of the very worst system of advertising. It is true it would makethe originator known, but, I cannot help thinking, would serve rather as a warning to avoid that studio, and accept even the alternative of the "second-hand stable." Another original gentleman, through the medium of an advertisement, asked his lady sitters not to come to him with their "hair done in the hideous skull-cap fashion now so prevalent." This, I opine, was not at all likely to make the ladies flock to that photographer.

Not very long since, an enterprising gentleman in the suburbs of London tried a novel method of advertising. He had some thousands of little circulars printed, and worded something to this effect: "Coupon.—Messrs. Camera and Lens hereby agree to take twelve carte-de-visite portraits of bearer for the sum of two shillings and sixpence. This coupon is only available for one month from date." These coupons were distributed far and wide all over London. The bait took, and people rushed to the studio. The operator was working from early in the morning till dark, exposing instantaneous plates, and developed them after. The pictures were, I believe, fair ones, and though the same rush of sitters did not continue after the month, still I believe the advertisement considerably increased the business. Personally, I should not care to follow suit; I merely give the instance as one more sample of how photographers do advertise. Messrs. Camera and Lens did not say that the pictures would be superior to anybody else's, and the public did not expect them to be, so there was no deception. Had they have stated anything of the kind, though the first rush would possibly have been as great, I rather question if any permanent increase would have resulted.

One of the best methods of advertising is publication of good portraits of celebrities. Do you live in London, there are plenty of well-known people who will sit to you for the asking; it is a cheap method of getting your name known to the public, and a good one at the same time. If you live in a provincial town, there are the local clergy and the doctors; secure good pictures of these, and you secure their congregations or their patients, as the case may be.

One of the best newspaper advertisements I ever saw was something like this—

YELLOW & OKER,
Photographers and Miniature Painters,
1927, Broadway,
Old York.

At first sight it looked like a business card lying diagonally across the columns; everyone who saw the paper, necessarily saw the card. There was no puffing of patents or anything vulgar about it, but I do not doubt it had more effect than nine-tenths of the preceding kinds.

A very good dodge is to take gratis portraits of editors of local papers, who in return give a paragraph notice of your studio, which brings in far more than the portraits cost you.

If there is a "Literary Institution" in your town, join it; it all brings grist to the mill. But whatever you do, there is one thing I would warn all against: if you are religiously inclined, and a Dissenter, don't let it be known that you are opposed to the Church; or if you are a Churchman, be as friendly as possible with the Dissenters. Don't go and address meetings convened by the Church Association, or any other such warlike body; and, above all, don't dabble in politics; whether you be liberal, conservative, radical, or ultra-radical, let it not be known; we vote by ballot, so no one need know your opinions unless you openly proclaim them.

Possibly the best advertisement of all is to turn out uniformly good work; in a dozen pictures, don't let one bad one go, "just to make up the number, you know," for ten to one that single bad proof will do you more harm than the eleven others will do you good. Overhaul your specimen cases as often as possible, let no mediocre work be exhibited, and see that no fading pictures are left in the case a day longer than necessary.

Correspondence.

PACKING GELATINE PLATES.

Dear Sir,—Referring to a letter in the Photographic News of the 23rd ult., from a New Zealand correspondent, respecting fog in gelatine plates, supposed to be caused by the paper used in packing, I beg to say that I have met with the same difficulty, perhaps in a slightly exaggerated form, and have lost a large quantity of plates from that cause alone. For some time I was quite at a loss to understand the phenomenon, and attributed it to a defect in the dark slide.

One day, on developing a plate, I was astonished to find not only the usual fog, but part of the instructions for developing, plainly marked on the plate.

I may add that the plates used were all from one well-known maker. I have found three such negatives, and have forwarded them to you per rail for your inspection.—Yours truly, Chas. W. Horsley.

CARELESS TREATMENT OF EXHIBITS, ETC.

Dear Sir,—As yet another testimony to the fact that I am far from being alone in my complaint as to the above and other matters, I send you the following extract from the *Artist* for January:—"Great grumbling is going on from correspondents in the photographic periodicals about careless packing returns from the London Society's Exhibition. It is to be hoped it will have some effect. This deponent will testify that years ago he had an expensive set of frames much damaged from the same cause, and he ceased both membership and exhibiting for that reason. There are other details attention to which some correspondents think the 'parent Society' might be the better for."—Yours truly, H. A. H. Daniel.

EXHIBITION OF PHOTOGRAPHIC APPLIANCES.

Dear Sir,—Will you allow me to call attention once more, through the medium of your pages, to our Exhibition of photographic appliances? The day by which all those who wish to exhibit were requested to send in applications has just elapsed, and, I am glad to say, the number of applications is such as to render it certain that we shall have a very interesting and instructive exhibition. There must, however, be many more, both amateur and professional photographers, who have special pieces of apparatus, or illustrations of special processes, which it would be desirable that others interested in the science should have an opportunity of seeing. A good many such have already promised their assistance. Will you help me in making it known, to those who have not already done so, that the Society will be glad to receive further contributions, and that I myself am prepared to furnish any further information in my power to anyone who thinks it worth while to write to me on the subject? Most of the principal makers of photographic apparatus have liberally responded to my application, and I hope those who have not promised to assist will do so before the time comes for the Exhibition, which it is proposed to open on the occasion of the first lecture of Captain Abney's course here, namely, the 30th of January.—Yours faithfully, H. T. Wood, Secretary.

THE ELECTRIC LIGHT.

Dear Sir,—I was much interested, as no doubt were many more of the fraternity, with Mr. Swan's letter in your last issue, as a communication from a gentleman of his standing comes to us with authority.

It has long been my desire to obtain photographs by the electric light, and I, in conjunction with a friend, have tried many experiments to that end, but without much good effect. Now it appears to me that we have been kindly put in the right path.

Would Mr. Swan increase the obligation by clearing up a few difficulties which beset the experimenter in the first outset?

What size Bunsen elements, for instance, would be necessary to charge a secondary battery of forty cells? And of what size should the latter be? How are we to know when the secondary battery *is* charged? Again, when experimenting with Planté's accumulator, we have always found the charge either too weak or too small to be of much effect for photography. And in trying to construct a Faure battery, we were brought to a standstill by not knowing how to keep the red oxide of lead (which is a powder) upon the lead plates.

If Mr. Swan would clear up these few difficulties, he would be conferring a favour on many, and on none more than your Constant Reader.

ERASING HALATION FROM A NEGATIVE.

Dear Sir,—I have seen a good deal in the News of late about halation, and it referring chiefly to interior pictures, and my fancy being landscape, I have not followed the whole of the correspondence; but having a night with nothing particular to do, I just looked over my negatives of our first Society's trip of 1881 to Wingfield Manor, and found a negative which well illustrated the subject of halation. It was a negative of the crypt, which had been taken on a commercial plate, and was exposed for fifteen minutes during a bright period of the day.

No. 1 print is from the negative as developed, which you will observe has halation or blur round the doorway to such an extent as to totally obliterate all idea of a door. No. 2 print is from the same negative after I had played with it half-a-hour. My experiment was simply this: I got a bit of clean chamois leather, and soaked it in a solution of glycerine and water, about six drops of glycerine and two drachms of water. I then commenced careful rubbing on the negative with the piece of damp leather round the end of my finger. The gelatine soon became soft, when great care is required not to break it, but with a light touch, I believe all the detail can be brought out of the densest blur. Those who try this will find, after rubbing a short time, the leather will become very dirty, and a clean place on it must be taken, and so on, until the detail desired is brought out.

I hope this will be of as much service to the readers, as many hints I have got from the News have been to me.—Yours respectfully, W. B. Hadfield.

[The specimens sent well exemplify the value of this simple means of improving a negative which is marred by halation.—Ed. P. N.]

Proceedings of Societies.

Photographic Society of Great Britain.

The usual monthly meeting of this Society was held on Tuesday, at 5, Pall Mall East, the President, J. Glaisher, Esq., in the chair.

The following gentlemen were elected members of the Society:—Messrs. J. Jackson, C. R. Wilkinson, John Clarke, Q.C., and W. Brewis.

A paper "On Drying Cupboards," by Captain Abney, was read by Lieutenant Darwin. Captain Abney stated that after Mr. England described his drying-box some months ago, he found it answered perfectly, save in hot weather, when he found there was a difficulty in getting the plates to set quickly. He found also that the iron rods on which the plates rested left markings on the plates, and that the soot deposited on the chimney by the gas jet sometimes fell and caused spots on the plates.

Mr. England said he had never been troubled with the difficulties referred to by Captain Abney. He used a straight jet somewhat similar to the jets used in cigar shops for lighting cigars. If a flat flame which touched the sides of the chimney were employed, he could well understand how soot could be deposited. He had had his boxes in use for two years.

Mr. W. Bedford said he had used Mr. England's box, but instead of wires he had iron castings planed on the upper surface. He found, however, a difficulty from the iron being colder than the surrounding air, and he overcame this drawback by winding string evenly over the iron, and resting the plates on the string. Mr. England's plan of keeping up the circulation of the air answered very well in cold weather, but in hot he found an advantage in adopting Mr. Kennett's method, by which the products of combustion were not carried into the chamber.

Mr. Maxwell Lyte thought from his experience that drying by means of a gas jet produced insensitiveness. He used therefore to dry by means of air made warm by a hot water pipe and by sulphuric acid and quicklime.

Mr. England had tried boxes for drying sensitized paper warmed in hot water, but had not found them answer. He might observe, with regard to the markings mentioned by Capt. Abney, that he now used the wires curved, so that the plates only touched the wires at the edges.

Col. Wortley had found a box heated by means of a hot water coil to answer perfectly. He believed in a thorough desiccation of gelatine plates, as he had found greater sensitiveness therefrom. For this reason means should always be adopted to carry away damp air from the box. Some time ago he had a packet of plates sent to him which were quite damp in parts, so that they stuck together; but after they had been thoroughly dried they gave very good results, save in those portions affected by the damp. He also thought that the plates should be dried quickly, and immediately after they had set. After many experiments he had come quite to this conclusion.

Mr. Woods observed, with reference to Mr. England's remark as to flat flames, that Capt. Abney used a straight jet. No smoke could be seen, but it gathered after a time on the chimney.

The President then announced that the Progress Medal had been awarded to Mr. Leon Warnerke, and in so doing welcomed that gentleman back from Russia, and asked him to favour the meeting with any observations he might be able to make in reference to his Russian experiences.

Mr. Warnerke observed that he had really very little to say, since Russian photographers derived most of their ideas from England. In the course of his remarks, however, Mr. Warnerke referred to the fact that in Russia the gelatine process was scarcely used, and was in reality a novelty. In respect to drying-boxes, the difficulty he had found in Russia was not so much how to dry the plates, as to keep them from drying too quickly. This arose from the dry atmosphere, and the construction of the houses. He did not think that plates dried too quickly were so good as a more gradual desiccation. A plate dried in from two to three hours was, for instance, better than one dried in an hour. In regard to wet collodion, it was sometimes supposed that the light in Russia was of greater actinic power than in England. This, as tested by the actinometer, was found not to be the case, yet the exposures were shorter than in England, because of the absence of fog. In respect to the electric light, Mr. Warnerke mentioned that M. Levitsky employed it almost entirely, even in daytime, frequently making use of daylight to light the shadow side of the face only. Mr. Warnerke also referred to a plan he had adopted for determining when the ground glass in photographing architectural subjects was vertical, and referred to a method of hot-pressing adopted in Russia, by which results equal to enamelling could be obtained.

Col. Wortley said, in respect to drying gelatine plates quickly, he did not mean that they were to be dried as quickly as possible. The plan he adopted was to place the plate in the drying cupboard about seven o'clock in the evening. The flame heating the hot water apparatus was then turned off, and the pipes remained at a constant temperature of 80° to 88° two to three hours, and then gradually cooled, so that by morning the plates were quite dry.

The President announced that nominations for the Council must be sent in by Jan. 23rd, and Messrs. Acland and Heaviside having been appointed auditors, the meeting adjourned.

South London Photographic Society.

On Thursday, January 5th, this Society held the annual popular lantern meeting, at the house of the Society of Arts, Adelphi, Rev. F. F. Statham (President) in the chair.

The meeting was certainly as successful as any ever held in every way. The large room was packed, about 400 members and friends being present. We understand that as many as 850 slides were passed through the lantern. The addition of a little music was a great point. The lantern was most admirably managed by Mr. W. Brooks, and the music and reading were also ably done by Mr. F. A. Bridge. Altogether, the whole meeting was a complete success, and reflected great credit upon the management.

The Chairman made a few remarks relative to the purpose of the meeting; and the first slides shown were some excellent views in Switzerland, Isle of Wight, and the Paris Exhibition, by Mr. W. England.

Mr. Nesbitt then showed very good slides of sea views and shipping, and some excellent groups of gipsies on Mitcham Common.

Messrs. Harding then favoured with a song, "Darby and Joan."

Mr. W. Brooks then passed through the lantern some of his own slides, the most noticeable of which were an exceedingly fine portrait of the President, some views in Cornwall, and one of the best slides of the evening, "A Breaking Wave."

Mr. W. B. Bolton was the next exhibitor, his contributions consisting of some Welsh scenery; also a group of gentlemen whose names are household words in the photographic world. We presume this group was taken on one of the Saturday outings of the Photographic Club. In connection with this slide, Mr. F. A. Bridge said the *poet* of the Society had composed a few lines, which he sang as follows:—

"'Twas on a summer's afternoon,
A lovely day in the month of June,
These brave Camaronians went to test
Which made emulsion plates the best;
And when their stock of plates was done,
Their stock of chaff was soon begun
By Williams, and Wilmer, and W. Brooks;
But Cutchey grew touchey, you see by his looks.
Then on Chislehurst Common a wager was laid,
Was lost and won, and duly paid,
That W. B. and W. C.,
In a race upon donkeys, as here you see;
But when the donkeys felt the weight
Upon their backs of each, six stone eight,
They vented their mirth in a comical way,
Then kicked up their heels and galloped away.

Some interesting slides by Dr. Maddox followed.

Mr. H. Garrett Cocking then sang, "What will you do, Love?"

A series of slides by Mr. Payne Jennings were then shown; amongst others, four of them depicting the meeting of the waters.

Mr. F. A. Bridge then sang Moore's "Meeting of the Waters," as the slides were passed on the screen.

Some exceedingly good pictures of ancient buildings in London, by Mr. H. Dixon, and some of the well-known animal photographs of Mr. T. J. Dixon, were shown.

Mr. Harding then sang, the "Well of St. Keyne."

Mr. F. Howard's slides of views at Dorking, &c., and the interior of several cathedrals, were very good.

Some good photographs by Dr. Plaistow were then shown; also pictures of considerable interest by Messrs. Wood and Foxlee.

Mr. W. England then exhibited some excellent slides of statuary, the effects with different colours thrown on the screen, one after another, being remarkably fine.

Mr. H. Garrett Cocking then sang, "Love was once a Little Boy."

Mr. F. A. Bridge then proceeded to read the story of "Little Nell," illustrated by slides by Mr. York. These slides are a novelty, inasmuch as they are photographed from life, with pictorially painted backgrounds. The effect was good, both in this and the subsequent story of "Meg and her brother Ben."

Other slides followed by Messrs. Ayres, Pearson, and England, and some further music closed one of the best meetings it has been our good fortune to attend.

Thursday Evenings for Photographers.

At the meeting held on January 5th, 1882, Mr. Coles occupying the chair,

The question as to the best method of cleaning glass beakers, test-tubes, &c., was discussed, Mr. Cutchey recommending the use of "Smith's Cleansing Powder" for the purpose.

Mr. Henderson exhibited a mixture of ox-gall and gelatine prepared in March, 1880. The gelatine and ox-gall were thoroughly incorporated, and the only odour to be detected was a slight smell of methylated spirit. He also showed an improved form of cutter, for trimming paper prints, made on the principle of the wheel glass-cutters.

Mr. Cowan exhibited a sensitometer he had constructed after the plan of that shown and described by Messrs. Macklow and Spurge at the last meeting of the Photographic Society of Great Britain. The apertures, in this case, were so arranged that each admitted double the amount of light admitted by the one preceding it. The phosphorescent tablet was prepared by melting paraffin wax, and shaking sulphide of calcium into it.

The Chairman passed round specifications of "Schönheyder Patent Sanitary Stove," which he thought photographers would find of great service in drying plates.

Sheffield Photographic Society.

The usual monthly meeting of this Society was held at the Freemason's Hall, on Tuesday evening, January 2nd, Mr. T. H. Morton, M.D., presiding.

The minutes of the last meeting having been read and confirmed, the arrangements for the forthcoming exhibition were again brought forward, when it was resolved that coloured photographs be deemed admissible. It was also agreed to hold the lantern entertainment in a room adjoining. From the Committee's report, the exhibition promises to prove a satisfactory addition to the annual gathering.

Mr. Hadfield described an effective method of dealing with excessive halation in gelatine negatives (see page 22).

Mr. Stringfellow related a peculiar circumstance connected with a gelatine plate. His assistant had taken several whole plates in ordinary double slides for outdoor work. On handing over the plates to develop, one of them showed no image when immersed in the alkaline pyrogallic solution, proving that a mistake had been made in exposing. The plate was washed, drained, and placed, while still wet, in the camera, and exposed the usual time on an object in the studio. It was then immersed in the same developing solution previously used, and came out a first-class negative.

Mr. RAWSON exhibited a number of stereo. and other pictures.

Mr. DAKIN contributed a few platinotype prints for the album.

Mr. PATTERSON, of Ramsay, Isle of Man, exhibited views of some of the fine scenery of that island.

Messrs. D. H. CUSSONS, of Southport, sent copies of their pocket almanac for distribution.

The meeting shortly afterwards adjourned.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES PHOTOGRAPHIC ASSOCIATION.

THE annual meeting was held on Tuesday evening, January 10, at the Crown Hotel, Clayton Street, Newcastle-on-Tyne. Before commencing the business proceedings a large number of members and friends, including many ladies, partook of an excellent tea.

The chair was then taken by Mr. JAMES DOWNEY, who called upon Mr. J. B. PAYNE (Hon. Sec.) to read the annual report, as follows :—

"Your Council, in offering to you their First Annual Report, have much pleasure in pointing out the marked and gratifying success attained. At the preliminary meeting held just twelve months ago, there were 25 promises of membership received. At the present moment there are 67 members and two hon. members. The attendance at the ordinary monthly meetings has been very satisfactory, averaging fully two-thirds of the number of members enrolled. The attendance at the out-door meetings was not so good, and in consequence of this, the Association has suffered a small loss, as will be seen from the Treasurer's report. The best thanks of the members are due to the Council of the College of Physical Science, the Council of the Literary and Philosophical Society, for the liberal manner in which they have assisted the Association by placing their rooms at our service; also to Dr. Berwick, and Prof. Freire Marreco, and Mr. Gibson, for the contribution of papers; and to Dr. Berwick, Messrs. Laws, Gibson, Muras, Mendelssohn, &c., for the contribution of photographs. Three Lantern Exhibitions have been held, and proved fairly successful. Your Council hope that the members will take this branch up a little more vigorously, especially in the production of transparencies. Much may be done in this way in assisting each other by exchanging slides. The Association is indebted to Messrs. Mawson and Swan, for the loan of lanterns and screen, Messrs. F. York and G. Smith, of London, Messrs. Coote, Chadwick, Leigh, and Woodward of Manchester, for the loan of slides. The following members have also lent transparencies for lantern exhibition, viz.:—Messrs. Armstrong, Berwick, Gibson, Grimshaw, I'Anson, Laws, Marreco, Payne, J. H. Robinson, Sawyer, &c. As the success of the Association depends mainly upon the individual interest taken in it by the members, your Council hope that a liberal supply of papers, or subjects for discussion, will be brought forward at the ensuing meetings, and rely upon your generous support."

The Treasurer's balance-sheet showed that the Society was in a satisfactory financial condition.

The reports having been unanimously adopted, Messrs. Gray, Freeman, and Burrows were elected members, and the following gentlemen as officers:—

President—Mr. J. W. Swan, F.C.S.

Vice-Presidents—Professor A. Freire Marreco, M.A., and Dr. G. Berwick.

Treasurer—Mr. P. M. Laws.

Council—Professor Herschel, M.A., Messrs. H. S. Mendelssohn, J. Downey, E. Sawyer, L. Davidson, A. L. Stevenson, and W. Armstrong.

Hon. Secretary—J. B. Payne, F.R.M.S.

The business having been disposed of, the meeting took the form of a social gathering, songs, readings, &c., being contributed by the ladies and gentlemen. Too much praise cannot be accorded to Messrs. Sawyer and Son, for the very handsome manner in which they devoted themselves to the entertainment.

Talk in the Studio.

CANTOR LECTURES.—The next course of Cantor Lectures at the Society of Arts will be on "Recent Advances in Photography," by Captain W. de W. Abney, R.E., F.R.S. The first lecture will be given on January 30. It will be introductory, and will treat of the action of light, development, the Daguerrotype process, &c. The different molecular forms of the silver haloids, and the sensitiveness of the different salts of silver, will form the chief subject of the second lecture. Dry plate processes, instantaneous pictures, enlargements, the applications of photography to science, will be treated in the third lecture; while the fourth will be devoted to printing processes and mechanical printing processes, including photo-engraving. In connection with the lectures, an exhibition will be held of photographic apparatus, illustrations of new processes, &c.

To Correspondents.

CHURCH STREET.—We have reason to think that your assistant is quite right in his conjecture; but before making any claim for compensation, you must be in a position to establish this view. Possibly a satisfactory way would be to cut a print in halves and to mount one piece on the questionable card and the other on a sample of card which has proved safe; both prints being then kept in a moderately damp place for a fortnight. Let us have further particulars.

CRUCIBLE.—Rather over 6,000 grains if the sulphide were pure.

F. STANLEY.—We should be inclined to suspect the mounts. Before sending out any more pictures on the cards in question, it would be well for you to try the experiment suggested in answer to CHURCH STREET. We will test the cards for the presence of hyposulphite.

LITTLE PHOTO.—The negative is a very good one indeed; but it would print better if you were to print in a slow light, or to shade the printing frame with a few thicknesses of tissue paper. A weak sensitising bath for the paper will be found most suitable for such a negative. You must remember, however, that the variations now proposed will render the operation of printing much slower.

HANTS.—The formula you enquire for is as follows:—Citric acid, $\frac{3}{4}$ ounce; white sugar, $\frac{1}{2}$ ounce; ninety-grain solution of silver nitrate, 1 ounce. After these have been ground in a mortar, 16 ounces of the same silver solution are added. Blistering seldom occurs when a strong bath has been used.

THETA.—1. You will have no difficulty, provided that the original from which you enlarge is small enough to be well within the ordinary covering power of the lens. The lens you mention will enlarge from carte-de-visite size to any magnitude. 2. There is no such manual at present.

EDWARD FREWING.—No particulars are given, but we are tolerably sure that the following would answer well:—One ounce of white of egg, one ounce of water, and thirty grains of bichromate of ammonium. Let us know how you get on, or any difficulty you may meet with.

MANCHESTER MAN.—The rough milboard boxes are made to order by any paper-box maker, and the grooved wooden boxes are kept in stock by all dealers in photographic apparatus.

A POOR PHOTO.—1. Cut up the cardboard, and make a strong infusion in distilled water. Next filter this and test with a dilute solution of iodide of starch. A discharge of the blue colour indicates the presence of hyposulphite. 2. So great is the liability to fog, under the circumstances, that few use the addition you name; you can try adding a smaller proportion. 3. It depends on the condition of the bath; but five grains to a pint should do in ordinary cases.

A. LLOYD.—Will communicate with you by post.

MANFRED.—1. The sample marked "No. 3" is the most suitable, this being a genuine cardboard, and tolerably free from the various mineral substances often added to give weight or to form an artificial surface. 2. As regards the bronze lettering, it may be observed that mischief appears to have followed the use of such cards in some instances. There is no reason why real gold powder should not be made use of, as the quantity used is very small; one ounce, costing about £6, being sufficient for dusting no less than 20,000 devices such as you send on sample "No 5." 3. There can be no doubt whatever that if the firm you mention undertake to do the printing in gold, and inferior metal is used, they will not only be answerable for any damage done, but also liable to a prosecution for fraud.

LEICESTERSHIRE JOHN.—1. The mount for the panel portrait is 13 by $7\frac{1}{2}$, the size of the actual print ranging from $11\frac{3}{4}$ by 7 to 12 by $7\frac{1}{8}$; but to our taste this last is rather too large for the mount. 2. We will try and obtain the required information; and, if successful, will communicate with you by post.

J. LASHMER.—All these defects are certainly calculated to try one's temper, especially under the circumstances. Still, you should blame yourself for not having taken the simple precaution of trying one or two plates from each packet.

FERROTYPE.—The cut edges should be varnished. Dilute the bitumen varnish sold as "liquid jet" with twice its bulk of benzole, and pour out a layer a twentieth of an inch deep in a flat dish. All you have to do now is to dip each edge successively.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1220.—*January* 20, 1882.

CONTENTS.

GELATINE FROM A CHEMICAL AND PHYSICAL POINT OF VIEW.

Gelatine as a basis for the negative photographic image now holds a place comparable to that which pyroxyline held a few years ago; and in consideration of this fact it becomes necessary for the photographic world, and especially those who are engaged in the manufacture of plates, to take careful note of the general chemical character of gelatine, the manner in which it becomes altered or broken up by various reagents, and other circumstances which attend its reactions.

If a bone is soaked for some days in dilute hydrochloric acid, the whole, or greater part, of the mineral matter becomes dissolved out, and a soft cartilage-like mass, which retains the original shape of the bone, remains behind, this residue constituting the organic or essentially animal parts of the bone. The organic body thus obtained is known as ossein, and although ossein is in itself insoluble in hot or in cold water, it soon becomes changed into gelatine when it is boiled with water. This conversion of ossein into gelatine appears to be unaccompanied by any definite chemical change, the composition of the insoluble ossein and the soluble gelatine being apparently the same, and the following figures represent the composition of ossein or gelatine according to analyses which appear to be reliable.

Carbon	49·2
Hydrogen	7·8
Nitrogen	17·9
Sulphur	0·7
Oxygen	24·4
	100·0

Very many parts of the animal organism are of the same nature as ossein, if not actually identical with it; and among these may be mentioned the so-called connective tissue, the epidermis, tendons, and horn. All these substances are used in the industrial manufacture of gelatine, and the care or skill exercised in the manufacture determines whether the product shall be a fine white and clear gelatine, or the highly impure and partly decomposed product which is sold as a cheap glue.

The following may be taken as a general outline of the principal operations. As it is generally impracticable to use up the raw material as soon as it arrives at the factory, means are ordinarily taken to dry and preserve them, and this is effected by repeated immersions in a thick milk of lime, and drying in sheds specially constructed for the purpose. In this state the materials will keep well, and can be transported from place to place without difficulty or fear of nuisance. The next step is to re-dip into milk of lime, and when the dried animal matter has become softened, the lime which adheres to the surface is rinsed away, and the materials are exposed for some days to the air, in order that any lime which may have penetrated into the interior may become converted into carbonate by the absorbtion of carbonic acid from the air. In some cases a weak bath of chloride of lime is used at this stage, in order to partly bleach the animal matters. The still damp and soft materials are next boiled in water until those parts capable of transformation into gelatine have dissolved. In order to facilitate the removal of insoluble residues, which always remain behind, the skins and so forth are contained in a kind of metal colander which fits into the boiler, and can be lifted out at pleasure.

Two methods of clarification of the hot liquor are in use, alum being generally used when there is sufficient lime in the gelatinous solution to render it decidedly alkaline; and albumen is ordinarily employed when the solution is neutral or slightly acid. When alum is used, about one ounce is added to each hundredweight of hot solution. The reaction of the lime and the alum causes the deposition of a precipitate of mixed sulphate of lime and alumina, which precipitate carries down various impurities with it, five or six hours being ordinarily allowed for the hot solution to settle. When albumen is used, it is stirred into the hot solution, and, in coagulating, it carries the impurities to the surface.

The gelatinous solution is, in this country, usually allowed to set in flat receptacles, tables covered with plate glass being used for the finer kinds; while in France it is usually allowed to set in large rectangular moulds, the blocks thus obtained being afterwards cut into leaves or flakes. In any case, the flakes are spread on nets to dry—the operation of drying being one requiring the exercise of the greatest care and judgment.

The following method of purifying a commercial gelatine is so effectual that a highly satisfactory article can be obtained from the crude and impure gelatine sold as a low-priced glue.

The solution is allowed to gelatinize, and the jelly is cut up into fragments, and tied up in a coarse cloth. This is next placed in frequent changes of water which is slightly warm, but not hot enough to dissolve the bulk of the jelly. After the greater part of the colouring matter has been dissolved out in this way, the residual jelly is dissolved and strained; its own bulk of alcohol being then added. A clot of very pure gelatine is now thrown down.

Moist gelatine rapidly decomposes and putrefies in the air, but the addition of carbolic acid, alcohol, or ammonia, tends to prevent this. When subjected to dry distillation gelatine yields carbonate of ammonia and various basic oils. When boiled with water it is gradually changed into a body having nearly the same composition as gelatine, but soluble in cold water, this being usually called meta-gelatine. Cold sulphuric acid converts gelatine into leucine, glycocine, and other products, while hot nitric acid oxidises it, oxalic and saccharic acids being formed as principal products.

A substance very similar to gelatine, and known as chondrine, is obtained by boiling cartilage or imperfectly formed bone with water, and it differs from true gelatine by the fact that it is precipitated by alum, acetate of lead, and the sulphate of iron or copper. It is well suited for making carbon tissue, and it forms the base of the so-called grenetine, this being a high-class product manufactured by M. Grenet, of Rouen, from cartilage and the skins of young animals.

We shall pursue this subject in a subsequent article.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Photo-Engraving in Russia—Photographs of Celebrities—Dangers from Electric Lighting—Mounting Photographs.

Photo-Engraving in Russia.—Backward as the Russians are in some of the civilized arts, they occupy the first rank as regards map-making, it being said that there are "one million and thirty thousand maps in store at St. Petersburg, Warsaw, Wilna, and Kieff, ready for any sudden outbreak of European hostilities." Before such gigantic productions as this, the stores at our Ordnance Departments pale into insignificance. Of course, it must be remembered that in Russia there are few private map makers, the Government undertaking the whole of the supply; but even then we doubt whether any other country with its private topographers turns out so large a quantity. At the recent geographical display at Venice, Russian maps attracted a considerable degree of attention from the beauty of the workmanship displayed—workmanship in which photography played an important part. The improvement in Russian maps dates from 1866, when the "Corps of Military Topographers," founded in 1796 by the Emperor Paul, underwent a re-organization. Since 1866 every improvement has been taken advantage of, especially improvements in photo-engraving, until it must now be said that Russia possesses the most complete map manufactory in the world. During the last two years special attention has been paid to photo-engraving, and the process in use, the invention of a Pole, is said to possess immense superiority over the zincographic process adopted by our Intelligence Department. The method employed is kept a profound secret, and therefore has never been patented; but those who are curious on the subject may see specimens in the way of reproduced engravings in Percy Thornton's "Foreign Secretaries of the Nineteenth Century," and reproduced maps in Hensman's "Afghan War." One especial feature would appear to be the possibility of making alterations during manipulation, so that foreign names can be exchanged for English equivalents, and *vice versa*. As to the superior accuracy of the Russian maps over the English ones, it may be noted that Colonel Valentine Baker, in his "Clouds in the East," says that when he visited the Perso-Turcoman border in 1873, the secret and confidential maps he took with him from the War Office were found to be so worthless that he threw them away, and made use of the beautiful Russian maps of the country. It may be said that the authority for the above remarks is the *Globe* newspaper, which has a tendency to exaggerate the importance of anything done in Russia supposed to have the remotest connection with any possible injury to "British interests," and therefore the statements may be taken with the usual grain of salt. Mr. Warnerke, in his recent interesting communication to the Photographic Society having reference to the progress of Russian photography, said that the Russians derived all their ideas from us. Can he tell us anything about this mysterious photo-engraving process which the Russian Government has obtained, not from England, but from Poland?

Photographs of Celebrities.—A dealer in photographs is now-a-days as good an authority as can be found on the degree of popularity which public favourites enjoy. A London newspaper has been collecting statistics—with no very great success, be it observed—as to the portraits which are most frequently asked for, and mentions the Princess of Wales, Mr. Spurgeon, and Sarah Bernhardt as occupying the first places. Poets are said to be only moderately popular, and of them Longfellow bears away the palm. So far as the photographs exhibited in the windows are concerned, we can scarcely agree with this dictum, save in regard to the Princess. Mr. Spurgeon is rarely seen in the windows, though, no doubt, his portraits command a ready sale; and Mr. Longfellow is more conspicuous by his absence than by his presence. On enquiry of a peripatetic dealer in photographs, an extensive trade which has grown up of late in the streets, we found, odd as it may appear, that Mr. Irving and Miss Ellen Terry were the favourites, the demand for members of the Royal Family being very limited—a proof, we suppose, of the lamentable tendency of the lower orders towards Republicanism. Without photography the illustrated papers would be in sad straits. When the marriage of Prince Leopold was announced there was a frantic rush for the photograph of the Princess Waldeck. Not one was to be had in the London shops, as might have been expected, and the possessor of even a shadowy resemblance of the lady would have commanded a fancy price for it.

Dangers from Electric Lighting.—Insurance offices have been so long accustomed to demand increased premiums from photographers on account of "extra risks," that they are not likely to lower their charges because explosive collodion is abandoned, and non-combustible dry plates only used. If the electric light comes into use for photography—and this is by no means a distant prospect—it is quite possible the offices will consider it their duty to further increase the payments, if certain statements which have reached us from America are to be relied upon. We are told that not long ago the woodwork over the entrance of one of the New York theatres was set on fire by a break in the insulation which brought the naked wire in contact with the wood. The current fired the wood and melted the lead with which the wood was overlaid. Again, three distinct cases of fire were traced in New York to the heating of the metal staples by which the wires were fastened. The Randolph Mills, in Pennsylvania, were burned down by particles of white-hot carbon falling on warps of yarn—a danger to the possibilities of which it may be remarked the authorities at the British Museum are quite alive, as transparent saucers are now placed under the light, so as to catch any incandescent carbon which may fall. In connection with this subject it may be mentioned that the Franklin Institute has recently reported on the dangers of electric lighting, and the committee recommend a number of precautions to be taken which they specify. If the asbestos paint, experiments in the fire-resisting qualities of which were made a few days ago at the Crystal Palace, be really an effectual safeguard, it should prove especially useful to prevent fire arising from imperfect insularity of the wires.

Mounting Photographs.—Apropos of mounting photographs, on which something was said a few weeks ago in the Photographic News, those who would prefer to use glue will find an advantage in trying the powdered glue of Messrs. Cannon, of Lincoln. Glue in this form is especially suitable for small consumers, as it can be made simply by pouring boiling water over the powder, and only the exact quantity needed can be melted. For economy, cleanliness, and ease of manufacture it is certainly superior to the cake glue.

At Home.

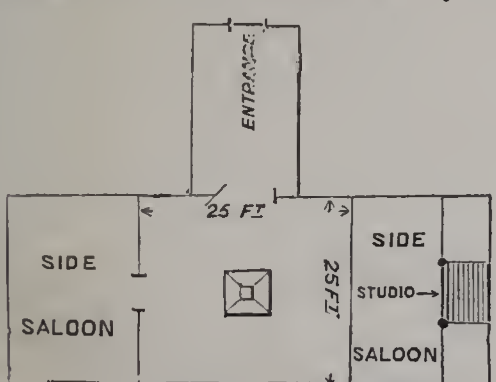
THE ATELIER ADÈLE IN VIENNA.

As in London, so in Vienna, it is difficult to say which studio is the very first. Nevertheless, we may say this of the Atelier Adèle, it is second to none in the Kaiserstadt; while we may also remark that in some respects it is the finest studio we have ever visited. In the first place, its glass-rooms—there are two of them—are not photographic studios at all in the ordinary sense, but brightly fitted *salons*. They are light, lofty apartments with elegant panels of white and dark wood, fitted with ornamental mirrors here and there, with a flooring of polished pine, and ornamental windows. The roof is of fluted glass, what glass there is, while the side light comes through matt glass windows, which have fancy panels figured over them. Everything appears as clean, bright, and new, as a modern dining-room or library, except that the woodwork is rather light, and there is an abundance of illumination.

There is little of photography in these elegant glass-rooms. A single camera is seen, and not even one example of a fancy background. Two or three plain backgrounds are all that meet the eye, with here and there a banner screen, made use of occasionally instead of the blue blinds, with which the glass may at any time be covered. One screen is exceedingly elegant. It is simply a light wooden frame, about five feet high, over which is negligently thrown two pieces of gossamer satin, one blue, the other white. Either one reflecting surface or the other is employed near the sitter as may be necessary, the delicate sheen of the glossy surface, either white or pale blue, yielding a very soft reflection; while to the eye, the pretty screen, with its shining fabric unstretched, is particularly pleasing.

Photographers who have not got on very well with gelatine plates, and still practise the wet process, may take consolation in the fact that the gelatino-bromide method is as yet unknown in the Atelier Adèle. "I have tried dry plates in my branch establishment on the Prater," says Herr Perlmutter, to whom, by the way, this beautiful studio belongs, "but only for equestrian portraits. But as I find I can get a very good wet collodion picture in the open air with a second's exposure, I do not find any necessity for adopting gelatine even there. I will not throw over collodion," continues Herr Perlmutter emphatically, "until I see that vastly superior results can be obtained with something else; and, in my opinion, gelatine negatives are not superior." It is only fair to say that the Vienna light is a very good light; the exposure for a cabinet picture is never more than seventeen or eighteen seconds, and frequently requires only twelve, while carte negatives are taken practically instantaneously.

The entrance to the Adèle studio is very imposing.



Viennese photographers have a way of locating themselves on the top floor of an hotel—Luckardt, it may be remembered, is to be found at the top of the Hotel National—and a stranger feels rather diffident at first about penetrating the depths, or rather heights, of a hostelry in order to pay a visit to the studio above. When, however, the summit of the Hotel Müller is reached, you are adequately repaid your trouble. Like the fine reception room of MM. Benque et Cie, in Paris, the Atelier Adèle is very dark. There are no windows in the broad corridor by which you enter, and you begin to think that they must have closed the shutters by mistake. The corridor leads into a central *salon*, still rather gloomy, for the two windows are draped with heavy curtains, and the furniture and floor are sombre to a degree. Everything is dark. The paper in one room is dark crimson, and in the other dark blue; here, in this apartment, the furniture is ebony and gold, in that, dark oak and gold; either drab velvet or dark satin covers the chairs; the floor is of dark polished wood, covered with dusky Turkey rugs; the portraits that are on the walls are deep and vigorous, and mounted in shining black frames, while even the books of specimens have dark binding.

In the centre of the main *salon* is a handsome vase with green foliage and fresh grasses, forming the middle of a luxurious settee. Altogether, the apartments are most richly furnished, and when once accustomed to the subdued light, you feel a repose and quiet in these cool drawing-rooms that is very enjoyable after the hot sunshine and dusty streets of Vienna. While waiting, the visitor may read some couplets over the doors, the gist of which is to warn him not to expect too much flattery from the camera. Here is one of them:—

Ein Schmeichler ist der Spiegel nicht
Er gibt dir immer dein wahr Gesicht.

The charge for cabinet portraits is fifteen florins per dozen, a florin being said to be equal to two shillings English, although it is not so much just now by threepence or fourpence. For boudoir portraits, a style as long as the well-known promenade or panel, but twice as broad, the cost is thirty-six florins a dozen.

Herr Perlmutter is occupying himself a good deal with equestrian portraits, as we have hinted; he finds that if it is difficult to secure a pleasing picture of man and horse, still, in the event of success, it is a success, indeed—both from an artistic and pecuniary point of view. In fact, Herr Perlmutter is thinking seriously of invading England, and coming to London to try his hand on this especial branch of photography, with which, our readers will remember, M. Disderi occupied himself at Brompton, many years ago. If there is work among cavaliers at Vienna, there must be ten times as much in our West End. It is a difficult task making good equestrian portraits, Herr Perlmutter admits; but he does not think photographers have ever fairly tried to do the work. If they did, they could not fail to get plenty to do, for those who own valuable horses are generally more anxious to get pictures of their property than of themselves. The number of people who own valuable horses is very large, and they represent a large *clientelle* to be had for the asking. In any case, Herr Perlmutter's heart is in his work, and he frankly says that if he succeeds in producing a good equestrian picture, it gives him ten times more delight than any photograph secured in the studio.

For all that, Herr Perlmutter makes some charming studies in his atelier. Large direct portraits as big as those submitted in the Crawshay Competition are to be seen in the waiting rooms, for he prefers securing pictures direct, rather than enlarging, if money is no object. He works mostly with Voigtländer lenses. "Have you no Ross or Dallmeyer on the premises?" we ask. Herr Perlmutter shrugs his shoulders. "I should very much like to have an instrument of Mr. Dallmeyer, but I cannot purchase one. There are none to be had ready made. I must order one to be constructed, and if I did that, it might not be what I wanted when I got it."

Silver printing, and no other, is employed in the Atelier Adèle, and black mounts edged with gold are evidently much in favour. The albumenized paper, here, as in most German studios, has a faint roseate hue, which, while pleasing in portraits of small size, is also chosen because of the idea that it may counteract any yellowness that may subsequently appear in the pictures. This, as it may be, rosy-tinted paper is a little out of place in a vigorous masculine portrait.

"Do you retouch much?" Again Herr Perlmutter shrugs his shoulders. "So far as ladies are concerned, we must retouch a great deal; otherwise our lady customers won't have the pictures—that's all." The matter is no longer in the hands of the photographer; retouching is absolute with the Viennese dames, and they require a great deal of it. "We generally use Faber's 2H," adds Herr Perlmutter.

We pass from the glass-room into the laboratory, where plates are being fixed and washed, the day's work collected on draining racks ready to be varnished. As a rule they are treble-plates, but in summer time the thin end is sometimes not exposed, as the third image in those circumstances leaves much to be desired. They are all wet plates, as we have said, and their manipulation presents no feature of novelty.

"The next "By-the-Bye" will be, "The Photographer's Elixir Vitæ"; the following "At Home" will be, "Herr Hofphotograph Koller in Pesth."

INSTANTANEOUS PHOTOGRAPHY.

From the "Magazine of Art," by permission of Messrs. Cassel, Petter, and Galpin.

ALTHOUGH it is the practice to speak of instantaneous photography now-a-days with a good deal of assurance, to any one who gives himself the trouble to think, the term is a very indefinite one. To take a photograph in the tenth part of a second would by many people be deemed instantaneous, and yet if it were so described, what should we call the exposures made by the French astronomer, M. Janssen, who take pictures of the sun by submitting a sensitive plate to the solar rays for the brief space of $\frac{1}{20000}$ of a second? The phrase "instantaneous photography," then, is simply a term of convenience, and to speak of rapid photography, as distinguished from ordinary operations, would be at once more correct and more intelligible.

Although feats of rapid photography were familiar enough in the Daguerreotype and collodion days, it is only since the introduction of gelatine plates that such work has grown into importance. Within the space of this brief article we cannot explain wherefore the sensitive salts of silver, when enclosed in a film of gelatine, should be more readily acted upon by light than when contained in collodion; we must refer the reader to the pages of the more

technical journals in which the chemical and physical aspects of photography receive the attention they deserve. Our endeavour here will be simply to show in what way instantaneous photography may be made use of by painters and draughtsmen, and also to point out that, with an artist behind the camera, it is possible to secure a photograph which has some claim to be considered an art-production.

Our illustrations will explain in a measure, how helpful the camera may be to the artist. Take Mr. Mayland's "Shipping and Smoke" as an example. An artist sent from abroad to obtain sketches of the busy Thames, with a view to producing a work on London, or a painter desirous of depicting upon canvas the crowded highway so indicative of our commercial prosperity, would value a photographic sketch of this nature very highly. Half a dozen such pictures, supplemented by a few rough drawings in his note-book, would amply suffice for his purpose. The massive screw-steamer gliding swiftly down the river, the dark-sailed barges, the black smoke from funnel and factory, indicate an amount of "life" which, if he had been able to grasp it at the moment, could not have been set down in black and white without much labour. But, in all probability, it would have been impossible to seize the effect with a pencil; the heaving water as the huge screw swings quickly round, the dense curl of black smoke blotting out portions of the sky, the barge tacking to avoid the steamer, the belching chimneys in the background—not one, but all of these effects go to make up the picture.

Another example of rapid work by which the artist may benefit is the "Swans" of Messrs. Marsh Brothers. It would need a quick eye to seize either the vivid movement of the fast-turning birds, or the iridescent effect upon the water, which has almost the viscid appearance of molten metal. Mr. Mayland's flock of sheep, full of life and animation, cropping the grass among gorse and heather as they advance, is another study that animal-painters would make good use of; while "Henley Regatta" and the "Cricket Match" are of a class which special correspondents and artists for the weekly illustrated newspapers will best appreciate.

The rapid gelatine plates permit much that was impossible before, and for this reason it is that painter and draughtsman will be able to derive greater assistance from the camera. Street scenes are not only capable of depiction, but by the aid of a clever apparatus recently constructed by Mr. Bolas, and which has received the name of "Detective Camera," they can be secured without the presence of the photographer being dreamt of. The camera, which was recently described in the photographic journals, is to all outward appearance a small portmanteau, a hand-bag, or even a boot-black's block, as the case may be, and this is set down for an instant on the pavement, the parapet of a bridge, or any eligible site. The photographer rapidly takes account of his lighting, his distance, and foreground, makes his exposure, and is away with the instrument before even his sojourn has been remarked. The results we have seen are quite Hogarthian in their character. An apple-stall at the foot of London Bridge, with a boy bargaining with the woman for her wares; two men seated on the paddle-box of a penny-steamer, the one relating an incident, and the other rubbing his forehead in doubt—such things are but sketches, it is true, but they would be invaluable to any painter of the life and manners of our metropolis. The rapidity of gelatine plates, therefore, permits of taking something more than set scenes and arranged tableaux, with which photographers formerly treated us; photographs full of life and being are now attainable, and this quality must ever be valuable to the artist.

To come to the second point of our paper. Now and again, as everybody knows, a most excellent result is achieved by the ordinary photographer; but if he is to produce you a photo-picture every time he sets up his camera, he must understand something more than the technicalities of his calling. We will go to Mr. Mayland's picture of the Thames once more. A similar scene may be frequently witnessed on our river, yet such pictures as his are scarce. To secure the result, the photographer had not only to wait until a disposition of the shipping proper to the exigencies of art was before him, but he had also to judge of the lighting, so that the massive shadows of vessel and smoke came between him and the sun, to produce due contrast, while at the same time the technical excellence of his photographic plate should not be marred. Nay, more; it was necessary for him not only to have some art-knowledge in order to choose and seize a picture, but to possess sufficient skill and wisdom to produce his shadows, high-lights, and half tones in harmony with the subject. In a word, he must so understand the *development* of the plate that he can give due effect to lights, shadows, and distance.

This endeavour to get something of fine art into camera pictures is successfully achieved in many of the photographs of to-day. At the last Paris Exhibition, indeed, one of our English photographers, Mr. H. P. Robinson, of

Tunbridge Wells, was granted the gold medal for the art qualities of the fine photographs he exhibited. It is perhaps only fair to say that Mr. Robinson, as an exhibitor at the Royal Academy, has claims to be considered a painter as well; but still it is on the ground of art-photography that he has gained distinction, and we will here try to show how it is that an artist who is also a practised photographer secures very different results to one who understands but the technicalities of the matter.

Given a landscape, and given a photographer who is so far a photographer only that he can perform all the technical operations satisfactorily. There is a patch of black firs in the foreground, there is a grey castle high upon the eminence, there is a slope of brown woods in the distance. It has been argued many a time that the camera is but a mechanical instrument that cannot go wrong, but must perforce reproduce any scene that happens to be in front of it. Very good. The exposure is made, the plate is developed, and we look at the result. The negative is clear and bright, and lacks nothing as a chemical result; but the brambles in the foreground look like dried faggots, the castle on the hill is only half the height it is in nature, the pines are represented by pitchy darkness on one edge of the picture, and the woods in the distance are lost in the bright sky-line. The technical photographer has a reason for all this; he will say that the brambles were so close that they were out of focus, the lowness of the hill is simply due to the lens, for all objectives have a tendency to depress the horizon, the pines are black in nature, and if the plate had been sufficiently exposed to photograph them properly, the sky-line would have fogged. In all these explanations he is right, but for all that a photographer with some pretensions to art-knowledge would have made a very different thing of it. Mr. Robinson, Mr. Mayland, Mr. England, Mr. Bedford, Mr. Payne Jennings, Mr. Harvey Barton—to take half a dozen names at random of our best landscape photographers—would have made a picture. The brambles, boldly limned in the foreground, would have contrasted with the soft brown woodland on the horizon, the castle walls of silver-grey would rise sharply against the sky-line, while the pines, with their clear dark shadows in middle distance, would complete the picture. If he were an artist as well as a photographer, he would first know what is required to make a picture, and then be able to make it. As a painter has to begin by choosing his pigments and mixing them, so in a measure he must bend his apparatus to his requirements. At the outset of his work he knows that if one lens will not fulfil his requirements, another will; he is aware that if he raises it a little out of the centre, he will correct that tendency to depression we were speaking about; but what lens he uses, and how he manipulates it, is all a matter of judgment. Next, to light the scene with effect, so as to secure massive yet transparent shadows, to decide which shall be the high-lights of his picture, to produce an effective rendering of this object, while another shall not unduly suffer, are all points to be considered. We need not dwell upon choice of foreground, or upon the composition of the picture, for it is only too evident that the photographer must study these, if he is to produce anything of an artistic nature; but in the *development* of the plate, the knowing exactly what he wants and what he is working for, there is again considerable scope for taste and judgment. He will strive to produce a negative which, while vigorous in part, shall yet show the gentle haze in the distance, and furnish a print so soft and harmonious in colour, that it looks like a sepia or charcoal drawing. He must, we repeat, know what is wanted in a picture, and be able to produce it.

Notes.

The Sheffield Photographic Society open their exhibition on Monday next.

To-night Dr. Huggins lectures at the Royal Institution on comets, and proposes to show some of his interesting astronomical photographs.

Mr. J. W. Swan on Saturday last lectured again at Newcastle on Electrical Storage of Energy; there was a large attendance, over which Sir W. Armstrong, C.B., presided. Verily! here is a prophet in his own country.

Monday next is the last day on which nominations for the Council of the Photographic Society are received.

Major Waterhouse, B.S.C., has returned to Calcutta to take up his duty of Assistant Surveyor-General of India. He carries back several improvements for the collotype process, and a set of velvet rollers for photolithographic work.

The *Photographische Mittheilungen*, the well-known Berlin journal conducted by Dr. Hermann Vogel, changes from a monthly into a fortnightly journal in the present year.

We ought, by-the-bye, to have announced that this year another annual has appeared in the German language, the *Deutscher Photographen Kalender*, of which Herr K. Schwier, of Weimar, is the editor. The other annual in German, the *Jahrbuch*, still flourishes under the able direction of Dr. Hornig, of Vienna, to whose courtesy we are indebted for a copy.

Never has the barometer been so high for forty years past as on Wednesday, when it registered 31·02, more than an inch higher than the average at this time of the year. The Kew barograms—as the photographic records made by the barometer are called—will be invaluable years hence, for, since this application of photography, implicit reliance can be placed upon the records. The dense gloom and cloud that photographers have been troubled with of late are doubtless connected with this high pressure upon the barometer.

Photographic societies abroad are raising subscriptions for a monument to Daguerre; at the last meeting of the Berlin Society for the Advancement of Photography one hundred marks were collected.

Tobacco smoke as a developer. Mr. Woodbury, who has just returned from Brussels, tells us of some "magic" photographs on cigar tubes, the pictures being developed on smoking.

Whether complaints against the insensitiveness of "commercial dry plates" are well or ill founded, it is certain that the glass itself, especially in the case of smaller sizes, frequently leaves much to be desired. Messrs. Valentine, of Dundee, for this reason adopt the expedient of furnishing the dry plate manufacturer with their own glass, a plan that may be recommended to all large or moderate consumers of commercial dry plates.

Mr. W. D. Valentine, one of the members of the firm, when in town the other day, gave an amusing account of that wet field day last year when the Volunteers of Scotland were reviewed by Her Majesty. From morn to eve it rained might and main, and the dripping defenders of their country had to go through their evolutions wet through. Quoth one gallant Volunteer, with damp skin and shivering gait, as he passed Mr. Valentine and his camera, "For goodness sake, if you are going to photograph us, do it with a *dry* plate."

It is gratifying to find, after a fortnight's experience of lighting the stage of the Savoy Theatre with the Swan electric lamp, that those whose business keeps them on the boards are still as enthusiastic as ever about the new mode of illumination. Mr. George Grossmith, whose clever impersonations in the Gilbert-Sullivan operas have had no slight influence upon their success, tells us the change is delightful, especially in the case of the footlights. The glare, hot vapour, and unsteady haze inherent to gas, and so productive of headache, at once fall away when the electric float is used, while the atmosphere behind the scenes is vastly improved, as much from decrease of heat as freedom from noisome odours.

The little electric room, at one of the wings, full of coils, switches, wires, &c., in which the electric engineer sits and directs the heightening and lowering of the lights, will become historical, since it is the first structure of its kind. To lower the light, the engine power is not slackened, but simply a portion of electric energy is permitted to run to waste. Each dressing-room is furnished with a Swan lamp, and here again Mr. Grossmith extolled the advantages of electricity, for flaring gas jets render these rooms sometimes quite uninhabitable, so deficient are the latter of ventilation. By the way, busy man as Mr. Grossmith is, he finds time to foster his old love for the camera, and he is still the ardent amateur of years ago. His success in opera-bouffe does not prevent him taking a deep interest in the construction of lenses.

The Bench is growing quite scientific. Mr. Justice Grove, whose battery is still a household word among chemists and electricians, has now been joined by Sir John Holker, the late Attorney-General, who, it seems, says of himself that "he understands a little of chemistry and nothing of law."

The Photometric Committee, consisting of Mr. Livesey and Professors Williamson and Odling, have made their report to the Board of Trade. As photographers are much interested in the establishment of a standard light, they will be glad to hear the result at which the committee has arrived. The standard sperm candle, by reason of the possible variations in its mode of manufacture, as also in its mode of burning, the Committee recommend should be discarded in future as a unit of light, although the quantity of light furnished by a particular source shall, as hitherto, be expressed in standard candles.

In place of the sperm standard candle, the committee propose that Mr. Vernon Harcourt's "air-gas flame" be used as a standard, since it is exceedingly exact and trustworthy. Briefly described, the "air gas flame" is a flame 2½ inches high, proceeding from a brass burner with a quarter-inch orifice. The gas is burnt at a definite rate, and consists of a definite mixture of air and the vapour of light petroleum. As Vernon Harcourt's "new unit of light" will in consequence of this report become of interest, we shall publish detailed particulars of it.

GELATINE EMULSION.

Mr. Andrew Pringle, in a communication to the Edinburgh Photographic Society, says:—

Before giving you a few details (and disasters) connected with the chemical parts of my march after rapidity, I may as well give you an idea of my premises and apparatus wherein and wherewith I work in my experiments. My dark room is most convenient in the matter of water, gas, shelves, presses, &c., but being at the top of the house is a sort of stove in summer, and an ice-house in winter. The latter defect is easy enough to remedy; the former would seem to militate against successful work with gelatine, but I am thankful to say the evils usually attendent on great heat never seriously incommoded me. I have an accumulated stock of gas stoves, furnaces, Bunsen's burners, kettles, &c., and as I make my own gas I have nothing to fear in the way of varying pressure or sudden extinction, except when, as happened lately, the holder is blown clean out of the tank.

I emulsify usually at about 100° Fahr., either by violent shaking in a hock bottle, adding the silver about a drachm at a time to the bromided gelatine, or by vigorous whisking in a round porcelain bowl. I may at once say that I question the perfection of both these methods, and am on the look-out for something better. Will any of you help me? I used to boil the emulsion direct in a stonewere vessel covered with a lid, but I now boil in the hock bottle loosely corked in a tin can half full of water. This can I set upon a ring burner on Bunsen's principle, and as the hock bottle is a deep red colour, I fear not the light. Having boiled the required time I add my larger quantity of gelatine—of which more hereafter—then pour the whole into a porcelain jar of cylindrical form and smallish diameter, and allow it to set slowly. I like the emulsion to set slowly, because thereby greater rapidity is obtained without risk of decomposition; in fact, the cooking goes on to a certain extent. I sometimes wrap this jar in flannel to make it set slowly. When set I cut it out with a silver spoon, place it in a bag of "Leviathan" canvas, and gnashing my teeth vigorously—for I hate the clammy operation—I squeeze the emulsion in long threads into a teapot of cold water. This squeezing is quite wrong; the heat of the hand melts some gelatine, a quantity of gelatine sticking to the canvas is lost; but I have now got an apparatus, made by Mr. Maynard, which looks like business. The emulsion being in the teapot I cover the lid-hole with muslin, and an Indian-rubber band to hold it; I stick the rubber pipe in the "stroup," connect the tube with the tap, and run in water for an hour. I have never seen a sign of undissolved nitrate in any emulsion I have ever washed by this method.

Having washed as stated, I run all the water off so far as I can, and then lay the emulsion in its jellified state on a frame covered with muslin, and there I leave it to drip or dry for an hour or so; if I admit this I find the emulsion too thin, and require to add more gelatine, which *de se* upsets all previous calculations. The jelly being dried, or rather dripped, in this manner, I melt it in a pyro-bottle and measure it; what is wanting, if any, I make up with absolute alcohol; any overplus I must perforce remedy with gelatine, but now the latter mishap rarely occurs.

I have been much bothered in the operation of coating my plates. I lost large quantities of emulsion when I tried to coat as with collodion; I spoilt plates when I tried to coat upon the cold level slab; and now I have got over the difficulty by laying the plate on a slab of wood lying on the marble slab, pouring a pool of warm emulsion in the centre, and guiding it smartly over with a glass rod, then immediately sliding the plate on to the level slab. My levelling-table is the top of a disused wash-hand stand (at least, it has been disused since I annexed its top); this is laid on a strong framework furnished with four iron screws, so that I can level it in a few seconds if it ever go wrong.

My drying-box has been my greatest misery. First I made one myself; but I could not keep down the heat, and the emulsion melted. Then I got a copy made of Mr. England's; but, not having a convenient exit for the draught, it would not dry a plate at any price. *N.B.*—This box is a capitally made one, and for any one who could arrange so as to have the exit flue led out of his room it would answer well. I am open to offers. Having failed so far, I set myself to a bit of joiner work; *i.e.*, I watched a fellow setting himself to it, and between us we turned a big press in my dark-room into a series of bars stretching from side to side, leaving the bottom shelf as it was so as to cut off ascending light. After many trials and many disappointments I at last arrived at the point where I and my press now are. We are now a press about seven feet high and thirty inches wide, with several rows of drying racks stretching from side to side; this is far superior to the plates lying on their backs, catching dust, and not drying evenly. At our top are let in two-elbowed three-inch zinc pipes, and between them a number 0 Archimedean chimney can, which I expected to rotate with the draught, but which shows an irritating composure of mind and body. Our bottom shelf does not reach either to the back or to the door; but light is excluded by two boards nailed at an angle to back and door so as to overlap the space left open by our bottom shelf. Below this shelf stands a paraffin-stove, single-wicked, and covered, where possible, with orange-paper. Two square holes are cut, one on each side of the stove, and a long hole in the front of the press close to the floor, and this hole communicates freely and directly with the bottom holes inside. A dish of calcium chloride is placed just inside the floor hole, and another on the inner shelf. My room at present is as damp as a room can well be, but in twenty-four hours my plates are perfectly desiccated. A red baize cloth covers the whole press.

But I have wasted a sad time on my apparatus, and I fear yon will never get through with my real subject.

I began with emulsion of pure silver bromide, something like this:—

Gelatine Nelson No. 1... ...	grs.	30	+ 170 added later.
Amm. brom.	,,	120	
Water	oz.	3	
Silver nitrate	grs.	200	
Water	oz.	3	

Boiled thirty minutes, washed forty-five minutes. Result—fair rapidity, but thin and bad colour of negative.

I soon after tried the same formula boiling forty-five minutes, but the result was still too slow. This seemed to me curious, as I knew others getting great rapidity by what appeared to me the very same process. This sort of thing went on for several times, when I bethought me that my tap-water, though splendid for drinking, might not be good chemically. I then made for myself a still, and renewed my experiments with distilled water, when I at once got a decided increase of rapidity, but no improvement in quality.

I next tried the following—

Gelatine N. No. 1	20 grs. + 200
Amm. brom.	120 ,,
Potass. iodide	11 ,,
Water dist.	3 oz.
Silver nit.	200 grs.
Water	3 oz.

Boiled one hour, adding a drop of hydrochloric acid. Washed as usual, coated, &c., as usual. Results—still slowish, but a very beautiful quality and colour of negative. I must remark that all this time I never could get my coated plates properly desiccated, and I have no doubt that fact would partly account for the slowness. I next tried Mr. Burton's formula, as published in the *Journal*, more with a view to try the precipitation process than expecting to find any novelty, and against my next three batches I find in my note-book, "Utter grief; would not precipitate." This seemed a bad look-out; but persevering, I at last got my emulsion to precipitate quite well, but when all was done I preferred my old love, and went back to my leviathan canvas and my tea-pot.

I may here say, that during the process of cooking it is very interesting as well as instructive to examine from time to time with a good microscope the granularity and other characteristics of the emulsion as the process of boiling goes on. The colour of the emulsion as it goes from stage to stage is as interesting as the fineness of the bromide of silver deposit. I almost always watch my operations with an inch objective; that is quite high enough power. The colour finally reaches a beautiful ruby violet, and at this point the emulsion ought to be very sensitive.

I found then that the iodide gave a marked improvement in the quality of my negatives; I showed some transparencies made with my iodised emulsion to a well-posted photographic friend, and he was quite struck with their beauty. But I further found that if the iodide did not slow the emulsion, it at least inculcated a considerably longer cooking; and I was advised by a friend to try the effect of a little chloride, and from that time my troubles ceased. It never rains but it pours; and not only did my emulsion turn out fine in quality, but with thirty minutes' boiling and other operations precisely as before, I have now got an emulsion as rapid, so far as I can judge, as any I have seen, but possessing all the good qualities that I had been searching after, —density, clear shadows, and a good printing colour.

ON LIGHT.

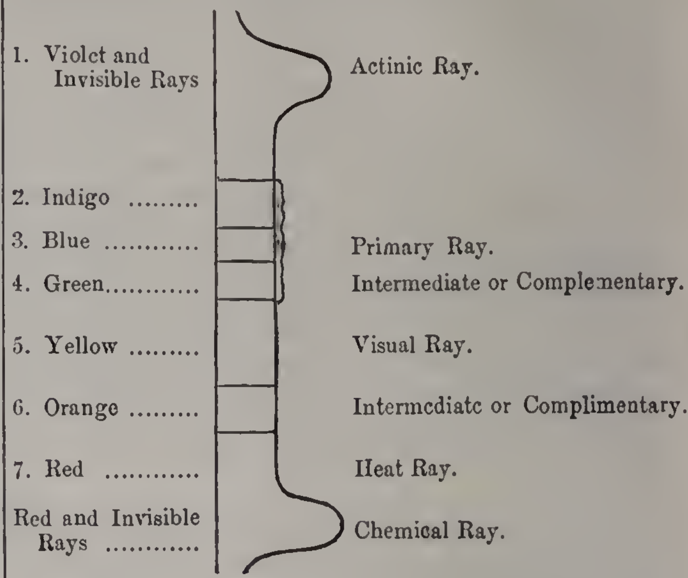
BY W. HARDING WARNER.*

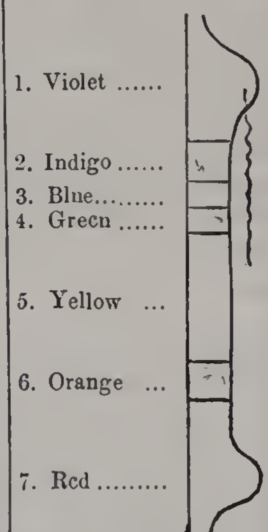
STRANGE as it may appear, few know, or care to know, the origin of light; yet to photographers, and to amateurs specially, it ought to be a matter of interest and importance; for without that knowledge we can never hope to make photographs in the colours of nature. We may be excellent chemists and scientists, and yet we shall fail. At the present time light is to the photographer what steam is to the engineer; it enables us to annihilate time and space, to work even quicker than its sister, steam, and, though so widely different in its appearance apparently, I hope to show you the analogy existing between them.

Some, doubtless, when in London in the days of the old Polytechnic Institution, will have seen there the great steam electrical machine. It consisted of a boiler constructed in a similar manner to that of a locomotive, and so arranged on its upper and outer surfaces that a number of jets of steam generated at high pressure should play upon a long brass rod called a "conductor," and be from thence led by a chain into a large Leyden jar or box, there to be stored up for future use. I am surprised that this simple mode of generating electricity for lighting purposes has never been thought of and taken up by some talented civil engineer. I feel sure that the present expensive system might be modified, for a box or jar so charged would give off a stream of electric fluid to last for an indefinite period without risk or loss of power; and it might be so readily kept up and renewed—a bucket of hot water in a tremendous perspiration to light the world! And yet so it really is.

Some years ago the late Sir Charles Wheatstone invented a machine which, shortly described, consisted of a horse-shoe magnet supported on an iron bar, round which was coiled soft iron wire, one end of which projected in such a way that, on the revolving of the magnet, each pole alternately touched the wire helix, and thus, in a short time, a current of electricity was generated which, collected together, formed light. The whole was set in motion by a large flywheel moved by hand, so that, by friction of the particles of metal, light was produced. Thus by the human arm light came into being.

Turn we now to the solar spectrum.





This, explained photographically for wet collodion for landscapes, may be expressed thus:—Spring, autumn, also in early morn in summer, always presenting a greater or lesser degree; but there must also be a proportion of No. 7 to soften, round, and temper it.

This and Nos. 5, 6, and 7, when in excess, compel the use of a strong bath, and plenty of bromide in the collodion. They are found often in summer, also in the winter at times, in various forms in the atmosphere; and Nos. 5 and 6 always at decline of day and the opening dawn of summer.

No. 7, when in excess in summer, gives great trouble, as it swamps the actinic ray, requiring long exposures and weak developers to get good results.

Violet, *Indigo*, *Blue* } are like the treble notes in music. To produce them in nature they take 600 millions of millions of vibrations to produce one ray of white light.

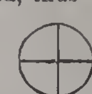
They photograph—Black printing white descending the scale.

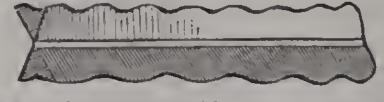
Green, *Yellow*, *Orange* } Dirty white to grey. Grey to black. Brown to black.

Red—Black to intensity excepting pink, which, partaking of the violet ray, is very actinic. } 400 millions of millions of vibrations produce one ray of red light.

They are longer than the violet rays by ten feet, and answer to the bass notes in music, which take long strings, giving deeper sounds from the length of vibrations.

The shape of a ray of light is four-sided, thus—





Long and wavy, and every ray of heat contains a ray of light ten feet shorter than the heat ray. When the clouds are low the wind blows, and the undulations of the rays are longer, confused and mixed up together, and thus there is what is termed a "bad light."

* Abstract of a communication to the Manchester Photographic Society.

For Gelatine.

Violet } Equal white, which, when subdued like unto ground
Indigo } glass or the light of a foggy morning, produces har-
Blue } mony and clearness, while by itself as pure white it must be used sparingly.

Green } May be largely used in their many shades, and pro-
Yellow } duce most exquisite pictures.
Orange }

Small church windows, when white or of rolled cathedral glass without colour, may be shaded with yellow paper, and give most harmonious and pleasing results.

Red equals black, and must be used with care when in conjunction with the other colours ; otherwise with some makes of plates, you get, if you expose for the shadows, a soot-and-whitewash appearance. Like collodion, you should over-expose for the shadows and let the high lights take care of themselves, managing all in a careful development of the subject.

Gelatine specially deals with what collodion fails in altogether, or requires a very long exposure to compass. If, in taking a landscape subject, a study be not made of the colours, a true estimation of exposure can only be guessed at. The deepest shadows should be looked at first. If of green, according to depth, long or short ; if of grey, the same in proportion ; of red, the same as green (except pink, which, partaking of violet, may be short) ; of orange, same as red ; and of yellow, like dirty white.

White of intense purity should be avoided, as liable to produce halation ; or, if not that, hardness, softness and roundness of image being made up of shaded whites obtainable with a slow plate, a comparative exposure, and a moderately-large stop. With all this governing exposure and a perfect study and knowledge of the powers of the chemicals used for development, any exposure may be given, combated, and overcome without fear of failure or of over-exposure ; but you must work slowly. Your plate may be rapid ; but just as much as it is so beyond a certain ratio, so do your difficulties increase. If you desire perfection in landscape, all should be in harmony.

Correspondence.

DARK ROOM ILLUMINATION.

Sir,—In the Photographic News of the 6th inst. is an article by Mr. Samuel Fry, on the subject of "Dark Room Illumination." Mr. Fry does not content himself with expressing his present opinion, contrary as it is to that of most dry plate workers; but, in his own peculiarly pleasant way, assumes the infallibility of his notions, and says, "The persistence of error was never more abundantly specified than in the difficulty found in inducing photographers to work in a light room instead of a dark one." Mr. Fry advocates the use of a large quantity of light in the developing room. Of course, if there were any light which produces no effect upon a really sensitive plate, we might treat ourselves to plenty of it. No such light, however, has yet been found, and therefore the consensus of opinion is in favour of using as little light as is consistent with seeing the progress of the development.

Mr. Fry mentions two methods of illumination, both of which he asserts to be safe, even with a large surface of window. One of the methods—namely, the use of two thicknesses of orange paper stained with aniline magenta, and oiled—I have had in use, except that I used crimson, but with the addition of a ruby glass, without which a transparency could be printed upon a really rapid plate. The other plan, and that which Mr. Fry appears to prefer, consists in the employment of an outer screen of yellow tissue paper, and an inner one of red twill. This does not commend itself, as in all such textile fabrics a certain amount of light (in this case merely tinted yellow by the tissue paper) passes unaltered through the interstices of the material.

It should be remembered that assumption is not as good as argument, and accusations of "persistence in error" against those who hold views different from Mr. Fry's are quite out of place. The expression of Mr. Fry's opinion is not quite such conclusive evidence upon any point as his authoritative dictum might lead the uninitiated to suppose. Mr. Fry has reason to retract sometimes. Probably he is not himself so "persistent in error" as to now maintain the direction he gave at one time to photographers to mix their alum and hyposulphite solutions for the purpose of fixing gelatine negatives.—I am, yours obediently,

W. E. Debenham.

Dear Sir,—Having read Mr. Fry's letter in the News of January 6th on light in the dark room, I must say I am of his opinion that it is not necessary to work nearly in the dark. You may have plenty of light if it is of the right colour, but not ruby glass, as it makes the place so very dark and unpleasant to work by. I did work with it, but discarded it. I now use the following, which answers well for the most sensitive plates :—I put thin orange paper over clear glass—that is, stick it on with starch. I then take crimson lake, raw sienna, and burnt sienna mixed in proportions to bring about the colour required, and paint on the paper. If one coat is not deep enough, I give it another of course, with sufficient medium. If two coats of paint are put on, that will be all that is required ; but if only one, it will be better to oil or varnish the paper, to make it more transparent. Two other colours are very good, each in themselves—madder brown or burnt sienna, with medium as may be required.

I may say I have used some of the quickest plates with perfect safety, and I shall be glad to hear the opinion of any one who may try it.—Yours, Thos. Heaviside.

HOME-MADE TRIPODS.

Dear Sir,—Will you allow me to supplement Mr. Burton's "Topic" by giving a cheap method of shoeing the points of tripod legs with tin-plate.

After the legs have been glass-papered up, taper each to a point of about an inch or more in length, proportional to the stoutness, then take a piece of note-paper and wrap round this conical end, and mark it to allow one of its edges to overlap about an eighth-of-an-inch, as also round the leg at the height the shoe is required, and trim. Tin-plate shaped by this pattern can be made up by any tinman into what appear to be small extinguishers for about three-halfpence or two-pence each. The little caps thus formed, when driven upon the legs, will be found to accommodate themselves to any variation in section, and may be readily secured with headless shoe-nails drawn through holes pierced with a bradawl near the edges of the open end. Should the amateur be desirous of giving a finish, the rough edges may be all smoothed down with a file in a few minutes, and will look as neat and workmanlike as those turned out of first-rate shops.

In respect of serviceableness I can speak from experience, having two or three sets of legs thus shod, which have been in hard wear for several years, without showing signs of giving way.—Yours faithfully, John Harmer.

BROMIDE EQUIVALENTS.

Dear Sir,—For the last two months a week has not passed without an animated discussion on the equivalents of ammonium bromide. Mr. George Dawson takes in that discussion the part of defender of science, and by misrepresenting my statement, made some six years ago, accuses me of the crime of "propagation of scientific fallacies."

At the beginning of this discussion I chose to be silent, not expecting any good for the photographic public from personal wars. Observing, however, that considerable interest is shown in this controversy, and that very useful information based on my observation is ridiculed, I have decided to write this letter, in order to deny most emphatically that I ever proposed to alter any of the theoretical chemical equivalents.

On February 8th, 1876, I read a paper at the Photographic Society, entitled, "Investigations Relative to Emulsion Collodion." In this paper (*vide Photographic Journal*, February 16, 1876, p. 146), I said, "I shall scarcely surprise auybody wheu I say that most carefully ealeulated combiuing proportions of silver and different halogens, based on theoretical eqnivalents, will give most iuaeeurate results." I did not attribute ou that occasion the inaeeuraey to the error of equivalents, and did not propose to alter them, but after ehoosing my salts from one of the best houses in London (Hopkin and Williams), I ascertained its eombiuing proportions, aud having found that they did not vary appreciably iu the samples from other good houses, I published my data, being eouvineed that it would be useful to other photographie investigators. I think that logically, the imputed heresy cannot be based on the quoted statement. But I leave the personal side of the question in order to make a few remarks of a more utilitarian nature.

Since 1876, I have had occasion many times to test the bromides for the combining proportions with silver, and I found that the salts I got in London almost iu every case gave me the same data. (I generally got my chemicals only from first-elass houses, and I believe every reasonable photographer does the same.)

Consideriug that combiniug proportions of chemicals thus obtained vary eonsiderably from the theoretical, aud that lesser variatious exist between the samples from different dealers (best), I believe that a table of these practical combining proportions will be of great importance for experimental photographers, even of more practieal value than theoretical equivaleuts; for this reason I give here a eopy of this table. It would be an anomaly in the standard book of chemistry, but a photographic periodical is a proper place for it.

	Quantities necessary for conversion of 1 gr. of Silver Nitrate.	Silver necessary for conversion of 1 gr. of Bromide.
Potassium bromide ..	0·741 ...	1·35

Aluminum ,, ...	3·24 min.	—

Theoretieal equivalents are absolutely correct for absolutely pure chemicals, and we hope they will stand test of time; but the table annexed, and applicable to the chemicals photographers are most likely to work, is more eorrect, praetieally, at present, and it will stand the test until some improvement in the manufacture of these chemieals alters them; in that case, nothing will stand in the way to prevent the altering of the table to suit fresh requirements. L. Warnerke.

THE SOUTH LONDON SOCIETY.

Dear Sir,—Will you correct in this week's News an error in the report of the South Loudon meeting? It was Miss Harding, and uot Messrs. Harding, who sang; and Mrs. H. G. Coeking, and not your humble servant,

H. Garrett Cocking.

* Ordinary (not anhydrous).

† Bromine, 1 fluid drachm, dissolved in 1 fluid ounce of alcohol.

‡ Aqua regia formed from hydrochloric acid (sp. gr. 1·18), 2 parts; nitric acid (sp. gr. 1·420), 1 part.

THE ELECTRICAL EXHIBITION.

Dear Sir,—One of the earliest maxims instilled in my youth was that "womeu," children, and fools should never see things half finished; and the Crystal Palace Company have, in advertising their exhibition at least a month before the time, laid themselves open to several untimely verdicts on the above principle.

There is one thing, however, to be said in their favour, that they eould not well elose the Palace during preparation, espeeially at Pautomine time, so as to get everything in readiness, as was done in the Paris "Exposition," so that a complete exhibition could, on the openiug day, at onee dazzle the eyes of the public with its splendour.

If your correspondent on this matter had seen, as I did to-day (the 16th of January), huge boilers being carted into the Palace, he would not have wondered at the paucity of lights or other electrical appliances requiring machinery. A large number of engines and dyuamic machines are only just being placed in the basement, aud should he visit the Palace a month or two heuce, he will perhaps form a different opinion. My iusignificant exhibit to which he calls attention, and in which the priucipal features are like mauy others at present, eovered up, consists of a table on which is mounted as a cover an Ordnauee Surrey map of the district around the Palace. Over this is suspended a model balloon, with a model camera attached, to illustrate the system of suspension.

As the Company would not allow (for obvious reasons) the same to be filled with gas, it is suspended by cords from the girders, the cord representing that attaching it to the earth, leading to a small model of a transport car, sueh as would be necessary to eonvey the whole apparatus from place to plaee, having a drum to wind the cable ou, and a space for the empty balloon, &c. This car, to have been in proportion to the ehart, would have had to have beeu eonstructed about the 100th part of an ineh in size; as it is, the wheels cover the whole of the Paris grounds, as represented on the ehart. The principal object of my exhibit will be found the camera with its arrangement for exposing and ehanging the plates, the other portions whieh I have explained being added simply to illustrate more fully the purposes in view.

Walter B. Woodbury.

Proceedings of Societies.

Edinburgh Photographic Society.

The third ordinary meeting was held in 5, St. Andrew Square, on the evening of Tuesday, 10th inst., Mr. James Henderson, vice-president, in the chair.

The minutes having been read, approved, and signed, the following gentlemen were duly elected ordinary members:—Messrs. Andrew Watson, Charles G. H. Kinnear, Robert Hogue, and John W. D. Pottage.

A lengthy discussion took place concerning the sum of money to be expended on prizes for presentation prints. Two members wished the amount to be limited to £35. It was ultimately agreed to leave the matter in the hands of the Council, with power to expend whatever sum in their judgment was deemed necessary. The general opinion was in favour of offering gold, silver, and bronze medals, struck from the same dies, and of the same iutrinsic value as those of the celebrated exhibition of the Society held in the Royal Academy in 1876-7.

The Corresponding Secretary read a paper by Mr. Andrew Pringle, entitled "Gelatine Emulsion" (see page 31).

Mr. J. G. Tunny, in proposing a vote of thanks to Mr. Pringle, bore testimony to the value of several of the hints contained in the paper. He had had similar experiences in regard to the presence of chloride in the emulsion. He found that a chloride had a eompensating power, giving back to the emulsion those qualties of which it had been deprived by the iodide, without in any way introduciug any injurious quality. He had found such au emulsion possessed peculiarly favourable attributes for the production of transpareucies.

Mr. J. M. Turnbull considered that Mr. Pringle was in the forefront as an emnlsion maker. He himself did not think that extreme rapidity was the most valuable quality in dry plates, as they were not so universally useful; but working as Mr. Pringle did, their advantages outweighed their disadvantages, as he provided himself with the very best appliances, and apparatus specially constructed for the trying requirements of extremely sensitive plates.

Mr. J. Jameson exhibited an adjustable plate-box, made of corrugated zinc, with one side so arranged that plates of considerable variation in width could be securely held; also an ingenious automatic washing trough, in which the plates were placed face down upon perforated trays, the corners of the plates being firmly held by movable supports, that by an exceedingly simple arrangement could be adjusted to any size of plate. He also showed his simple apparatus for corrugating zinc, consisting of two pieces of grooved beechwood hinged together at one end, the grooves of one piece fitting the projections of the other. The simplicity, power, and results caused considerable surprise, especially as it had been in use for twenty years, and was still as good as when first made.

Mr. J. G. Tunny said he had been fortunate enough to secure a sample of the gelatine sent by a German firm for examination by members of the Society. He did not know the maker, but certainly it was the finest gelatine that had ever passed through his hands. It formed a hard, firm emulsion, setting quickly, and combined well with other makes of gelatine. It did not possess the few unsatisfactory qualities of the make of gelatine that he had hitherto considered the best.

Mr. James Balmain exhibited Boga's chronometric instantaneous shutter.

A copy of the *Montreal Herald* newspaper of Dec. 20th was laid on the table. Occupying a large part of the first page was a very fine collotype print.

The Secretary intimated that a copy of the Annuals for 1882 had been received from the Publishers of the Photographic News and the *British Journal;* also a quantity of Messrs. D. H. Cusson and Co.'s handy almanac.

Several interesting matters had to be postponed owing to the lateness of the hour.

A vote of thanks to the Chairman terminated the proceedings.

The first "Popular" meeting of the current session was held in Queen Street Hall, on the evening of Wednesday, 11th inst., when a splendid series of transparencies produced by Mr. W. J. Chadwick, of Manchester, illustrating a tour in the Isle of Man, were exhibited. The majority of the pictures were coloured in a most delicate and careful manner. A vote of thanks was awarded to Mr. Chadwick, and to Mr. Davies for his descriptive lecture. There were about 800 present at the meeting.

Photographers' Benevolent Association.

At the Board of Management meeting, held on 4th inst., it was decided to hold the annual general meeting at 8 p.m. on Wednesday, 25th inst., Mr. W. S. Bird in the chair. Every member who can possibly attend is earnestly requested to do so, and also to use his influence with those members of the profession who do not at present belong to the Association to at once join its ranks. Non-members are invited to the meeting.

Glasgow Photographic Association.

A meeting of this Association was held in the Religious Institution Rooms on the 12th inst., Mr. John Parker, President, in the chair.

The minutes of last meeting were read and approved of, Mr. A. H. Lewis was elected a member, and Messrs. T. Storey Davis and Donald Maciver were elected subscribers.

In reply to a question from the question box, as to why there were so few meetings,

The President said that the meetings at present were according to the constitution and rules of the Association, viz., once a month. Several members expressed a desire that the meetings should be more frequent, when it was agreed that for the remainder of the session meetings would be held fortnightly. As an extra attraction, Messrs. McGhie and Thompson offered to contribute some photographs to be balloted for amongst the members present.

The Secretary (Mr. John T. McLellan) gave a demonstration of portraiture by means of "a new photo-chemical light," and succeeded in taking two fairly good negatives. He prefaced his experiments by saying that in conformity with a promise made at last meeting he had selected the light that gave the greatest amount of chemical energy, and had succeeded in taking portraits by its means with an exposure of about one second, and proposed to repeat the experiments. The light employed was the result of burning one and a-half foot of magnesium ribbon in a globe of oxygen gas in the first experiment, and of burning a similar length of ribbon in a mixture of oxygen and air in equal proportion in the second; the first be recommended as giving the best result. A tissue screen was interposed between the sitter and the light; the focus of the lens was 6 inches, and the stop used was $1\frac{1}{4}$ inches; both plates were developed and shown to the members.

The remainder of the evening was spent in examining some fine transparencies thrown on the screen by means of the lantern, and the meeting closed with a vote of thanks to the Chairman.

Photographic Society of Ireland.

The usual monthly meeting was held in the Royal College of Science on Friday, 13th inst., Mr. Thomas Mayne in the chair. The minutes of the previous meeting having been read and confirmed, Messrs. Thomas Sherlock, Thomas James Robinson, Thomas McGovern, E. J. Hudson, Thomas Cranfield, Samuel Baker, and Henry Redding were elected members of the Society.

Amongst the many objects of interest submitted for inspection was a "gun camera," constructed and exhibited by Mr. John Russell. This instrument is admirably adapted for instantaneous outdoor work, and has the advantage of extreme portability. The inventor has adopted a contrivance of great novelty, enabling the operator to secure the subject in exact position on the plate, thus effectually preventing disappointment on finding that the object is so near the edge of the plate as to be of little or no use, or perhaps not on the plate at all.

There were also shown some very fine instantaneous views, taken last summer with the above, and which were as sharp and full of of detail as if the camera had been mounted "on solid rock."

A discussion arose as to the advantages of gelatine films, the difficulties of development, and the supporting them in the dark slides, as well as their keeping qualities, evoking a great amount of comment.

Mr. Thomas Mayne exhibited some gelatine transparencies made by Mr. Samuel Baker with the aid of a lantern, illustrating the advantage of using a good camera lens in conjunction with the ordinary condenser, instead of the usual lenses supplied, for procuring a greater amount of light, as well as greater definition of image in the pictures; and as a natural result the lenses were proved preferable for producing enlargements.

A new $7\frac{1}{2}$ by 5 camera, by Hare, was also on the table, and much admiration was expressed for several recent improvements, amongst them being the manner in which the double swings were effected.

Mr. J. V. Robinson, who has been working for some considerable time at the production of a solution for mounting photographs on thin paper which would prevent all "cockling," has succeeded in doing so, and an album of views taken at the late excursion of the Architectural Society of Great Britain was examined, the absence of "cockling" being very conspicuous, the prints not having been pressed in any way. These views do Mr. Robinson the highest credit, considering the difficulties under which they were taken. There were also some very excellent "moonlight" photographs on view.

The next meeting of the Society is intended to be held on Friday, the 10th February, 1882.

Thursday Evenings for Photographers.

A meeting was held on the 12th inst., Mr. C. G. Cutchey in the chair.

Mr. A. Cowan showed a further improvement upon Messrs. Mucklow and Spurge's sensitometers; the improvement consisted of a piece of perforated zinc over the apertures; the holes in this being all of one size allowed the amount of light admitted by each aperture to be much better regulated. Mr. Cowan used 2, 3, 4, 6, and 8 holes, &c. The light was admitted through a piece of opal glass, and with one minute's exposure to a fish-tail burner, three feet distant, Mr. Cowan said he could bring up six tints.

Mr. Brown exhibited two gelatine plates dried at varying temperatures, in each of which were three distinct bands of sensitiveness, that part dried at the highest temperature being the least sensitive.

Mr. Cowan showed a plate developed with Mr. H. Berkeley's sulphite of soda formula; he also showed the solution used to develop it, which was quite bright and clear. He said he had exposed two plates (giving the same exposure in each case), and developed one with fresh pyrogallic, and the other with Mr Berkeley's formula, allowing them to remain in the solution for the same length of time, the result being that there was no perceptible difference in the tone of either picture; that while the fresh pyrogallic solution was turbid, the other was perfectly clear.

Mr. Henderson exhibited a lamp for keeping emulsion warm whilst coating. It consisted of a food-warmer having a floating night-light swung on gimballs in the centre, and a piece of coloured medium placed over the side opening. Thus, not only did it keep the emulsion warm, but acted as a lamp for coating.

Mr. Brown used a heated fire-brick for keeping the emulsion warm, and found it answer the purpose well.

Mr. W. Ackland had experimented largely with vegetable gelatines, and said a very good gelatine, with strong salting power, was obtained from quince pips.

Mr. Henderson had experimented with the addition of gums to the emulsion, and found a decided advantage in the use of dextrine; he recommended six grains to an ounce of finished emulsion.

In answer to a question from the box, as to what value should be put upon the negatives in selling a business, Mr. Ackland said that the value of a photographic business should be from one and a-half to two years nett profits, the negatives to be included in the goodwill, stock and fixtures to be taken at separate valuation.

Dundee and East of Scotland Photographic Association.

The fourth general meeting of the above Society was held in Lamb's Hotel, on Thursday evening, 12th inst., James C. Cox, Esq., President, in the chair. In opening the proceedings, the President took advantage of the first meeting in the new year to convey the compliments of the season to each member individually, and to express the hope that the prosperity of the Society would continue.

After the minutes of last meeting had been read and approved, the President proposed that a vote of thanks should be given to the local press and the photographic journals, English, Continental, and Transatlantic, for their excellent reports of this Association; and that the receipt of annuals, &c., be acknowledged with thanks.

The next exhibition of lantern slides, comprising views in Sweden and Norway, &c., was arranged to take place on the 26th inst., and Messrs. C. Johnson (hon. secretary), Valentine, Macdougald, and Roger were appointed a committee to carry out details.

Mr. G. D. Macdougald, analyst, read a paper entitled "A Few Words on Gelatine Emulsions" (in our next), in which he demonstrated, with the aid of the blackboard and diagrams, the theory of bromide emulsion. He gave figures to prove the equivalent, and recommended the use of the microscope in watching the process through its various stages.

Questions and a discussion followed, in which the President, Messrs. Robertson, Donald, Roger, Anckorn, Ferrier, and others took part.

A vote of thanks was awarded to Mr. Macdougald for his paper.

It was resolved that a question-box be provided for the use of members in which to deposit queries to be answered from meeting to meeting.

A member exhibited an improved blow-through gas burner for laboratory or ordinary use, which met with much approval.

A vote of thanks to the Chairman closed the proceedings.

Talk in the Studio.

King's College Science Society.—A meeting of the above Society will be held on Wednesday, January 25th, at 8 p.m., when Mr. J. M. Thomson, F.R.S.E., F.C.S., will read a paper on "The Action of Light on Certain Substances, and its Application to Photography."

The Technical Exhibition.—The following are among the contributors to the Society of Arts Photographic Exhibition:—J. Spiller, W. Bedford J. Werge, P. Meagher, G. Hare, Lancaster and Son, Fallowfield and Co., Watson and Son, L. Warnerke, Marion and Co., the Autotype Company, the Platinotype Company, the Woodburytype Company, W. Brooks' Prof. Stebbing, W. Huggins, M. Jannsen, Prof. Roscoe, W. K. Burton, Captain Abney, E. W. Foxlee, D. Dallas, Horne and Thornthwaite, Prof. Piazzi Smyth, W. Rouch and Co., Francis Galton, Prof. Eder, W. Woodbury, F. York, the Kew Committee, the School of Military Engineering, Morgan and Kidd, A. L. Henderson, and the Photographic Supply Association. In all, the number of contributors is a little over eighty. Messrs Crossley have lent the Society one of their six-horse gas engines, which will be at work driving dynamo machines for the production of the electric light, when required, during the exhibition. Exhibits are to be sent in on Monday next, and the exhibition will open on the following Monday. It is announced that persons wishing to inspect the exhibition will be supplied with tickets on application to the Secretary of the Society.

To Correspondents.

W. Weston.—Thank you for the details of your experiments, which we will bring under discussion when we have gathered further information regarding some points bearing on the matter.

B. B. H.—In your own case we should be inclined to give a slight slope to the side looking towards the wall. If you can arrange for the whole or the greater part of the wall in question to be whitened or covered with white glazed tiles, the gain in light will be very considerable.

F. C.—1. The colour is doubtless a roseaniline salt. 2. If you brush a weak solution of sandarac in alcohol over the back of the paper, it will prevent the curling, and prove a partial remedy as regards the other difficulty you mention. Of course the solution must not be so strong as to render the paper partially transparent —perhaps 20 grains to 1 ounce; but much depends on the quality of the paper. 3. We cannot tell you what paper is used in the instance you refer to, but should recommend you to try to obtain a fine enamelled paper. You might also render the coating on ordinary albumenised paper insoluble by immersion in methylated spirit, and then wash to remove the chlorides; when dry, coat the face, and finally treat the back with the sandarac solution.

W. T. Martin.—If you make use of a small proportion of gelatine, in relation to the silver bromide, you will attain the desired end.

Academy.—1. He certainly can say so, but sensible people are not likely to believe him. 2. No diploma is usually required to enable one to tell lies regarding his own qualifications; but if your neighbour does better work than you do, make haste and surpass him in excellence.

A Subscriber.—1. See our "At Homes" in back Nos. of the News. 2. Yes. 3. Yes, quite as rapid if intelligent care be exercised.

W. B.—1. Not at all advisable. 2. An excellent practice, but only after thorough washing. 3. Methylated spirit.

W. Bradshaw.—Either slate or wood. An old petroleum cask answers well.

W. Griffith Medley.—They have probably but little commercial value, and your best way will be to sell the prints. You might write to some photographic publisher in London.

F. Stanley.—We certainly did find a trace of hyposulphite. You must remember that damp is necessary to enable the destructive salt to pass from a mount to the outer face of the albumenized paper.

T. W. W.—Far too complex and delicate an instrument for use under such circumstances.

Charles Linton.—1. We have already expressed our opinion, and, at present, see no reason to modify it. 2. An india-rubber tube can be made to serve very well if tape is wrapped spirally round the outside, so as to give it increased strength.

Ifford.—Nickel-plating answers well in such cases, but there is no reason why you should not make the article of the so-called German silver.

S. T. Simpson.—If your camera is provided with a front which can be raised sufficiently, you will very seldom require the swing-back, it being understood that you are working with the lens you name.

C. Cox.—The rotating cutter is the best tool for the purpose; a zinc templet being used as a guide.

J. Jensen.—It certainly looks rather suspicious, but you had better withhold your opinion until you have made further enquiries.

L. T. J.—The painted canvas sold as "target cloth" will be very suitable for the kind of background you require, as it is very strong, and will withstand the rough usage which you anticipate.

J. Wilkins (Sunderland).—The matter is still before the committee, but it seems doubtful if any satisfactory conclusion will be arrived at.

Indignant.—It is certainly a most impudent and fraudulent proceeding, but you probably will have to commence an expensive lawsuit in order to obtain redress.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1221.—*January* 27, 1882.

CONTENTS.

THE CAUSE OF VARYING SENSITIVENESS IN GELATINE EMULSIONS.

At a recent meeting of the Photographic Club, with Captain Abney in the chair, the question as to what is the cause of the greater or less sensitiveness of gelatine emulsions was discussed at some length. The chairman exhibited some emulsion plates which, although distinctly red by transmitted light, were, he said, extremely sensitive.

The general result of the discussion seemed to be to prove that it would be most interesting to all to know what really *is* the cause of the varying degrees of sensitiveness, but that at present no one is in a position to impart the desirable information.

The chairman said that it would be interesting to know whether or not the bromide of silver had ever been isolated in a pure and highly sensitive form, so that it could be combined again with gelatine to form a rapid emulsion, without any cooking process being gone through. If such had been done it would go far to prove that sensitiveness is due entirely to a molecular condition of the bromide of silver itself, and not to a chemical combination between the bromide and the gelatine.

Mr. H. Trueman Wood stated that, in making an emulsion by the boiling method with a small quantity of gelatine, he had boiled till the viscosity of the gelatine was totally destroyed, and until the bromide of silver had subsided to the bottom of the vessel; that he had poured off the supernatant fluid, had washed the bromide of silver, and on mixing it with the proper amount of gelatine and water, had got a highly sensitive and excellent emulsion. This, though it goes far to show that the change is in the bromide of silver itself, uncombined with gelatine, can scarcely be taken as a proof, unless the precipitated haloid had been carefully analysed to discover the existence or non-existence of combined gelatine. If the sensitizing action of boiling consists in a process which involves a chemical combination between the silver haloid and the gelatine, it is probable that such gelatine as had combined with the bromide would not be washed out.

Dr. Eder recognises two distinct molecular forms of bromide of silver having relation to the sensitiveness. There is, first, the "powdery" bromide, which gives a very slow plate, which is red by transmitted light; and second, the "granular" bromide, which gives a rapid plate, which is, *as a rule*, blue by transmitted light.

At the above-mentioned meeting the opinion was stated that there is no relation between the colour of an emulsion and its sensitiveness. To a certain extent this is true. It is impossible to state accurately from the colour of a plate whether or not it is highly sensitive. A plate which has a distinctly red tinge by transmitted light may be more sensitive than one which has a blue tinge; but, on the other hand, we may say that, working by any of the ordinary methods, there is a tendency for the colour to change from red to blue as the process advances, and that as long as this change of colour goes on, the emulsion will continue to become more and more sensitive. It must be remembered that there are various ways of examining the colour of a plate.

We took occasion a short time ago to point out that, if an emulsion be made containing but a small amount of iodide, the resulting plates, if thickly coated, will transmit, either before or after cooking, nothing but orange or yellow light; but that if, on the other hand, the emulsion be spread very thinly, so that on looking through it the form of a gas flame may be distinctly seen, this flame will appear ruby-red on looking through a plate coated before cooking, but blue after boiling, for the time required to gain the highest sensitiveness. This, to a certain extent, accords with the remark made at the Club, that when a very small quantity of a red emulsion is mixed with a considerable quantity of a blue emulsion, the whole appears far more red or orange than would be expected.

It is only by spreading a little emulsion very thinly on glass, and looking through this at a light, that we can give any information as to the degree of conversion from powdery to granular bromide which has taken place; but even then it is difficult—nay, impossible—to tell when the conversion is complete, because it is not possible to judge with sufficient accuracy of delicate shades of colour. We would point out a way in which far more accuracy may be attained; but it is only applicable to methods in which cooking is performed with a small quantity of gelatine—say, not more than six or seven grains to the ounce.

Place a drop of the emulsion to be examined on a glass plate; spread it very thinly, and dry it by gently heating the plate. Now, if this drop of emulsion be examined by transmitted light, it will be found to have divided itself into distinct rings or patches of red and blue emulsion. Examine this before boiling, it will be found that there is little or no blue; but as the boiling goes on, it will be found that the blue increases in proportion to the red till, when conversion is complete, there will be blue only. At any time the blue will be found to separate itself distinctly from the red; that is, as we have said, if only a small quantity of gelatine be in the emulsion.

It will be seen that although we cannot take the colour of a plate as definitely indicating its sensitiveness, yet we consider an observation of the change of colour to be a most useful guide to assist in telling when to stop operations in the case of ordinary methods.

It will be seen further that we recognise as the chief cause of increased sensitiveness the change from one molecular form of bromide of silver to another—from the powdery to the granular. That there must be something more than this, either some further molecular change or some chemical combination, appears evident from the following considerations:—

If different methods be used, and if in each the process be pushed until the conversion is just complete, the resulting emulsions may yet be of widely different degrees of sensitiveness.

An emulsion in which the conversion is not complete may be more sensitive than one in which the conversion is complete.

Under certain circumstances, sensitiveness may go on increasing long after conversion is complete.

It will be understood that we have, for the most part, been considering emulsions containing silver bromide alone. When other haloids are introduced, the question becomes still more complicated. In any case, it is one of the deepest interest, and one which deserves more attention than it has had. Until we know more than we at present do as to what changes take place in emulsions in relation to increase of sensitiveness, we are only working by rule-of-thumb. The question is one which we should like to see discussed in these pages by those of our correspondents who have given attention to the matter.

GELATINE FROM A CHEMICAL AND PHYSICAL POINT OF VIEW.

SECOND ARTICLE.

THE gum-like product obtained by the prolonged heating of an aqueous solution of gelatine, and alluded to in our article of last week as meta-gelatine, is largely present in some of the commoner kinds of commercial gelatine, such as a cheap glue; while such products as Coignet's gold label gelatine are almost free from it. The presence of even a large proportion of meta-gelatine is often advantageous, as for example in the preparation of carbon tissue; but in other cases it is an undesirable impurity.

The property which gelatine and its primary source—ossein—possess of forming insoluble compounds with the various forms of tannic acid, is of fundamental importance with respect to the art of manufacturing leather; and a solution of tannin has been found of considerable use for hardening negatives and collotypic films.

When gelatine is impregnated with about one-sixth of its weight of a soluble bichromate, as that of potassium or ammonium, it becomes so sensitive to light that a sheet or film of the material may be impressed with a tolerably vigorous brown image when exposed under a negative for rather less time than would be required to produce a print on albumenised paper. Such an exposed film of bichromated gelatine possesses properties which form the basis of the greater part of the photo-mechanical processes now in use. If it be soaked in water, those parts which were protected from the action of light, rapidly swell to more than four times their original thickness, while the exposed portions refuse to absorb water or to swell. A plaster cast may now be taken from the film, and on casting type metal in the plaster mould, we obtain either a relief suited for decorative purposes, or a type block adapted for ordinary relief printing, the latter being produced when the original negative consisted only of extremes of light and shade, as in the case of one taken from letter-press or a pen-and-ink drawing.

If the soaked gelatine film be rolled with an ordinary printer's roller charged with printing ink, it will be found that the fatty ink will refuse to adhere to the swelled and wet portions of the film, but it will readily attach itself to those parts which have been acted on by light. The inked film, if now pressed against a sheet of paper, yields up some of its colour, and thus prints a photograph in fatty ink. Fresh copies can be obtained by re-inking the gelatine film. Here, then, we have the basis of the collotypic process and of the ordinary method of obtaining a photo-lithographic transfer.

Let us suppose, now, that the exposed gelatine film is treated with warm water instead of being soaked in cold water. In this case the protected portions will dissolve to a depth proportionate to the opacity of the corresponding parts of the negative; and if the action of the hot water be stopped at the right time a relief will be obtained in which the thickness of each part will correspond to the extent to which light has acted. To thus obtain a solid gelatinous reproduction of the negative is the primary operation in the Woodbury photo-mechanical process, and similar reliefs charged with a suitable pigment form the so-called carbon prints.

Of the use of gelatine as a vehicle for the sensitive bromide of silver of the negative plate we need say nothing here, as this is a matter of every-day discussion at the present time.

A few words on the principal gelatines of commerce will be followed by some notes on a method of testing the setting quality or tenacity of samples.

Isinglass consists of the sounds or air-vessels of various species of sturgeon, and the principal supply comes from Russia. It generally contains a notable proportion of saline matter, which can be readily removed by a moderately long soaking in cold water. A solution of isinglass, when carefully filtered, gives a remarkably hard and structureless film, well suited for collotypic or gelatino-bromide work. Isinglass should be purchased in an uncut state, as the fine shreds are often adulterated with cheaper qualities of gelatine.

Grenetine is a clear and transparent product, consisting principally of the substance already referred to as chondrin, and it is especially suitable for making Woodburytype reliefs, the Pretsch process, carbon printing, and also for collotype work when only a small number of copies are required. A product having most of the useful properties of grenetine is sold in England as "Nelson's Transparent Sheet," and a somewhat harder gelatine which is adapted for similar uses is known as "Nelson's Amber Gelatine," this latter being very well adapted for preparing gelatino-bromide plates in cold weather.

Coignet's Gold Label Gelatine, which is sold in packets of one kilogramme, is a product of great value to the photographer and the photo-mechanical printer, as its solution possesses great setting or gelatinising power, and it yields an unusually tough and tenacious film. For preparing collotypic plates when long numbers must be printed, for coating transfer papers, and for gelatino-bromide work in hot weather, the gelatine in question is invaluable. It has, however, the disadvantage of being liable to yield films which are either pitted, or covered with ridges which arrange themselves in map-like forms; but the addition of ammonia, and vigorous churning of the solution, tend to overcome these difficulties. It is often possible to purchase an excellent imitation of Coignet's gelatine at about half the price of the genuine article; but careful judgment must be exercised in selecting the sample.

"French Medal Glue." This is usually sold in clear yellow tablets about nine inches square and nearly half an inch thick, and the quality is generally excellent. It may be used in making carbon tissue or Woodburytype reliefs, and it forms a very good mounting material, but its solution should always be tested with litmus paper, and if any acid reaction is observable the sample ought to be rejected. Scotch glue is similar in character to the medal glue, but is generally somewhat darker in colour.

Russian glue is usually a very high-class article, being excellent as a mountant; but as it often contains a considerable proportion of phosphate of lime, is not well adapted for general photographic uses.

The lowest quality of commercial gelatine is a cheap glue, sold in the oil shops at about fourpence per pound. It is generally soft and in a state of incipient decomposition; in fact, it will almost dissolve in cold water. It is, however, very well adapted for sizing canvas or other material which is to be used for backgrounds, as it does not become extremely hard and brittle on drying.

The quality of a gelatine can be measured approximately by estimating the gelatinising power of a solution of definite strength, and various samples can be easily compared together by the method of Lipowitz. For this purpose each sample is dissolved in nine parts of water, so that the solutions shall contain exactly ten per cent. of solid matter. The testing apparatus consists of a small beaker, to which is fitted a tin cover, and through this cover a stiff wire slides, the lower extremity being provided with a spherical terminal half an inch in diameter, and the upper end is fitted with a small tin box. Each sample of gelatinous solution is poured into one of the testing beakers so as to half fill it, and after a rest of twelve hours, a cover is fitted to each beaker, and the ball is allowed to rest on the surface of the jelly, sufficient shot being next poured into the tin box to force the ball fairly into the mass of jelly. The weight of shot required serves to indicate the relative strength of the several samples.

Although the above method may be objected to as subject to some deficiences from a scientific point of view, it is found that in actual practice the results are satisfactory.

It sometimes happens that a fictitious hardness is communicated to gelatine by ordinary alum or chrome-alum, the hardening power of the latter being very considerable; a large proportion serving to induce complete insolubility.

SHEFFIELD PHOTOGRAPHIC EXHIBITION.

The Exhibition of Photographic Art now open at the Cutlers' Hall, Sheffield, deserves some notice at our hands. Although comparatively small, it is by no means an insignificant display of talent, as the pictures are sufficiently meritorious to afford pleasure and profit by inspection. If exhibitions are to become the fashion, and every society is to have one—and we see no reason why they should not—the present example may teach, like its predecessors elsewhere, what are the elements of success, or the reverse. The Sheffield Society wisely decided at the last moment to dispense with a catalogue, and passed a resolution that pictures, &c., being the work of an exhibitor should bear the title of subject, and also the artist's name, but in examples not the exhibitor's work, the title only be placed on the frame. By adopting this arrangement the task of identification is rendered easy, and perhaps preferable to consulting a catalogue, which is sometimes rather suggestive of Bradshaw. The room selected was on the whole well fitted for a temporary art gallery—a spacious lofty apartment, forty feet long and about twenty wide, with five large windows having north aspect. The pictures were well arranged on wall and screens, attention being paid to position, a few large ones only exceeding an altitude of seven feet. Tables for apparatus were conveniently placed.

The pictures numbered between three and four hundred, and contributors about forty. Home-made work was in excess of that from a distance, although there were imports which had travelled and done good service before. Woodbury, Autotype, and other enlargements were abundant, but it was remarked that distant friends had not responded very freely to Sheffield's invitation. Are exhibitions held too close together? Do pictures suffer by careless packing? Or does the absence of medals from a programme make contributors shy? Our readers may draw their own conclusions; but, whatever view is arrived at, there can be little doubt that the individuality of a district should be well represented in all local exhibitions, competitive or not. Of members' work, the first series of pictures attracting notice on entrance are a set of well-mounted studies by Mr. Crosby, and enlargements. The portraits—large size—show artistic skill; one, entitled "The Reader" (a recumbent figure intent upon a book), and portraits of Nelly and Fanny Crosby, are commendable. The landscape is well chosen, but the shadows are too strongly pronounced.

Mr. G. V. Yates is a large contributor. The varied subjects in frames bearing his name are of a uniformly high-class order; his Derbyshire scenes and a case of portraits showing, by much careful finish, an experienced hand. Mr. Stringfellow's productions, some on wall and others on screen, are very good samples of gelatine and collodion. Of the former a pair of small pictures, the Rivelin Valley, early morning, please by a refreshing crispness and soft detail, as also Isle of Man views. His Scarborough 15 × 12 collodion, compares favourably with the now universal gelatino-bromide process. Some excellent Autotype enlargements show what can be done with a first-class negative. Mr. W. B. Hadfield has three frames of small pictures, just the little bits a tourist ought to pick up in Derbyshire and Isle of Man, and portraits of one little Wide-awake are remarkably pretty.

The pictures by the Hon. Sec. (Mr. J. Taylor) are of local and general interest, and prove that he can turn to account both collodion emulsion and gelatine. The most notable of his specimens are views in Douglas, and landscapes in Yorkshire and Derbyshire.

Mr. J. D. Leader, F.S.A., has on the screen a choice collection of prints, delightful in the antiquarian mind. The president of the Society (T. H. Morton, M.D.) sends a large number of pictures, including frames which he exhibited in London and elsewhere. He has fortunately secured natural clouds in many views, which always enhance the value when acquired without under-exposure.

Mr. Fred. J. Hall has mementoes of towns in Norway, and also some excellent local views, as Roche Abbey and the Lake at the Farm. Mr. Hicks is represented by a case of capital portraits and a fine Autotype group of Canon Blakeney and family, perhaps the best thing of this class in the room.

Mr. Daken lends an enlargement from one of his portrait negatives; Mr. H. P. Collinson, views in Miller's Dale; Mr. Rawson, numerous stereos, artistically selected—evidently his *forte*; Mr. T. Firth, a charming view near Roche Abbey; Mr. T. Bromley, stereoscopic views in his usual fascinating style—Haddon Hall Terrace and Lath Hill Dale are particularly nice.

Contributors from a distance, as before observed, were few and far between.

We noticed a splendid winter scene, by Geo. Renwick, Burton—Frost Study—an ice-bound lake, surrounded by trees loaded with snow and hoar frost, skaters on the ice animating the view.

Mr. James Stoyle sends strikingly-effective interiors and *souvenirs* of Ilfracombe on the tables.

Messrs. Cubley and Preston send a goodly array of stereoscopes, a lantern, and changing tent; Messrs. Hunter and Sands, their well-known cameras and rapid shutters, and views taken by them; Moorse and Co., studio and other cameras; Shew and Co., changing box and apparatus.

On the tables, in addition, were lantern slides by the President, and stereos by Mr. Rawson, who also had a large transparency in a graphoscope.

Mr. Taylor forwarded his new 12 by 10 camera and hinged tripod, and there were also burnishers by the Sheffield makers—Mr. H. Rock and Mr. Woodson.

FRENCH CORRESPONDENCE.

Œleoccoca-Oil Sensitive to Light—Vegetable Mucilage—Oscillating Bath—Gobert's Engraving Process.

Œleoccoca Oil Sensitive to Light.—At the last meeting of the Photographic Society of France, M. Fleury-Normagis exhibited specimens of œleoccoca oil, which, as he maintains, is sensitive to the action of light. This substance, which has not yet been used in photography, possesses the property of hardening when acted on by the luminous rays, becoming opaque and of a waxy consistency. Every substance which is sensitive to light is worthy the attention of photographers, and for this reason M. Fleury's statement possesses great interest. The oil should now be investigated from a photographic point of view, and to isolate the sensitive element, so as to discover what use it can be turned to. M. Fleury distributed to several of his colleagues specimens of the oil, to enable them to analyse it, and to find out to what photographic purposes it can be applied.

Vegetable Mucilage.—M. Fisch presented some bottles of a vegetable mucilage, the origin of which he did not make known. He merely said that it is a very inexpensive substance, and is made from a very common plant. It is a sort of vegetable albumen, which can be used in some photographic processes in place of animal albumen and gelatine. This substance does not set quickly, but it can be bichromatized and flowed over paper or plates, where it will dry. It can also be tinted with colouring material as is done in the carbon process. According to M. Fisch, it is well adapted for the preparation of photolithographic paper. I am just now engaged in making experiments with it as a substitute for albumen in coating plates to be engraved, and as a substitute for gelatine in carbon printing. As this mucilage does not solidify like gelatine, it cannot be used for the preparation of emulsions. It is vexing not to be able to tell what this substance really is; but, if it is useful and valuable, I hope that it will soon become known.

Oscillating Bath.—In the course of remarks by M. Sans he stated that during development the bath must be kept oscillating, and this he effects by means of a turning jack. In the discussion which ensued, M. Chardon remarked that the jack will not run for more than half-an-hour without being fresh wound, and he had adopted a plan of moving his oscillating bath by means of a small electric motor set in action by a couple of Daniell's cells. This motor is a modification of one exhibited by M. Trouvé at the late electrical exhibition. This arrangement is a very simple one; it can be set up in any suitable part of the laboratory, when, directly contact is made, permanent oscillation is obtained. The expense for generating the electricity is extremely small, and may, in fact, be neglected. In consequence of a failure on the part of the mechanic whom he employs, M. Chardon was not able to show his ingenious apparatus, but we may hope to see it at the next meeting. I have already had occasion to insist on the advantage of providing every well-arranged laboratory with electric power, which can be used for a great number of purposes. We can employ it not only in making the baths oscillate, but also in turning the tables for engraving plates; also for acting on the shutters and on the bell of the oxalate of iron photometer; for sifting fine sand, and for the incandescent lamps. In short, the time will come when this electrical arrangement will be absolutely indispensable in every properly-arranged laboratory. I might have added that the motor could also be used for turning the table on which the frames are exposed to the light; a table supporting several frames could by this means be made to turn so as to expose each side in succession to the light.

Gobert's Engraving Process.—The process of engraving introduced by M. Gobert is so very simple and practical that I am induced to say something more on the subject; I am anxious that it should be tried, for I feel sure that its value will be appreciated. To begin at the beginning: an etcher, we all know, works with a needle on a plate of copper which has been coated with a special kind of varnish. Drawing with his needle the lines which he desires to have etched, he lays bare the metal. Now, to obtain good results in this way, it is necessary to have some amount of skill, and the operator is often exposed to accidents, due either to improper varnish or to his own want of skill, and these accidents frequently are the cause of the work having to be done all over again. But by employing a photographic process these difficulties are obviated; besides which, the original drawing is preserved, and from it as many copies as may be desired can be reproduced. On the other hand, any one having in his possession a line drawing can take from it an etching superior to the copy produced by the manual labour of the most skilful artist. These considerations make it one's duty to insist very strongly on the Gobert process, as being one which can be worked with the greatest facility. An engraving, either in line or mezzotint, can itself be used as the negative, provided that it has been executed on somewhat transparent paper. The copper plate is coated with bichromatised gelatine, quickly dried, and then exposed to the light beneath the engraving. Owing to the bichromatised albumen being very sensitive to light, the exposure need not have a long duration; but in any case it is much shorter than would be required for a film of bitumen. The development with cold water is readily managed, and on account of its colour it is easy to watch how the image comes out. To etch the plate, we use a solution which does not attack the photographic film; but, on the contrary, hardens it still further, so that we may be certain that the copper will only be etched in those places where it has been laid bare. We may also rest assured that the action of the mordant, even if it were prolonged still further, would not have the effect of causing the film to scale off, and thus spoil the result. This mordant, as I have already explained, consists of a concentrated solution of perchloride of iron in rectified spirit. In the whole process there is nothing absolutely new, excepting that for a layer of bitumen is substituted a much more sensitive substance, and that in place of diluted acid is used a solution of much greater reliability.

Leon Vidal.

A SIMPLE APPARATUS FOR WASHING GELATINO-BROMIDE EMULSION.

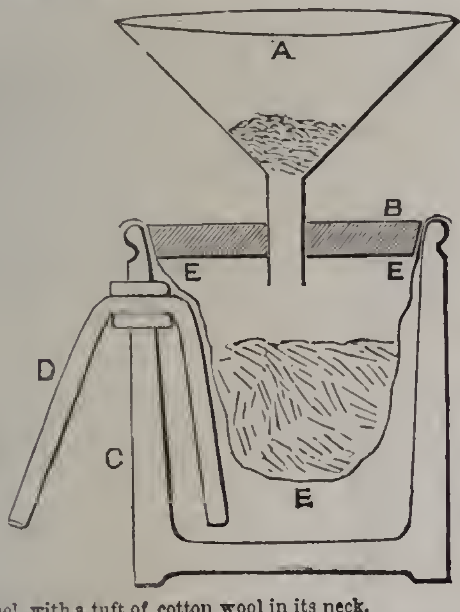
BY WILLIAM BIRRELL.

I obtain a common white two-pound jelly-pot, for which I pay twopence, and I then take a diamond-pointed steel drill (such as used by blacksmiths and others), and make it as hard as possible by heating it to redness, and quenching in cold water. Then put it into a joiner's brace, and bore a one-inch hole in the side of the pot, about two inches from its upper edge (the drill has to be ground several times during the operation, as it soon loses its edge). I then fit a cork tightly in the hole, after which a half-inch hole is made in the centre of the cork, and a piece of india-rubber tubing, long enough to reach to the bottom of the pot inside, is fitted in this hole; the other end passes below the bottom outside. This acts as a syphon.

I then obtain a cork or bung large enough to fill the mouth of the pot, and make a hole in its centre, into which is inserted the tube end of a gutta-percha funnel, the tube being allowed to project fully through the under side of the cork. A piece of muslin is next fastened over the mouth of the pot in such a way that it falls down bag-fashion to within one-third of the bottom of the pot. I found that the syphon would work well as now arranged, and to use the apparatus the emulsion is put into the muslin bag, and the cork or bung is put in its place, a plug of cotton-wool inserted into the neck of the funnel, and the whole apparatus is placed under the tap. The water goes down through the gelatine, then rises up to the syphon, and when this acts it immediately drains all the water off, and as this sudden drawing off is repeated every time the jar fills up to the bend of the syphon, the soluble salts are very soon washed away.

I think this is a far better plan than either soaking, or pouring water over the emulsion, as the apparatus now described both soaks and drains. With this thorough washing, the emulsion does not require to be cut up into such small pieces as would otherwise be necessary, a point of some importance. Captain Abney advises us to squeeze the emulsion twice through coarse canvas, but I have found when that was done it was impossible to get all the superfluous water out of it by any reasonable amount of draining over hair sieves or otherwise, and the plates coated with such an emulsion are poor and thin—or, in other words, totally useless. No doubt alcohol is to be recommended to abstract the water, but this is an expensive complication; at any rate, I have found I can get as good a result by using the apparatus as I can with the alcohol, and as thick a film; so the alcohol and extra labour are saved. I am indebted to Mr. William England's article in the News for the idea of filtering the water, and I think a great number of spots on the plates arise from impurities in the washing water.

My apparatus could be made of gutta-percha or ebonite; perhaps properly japanned iron or tin plate would do. The following diagram will be readily understood on reading the reference notes.



A. Funnel, with a tuft of cotton wool in its neck.
B. Cork or bung.
C. The jam-pot, provided with a hole to carry cork, which holds—
D. India-rubber tube;
E. Muslin bag, held in position by the bung, and containing the fragments of emulsion.

A CURE FOR YELLOW GELATINE NEGATIVES.

BY H. B. BERKELEY.*

Judging by the greater part of the pyrogallol-developed negatives which we see, there is great room for improvement in the method by which they are produced. I refer to the all-pervading, dingy-yellow colour of the image, even the shadows of which partake of the same sickly tint.

Some of the members are aware that I make use of a nostrum of my own, a "sure and certain remedy" against "yellow-sickness," and perhaps some have disrespectfully spoken of it as my "fad." It is my intention to-night, therefore, to show you this "fad" applied to actual practice.

Before adopting my method in its present form, I added sulphite of soda to the water used for making this alkaline developer; the pyrogallol was dissolved in a small quantity of alcohol, in order to preserve it, and a few minims of this were added, together with soluble bromide and ammonia, to the required quantity of solution.

The bottle of alkaline developer I now hold in my hand was made last May in this way, and in it was developed a negative during half-an-hour. One minim of ammonia was added to each ounce of solution, and three minims of pyrogallol. This may serve, perhaps, as a striking instance of the efficacy of my "fad" in preventing the oxidation of the pyrogallol.*

The method I now employ is somewhat different in detail, though the same in principle. Forty parts of crystallized sulphite of soda are placed in a graduated measure and made up to nearly a hundred parts with water. When the crystals are dissolved, the solution is nearly neutralized by citric acid (the neutral sulphite will be found to be alkaline; indeed, itself is an alkaline salt); ten parts of pyrogallol are then added, and the whole is made up to one hundred parts with water. Every ten minims of this solution contain one grain of pyrogallic and four grains of crystallized sulphite of soda.

I have here a bottle of solution so made on 13th of October last. I do not perceive any change in it since that time. The bottle has been simply corked.

In this bottle I have a solution of pyrogallol made one year and five months ago; it is still practically colourless. The pyro used had been previously kept in alcohol, and the solution was much discoloured. The quantity of pyro in this solution amounts to three grains per ounce. The solution should contain hydrosulphite of soda, which has a greater avidity for oxygen than has the neutral sulphite. A small piece of metallic zinc has been kept in the bottle, with a view to preserving the de-oxidised condition.

The first negative I now pass round—"On the Banks of the Wye, near Rhayader"—was thought to be rather under-exposed, and development began thus: Moistened with water; then pyrogallic $\frac{3}{4}$ grain, and ammonia $1\frac{1}{2}$ minim. The image came up too quickly: $1\frac{1}{2}$ grain ammoniac bromide added; in one minute, $\frac{3}{4}$ grain more pyrogallic; in five more minutes, 1 grain bromide. Development lasted sixteen minutes. The second negative—"In the Bed of the Wye"—was developed thus: Moistened with water, pyrogallic $1\frac{1}{2}$ grain, ammonia 2 minims, and bromide $\frac{1}{2}$ grain. Sky and water appeared in one minute; nearly full detail in seven minutes. The development lasted $8\frac{3}{4}$ minutes.

I may add that I keep, as nearly as possible, exact account of exposure and development of negatives, not the least important item being a record of the length of development.

The plates were prepared from precipitated and boiled bromo-iodide emulsified in Coignet's gelatine.

To the above remarks Mr. Berkeley has since added the following:—Some misconception seems to exist as to the object of adding, and functions of, the citric acid. The intention is to neutralize the alkalinity of the sulphite, which, besides being itself an alkaline salt, commonly contains carbonate as an impurity, the crystallization being very imperfectly carried out. The alkalinity might tend to the oxidation of the pyrogallic, and cause the solution to have less perfect keeping properties. Probably from this point of view it is a refinement of no great value; but we prefer to consider our pyro. to be neutral. One slight objection to citric acid alone as a preservative of pyro was the necessity for allowing for the amount of citric acid present in each developer, and this, of course, varied with the quantity of pyro. solution used. If, on the other hand, a slightly alkaline solution of pyro. were used, the amount of alkalinity could scarcely be estimated by taking account of the ammonia added to the developer. In practice, however, where no exact experiments are to be instituted, the pyro. stock solution may doubtless be simplified by leaving out the citric acid altogether.

Now, with regard to the colour of the negatives produced in this way, it has been suggested to me that the colder tone may be due to "sulphur toning"—that sulphide of silver is produced in the image. This appears to me not to be possible. I have no well-founded statement to make on this point, but may say that we all know that a large portion of the ordinary alkaline-developed image is not metallic silver. My impression is, that when sulphide is used, this deposit of organic matter in the image is prevented; and, time being given, a strong image of pure, or nearly pure, metallic silver is the result.

* Read before the Technical Meeting of the Photographic Society.

* A body of the liquid, about two inches thick, transmits light of a straw-colour.

Notes.

Honours to the Vienna Photographic Society! His Majesty the Emperor of Austria has nominated the honorary president, Herr A. Martin, a Councillor of State.

Mr. Woodbury is expected in Vienna to give a demonstration of his improved process before the Society of the Kaiserstadt.

Mr. J. W. Swan's lecture at the Royal Institution, on "Electric Lighting by Incandescence," is fixed for March 10. Captain Abney will lecture on the friday following, on "Spectroscopic Work with the Infra-red Rays of the Spectrum."

A photographic portrait seems to have become a necessary adjunct to a warrant of arrest. Mr. Nicol Fleming, one of the Glasgow Bank directors, who was arrested on Monday in London, was identified by the police officer by means of a photograph.

The most interesting exhibit at the approaching Society of Arts gathering will, in all probability, be the gelatino-chloride transparencies of Dr. Eder and Captain Pizzighelli, the preparation of which is described at some length in our Year-Book.

A rectification of peculiar importance to photographic chemists is contained in a paper by Professor Cook, of Harvard College, which has just been presented to the French Academy of Sciences. The atomic weights of bromine and silver are both altered in this memoir, the equivalent of the first being fixed at 80, and that of the second at 108.

There was not a single hour's sunshine in London last week—or, rather, in Greenwich. To put it accurately, the amount of bright sunshine amounted to 0·8 of an hour. As the sun was above the horizon for a period of 58·7 hours, it is obvious that we only got 1·4 per cent. of the maximum amount of sunshine. No wonder photographers cry out for a quicker process of printing!

The record would have been different, no doubt, if, instead of being taken at the Royal Observatory in murky Greenwich, in the midst of the smoke and thick vapour that comes over from the Isle of Dogs, the observation had been made in a clear atmosphere and at some elevation. Thus, the new Etna Observatory, which has just been completed by the Italians, is likely to give us far more valuable records in respect to meteorology and solar physics than any we have yet obtained. It is built on a small mount near the crater, and is so placed that a current of lava descending the volcanic mountain would probably divide and avoid the building. The Etna Observatory stands more than 9,500 feet above the sea, and is more than twice as high, therefore, as Ben Nevis, where Scotch meteorologists have recently established a temporary observatory.

We are glad to state that Mr. W. J. A. Grant is safe home again after his fourth voyage to the Polar Seas. The voyage this time has proved more difficult and perilous than usual; but we believe Mr. Grant has brought home with him, in the stout little whaler the *Willem Barents*, an important addition to the series of Polar photographs which form so trustworthy a record of frozen wilderness that lies around the North Pole.

The Salzburg School of Photography—the only establishment in Europe in which photography in all its branches and applications is made the sole study—mustered 39 students last year. Of these, eight were youths from 14 to 18 years, who had no knowledge of photography; and the remainder, assistants and principals from various studios in Germany who attended the classes, laboratory, and work-rooms to seek chemical and technical instruction.

The telelogue is a system of optical telegraphy proposed by Captain Gaumet. There is apparently very little of novelty in the suggestion. An oblong board several feet in height is marked with a huge letter, painted in silver on a dead black ground, and this is exhibited at one station and read at another some four or five miles off by the aid of a spy-glass. In a word, you spell at a great distance. If such a method of signalling were of value—which we very much doubt—there would be no reason why the signals should not be recorded by photography. The sender and receiver might be governed by a clockwork instrument working at the same speed, and every ten seconds or so an exposure might be made—the sensitive plate being shifted a little after each—so that the signals are written down. By placing the developed plate in a suitable magnifier the message might afterwards be read.

The circumstance calls to mind the little use that is made now-a-days of a telescopic tube in front of the camera. In the case of tiny objects seen at a distance, a tube in front of the camera adds to the vigour of the image by cutting off extraneous light. For this reason we have always advocated the use of a tube in front of a balloon camera, for a photographer in the clouds is flooded with hurtful light on all sides, and the earth, far away, which he wants to depict, is the darkest of all. Some years ago our duty led us to depict the embrasures of a fortress at a distance of upwards of a mile, to see if a photograph of any value could be obtained of out-works in war time; the picture had, of course, afterwards to be enlarged, and we found that its sharpness and clearness were decidedly improved by the employment of a long tube.

Let any one try the experiment upon a church tower a couple of miles off—we have photographed Barking Church, across the Essex Flats—taking pictures with a tube and without it; he will be surprised at the difference of results. Only, in exposing, he must remember that in long-distance photography the proper lighting of the object is all-important, and in developing, that the result at best can only be a faintly-detailed one. Naturally, a clear day and a long focus lens are very desirable.

In Germany, a complaint has arisen among photographers about the extortion of certain agents connected with actors and actresses, who seek to levy black mail. An *artiste* is photographed, and subsequently the agent appears, and demands his *douceur*. In one case, in Berlin, 300 marks (£15) were demanded; but, in the end, 100 marks were taken. The German photographers are asked to band themselves together, in order to withstand such demands in future.

An opinion by one qualified to give it is always worth noting, and for this reason we call particular attention to Mr. Ackland's recent remarks upon the subject of buying and selling a photographic business. Mr. Ackland, as some of our readers may know, is the guiding spirit of Messrs. Horne and Thornthwaite, and may be credited, therefore, with some experience on the subject of which he speaks. According to his views, then, the value of a well-established photographic business, including all negatives, is equal to the nett profits of the business for a year and a-half or two years, the fixtures being taken at a separate valuation.

The *Wochenblatt* is exercised in mind about some lamentably erroneous statements that have recently appeared concerning a certain Persian potentate who is in Berlin just now for the purpose of studying photography and retouching, and having his right eye cured of cataract. In the first place, he is not the "uncle of the Shah" at all, as some people want to make out; his name, our Berlin contemporary rather indignantly tells us, is Prince Sultan Oveis Mirza, Ihtisham el daulet being not an uncle, but a cousin of a son, Firuz Mirza, of the uncle of the Shah. This, obviously, makes all the difference. Again, as to the doubts which have been thrown upon the advisability of a man suffering from ophthalmia taking lessons in the art of retouching, the *Wochenblatt* points out that the left eye of the prince is still in the best state of preservation, and consequently quite competent for the work. Altogether, we think our contemporary comes out of the matter very triumphantly.

ODD JOBS.

BY THE AUTHOR OF "LOOKING BACK."

No. 7.—St. Mary's Island.

In local parlance this little romantic place is termed the "Bates"—"Bate" being the popular term for bread, cheese, and beer, on the Northumberland and Durham coasts. I may state that St. Mary's lies about nine miles north of Tynemouth, and eighteen south of the Coquet. It is a wonderful little island, or, to be more particular, peninsula: for you can during the ebb of the tide walk dry-shod from the mainland, a distance of about half a mile. To give a graphic description of St. Mary's, I may term it a little bit of rock with a low sprawling house upon it, the latter bearing an old-fashioned sign-board, intimating to all whom it may concern that the proprietor is "Liscenced to sell," &c. The whole place is surrounded by huge masses of rock covered with seaweed, that float with the rising tide, and wave their long arms about on the waves as if they were things of life. There is a natural harbour towards the open sea where picnic parties, steam tugs, and pilot boats run in to rest or refresh. Entering the house, you pass through a sanded tap-room, redolent with the fumes of stale beer and tobacco smoke. Beyond this, and almost dug out of the hill, towards the sea, is a snug little parlour, where the worthy landlord will proudly show you a couple of skulls that were found when digging the foundation; and likewise display a letter from the Bishop of Durham expressing his belief that St. Mary's at one time was the site of a monastery, and that no doubt the skulls in question were those of some famous abbots who had been buried within its walls. And now the Hartley pitmen drink beer and play quoits on the site where once bell, book, and candle reigned supreme.

Not only is St. Mary's remarkable for its bygone sanctity, but there are legends of smugglers having haunted the place, and if you wish to see the landlord mad, just mildly suggest that the two skulls might be the remains of some of their brutally-murdered victims.

I was there, autumn was a year, during a short holiday, and, with my usual luck, had the pleasure of being locked up in the house for the space of three nights and days during the raging of a most tremendous storm: the doors were never opened during the time, and the windows barricaded with storm-shutters. Had it not been for a French hurdy-gurdy the landlord had won at some lottery, and a dirty pack of cards, I do not know how we could have passed the time while the wind was howling as only an east wind can howl, and the spray and foam flying over the roof in clouds. On the second day, while we were peering through the pigeon-hole of the storm-shutter, a Dutch lugger, without a shred of canvas, and her foremast gone, came sweeping between us and the mainland. In vain the drenched and bare-headed man at the tiller strove to keep her in mid-channel. A great roaring wave or two, a furious gust of wind, and she struck on the rocks opposite. In a moment or so we saw the man wade ashore through the surf, and, seeking shelter in a hollow in the bank, coolly light a pipe that by some means he had kept safe from the wet, and, puffing away, philosophically sat watching the breaking up of his bark.

At last the leaden clouds broke up, the wind gradually lulled, the roar of the waters around us softened, and at length the door was gradually opened. Never in all my life did I see such a conglomeration of foam! The house—the island—was literally smothered in it. After creeping through this mass of soft bubbles, and literally digging out the boat, we launched it; and, amidst a splashing, short surf—through which I hugged the camera and dark slides in the most careful manner—we pulled over to the mainland, and landed under the lee of the lugger, that still seemed to hang bravely together, despite the awful buffeting she had received.

After sundry futile attempts to get on the beach dry-footed, and, bearing the satire of our sea-dog of a landlord about town-bred people being so tender that they were afraid to even wet their little toes, I got indignant, and, with the air of an amphibious animal, stepped from the boat, and walked slowly up the beach, receiving on the way two drenching showers, that ran down the back of my neck, and nearly took me off my feet.

However, my camera and slides were safe from the briny, and not heeding the grins on the boatmen's faces, I fixed up the apparatus, and exposed two whole plates—one second, and two seconds, making one of the wildest pictures one ever saw—the raging sea still covered with "white cats"; the foam-girt island; the wrecked lugger, and boat in the foreground.

It was a week before I could get them developed, and the one-second exposure came first. When looking at the surface of the plate I was chagrined to see that it was spotted all over with small round yellow ticks. However, upon developing, I found that they were not the worst fault the plate had, it being greatly under-exposed. After, for curiosity, fixing this negative, albeit the spots still remained when looking down upon it, they were not to be observed when looking through it. I dare say they were produced by the action of the saline. The second plate was a wonderful success—having altered the developer by adding more bromide—the only fault in it being an undefinedness as to where the ocean stops and the sky begins; but that is a fault easily rectified by blocking out the latter with opaque, and printing in heavy clouds to suit the wild picture. The foam round the island likewise wants a little dodging in the printing, inasmuch as if printing along with the rest, it looks as if it were some flaw or blur on the negative; to obviate this, I have to give the foam double printing. The white tips of the waves I worked upon with indigo blue—on the wrong side of the negative, of course—which improved the picture immensely.

Altogether, I do not regret my three days' seclusion, nor my ducking when coming away from St. Mary's Island.

ABOUT DRYING CUPBOARDS.

BY CAPTAIN ABNEY R.E., F.R.S.*

Last session Mr. William England brought before the notice of the Society a drying-cupboard, which I at once adopted, and have had in use till the present time. Except in very warm weather, I have found that it worked perfectly, when I found that sometimes markings due to the iron rods showed upon the plates dried in it. I have annexed the cut of the original drying-

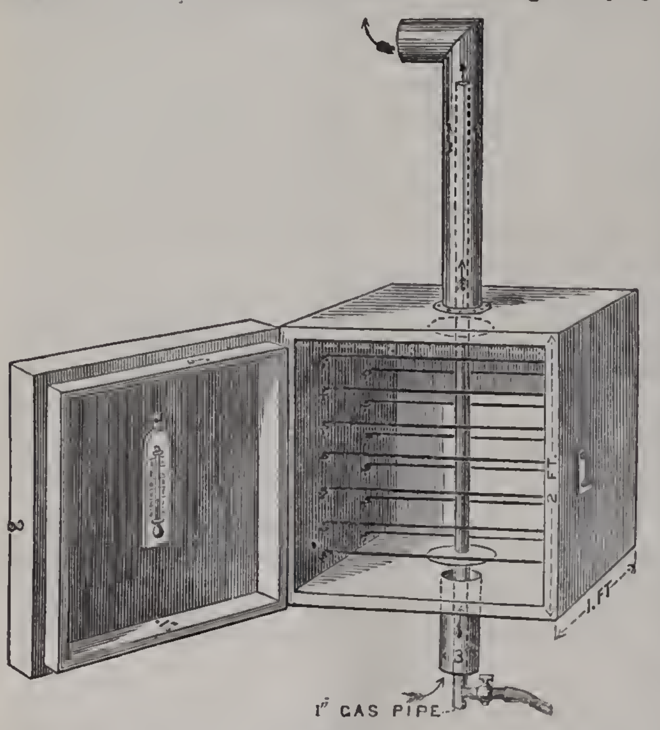


Fig. 1.

box as it appeared, which will render my explanation more easily understood.

It will be seen that the gas piping terminates a little below the tin tube. This I have found to be conducive sometimes to black specks depositing on the plates, owing to the carbon from the gas depositing on the sides of the tube. This is carried up by the up-draught, and then falls down the tin tube. The remedy for this is, of course, very easy; it only needs a wire brush passed down the gas tubing occasionally, to free it from accumulations.

During the hot weather of last summer, I was much annoyed at the length of time plates took to set on the glass revolving shelf, and also on their melting when placed in the cupboard, more particularly when ice had been used for hastening the setting operations. This, and the fact that the wire sometimes caused marking, induced me to alter my cupboard, placing glass shelves instead of the wires. The idea was given me by a gentleman whom I met abroad, but whose name escapes me. The shelves are three inches broad, and the length of the cupboard will thus carry a whole plate. One end of such a slip is supported in a stirrup shown in fig. 2, in the top of which is a slot, through which a screw is passed into the cupboard.

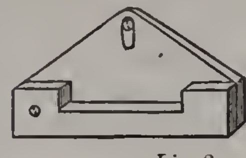

Fig. 2.

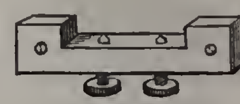

Fig. 3.

Opposite to this is another stirrup, fig. 3, into which are inserted two thumbscrews, as shown; this is placed exactly opposite the first stirrup in the cupboard. The strip is placed between these two stirrups, and is first levelled crossways by means of the thumbscrews. When level in this direction, the length of the strip is levelled by raising or lowering the first stirrup; and when in position, the screw in the slot is screwed home. When once levelled, the strip will always fall into position. In my cupboard I have seven such strips placed across the cupboard, every alternate strip occupying the position of a back wire. When plates are coated, the back strips are filled first, and then the front strips, and the plates set, and are dried on these strips without being shifted. When I referred this matter to Mr. England, he said that in some experiments of his, he found that the strips were apt to cause markings, owing to the fact that the gelatine set just where the back of the plate was in contact with the glass. To avoid all danger, I have adopted two different methods:—First. I placed strips of cardboard along the shelves, through which the points of drawing-pins protruded, so that each plate might rest on three points. Drawing-pins have the same length of pin, as a rule; but, if not, a file speedily reduces the longer ones to the proper height. Second. The shelves were coated with thin gelatine, and buckshot sprinkled over them. These were equally effective. The idea of allowing the plates to set in the same place as where they are to dry is by no means a novelty; but I have thought that it might interest the members to show how an England cupboard can be adapted for this purpose. There are other details which might be altered for hot weather. For instance, an up-draught might be created by giving the tin tube another bend upwards, and placing a gas jet in it; the air for the supply of the gas jet would have to come through the cupboard. If the tube fixed on the up bend be made long enough, no more gas need be used than by the present arrangement. The jet can be lighted from a hole in the side of the tube, which can afterwards be plugged with a cork. Mr. Cowan's method of heating the inlet pipe itself might take the place of the inner gas pipe, when the cupboard is used in cold weather. The hot air can be distributed by perforated zinc or wire guaze, such as is used in chemical operations.

I give this method of heating, as I have found a tendency sometimes for the gelatine nearest the gas pipe to run, owing to its heat. If the gas pipe be polished outside, or be covered with some bad-radiating surface, this is not much to be apprehended. Brass tubing should answer bet er than ordinary gas tubing on this account.

Mr. England uses his cupboard, he tells me, for drying sensitized paper, and, from my experience of it, it is certainly most efficient for such a purpose.

* Read before the Photographic Society of Great Britain.

AN OUTBURST OF SUNSPOTS.

On the 25th July last, certain astronomers announced that they had seen a sudden outburst of spots on the face of the sun. Mr. Hennessey and Mr. Clarke, who have an observatory at Dehra Doon, in the North-West Provinces of India, were the first to announce the fact, stating that they had secured a photograph of the phenomenon. As, however, a critic has recently remarked, "I fancy your sudden group of spots is, after all, a curious system of blemishes in the negative," Mr. Clarke thus writes in *Nature*:—

"On July 25th, 1881, the sun was quite invisible, owing to clouds, until towards 4 p.m., when a temporary break occurred, and I took negative No. 1175 at 3h. 58m. p.m. After this the sun again became invisible, while the rising clouds were so dense as to present little hope of getting another negative; so, as evening was approaching, I was thinking of closing work for the day, when, while I was still watching at the camera, an unexpected opening occurred in the rising clouds below the sun, and, soon after, the sun's image appeared on the ground glass used for focussing. To my surprise I now saw, at about 4h. 35m. p.m., a large group of spots about the sun's centre, which were quite absent in the previous negative, No. 1175; little expecting anything of the kind, or indeed to see the sun at all that evening I was not ready to expose a plate, but now seeing what had happened, I determined to persevere, though the clouds were very unpromising of another break. So I at once took points on my blue setting glass, as is usual to set the instrument by (so as to avoid needless hiding of spots behind the wires), and having done this, I prepared a plate as quickly as possible, and set the exposing slide all ready, though the sun now was invisible; fortunately, another opening occurred at 4h. 47m. p.m., when I took negative No. 1176, in which appears the group of new spots about the sun's centre, which new group I saw without doubt at about 4h. 35m. on the ground glass for focussing. I then continued to watch for another negative until 5h. 30m. p.m., when, the sky having become quite dark, I gave up work for the day."

PHOTO-CHEMISTRY OF SILVER CHLORIDE.

A recent paper presented to the Vienna Academy by Dr. J. M. Eder and Captain Pizzighelli on this subject is thus summed up in the Journal of the Chemical Society. The three following questions are investigated:—

1. How should silver chloride be prepared so as to be sensitive to light, and fit for chemical developers?

2. What are the general properties of the silver chloride undeveloped picture?

3. What are the best re-agents for the development of this picture?

The authors point out that homogeneous silver chloride films can only be obtained by using an emulsion made from silver chloride and collodion or gelatine, &c. Silver chloride precipitated in presence of excess of a chloride is better than that precipitated in presence of excess of silver nitrate, on account of the tendency to irregular decomposition in the latter case. The sensitiveness of a pure silver chloride collodion emulsion is greatly increased by the addition of such bodies as tannin, gallic acid, and morphine acetate, both as regards light and developers; the improvement is specially marked in the latter case. Silver chloride gelatine emulsions are much more sensitive than collodion emulsions. Digesting the emulsion only slightly increases the sensitiveness. The production of a latent picture is checked by the presence of alkaline chloride, and in a still higher degree by acids, such as hydrochloric and nitric. Ammonia greatly promotes the decomposition in light; ammoniacal silver nitrate can therefore be used to advantage for precipitating the chloride.

With regard to the second question, they show that the film changes as soon as it is exposed to light; it is blackened by a short exposure, owing to the formation of a sub-chloride insoluble in nitric acid; this is reduced to metallic silver by developers; by prolonged exposure, the plate becomes solarised. By treating a prepared plate with potassium bromide after exposure, the chlorine is replaced by bromine, and the plate becomes a silver bromide plate.

Several developers are mentioned; ammonio-ferrous-citrate in presence of free citric acid is recommended as the best, and is prepared as follow:—600 grams of citric acid are dissolved in 2 litres of water, and neutralised with ammonia; 400 grams of citric acid are now added, and the solution is diluted to 4 litres. 90 c.c. of this solution are mixed with 30 c.c. of a cold saturated solution of ferrous sulphate, and 6 c.c. of a sodium chloride solution (1 : 30). In all developers the addition of 0·1—0·3 per cent. of sodium chloride is very advantageous. Silver chloride plates require longer exposure than the bromide or iodide plates. The time depends on the developer, being less when the developer is concentrated, or when its action is very energetic. The reduced silver formed on treating an exposed plate with developers, when seen by transmitted light in thin films, appears of different colours, according to the method employed, *e.g.*, that from ordinary silver chloride is yellow-red to red-brown, whilst that from silver chloride which has been digested for some time, or that prepared from ammoniacal silver nitrate, is dark-brown, black-violet to black. When developed with ammonio-ferrous-citrate, the silver from the former is red-brown, from the latter black-brown. With other developers yellow-brown or red, or red-brown silvers are obtained. Silver chloride gelatine is sufficiently sensitive to produce by direct gaslight in twenty to thirty minutes a completely finished positive from a photographic negative,

Silver chloride is preferable to the more sensitive bromide for the production of more modified pictures, because the development can be better controlled.

The best re-agent for fixing silver chloride plates is sodium thio-sulphate.

SPECTRUM IMPRESSED ON SILVER CHLORIDE, AND ITS BEARING ON SILVER PRINTING IN PHOTOGRAPHY.

Captain Abney, in a contribution to the *Chemical News*, says:— The place of maximum intensity at the least refrangible part of the spectrum impressed on silver chloride was observed to be at H, and when silver albuminate was used, the maximum effect was produced at D. In ordinary albumenized paper, both silver chloride and albuminate are present; in dull weather, the light is deficient in the ultra-violet rays; hence the larger proportion of work falls on the albuminate, and a lack of brilliancy in tone is the result. Care must therefore be taken in maintaining the right proportion of haloid to organic salts. The author suggests that the above facts may be made the basis of a scientific measurement of the radiation of total daylight.

Correspondence.

ON LIGHT.

Dear Sir,—" A little knowledge is a dangerous thing.' The truth of this saying I have seldom seen more fully exemplified than in the paper printed in your last issue (January 20, page 32) on "Light," which contains a larger amount of mischievous nonsense than I have ever seen concentrated in so small a space before. To justify such strictures, I will, with your permission, point out a few of the grossest blunders.

Mr. Warner begins by drawing a supposed analogy (where nothing of the kind exists) between steam and light, basing it on an old experiment of Sir W. Armstrong's, and investigated by Faraday, in which electricity of high tension is produced by the friction of water-particles carried forcibly through jets by steam from a boiler. But the electricity of high tension thus obtained, which can charge a Leyden jar and be discharged by a single spark, and electricity of quantity, obtained from a battery or dynamo machine, which can be stored in an accumulator and takes hours to discharge on connecting the terminals—these are all one to Mr. Warner.

From his next paragraph I can only gather that he has been looking at some old magneto-electric machine in which the wire round the armature has got loose, and knocks against the poles of the magnet, and *thus* (shade of Faraday, what an explanation!) produces an electric current. Mr. Warner doubtless supposes that in the machine supplying the lamps along the Thames Embankment (for example), the electricity comes from the tag end of a loose wire rattling against a magnet.

Passing over the enigmatical sentences about the seasons, there is a reference to the abstruse subject of the rates of vibration and the wave-lengths of those vibrations which cause the sensation of different colours in the eye as follows:—

"*Violet* / *Indigo* / *Blue*" } are like the treble notes in music. To produce them in nature, they take 600 millions of millions of vibrations to produce one ray of white light.

Passing over the grammatical absurdities in this sentence, we gather that a ray is produced by six hundred millions of millions of vibrations. Now a ray is defined in the text-books as "the direction in which the light under consideration travels;" in other words, a ray is simply a straight line. To say that there are six hundred millions of millions of vibrations in a ray, is as sensible as to say that there are six hundred million million grains in a mile, or seconds in a cubic foot. The statement should be somewhat as follows:—The sensation of green light is produced by a rate of vibration in the ether (or hypothetical medium in which light is propagated) amounting to six hundred million million vibrations per second. I say green light, because the rate corresponding to indigo is not six hundred, but six hundred and eighty-six million million, and for red the number is five hundred, not four hundred million million vibrations per second.

But what is one to say of the astounding statements lower down about the length and shape of rays of light? Are they like sticks of sealing-wax, or fiddle-strings, or (see diagram) like hot cross buns, or bits of corrugated zinc, long and wavy, and all ten feet shorter than the heat rays inside which they are snugly esconced? And if you get within ten feet of a gas burner, does the light go out while the flame still stays hot? (It certainly ought to, according to Mr. Warner.) And when the clouds are low and the wind blows, what becomes of the extra ten feet of heat rays at the end of all the rays of light, flapping about in the darkness? What a tangle there must be!

Sir, the smatterings picked up by this gentleman on the difficult subjects of the polarization of light and the nature of colour may be entertaining to himself; but on behalf of your readers, some of whom may not have studied the subject of light even in one of the little science primers which can be got for ninepence at any bookseller's, and may have expected to learn something about it from Mr. Warner's paper, I do protest against the insertion of such misleading rubbish in a paper so admirable as yours is when it deals with the details of its own subject.—I am, dear sir, yours, &c., W. F. DONKIN.

St. George's Hospital, January 21, 1882.

LIGHTING OF DARK ROOMS.

SIR,—Having read the correspondence of late as regards the lighting of so-called "dark rooms," I am of opinion also that it is not necessary, as consistent with development, to work nearly in the dark. I use the following with perfect safety, with which I consider the most rapid commercial plates may be worked, and have never had an instance of fog, but clear glass at edges and clean shadows, which proves the lighting safe. And it makes your development much safer to have plenty of light to see every bit of detail than to judge partly by time and partly by the appearance of the image at the back of plates. I have a glass window 10 by 8, and another piece of glass working on a hinge, the system of a door, covered with one thickness of ruby paper; also a piece of ruby glass in a groove, so that if the light is strong, you may modify or strengthen at pleasure, as you do not require the same amount of ruby glass in a weak light (the fall of afternoon) as in strong.—I remain yours, obediently,

OLIVER GODFREY.

SIR,—Having had recently occasion to rebuild my dark rooms, I made my windows as follows.

I have three frames, 30 by 24, one glazed with plain glass, which is hinged to the casement at the side and opens outwards; the second, which is a sliding frame, is glazed with ruby *pot metal*; the third is plain glass covered with orange paper, as recommended by Mr. Fry, and slides in front of the other two frames. Now I find that for the latter frame I have no use, as I have never found a plate fog (even the most sensitive) with the light that comes through the one thickness of ruby pot-metal; and as I have two windows of the above size in a room 14 feet by 7 feet, it will be apparent that it is by no means dark, but comfortably light; also there is nothing outside to obstruct the sky view, so unobstructed daylight falls full on the window. I develop close to the window with confidence, and have no recourse to quick manipulation or dodging to screen the plate. Such experience as mine confirms the prevalent notion that it is not at all necessary to work in a dark room. By this term, I do not mean you can develop in open daylight, but that your dark room need not be so dark that you cannot see anything therein, or work with comfort, as I, along with others, no doubt, used to do, and as all the plate-makers insisted on. W. BARRY.

Proceedings of Societies.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held at the Mechanics' Institution, on Thursday, the 12th inst., Mr. E. LEADER WILLIAMS, M.I.C.E. (President), in the chair.

The minutes of the previous meeting were read and confirmed; after which the following gentlemen were duly elected members of the Society:—Messrs. John Dale, Edwin Eccles, Fredk. Livesey, J. Ford, W. Copeland, W. Gilbert, and J. Scotson.

Mr. ALFRED PUMPHREY, of Birmingham, was then introduced to the meeting, and, after some very happy introductory remarks, in which he thanked the Society for their kind invitation to the meeting, he read a paper, and gave a very interesting demonstration, on "Gelatino-Bromide Films, and Cameras for the Same." Referring to what had been done by the Rev. H. J. Palmer, of Liverpool, in the matter of films, he gave his own experience of the value of films, having used them for photo-mechanical printing for more than five years, stating that he considered the first and primary advantage was that they were capable of yielding more prints than glass negatives, and that the chances of long life to a film were greater than to the same picture on glass. From experience he had found that the lifetime of a good wet collodion negative, ever so well varnished, used in *daily* printing, rarely exceeded eighteen months, whereas such collodion films being transferred to gelatine he had used them more than twice that time, and were still in good condition. In the matter of portability, he clearly showed that, substituting films for plates with the ordinary camera (carrying a dozen glass plates and dark slides), the weight was reduced at least one-third, and with the new camera which he exhibited, carrying 100 films, the weight could be reduced seven-eighths as compared with the old methods.—Then followed the explanation of the 100-fold filmograph. The one shown was a half-plate size, and which, fully charged, weighed five pounds. The method of working in the camera was illustrated by a skeleton model (made purposely), so that all could see and understand the simplicity of the arrangements. A picture was taken in the camera by lamp-light, and developed before the members. During the development he (Mr. Pumphrey) showed what he believed to be the best method of manipulation, and proved beyond doubt that the process was quite as simple as upon glass; and, in reply to various enquiries as to the tenderness of the films, he astonished many of the members by rubbing the film with his finger during the process of development. He said that when all the principles of working were fully understood, the whole process, inclusive of washing, should not occupy more than half-an-hour, and, to further expedite matters, several might be going on at the same time. He strongly recommended following the hyposulphite solution with a saturated solution of alum to eliminate the former. The methods of drying were then shown and explained by various interesting samples. Following the demonstration of the working of the process, he (Mr. Pumphrey) exhibited a series of seventy gelatine film negatives, with prints and lantern transparencies from the same. They were taken by a gentleman in Switzerland in June last year, and although these films were prepared before he (Mr. Pumphrey) was ready with them commercially, the results compared very favourably with a series of negatives taken on Swan's plate by the same gentleman in the previous year. He (Mr. Pumphrey) replied to a great many questions put by the members, and altogether the demonstration was very highly appreciated.

The CHAIRMAN expressed himself much pleased and interested in the proceedings, and proposed a vote of thanks to Mr. Pumphrey, which was carried with acclamation.

Mr. W. Blakeley exhibited some large and very interesting photographs of the interior of the large room in which was held the late exhibition of photographs. They were taken by ordinary gaslight; the exposure was two hours, with a Ross' medium-angle doublet lens.

Several other members had sent negatives, prints, and opals, besides sundry apparatus, &c., all of which, owing to the lateness of the hour, were postponed to the next meeting.

Amateur Photographic Association.

A Council Meeting of this Society was held on Thursday, the 19th inst., Captain Lewis, M.A., in the chair.

The minutes of the previous meeting having been read and confirmed, the following members were elected :—Messrs George William Palmer, J. Hedley Robinson, R. De Salis, Stewart R. Majendie.

The prizes awarded at the annual meeting were then laid before the Council, and approved. They were as follows :—For Messrs. Schwabe, a silver-mounted claret jug; W. D. Howard, a silver goblet; W. S. Hobson, a ditto; R. Murray, a water-colour drawing by Earp; W. Adcock, an album elegantly bound in morocco; J. C. Hannyngton, a ditto; R. O. Milne, a ditto; T. R. Shervinton, an oil-painting in frame by W. McEvoy; S. Norman, a ditto; Arthur Hill, a ditto; and J. L. Rinking, an album elegantly bound in morocco. The prizes will be on view until the end of next week.

Sheffield Photographic Society.

An exhibition of photographic pictures and apparatus, under the auspices of this Society, held in the hall belonging to the Cutlers' Company, was thrown open to public view on Monday, January 23rd. The preparation as arranging and hanging pictures, &c., had, by a united effort of the members, been brought satisfactorily to a close on Saturday evening preceding, and only needed an appreciative public to render their exertions a success. The wishes of the promoters of this new departure were to some extent gratified, as troops of friends responded to the call, visiting the building during the day, and again in the evening to witness a lantern and musical entertainment.

The President of the Society, Mr. P. H. Morton, M.D., took the chair, and in opening the proceedings said :—

It was extremely gratifying to the members of the Society to see so many friends present, because it was an evidence that photography was understood and appreciated. This was, he believed, the first public exhibition of photographic pictures and apparatus held in Sheffield, and although they could not expect to excel the exhibitions held in London, Manchester, and other large centres, still they would find on those walls some excellent work, quite sufficient to show what could be done by photography. At least they could say it was very creditable for a first attempt. That was not the time or place to enter into long descriptions; but he wished to say that photography had progressed much during the last few years, and this progress was due partly to the introduction and general adoption of gelatine as a medium for the sensitive salts employed. By this means films or plates were prepared of almost any degree of rapidity, so that pictures could be taken of objects in motion, and under circumstances quite impossible in the early days of the collodion process. Photography was also more largely employed in other ways. It was used frequently in astronomical, microscopical, and other scientific investigations; and also in our arts and manufactures. They would, no doubt, have observed of late years the great improvement in the pictorial illustrations that embellished our books and periodicals; and although he readily admitted that the skill of the draughtsman and engraver was never better than at the present time, yet he was convinced that they were indebted in many instances for the accurate portraits of eminent persons, and views in distant countries, to the indefatigable exertions of the man with the camera. Photography had made some extraordinary attempts to obtain views, even of the bottom of the sea. Photography had been up in a balloon, but owing to the peculiar gyrations and movements incident to that mode of progression the pictures had not, as yet, been satisfactory. But they could easily understand that a captive balloon, carrying the plates and necessary apparatus, worked by an electric current from below, could secure pictures at a high elevation, pictures which would be very important in military operations as showing the position of the enemy. He dared say the military authorities would investigate this matter, especially as the Royal Engineers had an excellent school of photography, and turned out very good work. But it was not from a scientific or utilitarian point of view that most of the amateur members had turned their attention to this art. It had been more from an æsthetic desire. Now he did not wish this word "æsthetic" to be misunderstood. There were some individuals who professed to have a claim to be æsthetic because they had a sunflower in their garden, a dado on their walls—people who surrounded themselves with the monstrosities of the last century, and had ample leisure to look disconsolately at pieces of indifferent blue china. In cases like this he should be inclined to recommend one of the ordinary anæsthetics, such as chloroform or chloral, until that morbid sensation had passed away. The æsthetic principle of photography was sustained by the power they possessed of bringing home some of the lovely scenes to be found in this and other lands, with all the variety of light and shade, cloud, and breaking wave, and rippling stream. They had also the power of making fac-similes of those extraordinary architectural remains that showed the wondrous skill of a past age. The contemplation of such objects as these he need hardly say elevated the soul, enlightened the understanding, quickened their sympathies, and kept their memories green.

Thursday Evenings for Photographers.

At the meeting held on the 19th inst., Mr. A. Haddon occupying the chair,

Mr. McKillich exhibited some excellent negatives of microscopic subjects, taken on Wratten and Wainwright's rapid plates, with a one-inch objective (uncorrected), and a condenser of about two inches focus, the illuminator being a small paraffin lamp about eight or nine inches from the object; and he enquired if anyone could suggest how best to bring out all the detail of an object, some parts of which were much more bright than others.

Mr. Henderson suggested using slower plates, and giving longer exposures.

Mr. Cowan exhibited a bottle containing an ounce of pyrogallic developing solution (Mr. Berkeley's formula), with which eight plates had been developed; he also showed the eight plates, which had all received the same exposure, the first six having been left in the solution for one minute, and showing a very slight gradual decrease in detail. No. 7 was left for four minutes, and No. 8 for ten minutes in the developer. The solution was of a bright sherry colour, and, judging from the results, its developing action was far from being exhausted.

Mr. Brown suggested that if fresh ammonia were added to the solution, the pyrogallic would be found to have lost none of its energy.

In the course of a short discussion on various liquid non-actinic mediums, Mr. Pearsall suggested that the liquor obtained from red cabbage by boiling it with sulphuric acid would be found to answer the purpose. This liquid, he said, was much used by chemists for lecturing and similar purposes.

Bolton Photographic Society.

The monthly meeting was held at the Baths, on the 12th inst., Mr. Parkinson in the chair.

The general business having been despatched,

Mr. Hampson, who officiated in the absence of the Secretary, read a further communication from Captain Turton.

After a long and desultory discussion it was resolved that the letter be laid on the table.

Votes of thanks were passed to the editors of the photographic journals for copies of their almanacs, and also to Messrs. Cussons, Southport, for a number of copies of their handy little memoranda and almanacs.

Talk in the Studio.

Photographic Society of Great Britain.—The next Technical Meeting of this Society will take place on Tuesday next, January 31st, at the Gallery, 5a, Pall Mall East. The chair will be taken at 8 p.m.

South London Photographic Society.—The next meeting of this Society will take place on Thursday next, February 2nd, at eight p.m., in the Rooms of the Society of Arts, John Street, Adelphi, when Mr. Cobb will read a paper on "Co-operation in Matters concerning Photography."

The Technical Exhibition.—Any reader wishing to visit the display of photographic appliances which will be inaugurated at the Society of Arts on Monday next can have an admission-ticket by applying at our publishing office.

Photographers' Benevolent Association.—The dense fog which prevailed on the 25th instant prevented a sufficient number of members attending the meeting convened for that date to constitute an annual general meeting. It was therefore postponed until February 1st, at 8 p.m., and it is sincerely hoped that every member will make a point of attending on that occasion.

The Clonmel Riots.—Mr. Henry Holborn forwards us a picture of the charge of the 20th Hussars during the Clonmel riots. It is a "freehand" sketch with a photographic background, apparently, and as "many hundreds of it have been sold," we congratulate Mr. Holborn on its production.

A Quick Shutter, by Mr. R. G. M. Conybeare.—The above-named gentleman has forwarded us an extremely convenient and compact form of the blind shutter, the blind taking the form of an endless band working over two small rollers, its length being thus considerably reduced. One of the openings is framed with thin tin plate, and to this frame an elastic band is attached which gives the required impulse. As Mr. Conybeare has promised us a detailed description, we need not say more in this place.

Substratum for Gelatine Plates.—Mr. Warnerke has described a substratum for gelatine plates, to prevent the defect well known in gelatine plates under the name of frilling. This substratum is a cure for that defect. The formula is as follows:—Water, 2,000 c.c.; soda silicate, 10 grammes; white of one egg; ammonia, a few drops. After this mixture is made, about 30 c.c. of alcohol is added, and the whole carefully filtered. This solution is used in a porcelain dish, the glass plate being placed in the dish, resting on one end, and then gently let down on its face, until it touches the surface of the mixture. It is then removed, drained, and dried. On the glass so prepared, gelatine emulsion flows the same as collodion.

Mrs. Brassey's Dark Room on Board the "Sunbeam."—A bath-room, lined with orange-coloured American cloth, and provided with an extra yellow glass to fit over the ordinary scuttle, makes an excellent dark-room for developing photographs. A tank for distilled water and a small sink with india-rubber tubing are easily managed, so that no mess need be made even when the yacht is rolling slightly. In the odd corners shelves with holes are fitted for the bottles of chemicals, while in yet another corner is the medicine-chest, the contents of which can be seen at a glance.—*Magazine of Art.*

The late Dr. J. W. Draper.—In alluding to the work of the late Dr. J. W. Draper, who died this month at New York, and who must not be confounded with his son Prof. Henry Draper, whose labours in spectrum-photography are so well-known, *Nature* says:—In 1837 began the notable series of researches upon the nature of rays of light in the spectrum with which the name of Draper will always be associated. His paper that year bore the title "Experiments on Solar Light," but it failed to attract much attention in Europe. He was now devoting himself to photography and photo-chemistry with great zeal. His paper "On the Discovery of Latent Light," in 1842, dealt with the images produced by rays of light which are only subsequently developed by some chemical reaction—a process with which the art of photography has made us familiar, but which was then a curious and novel phenomenon. It was Draper who first discovered that in the ultra-violet part of the spectrum there are absorption bands like the Fraunhofer lines in the visible part of the spectrum. To enumerate the works which proceeded from Draper's pen upon the chemical and physical properties of the ultra-violet, or, as he styled them, tithonic rays, would be inadmissible here. Suffice it to say that the greater part of the fifty memoirs mentioned in the Royal Society's Catalogue related to this subject, and the most important of them are to be found reprinted in his "Scientific Memoirs," published in 1878. In this volume may be found the pregnant suggestion for a standard of white light for photometry of a piece of platinum foil of given size and thickness, raised to a white heat by an electric current of specified strength. To guard against fusion he suggested that an automatic short-circuiting apparatus should be constructed by some "skilled artificer." He thus exactly anticipated Edison's first incandescent lamps; though the satisfactory standard of white light appears to be as far off as ever. The latest papers Draper published were entitled "Researches in Actino-Chemistry," and treated of the distribution of heat and of chemical force in the spectrum.

To Correspondents.

*** "By-the-Bye" and "Topic" are compelled to stand over for want of space.

P. T. sends us two photographs of yachts taken from the deck of a third craft. In both pictures the yachts appear to be going almost at racing speed, their spreading canvas bending to the wind, and white patches of broken water falling from the cut water. They are, in a word, most successful productions. P. T. tells us they were taken by a Steinheil eleven-inch focus aplanatic lens, and a drop shutter with aperture about half the diameter of the lens.

H. Bryant.—Use Nelson's No. 1 Photographic Gelatine.

N. E. D. Jones.—The simplest way will be to write to him and ask if he is willing to make an arrangement, as you have certainly no right to reproduce the picture without permission.

Lantern and Lerebour.—1. It is probably as suitable as any of its kind. 2. The carte-de-visite lens you mention would undoubtedly be much superior. 3. Probably not, but slightly better results are *sometimes* obtained by reversing. 4. Yes, in most cases, but focus with the full aperture. If you find that an image of the flame shows on the screen, and it cannot be got rid of by shifting the light, you had better place a piece of very fine ground glass on the lamp side of the condenser. This proceeding involves loss of light, and is essentially a makeshift method; but it often enables one to obtain a better result than would otherwise be practicable with a paraffin lamp as a source of light.

O. S.—If you wish to work on 10 by 8 gelatino-bromide plates, we would recommend you to go to one of the best makers and obtain a rapid rectilinear or symmetrical lens of about thirteen inches focus. With the full aperture this will give admirable portraits or instantaneous pictures in a good light, and if stopped down will give almost microscopic detail over the whole of the plate. If only a narrow angle of view is required, and a lens of long focus is consequently necessary, either the front or the back combination may be removed, the stops remaining in position; but the marginal lines will not be quite straight in this case. When, on the other hand, it is necessary to include a very wide angle, a lens of short focus must be employed—a portable symmetrical or wide-angle rectilinear having a focus of six, seven, or eight inches. In this case the smallest stop must be employed.

Tripod.—You had better let it be six inches higher.

D. A.—Commercial barium peroxide is dissolved to saturation in dilute hydrochloric acid, and enough baryta water is added to commence the re-precipitation of the peroxide. The solution being now filtered, excess of baryta water is added, when the whole of the barium peroxide is thrown down in a state of almost complete purity; and if this be kept in the moist state, it is merely necessary to add it to dilute sulphuric acid (one part to six of water) until this is saturated, in order to obtain the required product; this being poured off from the precipitate.

An Operator.—This correspondent wishes to meet with someone who can give him information as to the best locality for a photographic business in Australia, what it would be advisable to take out, and if there would be a good chance of obtaining an appointment as an assistant. Can anyone of our readers give the required information?

S. P.—As full details are given in the Year-Book, we cannot occupy valuable space in reproducing them in this column.

V. M.—So much depends on circumstances that it is difficult to advise without knowing more. A comprehensive article on the subject will appear shortly.

C. E. W. (Bradford)—If you purchase either of the old-fashioned instruments, we would recommend you to purchase the first on your list, provided that it is in good order. It will give equal illumination, and very nearly straight marginal lines. No. 3 would be a somewhat more useful lens, but is not worth the considerable difference in price. You would, however, find it better to obtain a modern lens of class referred to in the postscript of your letter.

Yorkshire.—An article on the subject shortly.

Limestone.—Use an old collodion and somewhat acid bath, giving good exposure, and using a weak iron developer. Fix and wash well, finally rinse with distilled water; next place in following bath:—

Red prussiate of potash	6 parts
Nitrate of lead	5 ,,
Distilled water	100 ,,

After about fifteen minutes, remove and wash well, next immersing in a mixture of one part of sulphide of ammonium and four parts of water; and finally rinse, dry, and varnish.

J. S. S.—1. The C.D.V. lens you refer to. 2. You can manage it without first making a transparency; but your quickest and best way will be to make a carbon or gelatino-bromide transparency first, and then to make a wet plate negative from this.

Several Answers are unavoidably postponed until next week.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1222.—*February* 3, 1882.

CONTENTS.

RECENT PHYSICAL RESEARCHES ON THE IODIDE OF SILVER.

It was in 1839, as our readers know very well, that M. Daguerre announced that he had succeeded in obtaining images by the action of light upon carefully-prepared silver plates which had been exposed to the vapours of iodine. A perfect surface of silver having been obtained, it was placed for about twenty minutes in a box containing iodine, at the end of which time it was found to have acquired a "fine golden tint." A more lengthened exposure produced a purple tint, and the plate was then useless. The golden-tinted plate was introduced into the camera, care being taken that no trace of light should fall upon it. After exposure in the camera, the plate was submitted to the action of the vapour of mercury, and then only did the image make its appearance. It was afterwards fixed by a solution of salt and hyposulphite of sodium. But the process was tedious—an exposure of twenty minutes in the camera was often necessary, and it was only when bromide of silver was used in conjunction with iodide that a workable system of Daguerreotype was possible.

During the last few years the physical properties of the iodide of silver have been studied by Mr. G. F. Rodwell, and the results communicated to the Royal Society.

In the first research on the subject (*Proceedings Royal Society*, 1875), the author commences with a description of some experiments on the effect of light upon the iodide. On this subject great diversity of expression exists in the text-books; thus Gmelin says, "It turns brown on exposure to light, but less quickly than the chloride." Fizeau describes it as "*noircissant lentement à la lumiére*." Miller says, "It is but slowly acted upon by light." While Vogel (*Jahresbericht*, 1863) affirms that if it be precipitated with an excess of iodide of potassium it is scarcely affected by light, whereas if precipitated with an excess of nitate of silver it changes colour, but undergoes no chemical change. The general idea that the iodide of silver is nearly as sensitive to light as the chloride is altogether erroneous. We must remember that the change produced by light is not apparent until the developing solution containing certain reducing agents has been employed; and the exact nature of the change is very obscure. The author of the article on photography in Watt's Dictionary of Chemistry speaks of it in the following terms: "The atoms have apparently acquired a certain degree of mobility, in consequence of which, when submitted to the action of reducing agents, such as ferrous sulphate or pyrogallic acid, they suffer decomposition, the silver being reduced to the metallic state, and forming a metallic film on the parts of the surface which have been exposed to light."

In order to ascertain the sensitiveness of iodide of silver to light, Mr. Rodwell made the following experiments:—

1. "By means of a large lens the rays of the electric lamp were brought to a focus within a glass cell containing a solution of iodide of potassium; a solution of nitrate of silver was then introduced by a pipette at the apex of the cone of rays. The precipitated iodide of silver possessed its usual pale colour.

2. "Freshly-precipitated iodide in suspension, with a slight excess of iodide of potassium, remained in the bright glare of a July sun without undergoing any perceptible change; neither did it subsequently darken.

3. "Freshly-precipitated iodide in suspension, with a slight excess of nitrate of silver, underwent no immediate change on exposure to a July sun. At the end of an hour it had become slightly grey, and subsequently darkened.

4. "Organic matter in the shape of starch paste did not induce any change when mixed with freshly-precipitated iodide in suspension with a slight excess of iodide of potassium. Albumenized paper with iodide precipitated upon it did not undergo any immediate change.

5. "Some dried and powdered iodide was found to have acquired a slight greyish metallic tinge after an hour's exposure to the sun. A freshly-broken surface of fused iodide became very slightly darker after exposure to the sun. A very pale microscopic crystal of iodide, removed from the interior of a crystalline mass, became slightly brown after several hours' exposure to diffused light.

6. "Crystals of iodide of silver produced by direct solution of silver in hydriodic acid were not affected by light; neither were crystals of hydro-argentic iodide (AgIHI), nor crystals of argento-potassic iodide (AgIK3).

7. "A sheet of silver leaf was exposed to the vapour of iodine (produced by spontaneous evaporation) for five minutes; it possessed a faintly yellow tinge, which on exposure to the sun instantly became pale green, but, on further exposure, returned to its original pale yellow. A second sheet was exposed for ten minutes to the vapour of iodine; it acquired a golden-yellow surface, which, on exposure to diffused light, acquired a purplish-red colour, and on exposure to the sun became greenish-purple. On continued exposure this colour disappeared, and the plate returned to almost the original yellow colour.

8. "A sheet of silver leaf was exposed to the vapour of iodine for half-an-hour, at the end of which time it possessed a decided golden yellow colour. On exposure to the sun, it instantly acquired a dark purple colour, edged with green, at those parts least exposed to the direct vapour of the iodine. On continued exposure the purple became paler, but the sheet did not return to its original yellow colour.

9. "A developing solution composed of ferrous sulphate, alcohol, acetic acid, and water, when applied to the exposed sheets of paragraphs 7 and 8, which had been purple, but on continued exposure nearly regained their original colours, produced a reddish-brown colour,

10. "A sheet of silver leaf was exposed to the vapour of iodine for many hours. It was found to be converted into a slightly adherent film of lemon-yellow iodide. Light had no effect upon it, even after a long exposure to a July sun; neither was any colour produced on the addition of a developing solution.

"The pure iodide of silver would thus appear to be scarcely affected by light, except when silver is present, either in the form of nitrate, or, as in the case of the silver films, as metallic silver."

In connection with this question, we may point out that a very important paper, "On the Photo-Chemistry of Silver Chloride," has lately been published by Messrs. Eder and Pizzighelli, in the *Wiener Academie Bericht*, 82, pages 144-160, to which we have already referred in these columns.

The properties of the silver iodide in relation to heat are even more remarkable than its relations to light. As far as we know, it is the only solid body which contracts on heating. The conditions of this contraction and its extent have been examined by Mr. Rodwell during the last five years, and the results may be found in the Proceedings of the Royal Society. He has also examined the co-efficients of expansion of the chloride and bromide of silver, and of various alloys of the iodide with the iodides of lead and copper, and with the chloride and bromide of silver. The latter were found to possess higher coefficients than those of the more expansible metals, such as zinc, and silver; while the iodide of silver is altogether anomalous. It contracts slightly during heating between 0° and 142° C.; between 142° and 145°.5 C., it undergoes considerable contraction, and from this point to the melting point (527° C.) it expands. Moreover, the iodide passes from the crystalline into the amorphous condition between 142° and 145° C., and possesses a point of maximum density at 142° C. Below 142° C. it is a pale green, highly crystalline body, while above that temperature it is a transparent, red, highly plastic, and amorphous body.

Some of the alloys of iodide of silver with the chloride and bromide possess the curious property of turning bright green on exposure to light; and when—if ever—the long-desired colour photography becomes an accomplished fact, no doubt these double iodide compounds will come largely into play. It seems to us that the right direction to work in, as regards the direct photographing in colours, is to seek, by the combination of iodide of silver and other silver salts with various bodies, to produce substances which are specially sensitive to certain rays of the spectrum, and which have certain colours excited upon them by the action of such rays. Purples and greens are already within our reach, and there can be no reason why, by diligent search, other colours serviceable for purposes of direct photography should not be found.

PHOTOGRAPHY AT THE SOCIETY OF ARTS.

Captain Abney's Lectures, and the Technical Exhibition.

It has been our lot to attend several courses of Cantor Lectures at the Society of Arts, and we have, on these occasions, been not only initiated into the mysteries of sugar refining, wool dyeing, bread making, and the coal-gas manufacture, but have also heard the late Rev. Arthur Rigg explain, with all the ardour of an enthusiast, the principles upon which mechanical tools are constructed; and have listened to Professor Colvin when he told how Greek and Roman art are sealed to him who is not properly versed in classic lore.

We have, however, not yet seen such a large or interestedly expectant assembly waiting for the advent of the Cantor lecturer, as was the case on the occasion of Captain Abney's first lecture, which was delivered on Monday evening last. Not only were all seats filled, but the approach to the lecture-room was densely packed with both men and women, who evidently regarded a remote chance of seeing and hearing as a sufficient recompense for considerable personal inconvenience; while many a one who had either been unsuccessful in obtaining the necessary ticket of admission, or had been dismayed by the remote chances of being able to find even standing room, took refuge in the library of the institution, where the collection illustrative of photographic technology was arranged; and we are told that it is intended that this technical exhibition shall be for a few weeks accessible to those interested in photography.

A demonstration of one of the earliest, and perhaps the most beautiful, of all photographic processes, was the first feature of the lecture, Mr. William England showing how the Daguerreotype plate is prepared, exposed, and developed, while the lecturer, in his well-known forcibly vivid style, elucidated the theory, and called attention to the practice.

Some transparencies which Mr. England made from old Daguerreotypes were next projected on the screen, and one picture of New York Harbour taken by Mead Brothers about twenty-five years ago, was regarded by those present as being quite comparable to the gelatino-bromide work of the present day.

Some electrotypic productions of Daguerreotype plates were next handed round, after which the Talbotype was discussed, and the various manipulations were demonstrated; the development being performed by supporting the exposed paper on an easel, and applying the developing solution by means of a broad camel's hair brush, so that the gradual appearance of the image should be visible to all present. At this stage the lecturer referred to the facilities which a paper process offers for artistic efforts on the part of the photographer; it being easily practicable to retard or accelerate the development of any part of the picture with the view of modifying the general balance of light and shade.

The deposition of metallic silver on the exposed haloid salt was compared to the growth of a crystal around matter of its own kind; the metallic or semi-metallic matter of the partially reduced salt attracting to itself the silver which continually tends to separate from a so-called physical developer. Physical development is then analogous to crystallization, and to illustrate this a wet collodion plate was prepared, and developed in a vertical glass trough containing the usual iron developer: an image of the plate being meanwhile projected on the screen by the electric light, a yellow glass serving to cut off the more actinic rays. Captain Abney then explained that he preferred to use the term chemical development in a sense differing from that usually accepted; and he would consider it as referring to a definite chemical reaction between a developing fluid and a body chemically altered by exposure to light. As an illustration of this view, some paper which had been charged with uranic nitrate and exposed, was treated with a soluble silver salt as a developer, metallic silver being deposited on the exposed parts by the reducing action of the uranous salt formed by the action of light. According to Captain Abney's use of the term, the production of an image on the usual gelatino-bromide plate would not be regarded as chemical development, the elective force which causes certain parts of the bromide to fall under the power of the alkaline reducing agent being physical rather than chemical. This view was elucidated by the experiment of exposing a bromo-iodide film, and then coating one half of the plate with a fresh layer of haloid silver salt. When this composite plate was developed the picture was not confined to the lower or exposed film, but extended also to the unexposed stratum which had been superimposed.

A consideration of the use of iodide of silver and chloride of silver with alkaline development, and of the various developers in use, next followed; after which, the bromo-iodide paper, which the lecturer recently brought before the notice of the Photographic Society, was referred to;

and a demonstration was given to illustrate its practical value. The development of a picture on this paper formed one of the most effective demonstrations of the evening, the picture rapidly unfolding itself in all its details. Captain Abney's lectures will probably prove to be the most successful course which has yet been given in connection with the valuable foundation of Dr. Cantor.

The Technical Exhibition, which has been organized by Mr. Trueman Wood, in connection with Captain Abney's course of lectures, was opened a couple of hours before the time of the lecture, and we must heartily congratulate the indefatigable Secretary of the Society of Arts on the success of his efforts to get together a collection which should be fairly representative of the present condition and bygone phases of this branch of applied science. On entering the Library, where the principal exhibits were arranged, the absence of large, shop-window-like stacks of highly-polished mahogany and brilliantly-lacquered brass was striking. In fact, the first object that met our view as we entered was a dingy apparatus nearly resembling a small and deformed cucumber-frame, which one out of a group of three persons who were examining it informed us was the first Woodburytype press, after which our informant led us to the other end of the room to see the first mould—an electrotype—and an impression from it. In other parts of the room, abundant illustrations of the various methods of practising the Woodbury process were to be found, including the old mode of working with the hydraulic press, and the new tinfoil method; also a mould in fusible metal, with the relief from which it had been cast, and a print on glass. Besides these, the so-called photo-chromie, in which a Woodburytype print is placed over a roughly-coloured ground, was well illustrated by numerous specimens, and examples of the work at various stages. Other photo-mechanical methods were duly represented, the Autotype Company sending a collection showing the various steps in collotypic printing; while Mr. Dallas and Mr. Wm. Griggs contributed good examples of block work on the one hand, and photo-lithographic work on the other hand; in each case chromo-printing being exhibited side by side with plain black-and-white. Examples of the highest merit in block and intaglio printing by Messrs. A. & W. Dawson, of Hogarth Works, Chiswick, are placed on the staircase, a block reduction of a page of the *Times* being a model of technical excellence and sharpness, while a "photo-intaglio reproduction of Mr. A. Dawson's picture "A Rainy Day under the Purbeck Hills," is far superior to anything of the kind which we have seen before, as it includes a fuller, deeper, and more extended range of light and shade than is usual in reproductions by processes of this nature; but in this case the plate had been to some extent retouched or worked on by the artist's own hand. The Pretsch process is represented by several old prints, and two or three copper plates, together with a reverse.

Archer's first camera for working the wet process in the field, one of his early fluid lenses, and other inventions of the discoverer of the collodion process, are shown. A small erection in glass and wood illustrates Messrs. Grover and Co.'s system of glazing without putty, the panes being fixed by means of strip pieces of very thin and flexible lead. Many advantages might result from the adoption of some method of this kind for studios, as in bright summer weather, obscured or ground glass could readily be inserted to replace clear glass. Mr. Galton's camera for composite portraiture stands in one of the glass cases together with numerous examples of composites and their component elements; while in another case will be found the arrangement used by Professor Piazzi Smyth in photographing the pyramids; and the negatives, though only an inch square, afford a good illustration of the wonderful technical perfection which may be attained by intelligent and careful work. One of these negatives enlarged to ten inches gives a picture which is itself remarkable for sharpness and fineness of detail.

The numerous appliances which have either been introduced in consequence of the present widespread use of gelatino-bromide plates, or have suddenly taken a new position of importance, is very considerable. Most of the quick shutters which have been described in the Photographic News from time to time are shown, and Mr. Warnerke exhibits a well-devised rotatory apparatus for testing their speed. Boca's new chronometric shutter is sent over by Mr. Stebbing, of Paris, and this gentleman also contributes an interesting series of negatives taken on his film-plates. Cheap and efficient portable dry-plate cameras are shown by the Sciopticon Company, Messrs. Jas. Lancaster and Son, of Birmingham, and others, while more highly-finished articles of the same kind are shown by Messrs. Rouch, Watson, Marion, Hunter and Sands, and other firms. The last-mentioned firm also show their new changing-box, which possesses features of novelty and convenience which are likely to give it the first position among apparatus of this kind. A double slide is used, and each pair of plates is in a separate frame. The changing-box is large enough to hold six of these frames, an opening at one edge serving to introduce the frames containing exposed plates, while a corresponding opening at an opposite edge serves to transfer frames containing unexposed plates into the double slide. As the column of six frames readily falls by its own weight from one side of the changing-box to the other, interior grooving is rendered unnecessary, and, moreover, it is impossible to remove the frames, except in their correct order, and no over-sailing or projecting parts exist, even while the box is being used. The box is about two-thirds the size and weight of the older forms, and the double slide can be used in the ordinary way when necessary. Messrs. Hunter and Sands also exhibit the photographic gun, recently described in the News, and several other objects of present and past interest.

Enamel photography is well represented; Mr. Henderson showing illustrations of the various stages in his method of working, while finished results are contributed by the Autotype Company and Mr. Henry N. White, of Finsbury Circus, this latter gentleman employing a powder process, while the Autotype Company make up a tissue with the required vitrefiable pigment, and after developing a print on the tile to be ornamented, destroy the organic matter in the enamelling kiln.

Some of the same series of decorative photo-reliefs which were shown in the Paris Electrical Exhibition, and referred to in the Photographic News, are on view here; but, although artistically excellent, it is evident that many of their good qualities depend on after-work of the nature of retouching or beating up.

A frame of magnificent transparencies made by Dr. Eder on gelatino-chloride plates stands opposite the entrance, and it is instructive to see what a great variety of tone has been realised. Dr. Eder's methods are fully detailed in his small treatise on the subject, which we observed to be attached to the frame; but our readers will find a translation in abstract by referring to the Year-Book.

Moule's Photogen lantern, together with a series of pictures taken by its light, will prove of interest to those who wish to practise portraiture of an evening.

A further description of numerous interesting exhibits must stand over for the present, there being about 400 exhibits, contributed by nearly a hundred exhibitors.

ON ACTINOMETERS.

BY DR. H. W. VOGEL.

Most of the actinometers hitherto introduced, and generally in use, consist of semi-transparent scales, whose thickness gradually increases from one end of the scale to the other. Under these scales are exposed sensitive paper or sensitive plates, and the degree of sensitiveness is ascertained by observing how far within a certain time the action of the light has proceeded towards the thicker end of the scale. These semi-transparent scales are either constructed of separate layers of paper under each other, the number of which increases as we proceed from the thinner to the thicker end of the scale—such is the actinometer for carbon printing—or they consist of a Woodburytype, as in the case of Warnerke's sensitometer.

These instruments have two defects:—1. The change of colour proceeds at first with great rapidity, afterwards it becomes slower and slower; 2. In penetrating, the light undergoes considerable modification, so that the more or less highly-coloured scale only permits certain rays to pass with readiness, the others with difficulty. Suppose we take the case of a scale constructed of several uniform layers of paper, and let us assume that in penetrating one of these layers the light is reduced to $\frac{1}{5}$ of its original intensity, then, after passing through a second layer, the intensity will have sunk to $\frac{1}{25}$ of the original, through a third layer to $\frac{1}{125}$ and so on. In general, if the light is reduced in intensity to $\frac{1}{n}$ of the origiual in passing through one layer of paper, then, after passing through x layers, it will be reduced to $\frac{1}{n^x}$. The intensity is therefore not in proportion to the numbers of layers 1, 2, 3, 4, 5, &c., but in that of the series 1, 5, 25, 125, 625, &c. For instance, if we take eight kilog. photographic paper, in passing though a layer of which the light is, in fact, reduced to very closely $\frac{1}{5}$ of its original intensity, and use it for the construction of such an actinometer, then the intensity of light, which in a certain time produces the discolouration of the fifth degree, must be 625 times as great as that of light which in the same time will produce the discolouration of the first degree. This circumstance is of the highest importance in considering the accuracy of the degree indicated, since the error of only a unit may lead to very considerable differences in the intensity to be found. In Warnerke's sensitometer the same fault exists, although in that case the relation depends on something of a different kind to a number of uniform layers of paper. That the colouration has also an effect in the quality of the light I have already shown.

For these reasons I have been endeavouring to obtain a photometer in which the intensity of the light is reduced more gradually than in the above-mentioned scale instrument, and which shall not contain any medium capable of producing a modifying effect on the quality. An instrument of the kind required will probably be formed by making use of the principle of the stop. In 1861, Dove, the late eminent physicist, adopted this principle in the construction of an instrument for general photometry, and

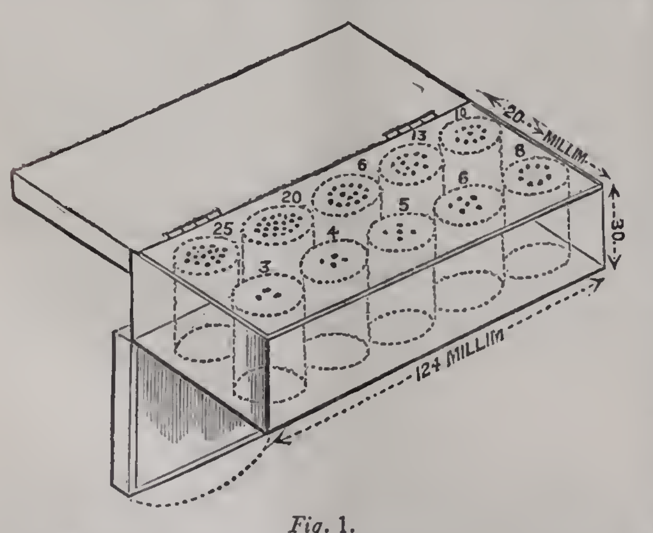

Fig. 1.

In 1869 Mr. A. Taylor recommended one of the same kind adapted to photographic purposes; the latter will be found described at page 19 of the Photographic News for 1869, and the accompanying wood-cut is reproduced from the same article.

"In a rectangular block of wood 108 millimetres in length, 58 wide, 41 millimetres in thickness, eight holes, 20 millimetres ($\frac{3}{4}$-inch) in diameter, are bored through the thickness of the block. These perforations are placed on two parallel lines, and each one is closed by a thin metallic diaphragm, the whole forming a group of cells, each of which is 40 millimetres in depth. The diaphragms are pierced with several small holes, all exactly of the same diameter, but the number of holes is different in each diaphragm. In the particular instrument now described, the diameter of this orifice is 2 millimetres. The first diaphragm has 3 orifices, the second 4—the following ones 6, 8, 10, 13, 16, and 20 respectively.

"It was no doubt to be supposed beforehand that the intensity of the action in each cell would be directly proportional to the number of the orifices in the diaphragm."

Thus it would appear that more than thirteen years ago an instrument had been proposed fulfilling the required conditions. It contains no absorbent medium, and the intensity in the cells is proportioned to the number of holes in the diaphragm. It is all the more interesting to notice that a similar instrument has been very recently introduced by Messrs. Mucklow and Spurge, the only difference being that it has only one orifice, whose size is different to that of both the diaphragms. Now Mr. Taylor had also provided for this construction; but he stated at the time that in such an arrangement the effects of diffracted light would be unequal, whereas in his own scheme this effect would be the same at all the orifices.

Soon after this description was published I had one of Taylor's actinometers made for my own use; but I found it to be not well adapted for the carbon process, although the author had expressly intended it for that purpose. This was due to the fact that the instrument, when placed in a horizontal position, received its light only from that portion of the open sky which was directly over the cells, while the printing-frame containing the carbon print was illuminated by the light of the sky from the sides as well. It occasionally happened that a white cloud covered the lower portion of the sky at an elevation of about 50°, which would have an effect on the print in the frame, but not on the actinometer.

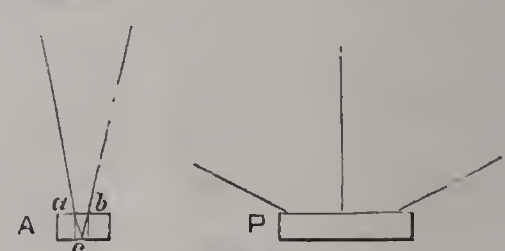

Fig. 2.

Suppose o to be a point at the bottom of one of the cells of such an actinometer; this point will be illuminated by the light of the sky included between the legs of the angle $a\ o\ b$. The negative in the printing frame, P, on the other hand, is exposed to light coming from a much larger part of the sky. Owing to this circumstance the indications of the instrument are not perfectly reliable, more especially in changeable weather.

For this reason I had given up the use of Taylor's actinometer until lately, when I again had recourse to it, for the purpose of ascertaining the sensitiveness of negative plates. If two plates be exposed in the instrument under precisely similar circumstances, and one of these, after development, gives a result of the third degree, and the other of the sixth degree, then the relative sensitiveness of the plates is in the inverse ratio of these numbers.

Now if, instead of this instrument, we use, as Mucklow and Spurge do, apertures of different diameters, this important advantage would be lost, for to regain it we should have to bore holes whose diameters increase in proportion to the square roots of the corresponding numbers; that is, for the series of numbers 1, 2, 3, 4, 5, the diameters must be in proportion to the numbers 1, 1·414, 1·732; 2, 2·236, &c. To bore holes with diameters corresponding to these decimal numbers is technically no easy matter, whereas there is not the slightest difficulty in boring any number of holes of the same diameter merely by using the same auger.

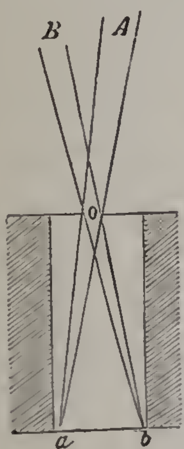

Fig. 3.

Still, in using the instrument, there are further difficulties to be overcome. When the instrument is exposed to the light of the sky, it is evident that the point *a* receives through the orifice, *o*, light from a different part of the sky to that which is received by the point *b*. Hence, if the whole of the sky be not equally clear—that is to say, if there be clouds present—the instrument will not give uniform results. It further appeared that the light from the sky acts much too intensely; even in cloudy weather, and with wet plates, all the parts under the cells are, in a very few seconds, so far affected, that, after being developed, they show a distinct impression. To reduce the intensity by covering the apertures with ground glass was found to be impracticable, since the glass does not diffuse the light evenly, and it would be almost impossible to obtain for different instruments a number of ground glass plates of exactly the same degree of transparency. The attempt to use the direct light of the sky was therefore given up, as also that to reduce its intensity by means of ground glass.

I then endeavoured to produce artificially an evenly illuminated surface, and succeeded in effecting this by means of a screen covered with ordinary photographic paper. This substance is the whitest fabric in existence, and is prepared from the very best material with the greatest care. No other substance is so uniform in texture, and no other, except, perhaps, freshly-fallen snow, reflects white light so completely; at the same time, no other substance of all that can be considered can be so available in photographic practice.

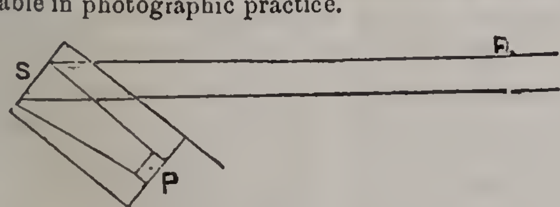

Fig. 4.

A screen of this kind, S, placed opposite to and at a proper distance from a window open to the sky, F, may be considered as perfectly uniformly illuminated.

(*To be continued.*)

By-the-Bye.

THE ELIXIR VITÆ OF PHOTOGRAPHERS.

It is not so long ago that at the London Photographic Society there arose a discussion upon the fleeting character of albumenized prints, and that one of the members, out of patience with the frequency with which the subject had been discussed, and the repeated fruitless attempts made to overcome the difficulty, suggested to the president the appointment of a committee then and there, who should go thoroughly into the matter, and once for all tell photographers how permanency in silver printing could be ensured. We call to mind even now the indignant, not to say defiant manner of the member in question, at being worried day after day by the vexatious problem, and his determination to put the matter down, as it were, by sheer force. The proposition met with little favour, for one reason because of the excited tone adopted, and for another, doubtless, because the Society were not so sure of the efficacy of the remedy suggested. Anyone "can call spirits from the vasty deep," they remembered, but like Hotspur, no doubt thought "But will they come when you do call them?"

This brings us to our text. Chemical and physical research is a mighty thing in its way, but it is not all-powerful as some photographers think. There is no harm in trying to find out the cause and remedy of a difficulty; indeed, unless we do try, we shall never be able to remove any of them. But, on the other hand, it does not follow that because we try, we shall succeed. Some time ago we listened to a lady dilating upon cremation. We agreed with her on many points; but for want of a better, we brought forward the well-worn argument about death by poisoning. Supposing some days after the body was burnt, there was a lurking suspicion that the man had been poisoned: what was then to be done, we asked? Her triumphant reply was that chemists, if requested, would soon furnish a series of "test papers," and these applied before cremation by doctors or friends would proclaim whether the deceased had swallowed anything poisonous. Our lady friend had evidently heard of blue and red litmus paper, or of turmeric paper, and knew how readily these proclaimed the presence of acid or alkali, and so rushed to the conclusion that chemists can give us any tests they may be asked for.

Now there is nothing more praiseworthy than investigating, and on every hand we find chemists hard at work upon original research. A bye-way of chemistry is taken up, and all the ramifications on this hand and on that are investigated. The colours we get from coal tar is a capital illustration. Perkins' purple or magenta, found out some twenty-five years ago, was the forerunner of a magnificent series of colours which have gradually been evolved from coal tar by chemists steadily working away at the subject, and jealously watching every action and reaction. Permutations and combinations are tried and re-tried, and, as a reward of all this labour, we have a most varied range of tints. But, it appears, a satisfactory aniline black has not yet been discovered. Over and over again the dyer has said to the manufacturer of these dyes, "Why don't you make a black? Get a chemist to find out one for you." For the chemist, to many people, is the *deus ex machina* that shall invent anything at will. But the dye manufacturers have done this: they have not only employed year after year the most skilled chemists to find out the desideratum, but they have, moreover, offered large sums of money for the process, should any outsider discover it. But notwithstanding the circumstance that nearly every other tint can be prepared, a good black is still unfound.

We do not believe there is a solitary case on record of any important discovery in chemistry or physics having been made in the hope of winning a prize. Of course, no investigator investigates for nothing; he is always alive to his interests. Either he desires to make a name or money by his labour, and if he is successful, he makes both. He is simply like any other workman, and workmen do not, as a rule, work without some chance of profit. But bidding a chemist discover a certain nostrum is like asking a man to unearth a hidden treasure whose very existence is doubtful. There are two elements necessary for his success: first of all, there must be a treasure; and secondly, he must dig at the right spot. Success must at least be *possible*, or it cannot be attained, whether it is a chemist or anyone else who works. Chemists are busy every day with the solution of problems, and "Nothing venture nothing win," holds good in their case as in any other; but, for all that, you cannot *buy* a discovery until it has been made, those photographers should remember, who contemplate the expenditure of money or time in the acquisition of something they are yearning for.

The past is a very good lesson for the future. The offering of prizes in money or gold medals for successful research is not a novelty. Most photographers remember the munificent prize of many thousand francs instituted by the Duc de Luynes, and in Italy and Austria similar incentives have been given. Nay, at this very moment there are prizes offered by Paris and Vienna for the attainment of certain results in photography, while the Paget Prize of fifty pounds was but awarded a year ago. Of all these we do not think there is one that has been given for the original object. The prizes have been awarded to persons who most nearly fulfilled the requisite conditions, and not one of the fortunate recipients, we make bold to say, ever gave the prize one thought while he was hard at work. If the discovery tallied pretty well with the conditions, this was a pure coincidence, and nothing more. The discovery would have been made just the same, even if there had been no prize. In fact, the prize is generally awarded in the end, not because the recipient has fairly gained it, but because the donor naturally does not like to withdraw the gift. Poitevin, who received the lion's share of the Duc de Luynes' prize, had it decreed to him because of a long list of researches which the prize committee specified. These had been undertaken year after year in his laboratory, quite irrespective, of course, of the chance of winning a premium. Poitevin, we hold, was more entitled to the award than any one else; but according to the strict terms of the competition, he was not entitled to it at all.

One word more. If other proof were wanting that prizes in money spontaneously offered are valueless in influencing research one way or the other, it is afforded by the fact that the Government has, during the past five years, spent twenty thousand pounds in the endowment of research. The money may have been well or ill-spent—we fear those who had most influence got most of it, and the needy inventor without friends is as needy as ever—but can any one point to a single investigation of value which would not have been undertaken but for this grant? So we say to photographers: research is always valuable; but do not suppose that you have simply to pay an investigator in order to get the panacea you require.

The "At Home" next week will be "Herr Koller in Pesth—A Studio with no Side Light"; the following "By-the-Bye" will be "What Photography does for Science."

Notes.

The Dundee Exhibition opens next week. We hear that the exhibits are likely to be both numerous and important, and that the photographers of Scotland are doing their best to make the gathering a successful one.

Mr. Alexander Ayton will, we hear, at the March meeting of the Edinburgh Photographic Society, give demonstrations of a new way of finishing prints, whereby permanency, if not rendered absolute, will be greatly enhanced. The chief point is the transformation of paper into vegetable parchment by immersion in sulphuric acid, which will greatly improve a picture. When suitably mounted, these prints colour well from the back.

Mr. W. J. A. Grant writes of his last Arctic journey that there was an immense deal of ice in the sea between Greenland and Novaia Zemlia, and for this reason the voyage was much delayed. He gives the following particulars of the stout little craft in which he made the journey:—"The *Willem Barents* is a little schooner, built by voluntary contributions, and kept going in the same way, in addition to help from the Dutch Government in the way of officers, &c. She is sent purely as a scientific ship to explore the sea in certain directions, and the work mainly consists in taking a large number of serial deep sea observations and dredgings, together with magnetical and meteorological observations, in which we all help. We have also to determine the average ice limit late in the season between Spitzbergen and Novaia Zemlia, and work as far north as possible."

Mr. Grant's photographic work this season was less than usual, as they had few opportunities. "This is my fifth voyage to the North," he writes, "and I suppose I shall go until I come to grief." We sincerely hope not, albeit Arctic exploration is certainly a most dangerous enterprise. "Mr. Leigh Smith's yacht—*Eira*, the ship I was in last voyage," writes Mr. Grant, "has not yet returned from her last expedition, and there are grave doubts as to its having shared the fate of the *Jeanette*."

M. Cornu suggests making use of a colourless fluor spar for lenses in photo-spectroscopic observations. "It is," he says, "quite as transparent for the ultra-violet rays as quartz, and its law of dispersion is so much in harmony with the latter, that with the two, a system of lenses of nearly perfect achromatism may be had." To give an idea of this achromatism, M. Cornu, according to *Nature*, can obtain on one *cliché*, with very satisfactory distinctness, the spectrum of all the photographic lines of metals from the three blue lines of zinc to the lines No. 32 of aluminium.

The general examinations in chemistry held throughout the country to test the knowledge of aspirants in that science, give rise to some curious answers by those who are not very clear as to the combinations and reactions of various bodies. Thus, to make quicksilver, a would-be chemist recently suggested the mixture of nitrate of silver and quick-lime, when nitrate of lime and quicksilver would result. This straightforward explanation reminds one of Mr. J. L. Toole's famous lecture on astronomy, in which, alluding to the stars, he naively remarks: "Eleven of these are called primaries, because they come first, and eighteen secondaries, because they come second."

Mr. William Bedford says that an admirable preservable sensitive paper may be obtained by sensitising in the usual way for about three minutes, and then floating for one minute on a bath containing 30 grains of citric acid and 30 grains of silver nitrate to each ounce, and that this paper tones well.

We are glad to hear that Mr. Jarman's very practical apparatus for electric illumination of the studio has been adopted by several firms in this country with success, not only for evening work, but as a valuable aid during the murky weather we have been troubled with lately. M. Levitsky, the Court photographer at St. Petersburg, as we recently stated, employs electricity in the studio for the same purpose, namely, to accentuate the high-lights in bad weather. A full description of Mr. Jarman's apparatus appears in the Year-Book.

The Lamson poisoning case, according to Mr. Wontner, the solicitor for the prosecution, is likely to lead to further restrictions in the sale of poisons, it being contemplated to amend the Act of Parliament on the subject. We are not sanguine as to the result. In any case, medical men must be trusted with poisons, and no Act can prevent the application of noxious drugs to patients in an illegal manner. If we are going to interdict the traffic of poisons generally, it will be necessary to fetter every profession and trade in the country.

Thus, among the photographer's paraphernalia, cyanide of potassium is usually singled out as the bugbear. It is a most virulent poison, no doubt, but there are other compounds to be found in every photographic laboratory very nearly as deadly, while far more painful to the patient. Pyrogallic acid, for instance, to which no second thought is ever given, is a terrible poison, and so, too, is bichromate of potash, which we are wont to handle in the most innocent manner. Nitric acid and its fumes are excessively dangerous, and as Mr. Vincent Elsden has pointed out in the Year-Book, of hydrochloric acid and sulphuric acid but a drachm or two only are necessary to cause death. We need hardly refer to oxalic acid, the lead and mercury compounds &c., as their poisonous nature is proverbial; but obviously, it will be impossible for the photographer to work unless entrusted with most of these

---

Topics of the Day.

THE SYREN—PHOTOGRAPHY *VERSUS* ART.

BY WALTER B. WOODBURY.

Anyone who is in the habit of giving a passing glance into the various shop windows where photographs and engravings are on sale, whether in London, Paris, Brussels, or other Continental cities, must have noticed one particular picture—whether in the form of a photograph of different dimensions, or as an engraving or "photogravure." It represents a calm sea and a clear sky, with a steam yacht lying some little distance from the shore; at the right hand, and in the foreground of the picture, is a portion of a pier or jetty, down whose steps a young gentleman in sailor costume is handing a young lady in a tight-fitting jersey to a boat lying in wait, manned by sailors. She has just descended the first step, and so the picture is in some cases called "Le Premier Pas," and in others, "La Syrene," presumably the name of the yacht which forms a part of the picture. This painting is now the subject of a lawsuit, and is creating quite a sensation in the city of Brussels, where the case is being tried. We shall, therefore, soon learn whether photography or art were the producers of this masterpiece. If it is proved that photography did it, then it will doubtless be a strong slap in the face for those who say there can be no art in photography.

That painters do make great use of photography, although they are loth to own it, is an acknowledged fact. There is a new class of shop lately sprung up in Paris, whose speciality consists in studies of all kinds—trees, rocks, stones, bits of foreground, cattle, sheep, figures, in costume and out of it, whose customers, I am told by the proprietors, are mainly artists. How is it that they seem to be ashamed to acknowledge the great assistance they derive from our art?

A Belgian writer on the subject, speaking of the use photography *might* be to artists, says: "An artist who finds it superfluous or beneath his dignity to use the resources that science has placed at his disposition, gives us the effect of an individual who prefers to go to Paris *en panache*, as was the custom thirty years ago, instead of using the railway. He would be mocked at, and with reason."

Up to within the last year or two artistic photography was almost restricted to still life; but since the introduction of gelatine plates and instantaneous shutters *ad. lib.*, facilities are given for securing the most artistic and natural studies of figures. Note some of the instantaneous studies in our last Exhibition. What artist could rival some of the quaint market groups of Whaite, or the marine studies of various other photographic *artists?*

The trial in this remarkable case commenced on the 4th of January, and, as there are many points of interest to photographers, I propose giving a short *resume* of what took place. Monsieur Lucien Solvay, a newspaper critic of some celebrity, publicly accused (in *La Gazette*) M. Van Beers of employing photography as a basis for his paintings, thus imposing on the public. M. Van Beers, with natural indignation, then writes to a friend: "They no longer criticise my works; they accuse me of falsifying my merchandise. I have never before taken notice of critics, but this time I shall do so." "After having read M. Solvay's article," says M. Van Beers' counsel, "persons who have purchased his pictures will have the right to say, 'Have I not simply got a coloured photograph instead of an artist's veritable work?' Is not this enough to cause a grave prejudice to my client, and give rise to the following question?—'Is M. Van Beers an honest man, or a '*grec*' (swindler)) in his artistic profession?' M. Solvay says to M. Van Beers, 'This is not a *tableau* that you sell for 20,000 francs (£800); it is only a coloured photograph, which has only a small value.' Is not this accusation of a nature to destroy the artist's reputation? Suppose a purchaser presents himself to M. Van Beers, would he not have the right to say, 'You have deceived me as to the value of the merchandise? And would not M. Van Beers then fall under the penal code, article 496? In France, it seems, M. Lisbonne, the regulator of the press laws, in reply to a letter of M. Sarcey, expressed his opinion that the painter could be prosecuted if the fact was established. In concluding his address, M. Van Beers' counsel says: "You have not proved your case, and, notwithstanding the opinion of the jury, you still hold your views. It is true you no longer talk of collodion, but of a photographic transfer and the camera (*claire*)! You, the man of material certitude, can't even suggest what process was employed! It only rests with me to call attention to the various proofs M. Solvay contemplates producing before the tribunal. These are: photographs on canvas, coloured photographs, and a picture representing two donkeys and their driver, and signed by M. Van Beers. They pretend that this painting was made over the photograph. If M. Solvay proves a hundred times that one can paint over or under a photograph, he has not yet shown that either the 'Syrene' or 'Lily' were done by a photographic process."

M. Moreau, the council for M. Solvay, in replying, began by saying, that M. Van Beers was an artist of talent; there was a time when he made grand pictures, to-day he makes grand lawsuits—this is a falling off. The public had a perfect right to criticise his works. Before this trial he was very little known, and could not easily dispose of his pictures, even when offered for nothing. Witness his "Van Artenelde," refused by the town of Ghent, to whom he offered it gratuitously, and which was finally sold by auction for 1,400 francs. It was little in comparison to the price he now asks for his pictures, which some people say are of less value than their frames. To-day, what do we see? An Antwerp painter of European reputation, photographs of whose painting, especially the "Syren," being exposed for sale all over Europe, often accompanied with a dolorous description of his misfortunes. Celebrity has arrived to him, and through the critics. "*Qui expose s'expose.*" The critic is provoked by the artist to give his opinion, and he finds himself in the position of a person to whom you address this question: "Come, now, give me your opinion as to my probity," and who replies, "You are a thief."

In conclusion, M. Moreau remarks that many painters make use of photography, and cites a pamphlet lately published by M. Thiel on the subject, which cites four different methods employed:—

1. A photographic image on canvas by salts of silver.
2. "Encre grasse" (collotype), which even by scratching could not be discovered, the materials being the same as the painting.
3. By the powder process.
4. By painting under a photograph.

M. Moreau then showed specimens of these four processes, which concluded the day's proceedings. The following day, in continuation, he called attention to the fact that the principal newspapers of Belgium and France, in their reviews of the "Salon," had all remarked the extraordinary photographic appearance of M. Van Beers' pictures; therefore, as this peculiarity struck all the world, it was not to be wondered at that M. Solvay should also be struck by it. Beyond that M. Solvay knew the different processes which certain painters avail themselves of to simplify their work. In proof of this he then exhibited the photograph of the "Donkeys and their Driver," which was *identical* with the painting. Is it to be believed that we are in presence of a painting to which the artist has consecrated several months, or one that has been (*baclé*) knocked up, in a few days by the aid of photography?

A reason why all ideas of photography being used should be put aside was, because photography presented always faults in perspective and disproportion. However, every photographer who is well up in his science knows that in the present day these faults in perspective and disproportion no longer exist. The jury have therefore retarded by twenty years.

The case was then adjourned for a week, and on the re-opening, the court was densely crowded, many artists and literary men being present. M. Jannsen, the counsel for Van Beers, began by remarking that, although Messonier painted from photographs, the most careful examination had failed in proving in his client's case either the use of silver salts, collotype, or powder processes. The first could have been easily discovered by chemical analysis—that in using fatty inks collodion was not called into play, while that substance had been mentioned; and as for powders, there were none that were transparent. That the opposite side had attacked the jury, pretending that not one of them knew anything about photography; while one of them (alluding, doubtless, to M. Rommelaire) had translated English works on the subject. In reply, among other remarks interesting to your readers, the following were made.

Has painting the right to call in the aid of photography? Opinions are divided, but the question is one of the greatest gravity. Without doubt photography should aid painting in certain cases, but the elect should not allow photography to lead them by the hand. We say that photography is found in your picture, you give us reality without art, and so squander your magnificent gifts. To judge this trial we must put aside, on the one hand, M. Solvay, and on the other M. Van Beers, and not dream of anything but the interests of art, the question being one of arresting the tendency of our epoch, viz., naturalism in our literature, and photography in our painting.

The President then ordered the papers to be placed in the hands of the Procureur, who would give his verdict at a future time.

As this is one of the first occasions when the relative positions of photography and art have come into a court of justice, and as I have thought the subject one of particular interest to photographers, I have been led into giving a more extended notice than I originally intended, for which I hope your readers will pardon me.

Correspondence.

EMULSION MAKING.

SIR,—I asked you a short time ago if you could tell me why, in preparing emulsions, I always had a sediment of silver bromide at the bottom of the vessel. You replied that it may have been because I filtered the emulsion through dirty muslin. My further researches, however, proved that the cause was in mixing the emulsion too hot. The warmer the gelatine, the more liquid it becomes; and the bromides combine too quickly and too roughly with the added silver solution. When the gelatine, on the contrary, is only heated to about 35° C., the liquid seems to be thicker, and the added silver nitrate can only slowly combine with the bromide in the gelatine, thus giving much finer bromide of silver particles, which are of course kept better in suspension, and the emulsion is much improved. Afterwards you may heat it as much as you like, even to boiling point, and it will not give this sediment.

Two to three grammes of a one per cent. solution of tannic acid to a hundred grammes of emulsion is the best thing I know to prevent frilling. Chrome alum is good, but it does not suit every gelatine and at all seasons. I also tried to mix tannic acid and chrome alum for the same purpose, as recommended in a recent formula, but that gives plates nearly fogged, with an appearance of over-exposure, and without any density.

Plates prepared by chrome alum are very easy to intensify by chloride of mercury. Tanned plates, on the contrary, are very difficult to intensify without getting a yellow veil. Mercuric salt and tannic acid mixed in solution gives a yellowish-brown mixture, and this instantaneously. Now could not this have been one cause, and is there not a medium to destroy or take off the tannic acid in the film, to prevent this yellow staining?

I hope there is in this matter something worth discussion, as it is only by reciprocal assistance that we can get over difficulties in new processes. Some have success in one direction, some in another, and by study of both we can often avoid mischief.—Yours truly, O. PFENNINGER.

DURABILITY OF CARBON PRINTS ON CANVAS.

Sir,—I had a carbon print done on canvas, for the purpose of painting on, about seven years since. The picture was duly painted in oils; but it soon showed minute signs of cracking, mostly where the gelatine was thickest, with a correspondent contraction of the canvas at the back. Now the cracks have so far developed, that wherever the shadows were darkest—*i.e.*, the gelatine the thickest—it is flaking off in patches, clean from the priming of the canvas; so that what should be a mass of black drapery is now like the sealed bark of a plane tree, and the back of the canvas shows nothing of the contraction before mentioned.

If you, sir, or any of your correspondents, should have had similar experience, or can throw further light on the subject, I and others might be glad to learn.—Yours truly,

A. Pierpoint Chambers.

PS.—It would appear as though the gelatine had temporarily contracted the canvas, and the subsequent expansion of the canvas threads had cracked the gelatine and the paint.

[Of course, if the transfer is faulty, a defect of this kind may arise; indeed, the application of a carbon film to canvas is at best a difficult job.—Ed. P.N.]

AN INTERNATIONAL PHOTOGRAPHIC EXHIBITION.

Dear Sir,—A desire has been expressed to have in England at an early date an International Photographic Exhibition or Convention, and the manager of the Royal Aquarium has kindly placed his building at the disposal of the profession for the purpose.

A meeting of the leading photographers will shortly be called for the purpose of considering the question, and, if favourably entertained, nominating a committee to carry it out. Medals and certificates will be offered for competition. In the meantime I shall be glad to receive the names of any gentlemen who may be willing to assist.—I am, &c.,

C. G. Cutchey.

Proceedings of Societies.

Oldham Photographic Society.

The annual soirée and exhibition of the above Society was held on Wednesday, the 25th Jan., at the Spinners' Hall, Oldham, under the presidency of the Mayor, James Yates, Esq., M.D. The rooms were tastefully decorated, on the wall were displayed a selection of choice photographs, and on the tables a collection of the latest inventions in apparatus.

His Worship, in the course of his remarks, said that he was glad to find that in a town so entirely devoted to manufactures, there was some attention paid to art, and he was only too pleased to be present and help to further the success of a society with such an object.

Among the photographs exhibited was an interesting collection of views by Mr. S. R. Platt, J.P., taken on board his yacht during a voyage to the coast of Norway. Most of the views were specially noticeable as being taken by the midnight sun.

Mr. W. G. Coote, of Manchester, kindly lent a series of well-executed photographs of North Wales, &c.

Messrs. Marion and Co. exhibited photographs of athletic sports and a variety of new apparatus.

A large collection of photographs from the works of Messrs. Payne Jennings, H. P. Robinson, V. Blanchard, W. England, &c., &c., were also shown.

Amongst the numerous local exhibits may be mentioned a series of enlargements, and specimens of gelatine photographs of interiors, by Mr. L. Knott; stereoscopic views, &c., by Mr. James Hall; views and enlargements, by Messrs. James Gartside, W. Thorpe, Jackson Brothers, &c.; microscopic photographs by Mr. H. Braddock. The apparatus exhibited were Marion's pocket camera and cutting boards, Warnerke's sensitometers, microscopic camera, enlarging apparatus, &c.; the various merits of each being described at intervals by the members.

A lantern exhibition worked by Mr. J. Wrigley was given during the evening, when slides from the members' negatives were thrown on the screen, explanatory notes being given by the Hon. Secretary.

The rooms were crowded with visitors the whole of the evening, and the soirée was considered the most successful the Society has had.

The ordinary meeting of the Society was held on Thursday, the 20th inst., Mr. G. Hall in the chair.

The business was chiefly in connection with the exhibition and soirée, and votes of thanks were passed to all who had kindly contributed.

Votes of thanks were also awarded to the editors of the journals for the annuals they had kindly sent, and Messrs. Cussons and Co. for their pocket manual, a parcel of which had been sent for distribution among the members.

Thursday Evenings for Photographers.

At the meeting held on the 26th inst., Mr. F. Reiman occupied the chair.

In reply to a question as to the effect of a little quite ripe (?) emulsion being mixed with a newly formed one, and so carried on through all the stages again, as, for instance, by using the same utensils without washing,

Mr. Henderson thought that by re-boiling the emulsion the sensitiveness would be increased, but that the particles of bromide would become more granular, and would probably be left on the filter.

Mr. Brown said he frequently used the same utensils without first thoroughly cleansing them, and noticed no ill effect.

Mr. Henderson said he found he could prepare a very good emulsion without excess of bromide, by using rather less than the usual equivalent of bromide of ammonium, and adding, after the bromide and gelatine is mixed with the silver, a solution of chloride of sodium, which converted the remaining free nitrate of silver into a coarse chloride, which could be nearly all filtered out.

Mr. Brown had prepared a very successful emulsion with the following formula, viz.:—

Gelatine	2	drachms
Silver nitrate	1½	,,
Ammonium bromide...	1	drachm
Water	4	ounces

When washed, well drain and saturate with alcohol, then drain again; this made 3 ounces of a rich sensitive emulsion, and allowed the plates to be drained after coating.

It having been stated that as much as 15 grains of nitrate potash could be added to each ounce of finished emulsion without causing any apparent crystallization, Mr. Henderson passed round three plates coated with an emulsion containing 10 grains of nitrate potash to the ounce. No. 1, unwashed, showed decided crystallization; No. 2, washed thirty seconds, slightly crystallized; No. 3, washed one minute, no apparent crystallization.

In the course of conversation it was mentioned that it had been stated by Mr. Bolas that if a plate was coated with a film of gelatine about one-sixteenth of an inch thick, and afterwards coated with an unwashed emulsion, the gelatine film would absorb the salts from the emulsion, and render washing unnecessary.

A discussion on Coignet's spots and their cause then took place. The Chairman and Mr. Debenham did not think they were caused by grease. Mr. Henderson considered that carbonic acid gas was the cause of some, at least, of the spots.

Mr. Brown exhibited a plate coated with a mixture of zinc oxide and gelatine in equal proportions, which he proposed to use as a substitute for opal glass. He also showed two pictures—one taken on a plate coated with emulsion over the oxide film, the whites in this case having degraded while in the hyposulphite solution; in the other plate, the oxide was mixed with the emulsion, and, in this case, the whites were but very slightly darkened.

Mr. Henderson passed round a gelatine plate which had been placed, while wet, under a Warnerke's "Actinometer," the marginal lettering, and also the grain of the cloth which masked the margin of the plate, being distinctly visible.

Mr. Haddon said an amateur had recently recommended to him Eau de Javelle as a preservative for prints; it was found that prints washed in a few changes of a weak solution of Eau de Javelle were much more permanent than others which had received prolonged washing in the ordinary way; and at the request of some gentleman present, he said Eau de Javelle was composed as follows:—

Hypochlorite of lime	2 ounces
Carbonate of potash...	4 ,,
Water...	4 ,,

Mr. Debenham had used a weak solution of alum for the same purpose.

Mr. Henderson had used the following formula successfully for restoring prints. Well wash the print in boiling water to remove as much of the starch and size from the paper as possible, then immerse in the following solution:—

Bichloride platinum	5 grains
Iodide potassium	1 drachm
Hydrochloric acid	1 ,,
Water	1 pint

Saturate the whole with iodine. When placed in this solution, the paper instantly becomes blackened; it should be left for about half an-hour, then removed and washed in several changes of water for two days; this eliminates the iodide of starch formed in the paper, and leaves an image composed of platinum. He had not succeeded in some cases, but attributed the failure to the presence of an insoluble compound of silver left in the albumen. He also exhibited an experimental lamp for darkroom purposes; it consisted of an ordinary paraffin lamp with a plain glass chimney enclosed in a box, the light passing through two glass baths, one containing a saturated solution of bichromate of potash, the other a weak solution of litmus. The light when passed through this in conjunction with the bichromate solution gave a very red light, which was pronounced to be wonderfully safe.

Dundee and East of Scotland Photographic Association.

The second popular meeting took place on January 25th, in the Hall of the Young Men's Christian Association. Mr. John Leng presided, and in opening the meeting said the Society, though only in the second year of its existence, was in various ways displaying great energy and vitality. This was the second meeting of the season at which photographic illustrations had been given by members of the Society. The first consisted of views of Scottish scenery, and on the present occasion they were to be favoured by illustrations of Norway and Sweden. Their friends, Mr. David Ireland and his son, had a holiday trip there last summer; and by the aid of the sun and the limelight, the audience were now to see very much what those gentleman saw, without the trouble, the weariness, and the expense to which they were subjected. The Chairman mentioned, as another instance of the vigour of the Society, that in the course of a few days it was to open an Exhibition which, there was every reason to believe, would not be second to any exhibition of photographs yet held in the kingdom. There were a number of enthusiastic amateurs in the Society who had come forward and offered such medals and prizes as had induced not only the leading amateurs, but also the principal professional photographers in the kingdom, to become exhibitors. He was happy to state that the Royal Engineers, Colonel Stuart Wortley, Captain Abney, and the veteran Horatio Ross, would be amongst the exhibitors. In addition to the photographs, all the latest and most scientific photographic instruments and appliances were to be exhibited. That there might be no suspicion of favouritism, it had been arranged that a number of distinguished critics from a distance should be the judges at this exhibition. These included Messrs. H. Baden Pritchard, H. A. H. Daniel, John Fergus, and Mrs. D. O. Hill. The only local judge would be Mr. W. D. Valentine, who was to be a large exhibitor, but not a competitor. The galleries were to be illuminated by the electric light, and the Council had decided that the season tickets should be issued at so moderate a charge as to preclude no one from attending. They would all look forward to the forthcoming Exhibition with great pleasure, and he trusted it would prove a decided success.

A very fine series of views in Norway, Sweden, and the Mediterranean, photographed by Mr. David Ireland, jun., was then exhibited by means of the oxy-hydrogen light, and a descriptive lecture was delivered by Mr. Frank W. Young.

A large number of slides of animals in the Royal Zoological Gardens, kindly lent by Mr. Frederick York, London, were also shown.

At the close, in moving a vote of thanks to the Messrs. Ireland, the Chairman said that, so far as form and shade were concerned, photography seemed nearly to have reached perfection; but there was still an important discovery to be made—that of photographing colours. Any young man in the room might attain both fame and fortune by making that discovery, and the Chairman commended it to the attention of the students in chemistry and photography.

A vote of thanks to the Chairman followed, and it was announced that there would be another evening devoted to a miscellaneous exhibition of slides by amateurs.

The next general meeting will be held on Thursday, February 9th, in place of the first Thursday in the month. As the Exhibition opens on the 10th, the 9th will be the judging and private-view day, when it is hoped that at the general meeting in Lamb's Hotel in the evening, a pleasant reunion of photographic celebrities from all parts of the United Kingdom will express opinions on the art.

Liverpool Amateur Photographic Association.

The monthly meeting of this Society was held on Thursday, the 26th ult., at the Free Public Library, Mr. W. H. Kirkby (President) in the chair.

The minutes of the last meeting having been read and confirmed, Messrs. R. Crowe, W. J. Little, P. Macdonald, P. H. Phillips, W. P. Riley, W. Ryland, K. B. Suckling, and the Rev. A. T. Scott were elected members of the Association.

The Hon. Secretary then read the following report of the Association's department at the *soirée* at St. George's Hall, on the 21st December last:—

"The Liverpool Amateur Photographic Association took a prominent part, as usual, in contributing to the interest of the proceedings of the evening; the Revs. T. B. Banner and H. J. Palmer, together with Messrs. Bean, Corkhill, and Maycock, having been appointed as a committee to make the arrangements for the Society's exhibition, devoted the whole day to this purpose. The executive committee allotted to the Association the Chancery Court and the barrister's robing room as their special department, and a good display of prints and apparatus was made. The appeal of the Secretary to the members to contribute Daguerreotypes, calotypes, and early specimens of collodio-bromide and gelatino-bromide work met with no response whatever, and, therefore, the proposed historical exhibition had to be abandoned. The display of photographs and apparatus, however, was a very fine one, and the rooms were crowded during the whole evening. About five hundred pictures were exhibited, contributed by Messrs. J. W. H. Watling, J. H. T. Ellerbeck, B. Boothroyd, W. H. Kirkby, H. A. Wharmby, and by the Revs. T. B. Banner and H. J. Palmer. The Autotype Company and Messrs. Robinson and Thompson exhibited some very fine enlargements. In the course of the evening a lecture was delivered by the Rev. H. J. Palmer, on 'A Popular History of Photography,' and later on Mr. J. A. Forrest showed a large number of transparencies with the lime light on a sheet of opal glass. Mr. Forrest delivered an explanatory lecture upon the slides, which were illustrative of some of the finest ancient specimens of ecclesiastical architecture in Europe. This entertainment excited the greatest interest, the room being densely crowded. On the whole, the Association may congratulate itself on taking so prominent and useful a part in the proceedings of the associated *soirée* of 1881."

An open meeting of the Association was held at the Free Library, on December 22, 1881. The lantern was exhibited to a large and appreciative audience in the Lecture Hall, the slides being contributed by Messrs. W. H. Kirkby, E. Twigge, J. H. T. Ellerbeck, A. W. Beer, and the Rev. H. J. Palmer. The walls of the adjoining room were covered with photographic prints exhibited by Messrs. Watling, Ellerbeck, Kirkby, and the Rev. H. J. Palmer.

The President for the past year, Mr. W. H. Kirkby, made a few valedictory remarks, and then vacated the chair, his place being taken by Mr. W. E. Roberts, the President for 1882, of whose interesting address we are unable, owing to late receipt of report, to give more than the following abstract:—

"Being one of the 'old originals' who well remembers the evening in December, 1863, when we held the large meeting in this room, and sat round these tables to draw up the rules and elect the officers and members of our new Association, I cannot rise to address you this evening without experiencing feelings somewhat 'mixed.' First, a feeling of regret that so many of those old faces should have been removed from our midst; and, secondly, a strong feeling of pleasure that there are still so many of those old members left who attend our meetings as regularly, and take as lively an interest as ever in the welfare of our Society. Few of the rising generation have any idea of what was involved in becoming an amateur photographer twenty years ago, and in these days of bought plates and small cameras —for in those days we had to do everything for ourselves—sensitise our own papers, prepare all our own plates, and in many cases we prepared our own collodion. And to see our members turn out for a day's excursion to Bettwys-y-Coed, Llangollen, Chirk, Corwen, or some other of the lovely spots in North Wales, was a sight indeed—each man loaded like a pack-horse, with a 12 by 10 or a 15 by 12 camera strapped on his back, a lens about the size of his two fists slung over his shoulder, and often a small stereo-camera in his coat pocket just to pick up any 'tit-bits' he might come across; and, in addition to all this, he carried under his arm what alone weighed as much as any modern outfit. It is no wonder, then, that we hailed with delight the introduction, in 1865, of the collodio-bromide emulsion process, which at once relieved us of a vast amount of work, and proved to be a first instalment of the good things coming. In 1839 we got Durand's sensitized paper, and began to feel that we were getting into smooth water; but it remained for Mr. C. Bennett to put the finishing touch to our happiness when, in 1878, he published his gelatino-bromide emulsion process, which at once revolutionised all our proceedings, and gave us what we had been longing after for years—a dry plate for instantaneous work. With gelatine dry plates we became at once possessed of quite a new power, and were able to shoot at game which before was much beyond our reach; and immediately there was a rush for small cameras wherewith to carry out the dreams of our youth, that, with small cameras and rapid dry plates, we might be able to take negatives for subsequent enlargement. Well, we have got our small cameras, and beautiful little things they are. We have also got our small negatives; but we have not yet got the enlargements, and I venture to express a hope that, during the present year, our members may show us some enlarged work, for I feel sure many of these small negatives, if enlarged up to 12 by 10, or 15 by 12, or even larger still, would make delightful pictures, and we should then have the satisfaction of seeing our tables covered with prints, which would prove a pleasure to the owner and a credit to our Society. There seems now only one thing wanting to make the art-science of photography complete—that is, to be able to secure the natural colours; but our experience of the past gives us hope for the future, and, knowing that there are some ardent workers in the field, we have no doubt that ere long this, too, will be an accomplished fact. I must be allowed to say a word or two on behalf of the stereoscopic camera, which seems to have gone out of fashion; but I really do not know why it should, for there is no class of photographic work that brings a view so 'home' to the observer; and with gelatine plates we can now get subjects which before were impossible. And then a well-made little bellows stereo-camera is quite as portable as any of our modern satchel cameras, and we have a much more useful negative. The past year has not produced anything very new or striking in apparatus. We have seen some ingenious cameras and slides from America and other places, but have seen nothing to beat our first-class English work. Lenses also remain much as they were; indeed, it is difficult to see how they can be improved, our opticians having brought them to such a high state of perfection. Instantaneous shutters, I think, have been about the most prolific crop of the season, and we have seen them of all shapes and sizes; but to my mind they nearly all have the most objectionable fault of being too large. This fact makes it all the more gratifying to be able to single out the small arrangement of our own member, Mr. Bruce, which, for portability and efficiency, leaves nothing to be desired. We still want a really good walking-stick-stand. Of the future of photography I scarcely dare venture an opinion. The electric light makes steady progress, and perhaps before long we may be able to take street views and other subjects by its means; but at present we must hope that the Sun, the best friend of the photographer, may favour us with a little more of his presence during the coming summer than he has done during the past few seasons."

A hearty vote of thanks to the late President, Mr. W. H. Kirkby, was carried by acclamation.

The Hon. Secretary described the Society's seal, which he had designed in accordance with the instructions of the last meeting. The badge consisted of a rising sun on a vesica-shaped shield, with the motto, "*Sol optimus pictor*," and the words, "Liverpool Amateur Photographic Association, 1863," round the margin. He had used the new seal for the first time upon the certificates of honour, and upon these would be found a line from Virgil's Æneid—

"Cuncti adsint meritæque expectent præmia palmæ."

This, translated freely, might be rendered—"Let all the members of the Liverpool Amateur Photographic Association join in the annual competitions, and let all aim at gaining the prize for the best picture in each of the competitive subjects."

The Chairman announced that the Council requested all members possessed of negatives suitable for enlargement for last year's presentation print to send the same to Mr. Ellerbeck's, Bold Street, on or before Thursday next, the 9th inst. In the event of no such negative being produced, the council would then select a negative for the purpose from the works of Mr. Bedford or of Mr. W. England, both of whom had sent down for exhibition prints of the highest excellence.

Dr. Kenyon then proceeded to demonstrate the process for preparing gelatino-bromide emulsion, which he had successfully carried out by daylight:—The solution of bromide, with a small quantity of gelatine, having been placed in a white earthenware jar, the silver solution, placed in a wash-bottle with mouthpiece and syphon jet, was blown in a fine stream into the bromide solution, stirred meanwhile with a wooden salad fork. The mixture completed, the jar was closed lightly with a cork, and supposed to be boiled for one hour. After cooling, the strong solution containing the full quantity of gelatine was added. He (Dr. Kenyon) insisted on the importance of getting the emulsion well set before attempting to wash. The setting is best effected in the jar in which the mixing and boiling has taken place by allowing it to stand in a cold place for twenty-four hours. Some previously-prepared set emulsion was then squeezed through fine napless canvas into a basin of iced water containing bichromate of potash ten grains to the ounce. The contents of the basin was afterwards thrown upon a fine horsehair sieve, and plentifully doused with iced water. The comminated emulsion was then collected, measured, replaced in the jar, and made up to the full quantity with water and spirits of wine at the rate of one ounce to ten ounces of finished emulsion, the precaution having been taken in the first instance to employ only four-fifths of the total water intended to be used. He (Dr. Kenyon) said that, although brilliant results were obtainable in this manner, he did not recommend the operations to be carried on in the daylight by preference, for then the negatives, though perfect in every other respect, were generally thin and frequently required intensification. He directed especial attention to the advantage of employing ice in the washing process, by which certainty and facility were absolutely ensured. In the absence of ice the water might inadvertently prove insufficiently cold, resulting in softening of the threads of gelatine and obstruction to the flow of water between, causing great annoyance and delay—a difficulty which, once encountered, could only be allayed by a free use of methylated spirit. He thought the secret of success in the preparation of sensitive emulsion would be found in the combination of a chloride with iodide and bromide.

The details of the process were watched with much interest, and gave rise to a discussion, in the course of which

The Chairman remarked that he had, many years ago, prepared a batch of tannin plates, collodionizing and placing them in the silver bath in bright sunlight. They were removed from the bath in the sunlight and taken into the dark-room, where the real sensitizing took place by the application to the films of the preservative solution of tannin. These plates were entirely free from fog; but negatives taken upon them were blue and thin.

Mr. W. H. Kirkby asked Dr. Kenyon if he could say whether silver had greater affinity for a bromide, a chloride, or an iodide; that is, supposing the addition of nitrate of silver to a solution containing bromide, chloride, and iodide, would the resulting combination be bromide, chloride, or iodide of silver?

Dr. Kenyon replied that this could only be ascertained by careful experiment.

Mr. W. H. Kirkby described an accident which had occurred to himself in making an emulsion with a glass diffuser like that employed by Dr. Kenyon for diffusing the silver in a fine stream through the bromised gelatine. The fine glass tube became plugged by some obstruction, and he had used considerable force in blowing the silver, hoping thus to carry away the clot; but on withdrawing the pressure a rush of silver into the mouth took place, with results the reverse of pleasant.

Mr. E. Phipps introduced the question of the relative sensitiveness of wet and dry gelatino-bromide emulsion, and was inclined to be incredulous as to the asserted superior sensitiveness of the former.

The Rev. H. J. Palmer gave a lantern exhibition of a large number of transparencies of Switzerland, by England, Ferrier, and himself.

Votes of thanks were cordially passed to the President for his inaugural address, to Dr. Kenyon for his demonstration, and to the Secretary for his lantern display. The meeting, which was very largely attended, was then adjourned to Thursday, Feb. 23rd. The exhibits were some beautiful stereoscopic transparencies made by the Chairman (Mr. E. Roberts) from his own negatives, and mounted on ground glass; a volume of prints from negatives taken last year by Mr. Ellerbeck; and an enlargement in autotype of a negative taken in Brittany, by Mr. E. Phipps.

Talk in the Studio.

Refraction of Light and Lenses.—Mr. W. K. Burton, C.E., will lecture on this subject before the Science Society at King's College on Wednesday next.

Photography in the Provinces.—On Wednesday, January 25th, 1882, Mr. Lyddell Sawyer delivered a lecture on "Photography," before the members of the Literary Society, Bath Lane Science and Art College, Newcastle-on-Tyne. The lecture was concisely and succinctly given, and was attentively listened to; and the lecturer dealt with his subject under three headings. 1st. The uses and adaptabilities of this art-science, its commercial value and importance, and its influence upon humanity. 2nd. Its history, discovery, and development, devoting special attention to the labours of Scheele, Wedgewood, Davy, Niépce, Daguerre, Fothergill, and Scott Archer, to whom we are indebted for our beautiful collodion pictures. 3rd. Practical experiments on the physical and chemical nature of the collodion and collotype processes. Mr. James Blakey (connected with the firm of Mawson and Swan) was chairman, and he paid a tribute to the lecturer which was evidently representative of the feeling of the Society. A hearty vote of thanks to Mr. L. Sawyer, terminated the meeting.

Ink for Photo-lithography and Photo-typography. By Toovey (*Chem. Centr.*, 1881, 288).—10—15 grams of white wax are dissolved in 100 grams of benzene, and treated with 12 grams of lithographic ink. A small quantity of the mixture is then spread over a lithographic stone and rolled with a lithographic roller in very thin layers on glass plates. Finely-ground chrome-orange is then sifted over the varnished plates. After drying, a mixture of 3 parts lithographic ink and 7 parts of turpentine is poured on the plates, and when dry a coating of fine "argentan" sprinkled on the plates. The draughtsman scratches with a point on this layer, having laid the plate on black paper. Through this his work is seen in black lines on a white ground. When the drawing is finished, it can be printed like a negative, the layer of chrome-orange effectually preventing the admission of light.—*Journal of Chem. Soc.*

A Gas Light Photograph of the Manchester Exhibition.—Mr. William Blakely kindly sends us a twelve-inch photograph of one of the walls of the exhibition, taken by a Ross doublet lens, which, if only as a feat in photography, deserves to be recorded. The exposure was two hours, and the only illumination the ordinary gas jets of the gallery. Of course the jets themselves are simply represented by patches of white, but in many cases the pictures are to be made out distinctly, and taken altogether the result is a most interesting and instructive one.

Estimation of Ferrous Oxide in the Presence of Ferric Oxide, Organic Acids, and Sugar. By Dr. J. M. Eder (*Chem. Centr.*, 1881, 469).—This method depends on the fact that potassio-ferrous oxalate precipitates metallic silver from a solution of the nitrate, being converted into ferric salt in presence of a sufficient quantity of silver nitrate; when the solution contains tartaric acid the precipitated silver is free from oxalate, and can be at once weighed. The process is carried out as follows:—The feebly acid liquid is treated with excess of neutral potassium oxalate, and then with excess of silver nitrate. After a few minutes, tartaric acid is added to prevent the precipitation of ferric oxide by ammonia, and then excess of ammonia with a little ammonium chloride. The latter serves to cause the precipitated silver to flake together; the silver is then washed with ammonia and ammonium chloride, and weighed. The presence of chlorides does not affect the result so long as silver nitrate is added in excess.—*Journal of Chemical Society.*

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News*" *Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed* "*Union Bank, Photographic News Co. Account.*"

Thanet.—You had better employ the varnish ordinarily sold as "crystal paper varnish."

Argent.—Nitrate of silver 180 grains, water 1 ounce; dissolve, and add sufficient ammonia to re-dissolve the precipitate. Next add 120 grains of powdered gum, sufficient indian ink to tint the mixture, and enough water to make up the quantity to two ounces.

H. F.—1. Three parts of a suitable gelatine (see article in last number of the Photographic News), one part of sugar, eight of water, and one-fortieth of a part of finely-ground lampblack or other suitable pigment. 2. The usual mills, as employed for grinding water-painters' colours, are used.

D. M. A. (Glasgow)—Probably an orthographic lens; but your description is not sufficiently detailed for us to speak with certainty.

Charles Banyard.—A quarter-plate portrait lens.

G. Hillidge.—We will communicate with you by post.

A. B.—1. Use Coignet's gold label gelatine, and saturate the hot solution with olive oil; that is to say, shake it with oil, and draw off from the excess. 2. When the mould has once become denuded of its film of oil, and has bonded itself with the gelatine, it is often less trouble to make a fresh mould than to get the old one in work. Write to us again if any further difficulty crops up.

E. G.—Three or four times as much as you have charged would have been a moderate fee for taking the negatives; but we think it would be to your advantage to charge less for the prints, as this is work which does not involve a similar delay; neither does it require the exercise of so much careful judgment.

Indebted.—Under the circumstances it will be best to print them singly; if enlarged, so much the better. Then paste them on the ground, retouch, and copy. They should not be vignetted, and a rather dark ground is best.

G. W.—Fine Paris black ground with the varnish you name will prove effectual.

C. T. H (Bradford).—1. No such compound as $CaCl_3$ is known; $CaCl_2$ is calcium chloride, and a tolerably pure article can be bought for two or three pounds a ton. 2. If a careful inspection and individual study will not help you, a few words here would be of no value.

G. Collier.—We have never tried, but probably no harm would result.

Young Tradesman.—1. They are due to the crystallisation of the superfluous salts in the emulsion, and you cannot remove them. Send the plates back to the maker. 2. Nothing is better than soaking in dilute cyanide, but this often fails to do good. In any case you should make a transparency from the negative before treating it.

J. Berryman.—Obtain the translation of Dr. Eder's book on "Modern Dry Plates," published at our office.

Enquirer.—Prussian blue as sold in the moist state for water colour painters is the best material to use, but you must provide yourself with a small sable brush of good quality for applying it. After some practice you will be able to judge the amount required in each case, and to avoid making the opaque rings to which you refer.

A Very Old Subscriber.—You have anticipated our intentions.

Judex.—We quite agree with you that a photographer who, without permission, publishes a portrait which he has been employed to produce, and of which the copyright is not his own, is much to blame, and he can be proceeded against for damages. If, however, he has taken a portrait for his own satisfaction, the case is different, as the copyright is then his. This latter remark would not apply to a duplicate plate exposed during a sitting in which the photographer was employed by the sitter.

T. Brandebury.—Probably from the use of impure or discoloured pyrogallic acid.

B. Meyers.—1. Not unless a definite agreement was made at the time. 2. Very doubtful.

Theodore Bell.—1. Reduce the proportion of iodiser somewhat, and sensitise in a weak bath. 2. Either French chalk or wax will answer very well, but we prefer the latter. 3. A very good method is to coat the tissue itself with plain collodion; this operation being performed either before or after exposure.

One in a Fix.—Evidently from the use of imperfectly cleaned plates. Soak for a few days in a chromic acid mixture. Ten parts of water, two of sulphuric acid, and one of potassium bichromate forms a suitable mixture.

Hypo.—Add a solution of crude sulphide of potassium until there is no further precipitate.

CONTENTS.

THE DUNDEE PHOTOGRAPHIC EXHIBITION.

Bonnie Dundee may congratulate itself upon its exhibition. The judges met on Tuesday to consider their awards, Wednesday and Thursday were set apart for the private view, and this morning the exhibition opens in earnest to the public.

The gathering is a very fine one, and says much for the pluck of the Dundee Society. Its creation is due in the first instance, we believe, to the spirited president, Mr. J. C. Cox, of Beechwood, Lochee, a wealthy amateur of the north, who takes a keen interest in the advancement of photography. His unflagging spirit is the source of much of the energy of the Society, one of the outcomes of which is the fine gathering of prints in the Albert Institute, representing photographic work from every corner of the United Kingdom. But if Mr. Cox is recognised as the originator, there is an executive body of three to whom most of the actual work has fallen, and these, who have borne the heat and burden of the day, deserve no less honorable mention. Mr. Silvester Rollo, the Honorary Secretary of the Exhibition, Mr. Lamb, and Mr. George Valentine may be said to have ushered the exhibition into being between them, and the careful way in which the exhibits have been handled, catalogued, and fixed—there are between five and six hundred frames—reflects high credit on these gentlemen.

We may begin by stating the awards, merely premising that several of the most distinguished exhibitors were out of the running, so far as the gold medals were concerned, for the simple reason that the conditions laid down were somewhat arbitrary, or perhaps, we should say, a little exacting. At the same time, they had been published to the world, and as it is the exhibition of the Dundee Society, no one can grumble at the Council of the Society arranging matters after their own will. To take a gold medal, a series of six landscapes or six portraits were necessary; this seems pretty definite at the outset, but presently the question arises, what is a landscape, and what is a portrait? A pure landscape or a pure portrait is easily determined; but there are many pictures exhibited now-a-days for which, without any very special pleading, the claim may be advanced that they are landscapes, because, besides the figure or figures, there are trees, ferns, woodland, water, &c.; and that they are equally portraits, because the figure or figures may represent Mrs. Blank, or Miss Blank, or both. Unless it is definitely laid down in future what is meant by a portrait, and what is meant by a landscape, we foresee that difficulties are likely to arise. Of course there is always the word *genre* to fall back upon, but then it is just as difficult to decide what is a *genre* picture—or rather, what is not a *génre* picture—when a series of photographs come to be displayed; while frequently, as in the present instance, this class is not eligible for a high award. One more word as to the conditions: the Dundee Society, rightly or wrongly, have set their faces against pictures placed upon glass, and hence it was that the charming contributions of Messrs. Payne Jennings, Whiting, Brightman, Hills and Saunders, &c., could only compete for a bronze medal.

The gold medal, for a series of six portraits, fell to the lot of Mr. Abel Lewis, who sent a fine frame of magnificent photographs. One of them, a young lady in jockey cap and smart riding habit (three-quarter length) leaning against an oak tree, was particularly charming; and so, too, was a little girl making her entrance between two curtains which she holds in her hands. Other portraits had tapestry backgrounds, which were managed with very good effect, and imparted an unconventional appearance to the pictures. The silver medal for large portraits was awarded to Mr. Marshall Wane, whose collection included several stupendous 24-inch pictures produced direct. Of these we have already spoken in praise, in our "At Home" at Mr Wane's, so that we need merely say that they are the same as called forth our admiration on that occasion. Mr. Nesbitt, of Bournemouth, took the bronze medal in this class. He shows a very large collection of good work, but all of it is familiar to the visitors of former exhibitions in England.

A silver and bronze medal were also given for small portraits. Of these, the first was awarded to Messrs. W. and D. Downey, of Ebury Street, for a collection of most elegant little pictures, including an exquisite portrait of Miss Violet Cameron as *La Mascotte*, and another of Miss Kate Vaughan. The bronze medal fell to the well-known Edinburgh portraitist, Mr Moffat, whose high-class work well deserved the distinction.

The gold medal for landscapes was decreed to Mr. Harvey Barton, of Bristol, and there are few who will grudge that worthy recipient the honour. Mr. Barton also sends a large collection, some of them exhibited for the first time. His rare treatment of bowery foliage hanging over limpid water is well known to most of our readers, as also his soft, sweet rendering of distant hill and sylvan woodland.

The silver medal for large landscapes fell to Mr. Pettit, whose fine series included the fascinating scene of placid lake and distant hills that gained a silver medal at Newcastle. Mr. Pettit's work combines softness and brightness in an unusual degree—qualifications that are especially enhanced by choosing his pictures in Lakeland. The bronze medal in this class went to Mr. Andrew Pringle, for the magnificent series of Italian views that have already earned him a medal at the Pall Mall Exhibition.

The silver medal for small landscapes went to Mr. Frank Sutcliffe, whose pictures included the "country lane" that took a medal at Newcastle-upon-Tyne, and some sunset effects which have been previously shown. The bronze medal was given to Mr. William England, who showed the grand collection sent by him to the Bristol and London gathering, works that stand in no need of further praise from us.

The medals for the best *genre* pictures, a silver and a bronze one, were awarded respectively to Mr. Adam Diston, and to Mr. H. P. Robinson. Mr. Diston's pictures are well known to all visitors of recent exhibitions, and right glad are we that he has received a medal on this occasion. But it is no less than ridiculous to find Mr. Robinson's name in the position it is, especially when among his contributions is, "When the day's work is done," a picture that has been recognised by the gold medal of the Paris International Exhibition, and by silver medals at the Bristol Exhibition and London Exhibition. As the picture has already taken gold and silver awards, it may have been for that reason why bronze was dealt out on this occasion. However, Mr. Robinson is in very good company, since Mr. William England, as we have said, received but a bronze medal, while Mr. Payne Jennings has no more. The latter gentleman's landscapes, being mounted upon glass, could not compete for gold or silver medals.

In the case of enlargements, there was practically no competition. The Autotype Company secured the silver medal generously placed at its disposal, and Mr. H. N. King, for his magnificent series of transparencies of Windsor Castle, &c., which he exhibited in London, took a bronze medal given for this class of work. An extra bronze medal was subsequently awarded to Mr. Manfield for two fine transparencies of exceeding fine tone.

One silver and one bronze medal was reserved "for the best and second best series of landscapes of 8½ by 6½ or under: limited to amateurs actually members of this association." Of these, the silver award was given to Mr. S Rollo, and the bronze award to Mr. J. C. Cox, an extra silver award being made to Mr. Ireland for some capital pictures of Norway. Why amateurs who made pictures above 8½ by 6½ should be deemed ineligible to compete is another inscrutable point in the programme of the Dundee Society that we were unable to compass.

Of apparatus there was but a limited exhibition; a large roller for burnishing prints, to be worked either by steam or by the foot, and in which a clever reversing action was noticeable, to work the plate to and fro, received a bronze medal. It was from a design of Mr. Cox, the president, and was exhibited by him; another machine of similar construction being at the present moment in use at the establishment of Messrs. Valentine, in Dundee. Mr. George Hare, of Calthorpe Street, received a bronze medal for a camera of superior workmanship, in which the adjusting back was particularly well-designed. Mr Husbands, the well-known optician of Bristol, also received a bronze medal for a light and efficient camera, with zephyr-like dark-slides, in which the diaphragms were constructed of thin ebonite.

The Albert Institute, in which the Exhibition finds room, is admirably adapted to the purpose. The gallery is divided into six alcoves, each lighted by a large window by day, and at night, by an arrangement of Swan's incandescent lamps. As the Dundee Society proclaims with pardonable pride, it is the first photographic exhibition illuminated by electricity. From the circumstance that there were so many pictures to hang (the Society considered themselves bound in honour to hang all), the pictures are, many of them, hung too high and too low. However, it must be conceded that there is scarcely a photographer who has not some of his contributions on the line, and where a long list has been sent, of necessity, if all are hung (which we consider a very grave mistake indeed), some must be skied. Thus, ludicrously enough, Mr. Robinson's picture, to which we have referred, and which has received higher awards than any other pictorial photograph, is "skied," and so, too, is another well-known medal picture —Mr. Nesbitt's "Tired Companions."

All contributions from the members of the Dundee Society are wisely put together in one alcove, and thus the exhibition is at once a local and a general one. We have no space this week to notice these—which should have our first care—nor, indeed, any other of the new exhibits, but they shall receive attention in our next issue. It is only natural, in a gathering of this kind, that by far the majority of the exhibits should be composed of work already known. We append a list of exhibitors, which we believe to be correct:—Messrs. T. M. Brownrigg, A. Williamson, H. Manfield, Colonel Fraser, Messrs. Marshall Wane, F. M. Sutcliffe, Marsh Brothers, A. Donald, W. Harvey Barton, H. B. Berkeley, Cecil V. Shadbolt, T. and R. Annan, A. G. Pettitt, Matthew Whiting, Edward Fox, Magnus Jackson, Mrs. Bingham Mildmay, Messrs. Horatio Ross, E. Yeoman, G. Renwick, Valentine and Sons, Lyddell Sawyer, A. A. Campbell Swinton, H. P. Robinson, John Jackson, John Annan, Andrew Pringle, Abel Lewis, W. England, Silvester Parry, A. Hendrey, E. Day and Son, Robert Murray, Autotype Co., Messrs. J. C. Cox, J. Mathewson, Silvester Rollo, Peter Kerr, jun., D. Ireland, jun., W. McLeish, N. H. Geddes and Son, G. Bremner, J. Chaflin and Sons, John Henderson, G. F. Rodger, W. J. Anckorn, J. Moffat, Alexander Donald, D. Prophet, W. and D. Downey, G. Nesbitt, J. Robertson, J. Terras, Hills and Saunders, J. Abbot, J. Lamb, G. F. Roger, Platinotype Co., A. Diston, E. Brightman, T. G. Whaite, Payne Jennings, W. Gillard, D. Hedges, T. J. Dixon, D. Johnson, J. Milne, A. F. Mackenzie, R. H. Buxton, A. T. Bothamley, and Mrs. D. O. Hill.

ON THE SENSITIVENESS OF THE RETINA.

Any photographer who has ever considered the subject of the human eye as a camera and lens must have been struck with the marvellous sensitiveness of the retina, the part of the eye which represents the photographic plate or film; but probably it has never come under his notice that this sensitiveness varies, and to a very great extent. We know that the iris of the eye changes in diameter without our being conscious of it, and that it forms, in fact, a most perfect self-adjusting diaphragm, and we know that by this means a larger proportion of the light reflected by surrounding objects is allowed to enter the eye when these are dimly lighted, than when they are brightly; but it is not generally taken into account, that there is a far greater change than this—that besides the change in the amount of light admitted, there is an enormous change in the sensitiveness of the retina. The very change is of such a nature as to prevent us from perceiving how very great is the range of light through which we can see distinctly. We shall take an example.

On a brilliant moonlight night, some hours after sunset, our friend, on looking round, remarks, "Oh, how beautiful, how bright the light; almost as bright as daylight," and really it almost seems to be so; yet we know that the light is in reality vastly less bright than sunlight. Let us look a little into what really is the ratio of the brightness of moonlight and sunlight. We all know, of course, that the light of the moon is but borrowed light—light received from the sun and reflected from its surface. Now, were the surface of the moon a perfect reflecting medium—that is to say, were it to reflect all light which reaches it, the amount which we should receive from a full moon would be only about a one hundred and eighty-thousandth part of what we receive from the sun in the day-time. But it is evident that the moon's surface will reflect but a small fraction of the light which reaches it. Probably its average colour is about the same as the colour of the rocky parts of the earth's surface, and it is likely that we are overstating the amount actually reflected when we say that it may be a fifth or a sixth of the whole received, yet this assumption leads us to the astounding conclusion that the bright moonlight which we have so much wondered at is really about a million times less bright than sunlight. It is quite evident that, besides the alteration in the area of the iris of the eye which has taken place, there must, in the few hours between sunlight and moonlight, have been an enormous increase in the sensitiveness of the retina.

We have stated the ratio of the brightness of the sun and moon as perhaps a million to one; but certain experiments in moonlight photography, which we made some time ago, lead us to the conclusion that the ratio is probably considerably higher—likely about two millions to one.

The limit of sensitiveness which may, so to speak, be excited in the retina, does not, however, stop here. Under certain conditions it may be still more increased, so much so that moonlight may in its turn appear by comparison an almost unbearably strong light. It is not, as might be expected, by remaining in total darkness that the maximum sensitiveness may be reached; it is by working and continually using the eyes in the least possible light for a considerable time. We have experienced such a sensation when experimenting with extremely sensitive emulsions. We have worked for several hours in our dark-room at night time by artificial light, and have kept the light just to the lowest point at which it was possible to see at all. On emerging from our room into the open air, the moonlight appeared so powerful that, for some seconds, it was painful to look at any white object lying in it. From this we conclude that the sensitiveness of the retina may become so marvellously great, that it can perceive objects, and follow the rapid motion of those objects, in a light which may be white, but so dim that, were the retina replaced by the most sensitive gelatine film, it would take weeks or even months for a developable image to be impressed upon it.

But what is the practical outcome of all this to photographers? Well, we deduce from it a lesson which all of them might take to heart. There is the most extraordinary difference of opinion as to what is, and what is not a safe light, in which to work in the dark room. Now, we believe that a great deal of this difference of opinion is due to the fact that the constant change in the sensitiveness of the retina makes it most difficult to judge of the amount of red light which is being used. For example, one man is in the habit of leaving his brilliantly lighted studio, and immediately entering his dark-plate room. At this time his retina is at its lowest sensitiveness. He will tell you: "I work in a place about as dark as pitch, and yet my plates fog if I do not keep them shaded from the apology for a light which I do have."

Another man exposes plates in the field. He brings a number home and develops them a few hours after sunset. He will tell you, "I use plenty of light. Ruby, doubtless, but a perfect flood of it, and my plates never fog." Now it may seem astonishing, but it is more than likely that the first photographer was working in a very much more bright light than the second, even although the non-actinic medium may have been of the same colour in both cases.

A room which will—for developing—appear brilliantly lighted when entered some hours after sunset, will appear absolutely dark if entered from the open air at mid-day. We believe we do not exaggerate when we say that the photographer sometimes works in the daytime with a light a hundred times more bright than one which he would not consider safe if he entered his room at night.

A PERMANENT PHOTOGRAPHIC MUSEUM.

When Mr. H. Trueman Wood set his project of a Technical Photographic Exhibition on foot, we suggested the desirability of forming a standing collection of objects of historical or technical interest, so that the collection should be available to future generations of photographers as an illustrated history of progress in the photographic art; and we suggested that the Society of Arts should take charge of the collection. Some difficulties have, however, arisen in connection with this proposal, and we have reason to believe that the Council of the Society in question will not take action as regards the institution of anything in the shape of a permanent collection, as the limited space which could be spared would hardly suffice for the adequate display of the objects which might be reasonably expected to come in were a call made.

A letter from Captain Abney, which we publish in our present issue, affords a satisfactory answer to the oft-repeated question as to what should be done with the various specimens of photographic interest which are now not only distributed among those who take an especial interest in photography, but are in many cases possessed by people who neither value them nor take care of them, merely regarding them as somewhat dingy and unsatisfactory pictures. As will be seen by reference to the Captain's letter, the Director of the South Kensington Museum proposes to devote a portion of that Institution to the housing of a collection illustrative of the history of photography from its earliest phases to the present time, and we are informed that suitable arrangements will be made for taking proper care of the collection, and adding examples illustrative of each step in advance as it is made.

CAPTAIN ABNEY'S SECOND CANTOR LECTURE.

On Monday evening last there was the same earnest competition for places as a week previously, and as early as seven o'clock a small cluster of people might have been seen waiting outside the door of the house of the Society of Arts; and the reply of the porter that there could be no admission till half-past seven did not appear to give universal satisfaction.

Attention was called to the ferrous citro-oxalate developer, and as this requires no restrainer, a more perfect rendering of the results of feeble radiation is attained when it is used.

Next in order came a study of Mr. Berkeley's method of adding sodium sulphite to the pyrogallic developer, this salt serving to absorb any free oxygen, which, under ordinary circumstances may oxidize the pyrogallic acid; by its use the pyrogallic solution is retained for a long time in a fit condition for work, and more actual useful work is effected, as the reducing action of the pyrogallic acid is now almost exclusively directed towards the decomposition of the silver bromide. A solution which contained four parts of the sulphite to one part of the pyrogallic acid was found to be quite good and fit for use after being kept for a month.

The hydrochinon developer was very highly spoken of, it also working without a restrainer, and in referring to recent reductions in the price of hydrochinon, the lecturer expressed a hope that this valuable developing agent may soon be manufactured on a considerable scale and at a low price. A collodio-chloride film on opal glass was then developed in a most satisfactory manner by hydrochinon; and as the operation was performed in a dipping bath with parallel glass sides, the gradual unfolding of the image was well seen by all present. A pure iodide film was next exposed, and the possibility of developing it with ferrous oxalate was proved, the image appearing with great rapidity and vigour.

The function of the so-called chemical sensitizers is immediately fixing or uniting with chlorine, bromine, or iodine liberated from the silver compounds by the action of light, and to illustrate the necessity of employing a sensitizer in order to attain a useful degree of sensitiveness two sealed bulbs were shown, one containing perfectly pure and dry chloride of silver, while the other contained a minute globule of mercury in addition. The former was unaffected by a prolonged exposure to sunshine, while the latter had become considerably blackened, as the mercury absorbed the liberated chlorine.

The relative effect of the various rays of the spectrum on silver chloride, bromide, and iodide was next demonstrated, and it was shown how those rays which are obstructed by a sensitive medium are alone effectual in changing its chemical character; and it was proved that in the case of the various physical modifications of silver bromide, the spectral position of the maximum of action was identical, although the relative activity of certain rays differs notably.

The question of a safe light for the dark-room was next brought under review, and several samples of ruby were shown which allowed a notable proportion of green and blue rays to pass, while the yellow and orange glass which was usually considered safe for wet plates was demonstrated to allow abundance of actinic light to pass. A combination of stained red and cobalt blue, or the usual green, was found to be of the safest possible character in almost every case; and for a varnish, a mixture of magenta dye and aurine formed an extremely satisfactory colouring matter; while a cell filled with somewhat old ferrous oxalate developer was by no means to be despised as a non-actinic medium. The lecture terminated with a study of the supposed action of some colours as optical sensitizers.

Several additions have been made to the Technical Exhibition, to which we shall probably allude next week.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

A Professional Beauty Show—Photography and the Transit of Venus—Photography and Tricycling.

A Professional Beauty Show.—The "professional beauty" craze has penetrated to New York, and has been seized upon by the wide-awake Barnum as a new feather wherewith to tickle the public taste. He has offered a prize of 20,000 dollars for the handsomest woman, the claims to be sent in by the 1st of February; and beauty in New York, we may imagine, is in a flutter in consequence. Probably foreseeing the overwhelming rush which would follow if applications were to be made by the ladies in person, the astute showman wisely announced that applications were to be sent through the post, and the award made after a careful examination of the competing photographs. A Chicago paper, commenting on this beauty show, says: "Barnum must be aware that the photograph often fails to do justice to the original. Some very fine-looking women will not take (except at a disadvantage), while others of ordinary appearance appear much improved; hence it is impossible to depend on a lady's photograph." This is true; but in these days of retouching there is more chance of a lady being flattered than the reverse. If Barnum adjudicates upon the faith of photographs alone, we fancy when the winner of the prize appears in person to receive the acknowledgment of her superior claims, that everyone will be disappointed. It is, however, rather unkind for the paper already quoted to hint that Barnum has probably long ago selected the woman he intends shall win the prize, and that the 20,000 dollars is only to give *éclat* to the exhibition.

Photography and the Transit of Venus.—From a remark made by Mr. I. R. Hind, the President of the Royal Astronomical Society, at its last meeting, it does not yet seem settled whether photography will be employed in connection with the observations of the transit of Venus of 1882. According to Mr. Hind, there has been a general feeling that photography should not be employed again; and if so, it would be interesting to know why. It is all the more important that some satisfactory reason should be forthcoming, since at the same meeting some valuable suggestions were made in a paper on the subject read by Mr. Maunder. Mr. Maunder pointed out that it would be much more likely accurate results would be obtained if the position of the planet were taken in regard to some particular spot or faculæ on the sun's surface, rather than in regard to the limb of the solar disc as a whole. He suggested, therefore, that under-exposed photographs should be taken at the various stations, by which the parallax of the planet (as observed upon such solar details) may be determined. Mr. Maunder further observed that the great difficulty in measuring the photographs taken during the transit of 1874 was found to arise from the fact that the light of the sun's disc fades off very rapidly towards the limb; so that, to get a good impression of the limb, it is necessary to give a comparatively long exposure, and the central portions of the disc are over-exposed. But for the method now proposed, it would only be necessary to give a slight exposure, and the parallax of the planet may be determined from any two stations, whether the place of the planet appears to shift towards the limb of the sun, or in any other direction, if there are suitable details in the immediate neighbourhood of the planet from which to measure. It is gratifying to find that Mr. Maunder's suggestion received cordial support from such eminent authorities as Mr. Norman Lockyer, the Astronomer-Royal, and Mr. Ranyard. Mr. Lockyer showed that observations by means of the sun's spots were the more reliable, because the limb of the solar disc depended upon the collodion employed. The absorption, said Mr. Lockyer, in the solar atmosphere seems to lie chiefly in the region of the spectrum between G and H, and consequently if any departure is made from the collodion ordinarily employed, you get a considerable difference in the intensity of the limb as compared with the centre of the sun's disc. We may remark on this, that now so much advance has been made in regard to gelatine, the reference to collodion sounds almost antiquated. Is it possible that our astronomers have not yet made themselves familiar with the powers of gelatine? Mr. Lockyer, we also notice, advocates the taking of photographs on a large scale (a suggestion which the Astronomer-Royal afterwards scarcely endorsed, remarking that the same results could be obtained if proper mechanical means were used to give a shorter exposure), and is of opinion that most detail comes out with an under-exposed picture, which does not come out immediately on being developed, but which needs to be intensified, and the details slowly brought out. Mr. Ranyard was also in favour of photographs of short exposure taken at short intervals and afterwards compared, and referred to M. Janssen's method as a case in point. In M. Janssen's astronomical photographs the exposure is reduced to such an infinitesimal fraction of time, that all the distortion of the moment of exposure is recorded, whereas the eye takes note of the mean position. The chief reason, said Mr. Ranyard, of the success of M. Janssen's photographs arises from the fact that the part of the solar spectrum near G is the first to impress itself upon the photographic plate; and to M. Prazmowski is due the credit of perceiving that this fact might be made use of. The idea was adopted by Janssen, and Prazmowski arranged for him a system of lenses, so as to throw an image which would be practically perfect for the G rays upon the plate. Looked at with the eye, the sun's image, as seen upon the plate in this Janssen instrument, is not optically good; but the photographic effect is so sharp, because the plate is accurately placed in the focal plane of the G rays. The tone of the discussion was universally in favour of photographic observations in respect to the sun's markings being reliable as points of measurement, and we trust that when Mr. Hind afterwards said, "it would not be too late now to make arrangements to use the photographic method partially," he spoke with authority. It seems, however, doubtful whether any but the Daguerreotype process can be relied upon for scientific measurements.

Photography and Tricycling.—The practice of photography is yearly being made easier—that is to say in the reduction of the impedimenta which used formerly to make landscape photography literally a "*labour* of love." We see no reason why this impedimenta should not be further reduced. The tricycle is only comparatively speaking in its infancy, yet it has become something more than a mere toy. So far as the photographer is concerned, what is wanted is not speed, but lightness and a proper adjustment of weight for which a certain amount of baggage may be carried without entailing treadmill work. At the present time there are many excellent tricycles in the market, but they all fail in one important particular—the capability of climbing a hill. As nature has not made England like Holland, this want of climbing power is a great drawback. But even as they are now made, it is possible to use them with convenience for the carrying of a small camera and dry plates, and we anticipate in the coming season that many outdoor photographers will combine photography with tricycling. *Apropos* of this subject, we might mention that during this month an exhibition opens at the Agricultural Hall at which tricycles will form an important feature. An opportunity will then be afforded of examining the advantages and disadvantages presented on the different vehicles which cannot fail to be useful. We might add that so far as our experience has gone, a small wheel machine is much better for hill climbing than the large wheel variety.

FRENCH CORRESPONDENCE.

Accumulators of Electricity—Platinum Printing in France—The Old Iron and Uranium Process—The Examinations of the Chambre Syndicale.

Accumulators of Electricity.—It is a pleasure to observe that in the photographic world we are beginning to take advantage of the applications of electricity. The remarks of Mr. Swan have not fallen on deaf ears, and the time cannot be far distant when this form of energy will be utilised in all our principal laboratories; by means of the electrical accumulator we are able to store it, and to draw off and distribute it as it may be wanted. I have myself been busily engaged in studying these contrivances, and I have succeeded in constructing them for my own use; but, unfortunately, the treatise of Mr. Gaston Planté, on secondary batteries, in which several forms of accumulator are described, is already out of print. Notwithstanding, the construction of a secondary element or electrical accumulator may be stated in a very few words, and nothing is easier or more simple. It consists of a couple of sheets of lead, each from 50 to 60 centim. long, and from 20 to 25 centim. broad, placed one flat on the other and then worked up, the two spirals being kept from contact with each other by means of four strips of india-rubber of the same length as the sheets of lead, and about 3 millim. in thickness. These india-rubber bands are placed between the metallic plates in such a position as to secure their being kept well insulated from each other. The first sheet of lead is laid flat on the table, and then two of the caoutchouc bands are placed upon it, parallel to the edges and at about 6 centim. distant from them; on these is then laid the second sheet, and on this again the two remaining bands in about the same relative position as the first two. When thus arranged, the whole is rolled up round a cylinder of wood. Care must be taken to solder to the opposite end of each sheet a metallic tongue which projects some two or three centim. beyond the spiral in the direction of its breadth, in order to be able to attach the conducting wires. The roll is now placed upright in a glass vessel of corresponding dimensions filled with water acidulated with 10 per cent. of pure sulphuric acid, taking care that the tongues or poles of the plates shall project beyond the vessel, and the whole is then sealed down, only allowing a small orifice for gas produced by decomposition to escape. Before placing the roll in the liquid, it is well to assure oneself by means of a galvanometer of the perfect insulation of the plates from each other; should any fault in the insulation be detected, they must be unrolled, and the defect remedied. It will be seen that such a secondary battery, by which we can accumulate for our own purpose the chemical work of a primary current, can be most readily made without having recourse to the instrument makers, whose prices are never of the lowest. Three of Daniel's or Bunsen's ordinary elements are sufficient to charge a battery of a dozen secondary elements as above described. When using the instrument, we arrange the elements in tension, and we have in a very short time at our disposal an energy equivalent to that produced by the long continuous action of the primary battery; we can by this arrangement obtain for a short time a very bright light, set a small motor in action, produce magnetic attraction, &c., &c. Not having seen anywhere in the Photographic News an account of these valuable instruments, I thought it might be of interest to my readers to give a rather detailed description of them, and I hope to be able to recur to the subject and to complete it.

Platinum Printing in France.—There is a good deal of reasonable surprise that the process of printing in platinum is not more cultivated in this country. Although Mr. Willis's process is specially worked in one of our most important establishments, the sum demanded for the Royalty, and the price of the papers sensitised with chloride of platinum, are so high as to effectually prevent its being more generally used. It may be added that the black tone of the prints produced seems no recommendation in the eyes of portrait photographers. The result of this state of things is that we have only the carbon process to fall back upon, in cases where only a limited number of prints is required which shall be of undoubted permanence. Now, much as I admire the carbon process, it must be confessed that it is difficult to carry out, unless one is equipped with all the special instruments and arrangements necessary for working it.

The Old Iron and Uranium Processes.—But, while we are still waiting for the invention of a simple and easily workable permanent process, why should we not have recourse to some of our old favourites, which seem to be already sinking into oblivion? There is, for example, the nitrate of uranium process; in this, the paper is sensitised by floating for only about half a minute on a bath composed of 15 grams of uranium nitrate dissolved in 100 grams of water. It is then quickly dried, and kept carefully protected from the light. The exposure takes place in the ordinary way, but requires, perhaps, a little longer time, and the plate is then washed in warm water. It is next dipped in a mixture of solutions of chloride of gold and chloride of platinum (each in the proportion of 1 gram of the salt to 1,000 grams of water), to which a drop or two of hydrochloric acid has been added. The image is formed of gold and platinum, and its development can be stopped at any required moment. This is the whole of the process, and it gives a print of perfect stability. Another method consists in using a direct mixture of the solution of uranium nitrate, and of gold and platinum chlorides, or, still better, perhaps, the following process may be employed:—Equal parts of 10 per cent. solutions of perchloride of iron and the chloride of platinum are mixed, in which the films are sensitized, and are then dried and exposed; the action of the light produces a white image on a yellow ground, which may be developed in a bath of chloride of gold, thus giving an image formed of gold and platinum. There is an infinite number of processes of this kind, from which it is easy to select one which gives rapidly and readily a permanent print. I hope to be able to publish the results of my investigations in this special line.

The Examinations of the Chambre Syndicale.—These examinations will bear more especially on the candidate's knowledge of practical photography, but there must necessarily be also some questions in theory in order to test specially the examinée's acquaintance with the principles on which the special branch of his art rests. Certainly, the examination as a whole must be thorough, that it may be a real guarantee of the ability of those who pass it.

Leon Vidal.

Notes.

Prince Leopold is to be president of the British Association at Southampton.

His Royal Highness is a member of the Royal Institution, and enjoys the reputation of being a good chemist. At Clermont, which is to be his residence after marriage, there is to be a well-appointed laboratory fitted up for scientific investigation.

The jurors who awarded the medals at the Dundee Exhibition were Mr. W. D. Valentine, of Dundee; Mr. Sinclair, late hon. secretary of the Edinburgh Society: Mr. H. A. H. Daniel, hon. secretary of the Bristol Society; and Mr. H. Baden Pritchard.

Vegetable gelatine, or *agar-agar*, as it is sometimes termed, has frequently been suggested as a substitute for gelatine in collotype work, and at the last Technical meeting of the London Society a question was asked as to its suitability for emulsion. It is interesting, therefore, to find that Captain Mitchell, Paymaster R.A., has actually employed the material for dry plates, the results he sends us being exceedingly promising, and far better than some of the earlier gelatine productions.

In a German contemporary, a correspondent naively puts the question: "Where can I best obtain specimens for my show-case?" Our answer to such innocence would be: "Where you choose, so long as you do not make them yourself."

M. Zenger commends to the Transit of Venus Commission a method of taking photographs which is likely to give more accurate results than the photo-spectroscopic processes in present use. Seeking a medium which, while strongly dispersing the rays, is at the same time perfectly transparent, and reflects totally red and violet light, he found that benzole combined with quartz eliminates the extreme red of an angle about 75°, while pure anethol at the same angle eliminates the extreme violet. Therefore, M. Zenger recommends a double liquid medium of this nature to be placed before the spectroscopic camera as the best means of observing solar protuberances and similar phenomena.

The price of incandescent lamps is lowering rapidly. For a long time the Swan lamp was the only form in the market, and these sold for twenty-five shillings each, unless a large quantity were taken. In view of the Edison lamp becoming a commercial article—we do not say that it is, for Edison has cried "Wolf" so often that people are growing sceptical—the Swan lamp has been reduced to twelve shillings and sixpence, and no doubt a further reduction will be made very shortly. The carbon filament in the Swan lamp, which becomes incandescent, is charred parchmentized thread; in the Edison lamp, it is charred bamboo fibre.

It is very common to see cameras in which the lens can be raised above the centre, but one rarely finds apparatus permitting the lens to be lowered below the centre. On this subject, we remember one of our best architectural photographers, Mr. Harvey Barton, saying: "I do not know if there are other cameras like mine, that permit the lens to be lowered, but I have never seen one."

Messrs. Valentine Brothers, of Dundee, employ zinc to deposit the silver from their waste hyposulphite washings. The washings are simply run into a tank in the yard, in which some pieces of zinc—old roofing and worn-out piping, for the most part—have been put. The silver, in metallic form, deposits itself upon the zinc surface, from which it is shaken or brushed from time to time. They find this more satisfactory than treatment with hepar sulphuris, or liver of sulphur.

The pocket Geneva time-piece is made, as the well-known advertisement informs the public, with steel works, balanced action, glass dome, enamelled dial, and metallic case. It is moreover guaranteed to indicate correct solar time in any climate, and can be had post free for 13 stamps.

It turns out to be a pocket compass, the card, which is attached to the magnetic needle, being in reality a small sun dial. If placed on a map, the map being ranged true to the points of the compass, the "Geneva timepiece" may give the photographer useful information as to how the sun's rays may be expected to fall in a given locality at any particular hour of the day, and it should save needless journeys or unnecessary waiting. Some slight allowance may be made for the season of the year in using the instrument.

The photographer who talks freely about art, and discusses points of view with much circumstance, will no doubt prefer to spend half a day studying his building; but when the man of business wishes to make the most of a day which promises sunshine, the case is altogether different.

'Cycling and photography. Many photographers have tried to combine the two arts, and, strange to say, their development has from the first been connected. Nicéphore Niépce, before he first secured a photograph in the camera, invented, in conjunction with his brother Claude, a species of velocipede. It was at the time when people were seeking after perpetual motion, and this invention seemed to the brothers Niépce to go as near perfection as possible. Accordingly, Claude was despatched to England—which then, as now, was considered the best market for inventions—to dispose of the machine. Claude died in England without effecting the sale; but indirectly, the world benefited by the invention; for if his brother had not been abroad, Nicéphore would never have written those interesting letters about his early experiments in photography, and in all probability there would have been no record of them.

Dr. Warren de la Rue, whose superb moon photographs are still among the best we have of that orb, has been elected manager of the Royal Institution.

The moral of *A Photographic Fright*, which has been played nightly for some time past at the Princess' Theatre, is a most whole some one—from a photographer's point of view. The heroine obstinately refuses to have her photograph taken even to oblige her husband, and, as a natural consequence, she gets involved in serious difficulties. And for this reason : as she will not be photographed by fair means, a photographic friend, who knows how much the lady's husband desires a portrait, depicts her surreptitiously as she sits on the Margate beach one sunny morning. Unfortunately, a gentleman in close vicinity is depicted in the photograph as well, so that when the husband gets hold of the picture his jealousy is aroused, and plenty of material for a farce is obviously at hand.

A NON-ACTINIC FILM FOR ETCHING OR TRACING WITH A NEEDLE.

We have received the following communication from Mr. H. Trueman Wood, the Secretary of the Society of Arts :—

There are many purposes in photography for which an opaque film capable of being etched with a sharp point might be useful. Such a film can be obtained by use of the following formula :—

Negative collodion	½ ounce
Ether	6 drachms
Alcohol	6 ,,
Shellac	30 grains
Aurine	2 ,,
Judson's mauve dye	30 drops
Water	30 ,,

A collodion thus treated gives a film which is perfectly non-actinic, and which allows the finest tracery to be executed upon it, without any tearing or chipping whatever. The film is the result of a good many experiments, and was devised by a friend of the writer for the purpose of reproducing tracings made by a geometric chuck in the lathe. As a general rule, these patterns, which form the delight of so many amateur turners, are either traced with a pencil suitably held, or by a glass pen charged with aniline ink, the latter being the more recent device which has superseded the old pencil. They are, of course, also cut upon wood or metal with suitable tools. By the use of a plate coated with a film of the above-described mixture, a steel point can be used. The glass plate is properly held in the chuck, and a steel point, which may be fitted with a spring, so as to prevent undue pressure or risk of breakage, is placed in the position usually occupied by the pencil. The pattern is thus traced in perfectly clear glass, and from the negative—if the term may be used—thus produced, prints can be taken on ordinary albumenized paper. As the film itself transmits practically no actinic light, the printing can be carried to any extent, and a perfectly black print produced. The film may also be etched upon with an ordinary etching needle, or even with a common needle, and prints produced from the plate thus obtained.

Another use of the formula is for the preparation of lantern diagrams. Any diagram can be rapidly traced upon a coated plate, and the diagram can then be thrown on the screen in the ordinary manner, appearing, of course, in bright lines on a black ground. A diagram of this sort is quite as effective as, if not more effective than, the ordinary black lines on an illuminated ground, as was shown by the very vivid way in which a negative diagram, recently employed by Mr. Bolas at one of his Cantor lectures, shone out upon the screen. It would, of course, be easily possible to obtain a printing-block by any of the ordinary methods from a plate etched in this manner.

The mixture requires some little care in its preparation, and especially as regards the addition of water. It is better to add the water gradually, coating the plate occasionally after each addition of a few drops. The formula might doubtless be susceptible of considerable modification ; but the one given above has been proved to give the best results of any which have yet been tried.

SEAWEED GELATINE.

BY CAPTAIN MITCHELL, R.A.

When I was at Rangoon, some time since, I had, without success, endeavoured to make gelatine emulsion plates. The cause of my non-success was my inability to get the gelatine to set, owing to the great heat and dampness of the atmosphere. This caused me to look about for something else which would answer the same purpose.

Walking through the native town I noticed that some of the shops sold a beautiful jelly for food. After some difficulty I found this jelly was made of a seaweed, which, I think, must be *agar-agar*.

With this seaweed I made an emulsion and some plates, and I found them answer very well indeed. I have two or three of the negatives with me now. Those of short exposure were hardly dense enough to please me ; but fifteen seconds to two minutes produced printable negatives. Of course they are but very rough experiments, but they are sufficient to show what can be done with seaweed.

The weed dissolves in boiling water, and with this solution the emulsion is made, carefully avoiding excess of silver. Thrown out into a dish, it sets immediately, when it can be cut up into small pieces, and washed in a bottle. Re-melt, and coat plates quickly ; they set at once, and can then be dried. The film is very tough, and can be floated on and off the glass.

The fault I found with this seaweed was that it contained small particles—I suppose seeds. These could be eliminated, I dare say, with suitable apparatus. All my apparatus consisted of two teacups, a bottle, and a spirit lamp. With this it is difficult to work on board ship in a small cabin.

I have no doubt that some of my brother amateurs would like to try a new process; if so, I have a small quantity of the weed, which I shall be glad to send you.

I enclose you three prints and a sample of the seaweed.

SYMBOLISM OF NATURE IN LANDSCAPES.

BY WILLIAM NEILSON.*

This subject is so extensive and involved that, dealing with it in limited space, I can only give some scattered thoughts in an abrupt and desultory manner. Though bearing neither on the science nor art of photography, I bring it forward as suitable for the consideration of the artist, whether he works in colours or chemicals, believing that any theory connected with art, if founded on truth, has a practical tendency.

In order to be successful in any line of life, a man must undergo two educations—one derived from the experience of others, and one derived from his own experience. This remark applies especially to the artist. His education in the academy is chiefly derived from the experience of others. In it he is taught to draw, colour, and deal with the technicalities of landscape. But, besides the academy, there is the school of nature in which his education must be derived chiefly from his own experience. This requisite education cannot be acquired by taking social trips to the country, and sitting down here and there to concoct a picture. Such pictures may be excellent in their way, and excite the admiration of those whose acquaintance with nature does not exceed that of the artist. But he who would truly interpret nature

* Abstract of a paper read before the dinburgh Photographic Society.

must be thoroughly acquainted with nature. Education is the completion of a long habit. His must be the habit of being alone with nature in all its aspects and conditions—hill, valley, wood, water, sunshine, and storm—not for the purpose of thinking, but in order to comprehend and feel all the expressions of nature. His delight will be to become imbued with the beauty and grandeur of nature—to feel as if the soul of nature, so to speak, had passed into his being. Then he will be able to put a charm into his pictures, which is alike beyond the reach and comprehension of the mere academy man. Many photographers have not the opportunity for acquiring such a knowledge of nature; but by picking up hints on the subject and meditating on them, they may turn to better account what opportunity they have; not that these will give him a personal acquaintance with nature, but they may shunt him into the right direction for acquiring that.

What is meant by symbolised emotion? The two words emblem and symbol have much the same meaning attached to them, being used to denote an object which embodies in itself the idea of something else. Having no fitter word for the occasion, I use "symbol" with a different meaning; the difference being that whilst "emblem" embodies thought, "symbol," as I use it, embodies feeling. When the eye rests on a drooping flower, and then on a mountain, we are conscious of a pleasant emotion arising from each; but in each case the emotion is as different as are flower and mountain. I may think of the flower as an embodiment of grace—call that the first result; the flower has become an emblem. But, without having ever thought of the flower as an emblem of grace, on looking at it I may feel the emotion that is excited by the idea of grace—call that the second result; the flower has become a symbol. And so with the mountain; as an emblem it gives the thought, and as a symbol the feeling of grandeur. In other words, flower and mountain, without suggesting the ideas of grace and grandeur, may none the less give the feeling connected with grace and grandeur. This feeling is symbolised emotion. Remember that if flower and mountain did not in some way express certain feelings, they could not excite these feelings in the beholder.

It may be asked, if flower and mountain naturally symbolise the feelings of grace and grandeur, why are these not experienced by every person with a like intensity? As a special faculty appreciates correct reasoning, so a special faculty, not always equally developed, appreciates the symbols of nature,—the æsthetic faculty, which is imagination influenced by the emotions. It perceives what is imaged by an object in nature; but, whilst it perceives what exists, it cannot alter the character of the image expressed; be it drooping flower, or mountain, or whatever else, it can only appreciate in each object the symbol of the emotion which nature has fitted it to express.

Here I must ask, What is beauty? No word, on this side of Bedlam, is so frequently misapplied; people are apt to apply it to anything that is merely satisfactory. It has been propounded that beauty is utility; if so, the beauty of the frying-pan can only be excelled by such things as the compost the farmer spreads on his fields. The last theory is, beauty is association. Association is a subtle power, by which it may raise the ugliest of our race into the highest region of esteem and admiration; but it can no more turn ugliness into beauty than make black white. The moon becomes a more interesting object when we think that all the men and women who have lived, savage and civilised, have gazed and gazed upon that pale face in the blue heavens; but such association does not add a jot to its beauty. A man who devotedly loves a very ugly woman may, by force of association, really think her beautiful; but that will not alter the shape of her nose, the colour of her eyes, nor the size of her mouth: the woman is the same; and the man has merely, in the insanity of love, trained himself to admire her ugliness, calling it by a wrong name. That "beauty" has never been resolved in satisfactory definition may be accepted as evidence that it is specially involved in the element of the mysterious which surrounds us, and cannot therefore be expected to be explained with the distinctness of a theorem in mathematics. Logic has its own jurisdiction; but in the region of beauty the æsthetic faculty is sole judge. We can only pick out some hazy facts, and piece them together as we may, and feel that there is a coherency among them. Certain as it is that we cannot fathom mysteries, it is no less certain that we may see them unite at the edges in practical result. What, then, is beauty? Is it wholly physical? If so, why do not all men see it alike, as they do a house or a horse? Then is it wholly mental? If so, why do you require to open your eyes before you become conscious of it? I believe beauty is neither mental nor physical, but a conjunction of the two,—a peculiar mode in which, by natural adaptation, matter responds to mind; in short, symbolised emotion.

The fine arts, after the pattern of nature, express themselves in symbolism.

A symphony consists of different passages, each with a different emotional expression; so that we say one passage is plaintive, another gay, another sad, and so on. The chief powers that give musical expression are variety and contrast—hope and fear, joy and woe, tenderness and rage, and so on in endless combinations, being symbolised by the thousands of notes that make up symphony. Whilst these notes conduce to the character of the different passages, they have at the same time an undercurrent of their own, swelling, rising, and sinking in infinite variety and contrast of symbols of a universality of emotions. The glory of fine art is to convey a feeling of the universal. Such a flood of emotions, if distinctly emphasised by the symbols of music, would distract and overwhelm the mind of the hearer as in a thousand-fold entanglement. But art controls all these, so that the result is wholly pleasant; subduing the interwoven symbols so that they excite in us the consciousness, not of distinct emotions, but merely the ever-varied kinds and degrees of pleasure connected with these; so that the harmonised progress of the symphony, in its necessary vagueness combining endless grades of beauty and grandeur, blends the whole in one ever-increasing vastness of delight—

"A mighty maze, but not without a plan."

Shall we be told that association can explain this mysterious music! He must be far astray in the land of modesty who thinks that it is his associations that give beauty and grandeur to Beethoven's music; as if one should read "Paradise Lost" and say its all owing to my associations. Association cannot create, but it may enhance, as when to the native ear it adds a charm to national music, making even the screams of the bagpipes not unpleasant—at a distance.

The symbolism of poetry consists of interwoven thoughts, figures of speech, and rythmic cadences. Mere ingenious thoughts that have no bearing on the emotional development of the poem, have no business in it.

A sentence or two must serve to apply the gist of what has been said to the landscape. Like music, the landscape may have prominent divisions of different character, to which conduce the endless thousands of objects, which yet have a vague symbolism of their own, the infinite variety and contrast of which constitute the enchantment of the view. What the symphony is to the ear the landscape is to the eye. A landscape cannot be analysed, but we may pick out two or three emblems in illustration. Suppose on the right hand a hill, at whose base some pine trees slope in different directions, as if with advancing decrepitude. Beneath them lies prostrate a noble birch tree, its white bark half-smothered with moss, typing the universal decay. Above the pines a slant of heather lies with its purple laugh on the brink of a solemn ravine, the hill tapering upward like aspiring hope. On the left hand is a precipice of rock typing the unattainable; yet, someway up, a foxglove hangs out its bells like a signal for encouragement; whilst on top of all an old Scotch fir stands like the hero of a thousand storms. In the centre ground a streamlet, kissed by drooping ferns, prattles like a child towards a lake, which lies in the calmness of content. The very silence gives a thought of infinity. The sky hangs like a blue dome hallowing the temple of nature; whilst above the hills, at the far end of the lake, the dying day lies in streaks of crimson and gold, like a vista to the immortal land. Now he who dissects nature in this fashion is not admiring nature; he is only admiring his own thoughts. Nature, like music, symbolises a symphony of feeling, and he who has the faculty to appreciate that, gives himself up, wholly receptive, to the exhaustless delight. A difference may here be noted. Associations connected with an object may be as different as the people who indulge them; but the symbolism of nature never changes, but invariably tells alike on all competent beholders.

It is said the artist must be true to nature; but how? When Shakespeare wished to give intense expression to the feelings of our nature, he so departed from the habit of nature as to make his heroes talk in blank verse, and so doing, he was true to art giving likeness of the one in unlikeness of the other. Artists are not true to nature in its magnitude and its endless details; but they may be true to art, not by mimicking whatever they can of all that lies before them in a scene, but by noting what are the chief symbols that give character to the scene, and putting these on their canvas, enhanced by what variety and contrast are suitable, and leaving out what, in their small canvas, would detract from the general effect; and thus they will be true to nature also, giving the same feeling that is experienced when gazing on the scene in nature. That is the end for which the rules of art should be applied. Then it has been said a picture should be suggestive. Surely it is a poor compliment to say that when one looks at a picture, its excellence lies in his thinking of things outside it. A picture should be sufficient in itself, and not need to be enriched with the alms of the spectator's imagination.

Correspondence.

DRAINING AND FILTERING GELATINE EMULSION.

Sir,—Having tried draining gelatine emulsion on muslin, canvas, and on a hair-sieve, as usually recommended, without getting the desired result, I thought I might try what coercion would do; so after it had lain on the hair-sieve for over two hours, I took it up and put it into the centre of a piece of good strong wash leather, free of holes or thin places, and twisted it with one hand and squeezed it with the other, and made it disgorge a good quantity of water. Now I take it from the washing apparatus, and put it into the wash leather, and squeeze and twist with all my force, and can do in a minute what hours of draining could not do. Then I scrape the emulsion off the leather with a china medicine spoon, and after the emulsion is melted, I pour it into a basin or bowl with a convex bottom. I have a paraffin lamp funnel, with its lower edge turned over, and the two plys of thick washleather over it: then I put the leather-covered end of the funnel on to the emulsion, and suck with my mouth at the other end of the funnel; the emulsion comes through in a very short space of time. When all the emulsion has come through, I pour it out at its upper end.

I would advise all to look through the wash leather towards a strong light, and reject all that has thin pieces or holes in it, and, when buying, look for it good and thick. The want of knowing this has caused me the loss of a good deal of time, money, and trouble.

Since sending the description of the washing apparatus, I put the hole near the bottom, and lead the syphon up outside. By this arrangement the tube never gets near the emulsion, and the water can all be drawn off at any moment by simply lowering the syphon.—Yours truly,

William Birrell.

SOUTH KENSINGTON MUSEUM.

Sir,—The Director of the South Kensington Museum is anxious to obtain a collection illustrating the history of photography from its commencement, and I have been requested to aid in this good work. Illustrations of early processes would be most valuable, also apparatus of an historical character. May I enlist the sympathy of the readers of the News in promoting the formation of a national collection? There are many, no doubt, who possess valuable specimens with which they would consent to part when they know that such will be housed and treasured in our National Art Museum. There is much of value at the Exhibition now open at the Society of Arts, and I hope that we may be able to induce the exhibitors to place them in the new collection.—Yours faithfully,

W. de W. Abney.

Proceedings of Societies.

South London Photographic Society.

The ordinary monthly meeting of this Society was held on Thursday, Feb. 2nd, at 8 p m., in the room of the Society of Arts, Adelphi—Rev. F. F. Statham, president, in the chair.

The minutes of the annual and lantern meetings having been read and confirmed, Mr. Robert Lindley was duly elected a member.

The Chairman said that with regard to the artistic competition, last year was not such a success as the first year had been; perhaps the novelty had worn off. The Committee had made arrangement for having the pictures for last year judged, and at the next meeting hoped to announce the name of the recipient of the medal. The Committee would also specially consider before the next meeting how the competition could be carried on so as to make it a success.

The Secretary acknowledged the receipt of photographic annuals, as also of tickets from Mr. Trueman Wood for the exhibition now open at the Society of Arts, Adelphi. These having been duly accepted,

Mr. W. Cobb then read a paper on "Co-operation in Matters Concerning Photography."

The Rev. F. F. Statham, in the course of some remarks, said that the field for discoveries was large and open, and it needed us to put shoulder to shoulder, and so co-operate for the general good. With regard to the matter of papers, the Chairman said it was not necessary for members to read long papers, but short papers that were merely to elicit comment and bring forth thought would be of great value. He also said that perhaps some of the members might not be able entirely to write a paper, but if they could jot down some crude ideas and forward them to the Secretary they could be put into shape by some one, and thus papers of interest might be forthcoming. The Chairman also remarked upon the amount of co-operation that was necessary to produce such a grand exhibition as Mr. Wood had recently got together The Chairman further mentioned the almanacs as exemplifying co-operation to a marvellous degree.

Mr. Edwin Cocking said he was reminded by the reading of this paper, of one read by Mr. Jabez Hughes some years since, before the members of this Society; the subject was the desirability of forming a gathering of photographers for the purpose of considering many matters affecting their interests, and which matters were quite outside and beyond the scope of any existing society. He could not but think that the time had arrived when such a meeting had become absolutely necessary, and which might be somewhat after the fashion of similar gatherings in America, which are called conventions. This would certainly be one way of carrying out Mr. Cobb's suggestion of co-operation.

Mr. E. W. Foxlee said that he thought, as the South London Photographic Society was able to establish the Technical Meetings—which had proved such a great success—he should like to see it (the Society) start a convention of photographers. The "copyright" question was one which might well be studied.

Mr. Fry said he had been told by a gentleman who had visited the American Convention, that he had seen more than double the number of photographers at one of the South London Society's meetings, and that not when anything special was going on, than attended the convention. He did not say this as wishing to throw cold water upon the idea, but merely as a fact.

Mr. Trueman Wood thought that photographers were the last to be scolded, as all seemed to come together and help each other; not so with other sciences, where each made out for himself, as it were, a piece of ground, and no one was to come near on pain of death. With regard to what the Chairman had said about the Exhibition, he had found all were willing, but some wanted stirring up, and those few who had held back would wish they had exhibited now it had proved such a success.

Mr. Pearsall said he could not tell what Mr. Cobb had been driving at. Could Mr. Cobb not give a number of heads under which co-operation in photography would be useful? The British Association was a glorious example of co-operation. The French, he said, nearly always worked in couples, and it was a fine and noble thing to see the way scientific men worked together.

The Chairman remarked that Mr. Foxlee's motion was one of great importance. This Society had always been useful in throwing out hints which, perhaps, others made more use of than the Society could. Mr. Pearsall had referred to the British Association, but they tabooed photography altogether, and it was said that people would not read papers before them because they were crowded out; but he believed that was altered now.

Mr. G. F. Williams suggested that heads should be given for papers, to see if any good would come of members writing upon a given subject.

Mr. W. Brooks, in alluding to the Falmouth Exhibition, said it was almost a co-operative society. As this year was the fiftieth jubilee meeting, he hoped all would co-operate, and so make a great success.

Mr. Cobb having replied, and a vote of thanks having been passed to him for his paper,

Mr. Trueman Wood said he wished to know if he could arrange such a thing as a night for the practical trial of different means of artificial light. He had a dynamo machine upon the premises for the electric light, and one of Sugg's immense gas burners, and no doubt Messrs. Sugg would fit it up, and perhaps other means of artificial light would be forthcoming.

Mr. Williams said he should be happy to co-operate with Mr. Wood, and he would lend one of Mr. Siemens' lamp.

A long discussion ensued relative to the different methods of artificial light and the general utility of them.

Mr. E. Dunmore then promised to read a paper at the next meeting on "Common Objects of the Studio." After a very pleasant evening had been spent, the meeting adjourned till March 2nd.

Edinburgh Photographic Society.

The fourth meeting of the current session was held on the evening of Wednesday, 1st inst., when Mr. Lessels, who was still suffering from recent indisposition, occupied the chair.

The Secretary having read the minutes of council and committee meetings, and those of the last ordinary, the latter were duly passed, and Messrs James Sclater and James Moore were admitted ordinary members.

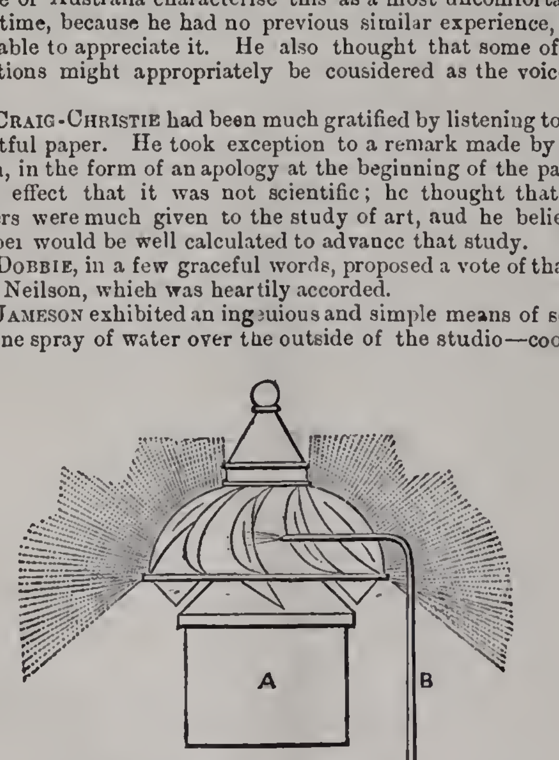
Mr. W. Neilson read a paper entitled, "Symbolism in Landscape" (see page 67).

Mr. Bow said he was impressed with the beauty of the paper, but thought that much of what Mr. Neilson designated the symbolism might legitimately be called association. It would be difficult to say that *anything* was pleasing to *everybody—e.g.*, the long "gloaming," so much admired by Scotsmen; he had heard a native of Australia characterise this as a most uncomfortable, dreary time, because he had no previous similar experience, and was unable to appreciate it. He also thought that some of the illustrations might appropriately be considered as the voice of nature.

Mr. Craig-Christie had been much gratified by listening to the thoughtful paper. He took exception to a remark made by Mr. Neilson, in the form of an apology at the beginning of the paper, to the effect that it was not scientific; he thought that the members were much given to the study of art, and he believed the paper would be well calculated to advance that study.

Mr. Dobbie, in a few graceful words, proposed a vote of thanks to Mr. Neilson, which was heartily accorded.

Mr. Jameson exhibited an ingenious and simple means of sending a fine spray of water over the outside of the studio—cooling



A. Howorth's Patent Ventilator. B. Water, pressure from the main.

the air within, cleaning the glass, and at the same time ventilating the premises. He said:—"We had a few years ago a paper and pretty lively discussion on ventilators, and it was remarked then, that when there was no wind to work them, we must send a boy to the top of the house to blow with a pair of bellows: if we have not a boy to send, we must employ some other motive power, and it is here that my *patent* comes in. It is more than a ventilator, it is a roof-cooler, and it is a glass roof cleaner. Instead of using the motive power to drive pulleys or blowers, I take the motive power—water from the main—through a quarter-inch gas-pipe with the end drawn to a point, and pierced with a fine needle; the water is made to play direct on the fans at the top of of the ventilator, at the same time producing a fine spray over the roof. You can take the pipe any direction you please over the house top, and with the stop-cock below you regulate the speed. I am sorry that I cannot give you a practical demonstration. It would have been a pleasure to me to have given you a duplicate copy of the late Royal Review to have saturated you with the elements, but respect for the table-cover prevents me; however, by means of a foot-blower, I can illustrate its mode of action: as soon as a current impinges on the exterior curved vanes, the hood revolves, and distributes a fine spray in a circle about ten feet in diameter, and at the same time sets in motion an interior Archimedean screw, which exhausts the air from the interior."

Mr. Christie, in proposing a vote of thanks to Mr. Jameson, said that it often happened when ventilation was most required, there was not sufficient wind to work the ventilators, but Mr. Jameson's device seemed to entirely overcome the difficulty.

The following questions were found in the box:—1. "Can a photograph, portrait or landscape, be enlarged (say) four diameters, and be equal in every respect to the original? and if so, by what means?" 2. "What is the best mode of mounting photographs in ordinary scrap books?" 3. "What is the best means of enamelling a photograph that is to be afterwards mounted?"

Mr. Bashford said it was not a difficult matter to produce enlargements of four diameters from negative or paper prints, which should be quite as good as, even better than, the original. One way which he preferred to employ was to make a good transparency the size desired, remove any imperfections from this, and then by contact produce a negative, which might require a little work, but could easily be made to produce prints quite equal to, or better than, the original, the enlarged prints requiring no touching.

Mr. J. M. Turnbull endorsed what had just been said, and mentioned the splendid enlargements of Mr. England which were exhibited at the Edinburgh Exhibition; they were produced from small stereos, and many were better than the originals.

Mr. W. D. Valentine had always failed to get the high-lights in the enlargements as clear as the originals. He thought this due to the enlargement of the spaces between the atoms forming the image being more pronounced than the atoms themselves; his enlargements had always appeared flatter than the originals.

Mr. M'Kean had had a similar experience, and said he had never seen an enlargement equal to the original.

Mr. Mathieson had recently seen a series of splendid enlargements produced by an Edinburgh amateur for the Dundee Exhibition, and they were certainly not inferior in vigour to the originals.

Regarding the question, "What is the best means of enamelling a photograph that is to be afterwards mounted?" Mr. Ayton proposed that the discussion of this matter be postponed till the next meeting of the Society, when he promised to make that the subject of a paper. He also made the important and startling announcement that he had discovered a process whereby the albumenized print was rendered absolutely permanent, improving the lights, giving them a pearly whiteness as in the opal picture, while the shadows were more velvety. As he wished the members to try it for themselves before the next meeting, he stated that the print after being dried was converted into vegetable parchment by immersion in strong sulphuric acid, and afterwards enamelled with collodion. Specimens of this mode of finishing he would submit to the meeting.

A vote of thanks to the Chairman terminated the proceedings.

Glasgow Photographic Association.

A meeting of this Association was held in the Religious Institution Rooms on Thursday, 2nd inst., at 8 o'clock p.m., Mr. T. Gilfillan, V.P., in the chair.

The minutes of last meeting were read and approved of.

Messrs. Wm. Lang, Jun., and Lorn Campbell were unanimously elected members.

The following questions were found in the box when opened,—viz., 1. What about the supper? This was not discussed with any degree of spirit. Mr. Goodwill ultimately moved that we have a supper, which was seconded by Mr. Thompson. 2. Have any members used iodide in the making of emulsion? Mr. Reid said that he had used it, and found plates containing it to be much slower than simply bromized plates. The secretary remarked that this also was his experience, and mentioned a curious result that he had observed. He said that he had found that an iodio-bromide plate, when exposed to direct sunlight under a negative, printed quicker than a simply bromized plate under similar conditions, but when exposed in the camera was much slower.

Mr. James McGhie then gave a description and demonstration of some recent advances in photography. Amongst the novelties he brought forward was Moryson's intensifier, with which he successfully intensified some otherwise valueless negatives, producing full detail in the shadows. Mr. McGhie spoke in very high terms of the qualifications of this method, and showed some magnificent photographs that had been submitted to its action. He also demonstrated the preparation of dry plates from Dr. Vogel's collodio-gelatine emulsion. The plates, when carefully prepared, were said to be quicker than the average *rapid* gelatine dry plates. Amongst the remaining novelties were a plate-washing machine, a handy little dark-room lamp, Chadwick shutter, and some beautiful specimens of the Lichtdruck process, all of which were examined with much interest, and carefully described by Mr. McGhie.

The Chairman invited questions, when

Mr. Urie asked if the ether and acetic acid would not evaporate from the emulsion and tend to leave it too thick? The remedy was to add a mixture of alcohol and ether as used in thinning collodion; it was also asked if the solution composing Moryson's intensifier consisted of mercuric chloride and sodium hyposulphite respectively.

Mr. McGhie could not say, the composition being a secret in the hands of the inventor.

A quantity of photographs were then balloted for amongst the members present, some of which, presented by Mr. Thompson, took a medal at Mr. Swan's exhibition in Newcastle.

At this stage the President joined the meeting and reported that Professor Grant could not at the present time find it convenient to deliver a lecture on Astronomy before the Association, but volunteered to open next session with an inaugural address, and very kindly invited a dozen of the members to visit the Observatory and inspect the photographic arrangements of that important institution.

The meeting then closed with votes of thanks to Mr. Mc Ghie for his instructive demonstration, and to the Chairman.

Thursday Evenings for Photographers.

At the meeting held on the 2nd inst., the chair being occupied by Mr. W. M. Ashman, the following questions from the box were considered:—

Does fog in the atmosphere cut off the actinic rays of light in the same proportion as it does the luminous rays? The opinion of the meeting seemed to be that it does in a larger proportion, the actinic rays being absorbed by the yellow colours of the fog.

Why is it that the ferrous oxalate developer is not used by professional photographers? In answer to which, it was thought that the objection to ferrous oxalate was that it was slow in action, and there was less latitude of exposure than with the alkaline developer.

Mr. Henderson enquired if anyone had tried Captain Abney's ferrous citro-oxalate developer?

Mr. Collins had carefully prepared the solution according to Captain Abney's formula, and obtained a picture after twenty minutes' developing which looked very like a wet plate. He did not find it necessary to use a restrainer.

A series of experiments, commenced at the last meeting, on the action of red light on phosphorescent tablets, then took place. A lamp was enclosed behind several coloured solutions and mediums, and the tablets, after being excited with magnesium wire, were exposed to its rays, when a slight de-sensitizing action took place; a tablet was then excited by gaslight, and exposed to the lamp for the same period, when it was found to be further excited; an unexcited tablet was rendered highly luminous by exposure to the ruby lamp. A solution of alum was then placed in the lamp in addition to the coloured mediums, with a view of testing whether the heat rays had any effect on the tablets; but it produced no apparent change in the result of the experiments.

Photographers' Benevolent Association.

On February 1st this Association held its annual general meeting, the attendance being above the average. Mr. W. S. Bird occupied the chair.

The minutes of the previous meeting having been confirmed the Chairman called upon the Secretary for his report, which was followed by the Report of the Board of Management.

Secretary's Report.

Gentlemen,—It affords me considerable pleasure to submit my Report to you, inasmuch as the receipts for 1881 are higher than in any previous year—viz., £50 16s. as compared with £42 12s. 6d. last year; the expenses for the same period being £23 10s. 11d., there results a clear gain of £27 5s. 1d., which carries the assets from £87 6s. 9d. to £114 11s. 10d.

The subscriptions from honorary members, I regret to inform you, shows a lamentable decrease.

The ordinary members' subscriptions have this year reached £18 15s. as against £11 9s. for 1880, thereby confirming the opinion expressed in last year's Report, that 1881 would see an improvement in this important item; and it only requires that this improvement should continue to place the Association on a sound basis, and prevent any falling off in either branch of its revenue.

I should then soon expect to have the extreme pleasure of congratulating the Board of Management and members upon this Association taking its proper rank among similar societies.

What is required is that every member should bring the existence of the Society prominently under the notice of every non-subscriber in the profession with whom he may be brought in contact. H. Harland, Secretary.

Board of Management Report.

In accordance with the usual custom, the Board of Management places before the members and subscribers a statement of the position of the Association.

Attention may be drawn to the fact that the Association, after having remained stationary for a considerable period, has, during the last two years, been steadily improving both as regards its funds and the number of its regular subscribers. As will be seen by reference to the annexed report of the Secretary, there has been a favourable increase in the number of ordinary members, which is now larger than at any previous time. This fact is of importance as a sign of more vigorous life; the prosperity of a society depending more upon the number of paying members than anything else.

The condition of the finances is more favourable than at any previous time, there being a nett gain of £27 5s. 1d. on the year, bringing the total reserve up to £114 11s. 10d.

The subscriptions from honorary members have decreased, a falling off due almost entirely to the fact that the Association made little progress in enlisting what may be called the working members, and apathy on the part of assistants is apt to make employers indifferent. Honorary members may be again expected to contribute liberally if the forward movement evident in the past year continues.

The evening at the exhibition resulted in a nett profit of £8 16s. 9d., for which your Board ask you to join with them in expressing their gratitude to the President and Council of the Photographic Society. The Board also offers sincere thanks to the Photographic Club for its kindness in devoting the profits of the soirée, £11 17s. 3d., to the funds of this Association, and to the honorary members for their support during the past year.

The Board also desires to acknowledge its sense of the favorable attitude of the editors of the photographic journals, as shown by notices and reports of the proceedings of the Association.

At present the operations of the Association are necessarily confined to giving temporary assistance to members in sickness or distress; but your Board is not discouraged by the slow progress of their benevolent work, but believing it will grow into power and success, will at the right time indicate further lines of usefulness, among which the subject of yearly pensions deserves the attention of the profession. It remains only to reiterate the advice that photographers generally should consider the desirability of the existence of a Benevolent Society to lend a helping hand to brothers of the craft needing it and should note that your Board sticks quietly and steadily to its task.

W. S. Bird, Chairman.

The report and balance-sheet were unanimously adopted, after which the meeting proceeded to the election of officers for the ensuing year, as follows:—

Vice-Presidents—Rev. F. F. Statham, Mr. J. H. Dallmeyer.
Trustees—Col. S. Wortley, Captain Abney.
Treasurer—Mr. H. B. Pritchard.
Auditors—Messrs. G. Taylor and L. Sisman.
Board of Management—Messrs. W. S. Bird (Chairman), H. J.

Thorne (Vice-chairman), W. M. Ashman, H. J. Burton, T. Bolas, F. H. Berry, C. G. Collins, J. A. B. Hall, J. O'Conner, J. Rolph, A. Strivens, S. Saunders, and R. E. Wilkinson.

Secretary.—Mr. H. Harland.

The meeting terminated with a hearty vote of thanks to the Chairman.

Talk in the Studio.

Photographic Society of Great Britain.—The annual meeting of this Society will be held on Tuesday next, February 14th, at the Gallery, 5a, Pall Mall East, when the election of officers will take place, the Report of the Council be read, and other business transacted.

The Newcastle-on-Tyne Chemical Society.—At the last meeting Mr. Swan read a paper on electrical accumulation, in which he referred to the gradual breaking down of the old distinction between the so-called static electricity of the frictional machine, and the currents obtained from batteries or dynamo machines. A striking experiment of M. Gaston Planté was referred to, a series of eight hundred tinfoil plates separated by sheets of mica being charged, when connected laterally, by a couple of Grove's cells. On placing these in series, by means of Planté's commutator, a flash which passed through several inches of air was the result. Planté's well known secondary battery was shown in some of its various forms, and Mr. Swan said that he had improved it by making the plates cellular, and filling the cells with spongy lead. We ourselves, some time ago, made a Planté battery by folding the lead plates over zinc wires or strips, and then immersing these plates in a solution of acetate of lead until the whole of the zinc had dissolved and was replaced by spongy lead. This battery worked well, and we may mention that thin lead answers best; that which we employed weighed four ounces to the square foot, and was obtained at the tinfoil works in Leather Lane.

An Evening for Photography by Artificial Light.—It is proposed to devote an evening at the Society of Arts to experiments in photography by artificial light, and for this purpose next Thursday, the 16th inst., has been fixed. The lights available on the occasion will be a Siemen's arc lamp, a Sugg gas-burner 200 candle power, magnesium lamps, and probably several pyrotechnical lights. It is also probable that some enlargements will be made from microscopic slides by means of the light of a paraffin lamp. Portraits will be taken by the various lights with various exposures, and perhaps a few direct prints may be made. So far as possible, opportunity will be given for any photographer who likes to appear on the scene with a camera, to make a few exposures. It is also proposed to try and take a general photograph of the whole of the room. Any photographer who is not a member of the Society of Arts, wishing to attend, should apply to Mr. H. Trueman Wood, the Secretary, and we have no doubt he would be furnished with a ticket of admission.

South Kensington Museum.—Until recently, considerable difficulties were put in the way of those who wished to photograph in the Museum; but we are pleased to be able to state that the following satisfactory regulations are now in force:—1. Application for authority to take photographs in the South Kensington Museum must be made in writing, addressed to the Secretary, Science and Art Department, South Kensington, London, S.W. 2. Applicants must state the purpose for which the photographs to be taken are required, and may, if thought necessary, be called on to furnish evidence of proficiency in the art of photography. 3. Objects on loan, and works by living artists, can only be photographed on production of the written authority of the owner or artist. 4. No permission can be granted for photographing oil-paintings or water-colour drawings. 5. Small objects which can be safely and conveniently shifted from the cases may be removed by the Museum attendants to suitable positions for photographing, but no large or heavy objects can be thus removed, and no change in arrangement can be made which will cause inconvenience to the public. The Museum attendant who removes an object will be present, and will remain in charge of it during the whole process of photographing, and no one else can be permitted to handle it. 6. A glass house is provided in which all chemical apparatus, &c., must be kept. No larger quantity of chemicals is to be brought in than is necessary for the work of the day, and no combustible chemicals may be introduced without the express consent of the Director. Only one photographer can work at one time. The use of the glass house will be allotted to each in succession according to the order in which the applications have been received. All apparatus, &c., must be removed on the expiration of the assigned term. 7. Two copies of each photograph taken in the Museum are to be furnished to the Secretary for preservation in the Art Library.

To Correspondents.

*** "At Home," and several other articles of interest, are crowded out this week.

R. Leamon.—The information you ask for will be found in the report of Captain Abney's lecture.

J. Gordon Rouse.—1. We do not think it would be practicable. 2. There are several methods, but, for the reasons pointed out in the article in question, they are not quite satisfactory.

Frederick Hurcham.—1. Probably not; you would therefore do well to make arrangements for a supply, or at any rate take the materials for their manufacture. 2. Things have improved of late, we are told.

T. K. Galland.—It is unreasonable to expect us to exercise any control over the business arrangements of advertisers. The usual course in such a case as your own would be to take proceedings for the recovery of the value sent.

M. C.—1. Use the solution while tolerably fresh, and employ distilled water for rinsing. 2. Quite as good, and more convenient. 3. Stretch the paper on a frame to dry, then it will be free from folds or irregularities. 4. Both methods are in use, but the latter is preferable for the finest work, as ensuring better distribution.

O. S.—1. The lens you now refer to would suit your purpose very well, and under the circumstances the exposure would often not exceed one second. 2. Merely a figure of speech.

H. S.—A mere formula is not much use, as you would require detailed instructions. See Captain Abney's book on Emulsion Processes in Photography.

A. Berry.—No two samples are precisely alike, so the information you require cannot be given.

H. G. M. Conybeare.—Received with thanks.

F. Sutcliffe.—To publish a wood-cut reproduction is certainly an infringement of any copyright which may exist in the case of a photograph.

J. Stevenson.—Thanks for your kind wishes. Our own experience with regard to the use of alum alone in very hot weather is confirmatory of your own.

Peel.—The defect appears to arise from an insufficient hardening of the film. Either sensitize on a stronger silver bath, or float on strong alcohol for an instant, and dry before sensitizing. Of course, when the film is tender, you must guard against mechanical injury, as from pressure against the blotting-paper which may be used in drying.

Inquirer.—We very strongly suspect that you either do not exercise sufficient care in cleaning your vessels after use, or that they consist of an unsuitable porous earthenware.

J. Berryman.—1. Try the application of a gentle heat. 2. The ring is seldom sharply defined, excepting in the case of certain instruments.

G. H (Preston).—The clear gelatine in uniform sheets, as used for making swelled gelatine reliefs, is to be obtained from Mr. Cornelissen, artist's colourman, Great Queen Street, Long Acre; but the special quality known as "Nelson's transparent sheet" is manufactured by Messrs. Dale and Co., of Dowgate Hill, Cannon Street, and can be obtained from any of the usual agents.

Saucy Samuel.—In such a case you would do well to employ collodio-chloride of silver; and we know that the article supplied by the firm you mention is excellent, but you should obtain it direct, as otherwise it may have become spoiled by long keeping.

Maynard.—Nothing is gained by such a procedure, and it is calculated to somewhat prolong the exposure.

Richard T——.—A full description of the apparatus in our Year-Book.

A Constant Reader.—Considering that the subject was fully treated of in an article which appeared in the Photographic News three weeks ago, you can hardly be a "careful reader."

Printer.—Soak some of the cardboard in distilled water, taking care not to use an over large proportion of water. At the end of a few hours, pour off a little of the liquid, and add a small quantity of the blue iodide of starch solution. If the blue colour disappears, you may consider that hyposulphite is present.

L. B.—If you warm your glass plates slightly, the difficulty will be overcome.

T. J. J.—In ordinary cases, each sheet of coated glass is placed in position over the surface of some dry calcium chloride contained in a drawer; but we have found it quite practicable to dry it in an ordinary room with a good fire.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1224.—*February* 17, 1882.

CONTENTS.

RECIPROCAL DISPLACEMENT OF THE HALOGENS.

Photography is so intimately connected with the haloid silver salts that any advances in our knowledge of the chemical relations of the halogens will be read with particular interest by all who take an interest in photographic chemistry.

The mutual reactions of the halogens, as well as of the haloid salts, has frequently been made the subject of investigation by chemists; and the results hitherto obtained at are somewhat remarkable on account of the apparently opposite results which have in some cases been obtained. For instance, it is well known that all the bromides are decomposed by chlorine, either at ordinary temperatures or upon heating, a metallic chloride being formed and bromine liberated. Upon this reaction depends the well-known method of preparing bromine from bittern, the liquor remaining after the less soluble salts have crystallized out from concentrated sea-water. The iodides are similarly decomposed by chlorine; and Davy succeeded in decomposing silver fluoride with chlorine, with the formation of silver chloride. In his efforts to isolate fluorine, Kämmerer also decomposed silver fluoride with iodine at a temperature of 80° C., with the formation of silver iodide; but Gore found that perfectly dry silver fluoride is not decomposed even at a red heat by chlorine, bromine, or iodine, but is decomposed at a higher heat, the liberated florine immediately combining with the substance of which the vessel in which the salt is heated consists.

Thus, with respect to the haloid salts, the affinities of the halogens appear to bo in the following order:—Chlorine, bromine, iodine, fluorine. These displacements of bromine and iodine by chlorine, and of iodine by bromine, are in strict accordance with the thermo-chemical theory. But apparently the reactions are not always so uniform, for Potilitzin's experiments seem to show that under certain circumstances the displacements take place in the reverse order. Thus, he found that bromine would displace chlorine from anhydrous metallic chlorides, and that if the bodies were present in equivalent quantities, then the percentage of chlorine liberated depends upon the atomic weight and atomicity of the metal in such a way that $\frac{A}{pE}$ is constant; where A is the atomic weight, p is the percentage of chlorine displaced, and E is the atomicity of the metal.

This apparent anomaly Berthelot has attempted to explain on thermo-chemical principles by dissociation of the primary combinations and the formation of secondary combinations, the inverse displacements being possible, if, in the formation of the secondary combination, a quantity of heat is evolved greater than that absorbed by the direct substitution in the primary combination. He found, moreover, that, in an atmosphere of pure and dry nitrogen, using porcelain vessels, when potassic chloride is heated with bromine, or potassic bromide with iodine, it remains unaltered, even at a temperature of 400° C.; hence he concludes that the inverse displacements of the halogens from haloid salts depend upon the presence of oxygen.

But this conclusion is again disputed by Potilitzin, who obtained the results both in nitrogen and in *vacuo*.

Thus, although the present condition of our knowledge in this respect is not quite satisfactory, it appears both theoretreally and practically possible that bromine liberates chlorine from metallic chlorides, and that the halogens may behave, under certain circumstances, in the inverse order of their apparent affinities. Such a condition of things might be easily understood to take place at the temperature at which the metallic salt is dissociated, for, in this case, the re-acting element would be able to unite with the free metal.

Action of the Halogens on Oxy-salts.—It is generally believed that the affinities of the halogens, in this case, are in the reverse order—viz., that iodine decomposes bromates and chlorates, but that neither chlorine nor bromine decomposes iodates, nor will chlorine decompose bromates. It has, however, recently been found that chlorine decomposes silver chlorate, silver iodate, and silver bromate, the result being the formation of silver chloride, and the liberation of oxygen; a bromide or iodide of chlorine being likewise formed. Here again is an apparent anomaly in the behaviour of the halogens, and in the order of their affinities.

Action of Haloid Acids upon Haloid Salts.—The action of haloid acids on haloid salts is generally the reverse of that of the halogens themselves. Hydriodic acid displaces hydrobromic acid, and hydrobromic acid displaces hydrochloric acid. These facts agree with thermo-chemical theories; but bromides are also decomposed by hydrochloric acid, although much less readily than the decomposition of chlorides by hydrobromic acid. In the same way, although the attraction of chlorine for silver is greater than that of iodine for silver, yet, when hydriodic acid acts upon silver chloride, mutual decomposition ensues, and iodide of silver is produced.

This reaction would appear incomprehensible, but for the thermo-chemical law, that in double decompositions the reaction always takes place, so that the greatest amount of heat is developed.

Reciprocal Action of Haloid Salts.—Field has shown that silver chloride is completely decomposed by digestion with potassic bromide, the chlorine and bromine changing places, thus:—

$$AgCl + KBr = AgBr + KCl$$

In the same way potassic iodide decomposes both silver chloride and bromide, thus :—

$$\left.\begin{matrix}AgCl\\AgBr\end{matrix}\right\} + KI = AgI + \left.\begin{matrix}KCl\\KBr\end{matrix}\right\}$$

These reactions are so complete that an ingenious method for the quantitative estimation of chlorine, bromine, and iodine, when mixed in solution, is based upon it.

To sum up the conflicting results of these investigations, we have the following facts confirmed by experiments.

1.	Chlorine	decomposes	metallic	bromides	Action of halogens upon haloid salts.
2.	,,	,,	,,	iodides	
3.	,,	,,	,,	fluorides	
4.	Bromine	,,	,,	iodides	
5.	,,	,,	,,	fluorides	
6.	,,	,,	,,	chlorides	
7.	Iodine	,,	,,	fluorides	

1.	Iodine	decomposes	metallic	bromates	Action of halogens upon oxy-salts.
2.	,,	,,	,,	chlorates	
3.	Chlorine	,,	,,	iodates	
4.	,,	,,	,,	bromates	
5.	,,	,,	,,	chlorates	

1.	Hydriodic acid	decomposes	metallic	chlorides	Action of haloid acids upon haloid salts.
2.	,, ,,	,,	,,	bromates	
3.	Hydrobromic acid	,,	,,	chlorides	
4.	Hydrochloric acid	,,	,,	bromides	

1.	Potassic iodide	decomposes	silver	chloride	Action of haloid salts upon each other.
2.	,, ,,	,,	,,	bromide	
3.	Potassic bromide	,,	,,	chloride	

Now let us see how these reactions apply to photography. In almost every photographic operation the halogens play a most conspicuous part, and without doubt many of the above replacements are, to some extent, continually occurring. There is, however, one instance in which we have a most important application of the chemical changes just explained—viz., in the at present most important branch of emulsion making. Without entering into the discussion as to the advantages or disadvantages of small quantities of iodides or chlorides in the gelatino-bromide emulsions, we may take it as a fact that many prefer such an addition, and endeavour to obtain it by precipitating silver nitrate with soluble bromide containing the required amount of soluble chloride or iodide. Since chlorine and iodine have a stronger affinity than bromine for silver, without doubt the chloride or iodide of silver will first be formed, even although, as is usual in emulsion making, the soluble bromide should be in excess. It is doubtful, however, *if the finished emulsion contains any chloride or iodide at all;* for a prolonged digestion, in presence of excess of soluble bromide, would, according to the experiments of Field, described above, convert the small amount of chloride of silver into bromide. It would be interesting to know if gelatino-chloride and gelatino-iodide of silver are decomposed by soluble bromides as effectually as in Field's experiments. If this is the case, those who have hitherto dwelt so emphatically upon the superiority of emulsions containing certain proportions of iodide or chloride, will do well to test their emulsions in order to be quite certain that the silver chloride or iodide has not been changed into bromide in the process of cooking, in which case it will be necessary, in future, that they should not emulsify in presence of excess of soluble bromide.

CAPTAIN ABNEY'S THIRD CANTOR LECTURE.

The special consideration of dry plate processes formed the staple of last Monday's lecture, and collodion emulsion was first brought under consideration. The conditions necessary for perfect emulsification differ somewhat in the case of the different haloid salts of silver, as but little difficulty occurs in obtaining the chloride or bromide in a satisfactorily fine condition, while the iodide has long been regarded as incapable of being properly emulsified. If, however, the silver nitrate solution is added to the collodion, partial precipitation takes place, and an emulsion of silver nitrate is the result. The previously dissolved iodide is now added, and double decomposition sets in, the result being a perfectly emulsified form of silver iodide; whereas, if the order of things had been reversed by adding the silver last, a coarse granular precipitate would have been formed. The above described method of working is also available and advantageous in preparing bromide and iodide emulsions, and might even be applied to the preparation of gelatine emulsion.

The greenish blue or green collodion emulsion which was used by the lecturer in photographing the ultra red rays of the spectrum was next brought under consideration, and its peculiar colour was shown on the screen. It was shown that those rays which can pass through a thin piece of ordinary ebonite will produce a sensible effect on the emulsion, and that a somewhat prolonged exposure to the radiations from a kettle of hot water will suffice to impress it. Ebonite in thin sheets is permeable to some of the visible orange and red rays, and also to a considerable proportion of the ultra red; and it is an interesting fact to note that the photophone is considerably affected by radiant energy which passes freely through ebonite.

After having practically illustrated most points bearing on the development of collodion emulsion plates, the rise and progress of the gelatino-bromide process was traced; the labours of Maddox and Kennet, as pioneers, and of Bennett, the first to thoroughly appreciate the advantages of prolonged emulsification, being alluded to; after which the Captain paid a striking tribute to the value of Dr. Eder's painstaking, exhaustive, and detailed investigations, which, as our readers are aware, have served to bring our knowledge of the minutiæ of the gelatine process to its present advanced state. Theoretical details having been now discussed, the extreme rapidity of gelatine plates was illustrated by allusions to Mr. Henderson's moonlight picture, which is shown in the Exhibition, and the results obtained by Mr. W. Brooks when paraffin oil is used as a source of light, these remarks being supplemented by an actual experiment in which a rapidly rotating disc was photographed by the light of the discharge from a small Leyden battery.

Vogel's emulsion was then stated to possess a degree of sensitiveness strictly comparable to that of ordinary gelatino-bromide; and Warnerke's new method, in which advantage is taken of the property possessed by gelatino-bromide films of becoming insoluble when exposed and developed with pyrogallic acid, was referred to, and the principal phases of the process were demonstrated, including the development of a picture from a film charged with pigment. Captain Abney's theory on this point is, that the bromine liberated by exposure reacts on the gelatine, and renders it insoluble; but this explanation hardly serves to account for the fact that a notable degree of insolubility sets in only when pyrogallic acid is used as a developer.

A considerable portion of the time was next occupied with a discussion of the conditions required for the production of the most satisfactory enlarged photographs, whether negative or positive; and Mr. Blanchard's method of first preparing an enlarged transparency, and then making a negative on ordinary albumenised paper, was highly spoken of. An interesting series of demonstrations then followed, enlarged pictures being most successfully made on plain bromide, paper, gelatino-bromide and gelatino-chloride; and the audience left at a somewhat late hour much pleased with what they had heard and seen.

The Exhibition of Photographic Appliances is still growing in interest, and the number of visitors increases daily; but we are reluctantly compelled to postpone our further notice until next week.

THE DUNDEE EXHIBITION.

Second Article.

As we have already stated, the Exhibition of pictures of amateur members of the Dundee Society is confined to one alcove. The largest collection is that of Mr. Cox, the President, who shows, among others, a series of three full-length portraits taken out of doors. The models—ladies in walking costume—are posed with singular grace and simplicity, and have a charm which more ambitious work often lacks. A couple of fisher boys, dressed in coarse jerseys and rough Scotch bonnets, who have clambered a big boulder on the seashore, is another successful work of Mr. Cox, who has besides many artistic sketches. Mr. Mathewson's pictures are, for the most part, hung in rather bad light; but of the series we like best, "Old Cottage near Aberfoyle." Mr. Sylvester Rollo, the Hon. Secretary of the Exhibition, has an extensive series of bright little yachting scenes, one of them, "The Turning Point," depicting a race of half-a-dozen little craft, in which forcible contrast to the crisp, clear water is deftly managed by showing a portion of a barge and figure in the foreground. "Highland Cottages," by Mr. Rollo, is another example of this clever amateur's work. Of Mr. P. Kerr's pictures, we like "Old Castle, Mains," the best, a bright and happy little photograph. Mr. D. Ireland's Norway sketches are, some of them, exceedingly good. "On the Baegna," for instance, we consider the best picture exhibited by the Dundee amateurs, it is so clear and soft. Lœrdalsæren and Freydenlund are also most successful pictures, since they treat with effect of Norwegian scenery—high rocks rising from the picturesque fjord, and quaint wooden villages nestling at the water's brink. Mr. Lambe is yet another amateur who exhibits good work.

Messrs. James Valentine and Sons, of Dundee, as might be anticipated, make a brave show. A series of woodland views, in which the fine lines of a silver birch, its elegant stem and graceful foilage rising from tufts of ferns and delicate undergrowth, are conspicuous, is among the best of their exhibits. But it is in coast scenery that they excel. Daybreak on the Tay is effectively rendered in several of their pictures, and in one, where the huge black hull of a vessel rising from the still water partially obscures the morning light, and creates a dark sea-way between the spectator and the monster vessel, the result is highly romantic. In all their Scottish scenery, Messrs. Valentine have preserved the spirit of rugged wildness that has rendered the land of Burns and Sir Walter Scott so famous; for the camera, as photographers know to their cost, if its idiosyncrasies are not carefully watched, has a trick sometimes of lowering mountains, decreasing grand proportions, and otherwise taming down a bold landscape. Messrs. Valentine's pictures—there are also some first-class portraits—were "out of the competition," or they would doubtless have secured a medal. Mr. A. Donald, also of Dundee, sends many of the fine laudscapes he has exhibited in London, the best to our mind being "Mains Castle." Mr. Donald, too, shows good portraiture.

Mr. A. Williamson contributes "Our Happy Hunting Ground," and several other landscapes, of which we like best "Carnock Glen." Colonel Fraser sends four characteristic views of Norway, one of which, a tearing white torrent leaping over huge silvery rocks, with some ragged black pines in the foreground, is eminently successful. Mr. H. Manfield forwards a vast collection of fine interiors —by the way, interiors were not in the medal programme of the Dundee Society at all—together with some little views of Madeira and South Africa, among the latter being a capital picture of an Ostrich Farm. Mr. Cecil V. Shadbolt's best contribution is "Middle Lake, Killarney," in which the foliage is managed with much skill and taste. Messrs. T. and R. Annan forward "Dumbarton Castle," which attracted considerable attention at Pall Mall" this year, and many other landscapes, not forgetting a frame of seven rustic little sketches, which will take the fancy of every lover of farm and homestead studies. Mr. Matthew Whiting, besides his magnificent series "Off Dover," sends another frame of bright pictures, but from the fact that they were mounted against glass, they could not compete for the landscape medal.

Of Mr. Magnus Jackson's pictures we prefer "Marshall Place, in Flood," in which the reflections in the water are most cleverly managed. Mrs. Brigham Mildmay's best exhibit is a frame of little "Devonshire Sketches," printed in platinotype; but she has also several clever portraits in platinotype. Captain Horatio Ross, a veteran photographer and deer-stalker, contributes numerous pictures representative of sport and game. Mr. E. Yeoman's scenery would have been all the better if not so deeply printed. Two charming little yacht scenes, in which the canvas and dancing waves are admirably pourtrayed, are exhibited, with other views, by Mr. A. A. Campbell Swinton. Mr. H. P. Robinson, of Tunbridge Wells, besides a magnificent series of pictures that have already gained distinction, forwards "Sheep," the sunshine which tinges the woolly backs with its silvery sheen imparting a degree of life and light rarely seen in a photograph.

Mr. J. Jackson, in Derwent Lake scenery, shows himself both clever artist and clever photographer; and in his Scottish Border scenery he is no less successful. Mr. J. Annan is represented by some architectural views in Edinburgh. Mr. Marshall Wane exhibits several landscapes, one representing a sweet weald of country encircled by softly-limned hills, being most to our taste. Mr. Robert Murray shows views in Argyllshire; and Messrs. Marsh Brothers, beyond their London exhibits, many fine landscapes of Thames scenery of large dimensions. Mr. Robert Murray, and Messrs. W. H. Geddes and Son, exhibit some good landscapes, the latter firm also showing portraits.

Mr. G. Bremner is an exhibitor of several frames of portraits, containing very good work indeed. Mr. Lyddell Sawyer's "Supplication," a fine female head artistically posed, is here, together with his well-known farm studies. Mr. John Henderson shows several portraits of considerable merit. Mr. G. F. Rodger is represented by several good portraits, and the same may be said of Mr. W. J. Anckorn. Of Mr. John Moffat's contributions—for the most part cabinets—we have already spoken highly; of Mr. R. M. Campbell's contributions, we like best "Cherry Ripe," which is modelled with much clearness and roundness. Mr. D. Prophet's portraits are vigorous, clear, and full of character, "Frank Hudson, M.P.," being the best. Mr. Robertson is also an exhibitor of portraiture, and so is M. J. Terras. Mr. James Abbot shows several frames of portraits, both of old and new, the older ones, in our opinion, being the better. Mr. John Lamb exhibits some good cabinets, as does also Mr. J. Milne; Mr. W. McLeish, besides a frame of Rembrandt portraits, sends three *genre* pictures, "Morning, Noon, and Night," which we also noticed at the Newcastle exhibition. Mr. Johnston, of Forres, forwards some good photographs, which are, however, considerably depreciated by the bright green mounts surrounding them. Mr. T. G. Whaite supplements his formerly-exhibited clever groups by others of the same character; and Mr. T. J. Dixon and Mr. Hedges show, their familiar, but no less wonderful, animal studies. Alas' the Dundee programme did not include a medal for photographs of animal life. Mr. A. F. Mackenzie sends two frames that include some marvellously fine groups, one of them, that might be aptly termed "Under the Greenwood Tree," denoting not only skilful technical ability, but the possession of most artistic taste in posing and lighting. Mrs. D. O. Hill, Mr. G. A. Simpson, Dr. Robert Dickson, and Mr. D. Johnston forward for exhibiton some interesting examples of old Collotype, Mrs. Hill's contribution including a number of portraits a quarter of a century old, which are remarkable alike for vigour, force, and delineation, and which, by reason of the absence of all retouching, read a valuable lesson to the portraitists of to-day.

Of the contributions of the following gentlemen, notwithstanding their high merit, we need say nothing, since their exhibits are practically the same as we have noticed in previous gatherings in London and elsewhere, viz., Mr. H. B. Berkeley, Mr. T. M. Brownrigg, the Platinotype Company, Mr. E. Fox, Mr. G. Renwick, Mr. Silvester Parry, Mr. A. Hendrey, Messrs. E. Day and Son, the Autotype Company, Messrs. J. Chaffin and Sons, Hills and Saunders, E. Brightman, Payne Jennings, W. Gillard, and R. H. Buxton.

At Home.

HERR KOLLER IN PESTH—A STUDIO WITH NO SIDE LIGHT.

"Mind you hear some Hungarian music," says Dr. Eder, as we shake hands at the Northern Railway Station in Vienna; "you get it to perfection in Pesth." We make a mental note of the advice, and our pleasant anticipations add something, no doubt, to the admiration with which we regard the beautiful country that lies between the capitals of Austria and Hungary. Now and then there are glimpses of the broad, placid Danube, and its green banks, with tiny villages grouped here and there—the churches surmounted by shining cupolas, which remind us more vividly than aught else that we are travelling in Eastern Europe. Near Pressburg we pass through miles and miles of vineyards; hill and dale are covered with the bright green vine, beyond which the dazzling white houses and red roofs of the town are just visible. Presently the hills grow bigger and become more rugged; the railway winds in and out beside vast precipices and giant peaks. We are among the Carpathians, and a magnificent range of mountains they are, viewing them at close quarters like this. By-and-bye, these lofty black pyramids are left behind, and the blue Danube favours us with its company once more. It is blue, of course, only in the sense that invisible green is green. But it is getting dusk now, and all one sees is a broad steel-like band in the moonlight, beyond which rise the dark irregular outlines of the Carpathians.

The proverb tells us, "All cats are grey in the dark," and it may be said with almost equal truth that all strange cities appear beautiful by night. And if this holds good with most towns, Buda Pest, which takes rank as one of the finest of European capitals, is naturally enough still further enhanced. Indeed, to the stranger who arrives on a moonlight night, who walks the acacia-bordered quays —for the broad Danube flows straight through the city— and watches the dotted lights of Buda opposite, their lurid reflection in the water at his feet—who sees the mighty fortress rising aloft in the gloom, all the more stupendous because of its indistinctness—the glitter of the palace across the water, the lamps of the bridges, the tall stone buildings that rise at every corner, the broad, lighted squares, the summer cafés—all life, mirrors, and bustle—he who sees all this must perforce believe he has entered an enchanted city. And the idea becomes stronger still when he alights at the broad steps of the hotel, and, looking beyond the corridor, sees a magnificent stone square, filled with white-clothed tables, flowers, lights, and music, where mortals are gaily supping in a scene all brightness and animation.

There is a reverse side to the picture, it is true. Our room is on the third floor, looking into the square, and we open the windows to gaze down upon the sparkling scene and listen to the Hungarian music we have been told to heed. It is pleasant, very pleasant. But when we have heard a dozen instrumental pieces, have supped our fill, and have retired to rest, we begin to think the music might be hushed with advantage. The day's travelling has been heavy, and we yearn for a good sleep; but midnight strikes, and the Hungarian music below is still in full swing. Next night there is as much and more of the Maygar strains, for it is a military band this time that comes and plays under our roof till the small hours. We begin to think there was no need for Dr. Eder's advice, after all.

And now the national music is off our mind, we will give our reason for coming to Pesth. Eight years ago a charming collection of photographs forwarded to Pall Mall from the "Seven Mountains," by Herr Koller, were very justly rewarded with a medal. Herr Koller, we heard, had settled in Pesth, and, as might have been expected, he at once took the lead among photographers in the Hungarian capital. Since we had a desire to visit one of the first studios in the kingdom of Hungary, we wrote to Herr Koller to receive us. He consented, and hence our visit.

A thorough chemist, a man of highly-cultivated taste, Herr Koller has a most amiable and winning manner. That his work is that of a master is known to our readers who saw the photographs we allude to; but to view the conditions under which that work is done is to see one example the more, that it is the man, and not the tools, that makes the mark. "You have never seen such a glass-room as this, I am sure," says Herr Koller, opening a door leading to the studio. We look round. It is surrounded on all sides by lofty buildings, and there is no clear view except over-head. Still we jokingly reply that we have: "At one of our prisons in London—Millbank, a place like your Kufstein—there is a studio with just such high walls on every side."

Herr Koller's studio is singular in this respect. *There is no side-light at all.* It has a large, low roof of glass, and all the illumination that enters gets in through the roof. Herr Koller may be said to out-Luckardt Luckardt in respect to lowness of roof; it has very little slope, and the greater portion is clear glass. The walls of the studio are painted—the upper portion a light blue, and the lower a dark brown. Of course, there are curtains; but, as a rule, only a light screen is used to modify the light upon the sitter. The illumination of the room, at its best, is never bright; but the light, if dull, is soft and pleasant, and is at once fit for photographic portraiture with very slight modifications.

As we have said, the studio is surrounded by walls. These are at a distance of some sixty or eighty feet, and rise skyward to a great height. He has painted these distant walls blue—or prevailed upon his neighbours to do so— "and for this reason," says Herr Koller, "there is more light in the studio than is at first apparent. Sometimes when I come in from the front, I wonder where the light is; but it is so diffused and manageable that I find I can take a portrait in any part of the room almost at any time of the day."

His exposures, nevertheless, are rather longer than elsewhere. He is well satisfied if he can make a cabinet picture with an exposure of twenty to twenty-two seconds. Like Luckardt, he works very much to secure delicate detail in the drapery of his sitters, and the subdued, diffused light of the studio appears to have much to do with success in this respect. Our readers may remember the in-door groups and interiors of Herr Koller, which secured him the medal at Pall Mall; their strong point was the marvellous detail in the shadows, and the absence of all inky blotches in corners and recesses. These effects are due to working with a more uniform light than that employed by most photographers.

In Buda Pest, which, it must be remembered, is the biggest city in a line between Vienna and Constantinople, there is as much life and gaiety as in any other European capital, while the people are more busy and go-a-head in their notions than their German neighbours. One sees this in photography, and Paris and London might take a lesson from Buda Pest in some respects. The finish of the pictures, the elegant mountings, and the assortment of styles is noteworthy in the show-cases of even second and third-class studios. The slender promenade or panel

—termed the *Makart*—is perhaps more popular here than in any locality in Europe; while the boudoir, which is very slow in making way with us, is almost as well known as the cabinet.

Herr Koller will accept an order for a single promenade portrait, and for this the sitter pays eight florins (roughly, sixteen shillings); then further copies are charged at a reasonable rate—namely, one and a-half florins (three shillings each). In these circumstances a dozen promenades cost forty-eight shillings—or, perhaps, more strictly speaking, forty-five—a price that compares favourably with other European studios *du premier rang*. This plan of charging for the first copy is a very good way of getting over the proof difficulty, as also the dislike of a customer for his portrait after he has paid for it. If he objects to the picture, he has always the consolation of knowing he has not disbursed a very large amount, and if he desires to re-sit, he can do so, at no great cost. At Herr Koller's establishment, as in Berlin, there is a counting-house attached to the studio, into which the customer first enters; this *comptoir* gives quite a business aspect to the undertaking, which is absent from our British studios.

Kerr Koller makes a speciality of one form of portrait, for which he receives orders frequently from places as far distant as Paris. This portrait is exquisitely coloured, very fine and transparent in nature, and does not usually measure more than twenty inches. Herr Koller puts a specimen in our hands, and asks us to guess how it is finished. It is a picture of two young girls with golden hair, and bright, hazel eyes. Its delicacy and translucent character are something extraordinary. "Is it upon enamel, ivory, or porcelain?" we ask. Herr Koller shakes his head, and will show us how it is done. The method is not novel, he admits, and success lies in the execution, rather than anything else.

To get the transparent effect he has recourse to the method which photographers are aware gives this property with effect. He employs two pictures, one over the other, as has been proposed over and over again, the last time in connection with the ill-fated "Colour Company." Says Herr Koller: "Photography plays but a subordinate part, you will perceive; success mainly depends, as a matter of course, upon the skill of the painter engaged in colouring the picture." To begin with, a photographic print upon algæine paper is produced; this may be a direct impression, or it may be an enlargement. Algæine paper permits of the most exquisite work by the water-colour artist; it is thin, and easily rendered transparent. The paper print is finely painted, and then placed upon a sheet of glass. It is now ready for treatment with an encaustic paste. "This," says our host, "is a preparation of my own, and made up with gum-dammar and Canada balsam." The whole surface of the coloured picture as it stands upon the glass is covered with the mixture, and submitted to a tolerably high temperature, which has the effect of impregnating the picture through and through with the compound, rendering the paper transparent, while it seems to heighten the brilliancy of the colours. The semi-transparent coloured portrait at this stage does not possess any particularly good effect—it looks, in fact, rather disagreeable, and it is only when it is placed over another roughly-painted sheet—the paper, in this case, being thick and coarse, and the colour only applied in patches—that the charming effect we have alluded to is produced. Herr Koller has firm faith in the permanence of the photographic portion of his picture for two reasons: There is no albumen, and there is the great protection afforded by the encaustic preparation. Herr Koller has made the process his own, and the labour he has spent in perfecting it has certainly not been thrown away.

The "By-the-Bye" next week will be "What Photography does for Science"; the following "At Home" will be "Messrs. James Valentine and Sons, at Dundee."

DEVELOPED PRINTS AND NEGATIVES ON PLAIN PAPER.

BY CAPTAIN ABNEY, R.E., F.R.S.

In compliance with your request to me, I beg to communicate to you the method of preparation of the bromo-iodized paper with which my lectures already delivered before the Society of Arts have been largely illustrated. Before the rapidity attainable by the gelatino-bromide paper, however, it cannot be hoped that it will be largely utilized. It has, however, the good quality of cheapness and ease in preparation, which the gelatine paper has not. The preparation paper was described at a meeting of the Photographic Society in 1880, and with one exception its preparation is the same as before.

The method of preparation must be adapted to the purpose for which it is intended to be used. 1st. For the production of paper negatives. 2nd. For the production of prints. In the first case the paper is soaked in the following:—

Potassium iodide	... ...	200 grains
Potassium bromide	... ...	300 ,,
Water	... ...	20 ounces

To this is added a solution of iodine in alcohol till it assumes a deep claret colour. (This is added for the convenience of knowing when the sensitizing is completed, and is not necessary.) After filtering the solution, the paper, which should be as smooth as possible (Saxe or Rives answers), is immersed in it, taking care that no air-bells cling to the surfaces, and allowed to remain soaking for half-an-hour. The sheets are turned once or twice during the operation. They are then taken out and allowed to drain and dry spontaneously, after which they are floated on—

Silver nitrate ...	... ...	500 grains
Glacial acetic acid	... ...	1 ounce
Water	... ...	20 ounces

The smooth side of the paper is floated as is done when albumenized paper is sensitized; after a couple of minutes the purple or brown tint at the back of the paper will be replaced by this yellow bromo-iodide of silver tint. After a couple more minutes the sheets are removed to a dish of water to remove the excess of silver. After another wash the paper is transferred to water containing about 50 grains of potassium bromide to the pint of water, and allowed to soak ten minutes. It is then thoroughly washed, and dried. By this plan the paper will be slow. In order to render it more sensitive, it may be given a soak in beer diluted to half its strength with water to which a little white sugar has been added, say one lump the size of a nutmeg to a pint; or it may be floated in a solution of potassium nitrate or sodium sulphate about half a grain to the ounce, and then dried. These would render the paper a good deal more sensitive than in its normal state, and can be used with safety. Any sensitizer, such as gallic or pyrogallic acid, might be mixed with the beer, but in this case care must be taken to wash it all out before applying the iron developer, since any trace left will form ink with the iron. The exposure is long, compared with gelatino-bromide paper—say thirty times longer. I now prefer to develop by brushing over the ferrous-citro-oxalate developer, using a nearly vertical plate on which to hang the paper, which should be previously damped. This is more economical than using a dish, and is a great saving in time. The ferrous-citro-oxalate gives even purer whites than the ferrous-oxalate, and I therefore recommend it. The brushes I use are three-inch flat badger hair brushes, and I have found no deterioration in them by use. From time to time the paper should be examined to see what density has been obtained, and when the image is through the paper it will be found sufficient for printing purposes. After fixing, washing in hot water (to remove the size), and drying, the paper is waxed in the usual manner.

To obtain prints, plain paper is brushed over on its smooth surface with the above solution, to which about five grains to the ounce of gelatine may be added. When dry, a second coating is given, and when that is dry, the paper is floated on the above silver nitrate solution for four minutes, after which it is washed and treated exactly as above, and developed in the same way.

Pure bromide paper answers almost as well. A solution of 30 grains to the ounce of potassium bromide is brushed over the paper twice, which is floated on the silver bath, and treated as before. To develop such paper it is, however, as well to add to each ounce of ferrous-citro-oxalate developer about five grains of common salt. This keeps the whites purer than they would be without it. Paper so developed should be beautifully bright and clear in the lights and shades, and gives excellent prints on which to work if considered desirable. There is a tendency, however, for the prints prepared with bromide alone to have a greenish tint. The use of the iodide gives a black. This is not astonishing when it is considered that silver iodide alone develops a ruddy colour. This mixed with the green gives a black tone.

I may add that many photographers apparently fail to make ferrous-citro-oxalate. The plan is as follows: Take 500 grains and dissolve in 5 ounces of water, warm the solution to boiling point, and then add to it 110 grains of ferrous oxalate powder. Shake this up immediately in a corked flask, and it will be found to dissolve. It should have a greenish-red tint, and is then in its most active state. I advise those who develop collodion dry plates, or gelatino-chloride, to try this developer, and use it without any restrainer.

Notes.

Mr. W. J. Stillman, M.A., the *Times* correspondent at Athens, whom rumour killed last week, is the well-known amateur who sat for several years on the council of the Photographic Society.

Hydrochinon, the developer proposed by Captain Abney for gelatine plates some time since, is likely to become much cheaper, a matter on which photographers may congratulate themselves, for it is but the high price of hydrochinon at present that prevents its adoption in the photographic laboratory. Nietzki has discovered a way of producing hydrochinon by oxidizing aniline with acid bichromate of potash, thereby reducing the price to one-twelfth its former cost.

At its present price, according to Dr. Vogel, it costs one shilling to develop an 8 by 5 plate with hydrochinon. In future, if Nietzki's process is a practicable one, the cost should be no more than a penny, still high enough, no doubt, but not much higher than oxalate development, which for the same size plate is put at three-farthings.

Port Said is one of the best markets for photographs in the world. Everybody going through the Suez Canal for the first time is a sure buyer. The wonderful Egyptian monuments are so close at hand, that whether the traveller pays them a visit or not, he likes to carry their photographs away with him, that he may be well posted in description, when it comes hereafter to tell tales of his journey.

The marriage service, gorgeously bound, with photographs of the bride and bridegroom by way of frontispiece, is looked upon now-a-days, it seems, as an appropriate gift to the wedding guests at "fashionable" marriages.

A delicate test for oxygen. A German chemist, Herr T. W. Engelmann, finds that very minute quantities of oxygen excite the mobility of bacteria, causing these tiny organisms to bestir themselves with considerable energy. To determine whether or no a liquid contains a little free oxygen, he proposes to introduce therein some of the species *Bacterium termo*, or other of the microscopic family, and see if these get into motion. This is all very well, but what will the Society for Suppression of Cruelty to Animals say?

Instead of fining drunkards, it is proposed, in America, to take their photographs while in a state of inebriation, and to expose them to the public gaze in different parts of the city or province. This would be a revival of the pillory by deputy.

Last week a Royal item of news was to the effect that Prince Leopold had joined the British Association; and now the Prince of Wales has allied himself to workers in "literature, science, and art," by becoming a member of the Savage Club. On the occasion of His Royal Highness's installation on Saturday last, we met several savages, whose names are well known in photographic art, either as professional members, or as amateurs. It was a pleasant novelty to have the Prince mixing with his brother savages in the homely club-room at the Savoy during one of the agreeable social evenings.

We have already referred to the assistance the stage might well derive from photography in the painting of scenery, and, as an instance of what can be done, we referred to a very pretty glacier scene produced in *William Tell*, not long ago, at the Gaiety, from one of Mr. William England's photographs. On Tuesday last, at a performance of *Tannhäuser* at Her Majesty's, we witnessed a spectacle where the aid of photography was devoutly to be wished. Wagner's opera takes place at the Wartburg Castle, beside the Hörsel Mountain, and, as the former stands now as it did in the time of the Landgraves, and the mountain is what it always has been, there is, surely, no excuse for not painting the scenes a little bit like nature.

Yet, though the opera has been newly mounted at great expense, and the utmost care taken to "dress" it correctly, the saddle-backed Hörsel Mountain is depicted as if it were one of the rocky-spired Dolomites; while the grey old Wartburg on its green pedestal has as many towers and minarets as Blue Beard's Castle. Any photographer in the Saxon duchies could have supplied photographs of the famous castle where the minstrels strove in song, and scenes could have been painted quite as romantic as the costly and unreal ones now employed in the opera.

A reaction of gallic acid, which photographers may note! Ammonium picrate produces in solutions of gallic acid a red colouration, which in a few seconds passes into a fine green. Pyrogallic acid and tannin give also a red, which remains unchanged. Possibly the latter fact might be made use of in development.

The *American Naturalist* speaks of a snail of which a lady made a pet. The snail, it is said, learned to know its mistress, would come to her when she called, and withdrew to its shell if anyone else spoke. After this, we should not be surprised to hear of a gelatine plate so sensitive as to refuse to develop when anathematized by an angry assistant in the dark-room.

Both the French and English Governments are occupying themselves witht he colours of different uniforms, with a view to choosing the least visible. Of course, the nature of background has much to do with the subject, but it is one, we should think, that photographers might aid in solving. At any rate, there would be no harm in undertaking photographic experiments side by side with the optical trials.

FRENCH CORRESPONDENCE.

Securing Exact Counterpart of Original Image—M. Chardon's Oscillating Bath—International Exhibition of Artistic Photography—Examinations for Assistants.

Captain Biny's Process for taking a Positive from a Positive, or a Negative from a Negative.—Captain Biny, to whose very interesting invention I have lately had occasion to direct the attention of my readers, communicated to the last meeting of the Photographic Society of France the details of a process by which he is able to secure on a gelatine plate an exact counterpart of the original image. Thus, from a negative plate he gets a negative copy, and from a positive plate a positive copy, an arrangement which is of great value in certain industrial processes, where it is necessary to obtain a reverse negative of the exact dimensions of the original, and yet a faithful reproduction of all its details. By the ordinary method of obtaining a reversed negative on a pellicle, it is exceedingly difficult to preserve accurately the relative proportions of all parts of the plate. The process was tried at the meeting with one of Monckhoven's gelatino-bromide plates; this was immersed for ten minutes in a four per cent. solution of bichromate of potassium, and then set to dry in a dimly-lighted place. When perfectly dry it is exposed in a copying frame, below the plate of which a copy is to be taken. By working beforehand with the same plate on bichromated paper, the exposure can be regulated so as to bring out all the tones of the original in the brown colour of chromium oxide. The plate is then taken into a dark room illuminated only by red light, and immersed in a gutta-percha bath of water, so as to dissolve out all the free bichromate. It is next rinsed in two waters, and then, being placed on the black ground of the bath, it is exposed to diffused daylight for from one to five seconds. The next operation is to develop the plate by the ordinary ferrous oxalate developer, when the image, negative or positive, will become visible according as the original from which the copy is taken is the one or the other. After this it is fixed by sodium hyposulphite, which acts in this case more slowly than in general, because it only penetrates with difficulty into the film of bichromated gelatine, rendered insoluble and nearly impermeable by the action of the light. Capt. Biny complained of his film stripping, so I recommended him to expose the back of his film to the light either before exposing it in the printing frame, or afterwards, an operation which secures the adherence of the gelatine to the glass. He now writes to me that he has adopted this plan, and finds it to answer admirably; he sent me at the same time an original plate, and its counterpart, produced by this process, and the latter seems to be perfect without the least sign of stripping. Repeating these experiments with M. Stebbing's pellicle, I found that this material, after being for some time in the bichromate bath, is affected by the light, not only so far as the potassium bichromate is concerned, but that the silver bromide which constitutes its sensitive part is not protected from the luminous influence by the bichromate; the effect observed by Capt. Biny is therefore not obtained with this pellicle. Whether other emulsions are liable to the same defect I cannot say, but with Messrs. Morgan's gelatino-bromide I have succeeded in getting the result which Capt. Biny describes.

M. Chardon's Oscillating Bath.—This bath, which I mentioned in one of my recent letters, is kept in motion by a very simple electro-motor. A flat iron bar turns on an axis in a vertical plane, and its ends make contact alternately with electro-magnets placed on each side of the axis. Foucault's commutator is the one employed; it is formed of a metal wire, of which the extremities oscillate so as to dip in turn into two cups of mercury. A groove is cut in the axis of rotation of the oscillating bar, and on this is adjusted a forked tongue, connected with a lever fixed to the movable table below the centre; on this table the bath is placed. There is also a balance long and heavy enough to regulate the oscillation, and to overcome the inertia of the dead point. M. Trouvé, the well-known electrician, has contrived this simple little machine, which he makes at the low price of 65 francs without the battery; this latter may consist of two of Grove's cells.

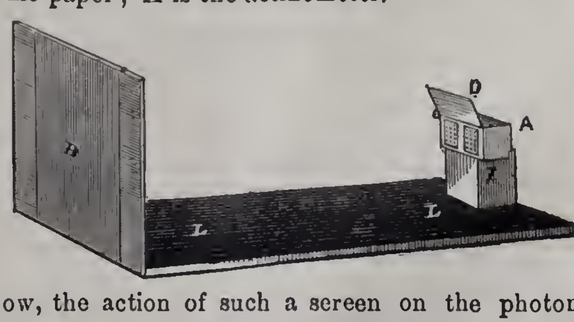
International Exhibition of Fine Art Photography.—The executive of the International Exhibition to be held by the *Union Centrale des Arts Décoratifs* have formed a committee for the photographic division; it consists of MM. Péligot, president; Davanne and Lévy, vice-presidents; and Léon Vidal, secretary. This exhibition is to have more especially a fine art character, and the prospectus, so soon as it is published, will be forwarded to the Editor of the Photographic News.

Examination of Photographic Assistants.—I have sent a copy of the syllabus for this examination to our Editor; it is to be the guide to the candidates as to the kind of questions they are likely to have set them. Already several candidates, both native and foreign, have applied to the President of the *Chambre Syndicale* for admission, and it is to be hoped that the diplomas granted on the examinations will be held in sufficient esteem to create in our profession a *corps d'elite* among our assistants. Leon Vidal.

ON ACTINOMETERS.

BY DR. H. W. VOGEL.*

The figure below shows the arrangement; B is the screen (about 40 centimetres square) covered with plain photographic paper; A is the actinometer.



Now, the action of such a screen on the photometer

* Continued from page 53.

depends very materially on its distance from the latter, since that action decreases in the ratio of the square of the distance. In order, therefore, to have the reflecting screen in a fixed position with regard to the photometer, I arranged a horizontal board, LL, of such a length that the distance of the metal plate with the orifices from the reflecting surface of the screen should be exactly one metre. On the side of the screen, opposite to the actinometer, it is lined with a clean sheet of ten kilo. photographic paper; this is done in the same way as mounting drawing paper on a drawing-board, namely, by cutting the sheet of paper accurately to the size of the screen, damping it, smearing the edges with gum, and then allowing it to dry, when it will be found to be smooth and tight.

The arrangement of the actinometer itself is extremely simple; in front is a turning shutter, *d*, and the back part is made like a dark slide. Immediately behind the apertures in the wood is placed a thin copper plate, in which figures are cut corresponding to the number of the orifices over it.

The manipulation of the instrument is self-evident. Two plates whose sensitiveness it is desired to compare are exposed, while the light remains as constant as possible. These plates are then developed in the same bath, and it is observed on which of the two the smaller number has made its appearance.

A necessary condition in using the instrument is, that the light shall have the same intensity throughout the experiment—a condition easily fulfilled in the case of artificial light, but not so readily attained with daylight. With a clear sky, the intensity of the light varies with the position of the sun; with a cloudy sky it depends on the extent to which the sky is overcast. In order, therefore, to be able to compare the two plates with certainty, they must be exposed simultaneously, and for this reason I have arranged the actinometer as a double instrument. It is fitted with two scales of exactly the same construction alongside of each other, and the number of holes in the wood under each scale amounts to 24, arranged in four rows of 6 holes each. The orifices over the holes have a diameter of $\frac{3}{4}$ m.m., and their numbers increase corresponding to the numbers of the holes from 1 to 24. The scale is at a distance of 10 centimet. from the sensitive plate, and the back part is so arranged that two plates of $3\frac{1}{4}$ by $4\frac{1}{4}$ inches can be exposed together. By this means the plates can be accurately compared as to their sensitiveness in any kind of weather, and the instrument can consequently be used as a sensitometer under all circumstances and in any kind of light.

On the other hand, it forms an equally valuable actinometer for determining the chemical intensity of daylight. In this case, we must take a number of plates of the same degree of sensitiveness, and after exposing them at different times, they must be developed under the same circumstances; the intensity will be found to be in the inverse ratio of the numbers which make their appearance.

Now, it is not possible to produce plates which have absolutely the same sensitiveness; but a number of plates prepared from the same emulsion may be considered as equally sensitive, and if it is then desired to employ a second emulsion of a different degree of sensitiveness, it will be only necessary to determine by experiment, as above described, the relative sensitiveness of the two emulsions in order to obtain results which can be readily compared with one another. Thus, the varying sensitiveness of the plates will have no effect on the accuracy of the results. It stands to reason, that in making observations in this way on the variable intensity of daylight, only one plate must be exposed at a time. With the same instrument may be compared with each other the intensities of different sources of light, daylight, electric light, gaslight, &c.

Further, different instruments of this kind possessing different dimensions may be compared with one another. For suppose that the diameter of the orifices of the scale in one instrument is o, and that of those in another instrument O, then the intensities of the light under the orifices in the two instruments are to one another as $o^2 : O^2$. Again, if the distance of the plate from the orifices in one instrument is d, and in the other D, then the brightness in the two cases is in the inverse ratio of the numbers $d^2 : D^2$. Hence the ratio of the intensity of the light in the one case is to that shown in the other as $\frac{o^2}{d^2} : \frac{O^2}{D^2}$. This advantage is not possessed by any other actinometer, and we see also that this instrument is capable of many different applications.

It may be objected that a new actinometer for the determination of the chemical intensity of light is scarcely necessary, since that of Bunsen and Roscoe (with chloride of silver paper) answers all our requirements. I may here remark, that this latter instrument is not sufficiently sensitive; Bunsen and Roscoe themselves state that when the sun's altitude is less than 12°, the instrument will not show the chemical action of the *direct* solar rays. Now, every photographer knows that even at the time of sunset, instantaneous pictures may be taken of the sun's image.

(To be continued.)

OPALS AND PAPER PRINTING BY GASLIGHT.

BY PERCY COLLES.*

The prints I show to-night are not put forward as any marvels of perfection, but will, I trust, be considered of sufficient merit to induce other amateurs to work in the same direction who have not hitherto done so. My main object in showing them is that the whole of the work—such as it is—with the exception of the exposure of the original negative, is carried out by gaslight—retouching the negative, exposure, and finishing of the prints, &c. The negatives are all taken on Swan's plates, and the opal prints are also taken (in contact) on Swan's plates. The emulsion paper on which the prints are taken was prepared by an enthusiastic photographic friend of mine, and I regret I am not at liberty to say anything as to its preparation beyond the fact that it is costly and troublesome to make.

My mode of procedure is as follows:—The negatives are retouched at an ordinary desk, with an argand gas-burner, using pot opal as reflector, with ground glass behind the negative. The gaslight should be elevated till it is about on line with the bottom of the negative when the latter is in its place on the desk; this screens the glare of light from the eyes. I make the exposure—say on a Swan's five times' opal—to a gas argand burner for forty or fifty seconds, some six or seven feet distant from the light, when a negative of average density is used; for thinner or denser negatives, I find it better to print at a greater or lesser distance from the flame, according to the character of the negatives, than to vary the time of exposure.

The vignettes are printed in the usual way—cardboard with opening covered with tissue paper (the latter must not be oiled, or the vignette will be too hard). The use of masks for opal printing somewhat reduces the sharpness, the negative and the opal not being in actual contact. Develop with ferrous oxalate—Swan's Nos. 11A and 12B oxalate of potassium ten drachms, sulphate of iron two drachms, with ten to fifteen drops of bromide (one to four). Do not spare the bromide! The image does not begin to appear for some two or three minutes, and requires twelve to fifteen minutes to complete. When I see that development has commenced I leave the plate in the tray, carefully covering the whole, turn on the white light, and prepare for another exposure. Care must be taken to use sufficient solution to well cover the plate while it is lying, otherwise the development will be uneven. With the most ordinary care, using this slow and weak developer, there need hardly be a single failure.

The plates are well fixed for at least thirty minutes in strong, clean hyposulphite (saturated solution one part, water two parts), then washed in running water for half-an-hour, and soaked in a plain alum bath for ten minutes. I have not found any tendency to frilling in Swan's plates, so I do not use alum until after fixing and washing. On taking the plate out of the alum bath, it will be found that it is very much stained by the prolonged development; but by immersing it for three or four minutes in a clearing bath of alum one ounce, water twenty ounces, oxalic acid two drachms, this stain will be entirely re-

* Read before the Manchester Photographic Society.

moved. Lastly, wash under the tap, and dry and finish by coating with a clear, colourless varnish.

Some of the opals shown are coated with an ordinary negative varnish, and have from this cause the appearance of being slightly discoloured. The light I use for developing is an ordinary gas behind a hinged frame, 3 by 4 feet, covered with two thicknesses of Swan's red paper—a comfortable and safe light. The emulsion paper prints are worked in all respects the same as the opals, except that the paper is soaked in water for a few seconds after exposure, to allow the developer to flow easily. The 8½ paper print of group is intensified with mercury, and the print in a double glass is worked up for a transparency.

Perhaps I might take this opportunity of saying to those who use ferrous oxalate as a negative developer, that the proportions mentioned for the opals (10 drachms to two drachms) will be found better for general use than those given in Swan's printed instructions A and B, the quantity of B there given being the maximum that can be used.

The two silver prints of a child dressed as an old woman are from negatives taken on a Swan's eight-times' plates, on January 8th, between two and three o'clock—a by no means bright afternoon.

Correspondence.

THE DRAINING OF EMULSION.

Sir,—Mr. Birrell will find the following a simple method of draining gelatine emulsion: place the washed shredded emulsion in a piece of fine muslin, and this again in the canvas used for shredding, and screw up as in that process; tie three feet of string to it; and go out into the garden and whirl it round until no more water will come off. Of course the operation is performed in the evening.—Yours truly, J. W. Leigh.

A SUBSTRATUM WANTED FOR PICTURES ON OPAL GLASS.

Sir,—Will you permit me to appeal through your columns for a little light on a subject which for months past has bothered me not a little? It is, how to make opal pictures to stick on the glass. I have now before me four half-plate opal pictures, clean, vigorous, and full of detail, but in every one the film is leaving the glass; the fact is, I cannot get them to stick; I have tried all sorts of remedies, but to no purpose. I have the News since 1873, but not a ray of light is there, nor in the Year-Books. I have orders which I cannot execute on account of this. Will some generous brother help a "lame dog over the stile?" I have tried the different kinds of glass, and various modes of cleaning the same, but with the same result—films flying off.

In the hope that in your next issue some good Samaritan may see his way to help, I subscribe myself,—Yours, &c., H. Howell.

THE DUNDEE EXHIBITION.

Sir,—There appear to be so many curious anomalies connected with the Exhibition now being held at Dundee, that I think it would be interesting to your readers, and perhaps useful to future exhibitors, to point out one or two of them. To do this I am aware is a delicate matter, as you were yourself one of the judges, but your liberality in the interest of all that is fair and square is so well known to your readers, that I am sure you will not object to honest criticism.

In your notice of the Exhibition you say that Mr. Payne Jennings' landscapes could not compete for gold or silver medals in consequence of their being mounted on glass. If this is true, if this photographer's contributions were disqualified for this reason, then I have no hesitation in saying that the Dundee Society has got together a large collection of photographs, and, worse still, taken money for space, on false pretences. It must be admitted by all that the only inducement that could have actuated nearly all the exhibitors was the medals offered for the best productions, and that all of them read and relied on the conditions issued by the Society. Now there is nothing whatever in these conditions prohibiting any kind of mounting or printing. Medals are offered for certain kinds of pictures, such as portraits and landscapes, but nothing is said about the processes by which they are to be produced. The wise judges, if it suited their purpose, might as well have prohibited all but collotypes or Daguerreotypes, or any other ancient process.

It is, perhaps, wrong to impute motives, but it is not difficult to infer that the object of the majority of the judges was to clear away the pictures of the best exhibitors on some side issue before the real business of judging began. Thus Mr. Jennings' exhibits were excluded from competing for the first-class medals for the cause already stated, and I find a series of well-known landscapes, which occupied a prominent position in the London Exhibition, and took a medal *as* landscapes, were, in the most arbitrary manner, classed in the catalogue as genre pictures because they contained figures—a most remarkable conclusion! These two exhibitors being "sided," gave the second and third-rate men a chance they have never enjoyed before.

I wonder if I should be thought impertinent if I asked Mr. Robinson and Mr. Jennings what they think of it themselves, and if they mean to accept these ridiculous awards. It seems to me to be their duty to uphold the honour of English photographers. Due South.

[Although we print the above letter, we must here, once and for all, declare our conviction as to the integrity of the judges.—Ed. P.N.]

Dear Sir,—I have been awarded the highest award in my class at the above Exhibition, but, unfortunately, it is a class in which I had not the remotest idea of competing, viz., that for *mounting photographs on glass.*

As photographs in optical contact with glass have never before been debarred from competition, I think this remarkable departure from the usual rules should have been expressed in the conditions in such a manner as to leave no room for doubt. I confess that I, for one, was misled. —Yours truly, Payne Jennings.

MEETING OF LEEDS PHOTOGRAPHERS.

Sir,—Photographers residing in and near Leeds will be pleased to hear that a photographic evening has been arranged for next Tuesday, the 21st inst., 8 p.m., in connection with the Leeds Naturalists' Club and Scientific Association, at their meeting room in the Leeds Mechanics' Institute. The leading idea in the mind of the proposers of the meeting is to provide for persons interested in photography a means of meeting together, and for that purpose it will probably be proposed to make permanent arrangement of some kind or other for the continuance of such meetings. I may add that various gentlemen, including Mr. Washington Teasdale, F.R.M.S., and Mr. T. W. Thornton, will exhibit various subjects of interest, and that all persons interested will be welcome to attend the meeting.—I am, sir, yours truly, B. Holgate.

Proceedings of Societies.

Photographic Society of Great Britain.

The usual monthly meeting was held on Tuesday, at 5a, Pall Mall East, Mr. J. Glaisher (president) in the chair.

Mr. J. R. Dunlop was elected a member.

Mr. E. Cocking (assistant secretary) read the annual report, which congratulated the members upon the important discoveries in photography which had taken place recently, and also upon the satisfactory condition of the Society. The technical meetings had proved highly successful, and would be continued for the future. The annual exhibition had been attended by a larger number of visitors than in any previous year, and was remarkable from the fact that there were five times as many pictures by the gelatine process as by any other process. The report also contained an obituary notice of the late Mr. R. W. Thomas.

The report was adopted on the motion of Mr. Maxwell Lyte, seconded by Mr. Berkeley.

Mr. Lyte then moved a vote of thanks to the president, council, and officers of the Society, which was carried.

Mr. J. Spiller (treasurer) read the balance sheet, from which it appeared that the receipts during the past year had amounted to £755 1s. 1d., of which £285 2s. was for entrance fees and subscriptions, and £161 14s. 4d. for admissions to the exhibition. The balance in hand was £242 17s., being £32 6s. 1d. in excess of the balance last year.

The President remarked upon the favourable nature of the balance sheet, and referred to the resignation of the treasurer, Mr. J. Spiller, who had served the Society faithfully for five years, but who now found it necessary to resign the office into other hands. He would propose that the cordial thanks of the Society be given to Mr. Spiller.

Mr. Spiller acknowledged the vote of thanks, and proposed a similar vote to the auditors, Messrs. Heaviside and Ackland.

The result of the election of the council and officers was then made known as follows:—

President—Mr. J. Glaisher. *Vice-President*—Mr. J. Spiller. *Hon. Secretary*—Lieut. Darwin. *Hon. Treasurer*—Mr. Bird. *Council*—Messrs. W. Bedford, Cowan, Dallmeyer, Payne Jennings, Lyte, and Col. Wortley.

The President then announced that since the balloting papers had been sent out, Mr. C. Bennett had resigned. Mr. Berkeley, the next highest on the list, was then elected in place of Mr. Bennett.

Col. Wortley asked if there was any objection to the numbers of those voting for the elected members being made known to the Secretary, so that anybody who wished to see them could do so.

The President, Mr. Bird, Mr. Heaviside, and Mr. Lyte objected to this course, as it was likely to cause some ill feeling, and as it had never been adopted before.

Col. Wortley said he did not wish to press the matter if it would cause pain to anybody.

The President observed that it would be better if the matter were settled once for all, and he would put it to the meeting.

A vote was accordingly taken, when the feeling was found to be almost unanimous against the communication of the numbers.

After a vote of thanks to the scrutineers, Messrs. Ackland and Payne Jennings, the President presented the Progress Medal to Mr. Leon Warnerke.

Mr. Sebastian Davis then proposed a vote of thahks to the President, remarking upon the energy and assiduity with which he carried out his duties.

Tho President having replied,

Mr. Warnerke made some remarks on lenses, the chief purport being the desirability of having a standard of rapidity for lenses. He had for some time adopted a method which he found answer well. He took Dallmeyer's 2C or "baby lens," the aperture of which was half the focal distance, as his unit, and made his calculations from that unit, marking each lens according to its rapidity. The usual method of marking diaphragms as No. 1, No. 2, and so on, in which the size of the aperture was supposed to decrease by one half, he contended was erroneous, and he showed by experiments made with lenses of the same rapidity, but of different focal lengths, that such diaphragms were very misleading. To bring about some uniformity and to settle the matter, he intended to propose that a commission be appointed to investigate the subject. The duties of the commission would be—1. To examine what system would be the best to produce the desired result; 2. To confer with the leading opticians so as to secure their co-operation, in which he believed there would be no difficulty. The matter was also simplified by the fact that the principal opticians were English, and if they ever took up the subject the foreign opticians would follow suit. Mr. Warnerke also suggested that the commission might discuss the question of the flanges of lenses. It was well known that where one did much landscape work, and had to travel with a number of lenses, great inconvenience was caused by the necessity of using a different flange for each lens. The same annoyance was experienced in regard to camera screws: whenever a new stand was bought, the old camera-screws could not be used. He could not see that any objection would be raised by camera makers in regard to uniformity, as the benefit to photographers would be so great. At the next council it was his (Mr. Warnerke's) intention to propose that such a commission as he had suggested be appointed.

Mr. England remarked that some ten years since Mr. Russell Manners Gordon had worked out a series of experiments resulting in a formulated list of stops and their relative exposures. If at that time the optician had taken up the matter, great benefit would have resulted.

After some remarks by Col. Wortley relative to Mr. Warnerke's calculations,

Mr. W. Bedford suggested that the matter be deferred until the next meeting, when a committee might be appointed.

The President pointed out that it was necessary that the matter should first be brought before the council. As to the desirability of uniformity, he thought it would be a great advantage if photographic apparatus could be made as uniform as microscopes were, so that, no matter who the maker might be, the different parts would correspond.

The subject then dropped.

The Chairman announced that the Technical meeting would take place on February 28th, and the proceedings terminated.

West Riding of Yorkshire Photographic Society.

The above Society held its eighth annual *soirée* on Wednesday, the 18th January, at the Market Tavern, Godwin Street, Bradford, when about forty sat down to tea. The walls were decorated with a number of pictures and enlargements contributed by Messrs. Passingham, Howarth, Wormald, Ledgard, Bridges, Jennings, Garratt, and others.

Mr. Forsyth exhibited two large stereoscopes and a number of admirable transparencies, principally from his own negatives.

After tea the President, in a short address, expressed the pleasure he had in seeing the faces of so many who had been connected with the Society since its commencement, and thanked the members for their adherence to the cause. The Society, he said, numbered about the same as on previous years (some fifty members), a few had retired, but new members had been elected, which filled up the vacancies. The Society had been somewhat short of volunteers to provide the necessary papers for the monthly meetings, but during the present session they hoped to do much better, as the new members, he trusted, would bring renewed vitality to the Society. The association, he was happy to say, apart from its scientific and artistic advantages, had been the means of cementing friendships which would, he trusted, outlive the Society's existence. These small reunions, he thought, were amongst the most pleasant meetings of the year, as there they could combine their art profession with its sister art of music, and also with certain creature comforts, to the charms of which they were all doubtless more or less susceptible. He wished to press home to each member the importance of furthering the cause and interests of the Society. The officers were, he believed, prepared to do their best, and they sincerely hoped the members would assist them in their endeavours. Photographic societies were springing up on all sides, and it would not be creditable that a society like theirs should sink in the background. Rather let them all do their best to keep up the standard they had all doubtless set up as their ideal of a photographic society.

After the Presidential address, a short time was devoted to dancing, friendly chat, and the examination and discussion of the pictures exhibited. During the evening Mr. Howarth gave a short lantern exhibition and reading of an extremely interesting and pathetic character. A number of songs were sung by Mr. and Mrs. Crosthwaite, Mr. Fawcett, and Mr. Kilner (the latter gentleman also ably presiding at the pianoforte). Mrs. Illingworth (of Halifax) gave several of her irresistably humourous recitations.

Towards the close of the meeting the usual votes of thanks were given to the Chairman and those who had contributed to the evening's entertainment, and the members separated with hopes of meeting again at the next annual *soirée*.

Sheffield Photographic Society.

This Society held its ordinary meeting at Freemasons' Hall on February 7th, Mr. Thos. H. Morton, M.D., presiding.

The minutes having been read and confirmed, a nomination of new members was considered, and the following gentlemen were duly elected members of the Society:—Messrs. J. H. Ainley, Frank Mottersham, S. Foxon, and J. Cartledge.

Mr. Stringfellow (the Treasurer) reported that the expenses connected with the late exhibition exceeded receipts, but that the funds in hand were sufficient to meet all requirements.

Mr. W. B. Hadfield said that now the exhibition was over, it would be well for the members to express their opinions, point out and remedy any shortcomings, so that it could be made more successful in the future. He proposed that suggestions be made in writing, and read and discussed at the next meeting.

The Chairman exhibited a print view of the interior of the room at the Cutlers' Hall, taken at noon, February 25th, on a Clarke's rapid whole plate, Grubb lens, large stop, with an hour's exposure. He said it was secured under most unfavourable conditions—a bad fog and light, and a crowd of people walking about all the time; yet the picture was fairly distinct, and showed no trace of the visitors present. It induced him to ask the question:—"What proportion of time, in a given exposure, was necessary to produce an image of a moving figure, or none at all?" We know that to get a sharp outline of a body in motion, the exposure should be more rapid than the movement of the individual, otherwise a simple blurr resulted; but it was not so easy to calculate, so as to keep the figure entirely out of a view in moderately short exposures. Practically it pointed to the use of slow plates in some cases, such as street scenes.

Mr. Hicks observed that it was not uncommon to stop down the lens for that purpose.

Remarks were also made by Mr. Yates and others, and Mr. Taylor proposed that the print be inserted in the Society's album as a record of the event, which was agreed to.

The President said that the lantern entertainment had proved a great attraction, and he moved that a vote of thanks, seconded by Mr. Stringfellow, be given to Messrs. Yates, Hadfield, Dakin, and Bromley, for their efficient services, which was carried unanimously. Thanks were also accorded to the executive committee, and the meeting then adjourned.

Photographic Society of Ireland.

The usual monthly meeting of the above was held on the 10th inst., in the Royal College of Science, Dublin, Mr. E. P. Johnson in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were proposed members of the Society:—Messrs. R. Forbes, Wm. Bewley, Thos. Mason, and Theodore R. Webb.

Mr. Herbert Bewley, who has been working the gelatino-bromide paper to a very large extent, communicated his experiences of the above to the meeting, illustrating the manner of manipulation. An ordinary Sciopticon lantern with a $3\frac{1}{2}$-inch condenser and a Dallmeyer short focus lens was used in preference to the ordinary lantern lens, thus giving a greater amount of light and better definition. One of the pictures developed was from a negative of Mr. Watson's of the Gough Equestrian Memorial in the Phœnix Park, Dublin, enlarged on to 12 by 9 paper. (This size was used for convenience.) Mr. Bewley has enlarged pictures on to full size sheets, 18 by 24, which were also exhibited.

A discussion ensued as to the best way of developing, Mr. Bewley having used a very old ferrous oxalate developer, and some members agreeing that that was best.

Mr. J. V. Robinson demonstrated that it was not at all necessary to use old chemicals, and subsequently exposed a sheet of paper in *direct contact* with the negative, and developed it with fresh oxalate, the discolouration which so many operators complain of being entirely avoided by judicious use of the protosulphate of iron.

The advantage of using old ferrous oxalate for producing transparencies was upheld by Mr. Thos. Mayne, he having spent one and three-quarter hours in developing a plate with oxalate eight months old, and on one occasion left the plate in solution the whole night, his experience being that the old developer gave more satisfactory results than that freshly made up. It is intended to hold a lantern exhibition of transparencies made from negatives of the work of the members of this Society, next month.

The meeting closed with a vote of thanks to Mr. Bewley for the able manner in which he treated the subject. The next meeting of the Society is intended to be held on Friday, 10th of March.

Dundee and East of Scotland Photographic Association.

The fifth ordinary meeting of the session was held in Lamb's Hotel on Thursday, February 9th, shortly after the inaugural opening of the Exhibition in the Albert Institute.

There was a large attendance, both of members and visitors. Mr. J. C. Cox (president) occupied the chair during the early portion of the evening, Mr. W. D. Valentine (vice-president) afterwards.

The Hon. Sec. (Mr. C. Johnson) read the minutes of the last meeting, which were approved and confirmed, and the following gentlemen were duly elected members of the Association:—Messrs Frank C. Young, H. F. Fraser, and P. H. Abbot.

The President then said that the Exhibition which had been opened so auspiciously owed its success in a great degree to the energy and unwearied exertions of Mr. Silvester Rollo and Mr. G. D. Valentine; he begged therefore to move a most cordial vote of thanks to those gentlemen, which was carried with applause. The President also proposed a sincere vote of thanks to the jurors for the skill and impartiality displayed in awarding the medals, which was carried unanimously. The President then congratulated the Association generally upon the success of the Exhibition, and urged upon the members to continue their efforts to carry it to a satisfactory issue.

Mr. G. D. Macdougald suggested the desirability of holding a *conversazione* during the time, the matter being ultimately referred to Committee.

Mr. W. M. Ogilvie introduced a new automatic changing-box, which, together with a camera, had been made to his order by Mr. Birnie, the improver. Mr. Birnie, assisted by Mr. John Thomson, showed and lucidly explained the construction. The improvement consisted in bringing the slots of two metal tubes—one working in the box, and one in the dark-slide, and acted upon by studs—into juxtaposition, excluding all light, and allowing the plate to pass through safely and simply. It was suggested that the changing-box and camera be placed on view at the Exhibition, to which Mr. Ogilvie kindly consented. Mr. Birnie was complimented upon his ingenuity and excellent workmanship, and a vote of thanks was passed for the exhibit.

It was resolved that the next Popular Lantern Exhibition be held on Wednesday, the 22nd, when Messrs. Robertson, Ireland, Kerr, Ogilvie, Roger, Ferrier, Donald, &c., promised to contribute slides.

At the next general meeting in March, Mr. J. Robertson (vice-president) will read a paper, the subject to be announced.

A sample packet of gelatine from Frankfort was received and acknowledged with thanks.

Mr. W. D. Valentine offered a cordial welcome to the visitors, and a vote of thanks to the chair brought the meeting to a close.

Manchester Photographic Society.

The usual monthly meeting of the above Society took place on Thursday, February 9th, 1882, at the Manchester Mechanics' Institution, Mr. E. Leader Williams, C.E. (president) in the chair.

The minutes of the previous meeting were read and confirmed. Messrs. John Copeland and W. S. Barlow were duly elected members.

The President made a financial statement respecting the late exhibition of photography.

Mr. John Pollitt, on behalf of Mr. Percy Colles, read a paper entitled, "Opals and Paper printing by Gaslight," (see page 80) and exhibited some very excellent specimens of opal prints, on Swan's opal plates, as also some paper prints; and notwithstanding some little discussion in connection with the above, the unanimous feeling was that the results were exceedingly fine, and reflected great credit on the artist.

Mr. D. McKellen exhibited a very ingenious and portable lamp for changing plates by when away from home. It folded so flat that it did not occupy much more room in the pocket than any ordinary envelope. The same gentleman also exhibited a flap shutter with a spring so arranged that it could be used for very rapid exposures; the flat shutter was made out of ebonite.

Mr. John Schofield sent a dark slide with a deep back arranged to carry a dozen plates. The object of it is to only carry one dark slide, and to carry a light-tight bag in which this slide can be put, and the plates changed from back to front.

Mr. John Dale exhibited one of the earliest collodion pictures taken in Manchester. It was a collodion positive taken by himself about thirty years ago.

The Hon. Secretary (Mr. J. W. Chadwick), on behalf of the Albion Albumenizing Company, of 96, Bath Street, Glasgow, exhibited one of E. T. D. Benzies' lamps, for taking portraits by artificial light. Although it was not convenient fully to demonstrate the working by such a light, the lamp was of such a practical character that a favourable impression was produced.

The Chairman drew attention to some pictures on the wall by Mr. J. W. Chadwick; they were 12 by 10 enlargements from quarter-plate negatives, and he expressed himself surprised to see so much atmospheric effect in them, and doubted if such could have been shown had the picture been taken that size direct.

A hearty vote of thanks was passed to all the gentlemen who had contributed to the interest of the meeting, which was then was adjourned.

Bolton Photographic Society.

The February meeting was held on the 2nd inst., at the Baths, Mr. R. Harwood in the chair.

After the usual formal business had been transacted,

The Chairman introduced Mr. Pumphrey, who, after a few preliminary remarks, said he had been very slow to believe in the gelatine emulsion process, but in the autumn of 1880, a gentleman brought to him some negatives on Swan's plates, to have lantern pictures from them, and at the same time saw the collodion film negatives for mechanical printing, and suggested that such, prepared for the gelatine process, would lighten the labours of the landscape photographer. On finding that such an article as gelatine films was not in the market, he had, in the early part of 1881, introduced those which he had made. A few of these were taken out in May into Switzerland, and he exhibited the resultiug negatives and prints, which were much admired. Mr. Pumphrey then explained the 100-fold filmograph, as already described in the Photographic News Almanac. This was followed by the exhibition of a newer and lighter style of camera to hold 100 films or 12 glass plates $\frac{1}{4}$-size, which weighed $1\frac{3}{4}$ lbs.; Mr. Pumphrey stated that he was manufacturing on the same principle, for larger sizes, one which would fold up, so that a 10 by 8 camera would make a most convenient shaped package for carrying about 11 by 11 by $4\frac{1}{2}$ inches. This he (Mr. Pumphrey) proposed to send to a future meeting.

A picture was then exposed in the 100-fold camera and developed, and the various methods of development, fixing, and drying explained.

Mr. Harwood (chairman) then showed some pictures he had taken on Mr. Pumphrey's plan, aud thought that a great advantage had been gained in dispensing with the paper-backing.

A Member remarked that Mr. Pumphrey used tin dishes—without varnish—for developing in, and inquired if he had tried them for developing gelatino-bromide films with the ferrous oxalate developer.

Mr. Pumphrey replied that he had, and fouud them quite satisfactory.

Mr. Thomas Parkinson then proposed a vote of thanks to Mr. Pumphrey, which was seconded by Mr. T. W. Hawksworth, supported by Mr. George Wharton, and carried with acclamatiou.

Thursday Evenings for Photographers.

The meeting on the 9th inst. was presided over by Mr. Collins

Mr. Marlow (of Birmingham) exhibited an apparatus for taking portraits by artificial light, which consisted of three pans of a pyrotechnic compound, placed on brackets and enclosed in a glass case somewhat resembling a fern case about three feet high, raised on a stand; the brackets were placed one above the other some little distance apart, in order to diffuse the light. The powder was ignited by means of fixed gas jets directed into the pans, and all three pans being instantly fired by a simple turn of the tap. The fumes caused by the burning compound are carried away by a flue, which can be placed into an ordinary chimney, or carried out at any convenient window or skylight.

A number of experimental exposures were made, the results of which will not be known till next meeting.

At the close of the demonstration, a hearty vote of thanks was passed to Mr. Marlow for the trouble and expense he had incurred.

Talk in the Studio.

Cameras permitting Lens to be Lowered below the Centre.—Mr. Geo. Hare, of Calthorpe Street, and Mr. Husbands, of Bristol, desire us to say that their cameras are now usually made with falling fronts.

Mr. Abel Lewis.—The *Manx Sun*, in the account of the visit to Ramsey of H.R.H. the Duke of Edinburgh, says:—"On Wednesday morning Mr. Abel Lewis, Finch Road, received an intimation from his Excellency the Lieut.-Governor that his Royal Highness the Duke of Edinburgh would honour him with a sitting at his studio previous to going on board the *Lively*. Punctually at ten o'clock His Royal Highness arrived, accompanied by his Excellency and Lady Loch and suite, and although early in the day, Mr. Lewis obtained several splendid photographs, in various sizes, of his Royal Highness. The honour was all the more flattering because entirely unsought for and unexpected."

Warnerke's Standard Sensitometer.—Messrs. Marion and Co. have been good enough to forward us one of these ingenious little instruments. We have, so far, only been able to make a rough test with the sensitometer, but its practical value was thereby well established, for it provides a most satisfactory means of arriving at the comparative sensitiveness of gelatine plates with very little trouble.

Alpine Photography.—M. Civiale has published a remarkable work, "Voyage Photographique dans les Alpes," to prepare which he has spent twenty-five years in arduous work. It is a collection of 500 large photographs, comprising forty-one complete panoramas, in which all the most interesting places of the Alps are represented. A volume of letter-press and two large topographic maps accompany the atlas, which itself forms ten enormous volumes *in plano*.—*La Nature*.

To Correspondents.

D. M (Dublin).—1. The super-oxalate is useless for the purpose; you must make use of the neutral salt. If, however, you add carbonate of potash or caustic potash to the solution of acid oxalate until neutrality is arrived at, you will form the required salt. 2. Because it is practicable to work it with a larger aperture.

Sale.—1. Use distilled water. 2. In ordinary cases the process you mention is as satisfactory as any other. 3. By either adding bromide in varying proportions, or by omitting it altogether. 4. They will keep indefinitely under these circumstances. 5. Only in the case of the iron solution. 6. We will forward the address by post if we can obtain it.

J. M.—We have found that equal parts of the bituminous varnish which Messrs. Hopkin and Williams sell under the name "Liquid Jet," and benzole answers well for coating them especially if the film is exposed to light until the bitumen becomes insoluble. It is well to equalise the coating by spinning each plate on a turn-table.

George Lewis.—1. It is the fault of the gelatine, and if you use a harder quality, such as Coignet's "gold label gelatine," there will be no difficulty. 2. Probably you mean "resins." Pure methylated spirit must not be sold without a licence, but when a certain proportion of resinous matter is added, it is called methylated finish, and may be sold freely.

Arbroath.—You only have a copyright in the photograph you have taken, and not in the man's face generally.

Luton.—Undoubtedly you can; but the process of compelling him may prove rather expensive.

F. Cowley.—1. Any dealer in prints or photographs will supply you with it. 2. The easiest way would be to make one yourself. 3. Hardly so good as by some of the older methods; will you let us have particulars as to which article you refer to? 4. A matter of taste; but few artists would approve of its use. 5. See our Year-Book. 6. During June and July many opportunities offer themselves.

A. R. Dresser.—A safe rule is to use no more light than is required for the satisfactory performance of the manipulations; but in order to follow this rule at all times, you will require extra screens, which must be used when the external light is intense, as a medium which is safe, or a dull day is by no means satisfactory when the sun is shining on the outside.

Discoloured Toning Bath.—1. If you take the precaution of thoroughly washing the prints before immersing them in the toning bath, your difficulty will no longer occur. 2. Yes; each one having been tried by ourselves, and found quite satisfactory.

Copyist.—1. Your difficulities are unaccountable, and we can only suggest that you may have washed the film insufficiently, and that you may have failed to use distilled water f r the final rinse or for making the solutions. 2. Cyanide is preferable.

Developer.—In most cases none is required, but we have rarely experienced cases when the addition of more than four drops of a saturated solution to each ounce was advisable.

W. J. D.—It is probably due to the presence of sulphur, a constant constituent of albumen; and we should recommend you to obtain the so-called permanent white, this pigment consisting of sulphate of barium, a salt unaffected by sulphur.

Lenses.—Either would answer well in a fairly good light, but we should prefer No. 2. The exposures might range from one-fourth of a second to four, five, or six seconds.

A. B.—In most cases a strong solution of Judson's aniline violet can be used, provided that reasonable care is taken. The difference in tint is not noticed, and there is no fear of removal during the operation of burnishing.

George P. Walker.—Thanks for your communication, which must stand over till next week.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1225.—*February* 24, 1882.

CONTENTS.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

Introduction.

Before entering on the actual lessons which we are about to give, we should like to explain our object in taking in hand the task.

After Archer brought out his collodion process, photography for the first time became a popular amusement with those who had a leaning to art or science, or both. The scientific interest and novelty attaching to the then comparatively new process, combined with a totally false idea of how easy it would be by means of it to make a "picture," attracted enormous numbers of those who had some spare time on their hands to take up the subject as amateurs. After a time many of these found that their expectations were scarcely fulfilled, and they found, too, to their surprise, that a mere transcript from nature was not necessarily a picture, but that as much art culture, if not as much skill, was required when the tools were the camera and lens, as when they were the pencil and brush. They found, also, that the skill required was greater than they had supposed—that at least a slight knowledge of chemistry and of physics was necessary, or endless troubles would arise.

The realization of these facts greatly thinned the ranks of the amateurs. Another era has, however, now arisen in photography—the era of the dry gelatine process. The skill necessary to produce a photograph has been greatly reduced. The plate is now no longer prepared by bringing into contact immediately before exposure two fickle and uncertain chemicals—the "collodion" and the "bath"; but it may be purchased ready made, will keep, so far as we know, indefinitely, and may be exposed at any time. True, the artistic feeling is as necessary as ever; but that uncommon combination—a mind equally artistic and scientific—is required to a less degree than before, and wider scope is given to the former capacity.

The consequence of this is, that the number of amateurs is now enormously on the increase. The man who has but a few summer days to spare may take up the camera and may work it with profit. There will probably be soon —if there is not now—an army of amateurs as great as there was twenty years ago. The ranks are continually being recruited, and greatly by those who have worked no other process before the gelatine one.

Now we come to the object of our "lessons" How is the dry-plate aspirant, who takes up the gelatine process as his first, to gain the necessary information to enable him to practise the art? If he has a photographic friend—if his friend and he have coincident spare hours, and if his friend has the ability of conveying to others the knowledge which he himself possesses (an ability rarer than is generally supposed)—then the way whereby the would-be photographer is to gain his information is clear.

In very many cases, however, the beginner has no such friend; then, where is he to turn? True, there are several excellent manuals published on the gelatine process, but most are quite unsuited for beginners; they presuppose a general knowledge of photography—at least, of the "wet process." Then there are the directions contained in the boxes of plates which the tyro will purchase. They also are excellent in their way, but they are necessarily laconic—they, as well as the manuals, are addressed to those who already are not unacquainted with photographic processes. They constantly refer to the collodion process as a standard, and they use technical language which is unintelligible to the beginner. Let our general reader try to cast his mind back to the times when he was tediously wading through the beginning of whatever was the first photographic process he ever worked. Can he remember when terms now so familiar to him, such as "detail in the shadows," "density in the high-lights," conveyed no idea to his mind? Perhaps he cannot; but such a time there certainly was for each of us, and now is, for every one who first attempts to solve the mystery of the language in which the modern dry-plate manuals and instructions in the plate-boxes are couched.

We know the case of many who have commenced photography since gelatine became popular, and who, feeling the want which we have attempted to explain—of anything to guide them to a direct knowledge of the working of dry plates—have familiarized themselves with the more difficult wet process for the sole purpose of using it as a stepping-stone to the former. In speaking of the gelatine process as easier than the collodion, it must be understood that we go on the assumption that the dry plates are purchased from the manufacturer, not made by the photographer himself. No beginner should attempt to make his own plates. He will find that he has quite enough to do to learn to work those which are made for him by others. In fact, we consider that the most experienced photographer who is wise will buy his plates, unless he takes an actual scientific interest in the manufacture. Dry plates can now be had so cheaply that he can scarcely expect to save money by making them. This, however, is a digression. To return to our subject. What we intend to do is to give, in future numbers of the Photographic News, a series of lessons in modern dry plates addressed to perfect beginners. We shall use no technical terms, or only such as we have already explained, and shall assume no knowledge of any photographic process.

Our endeavours shall be to give such instructions that those beginners who will follow them carefully may, without any other assistance, after a little practice, be able to turn out, with a fair approach to certainty, technically perfect negatives on plates purchased from any trustworthy maker. We propose to avoid theory altogether, and we do not intend to enter into the question of art. All we propose to do is to teach the A B C of the subject—the purely technical. To the higher branches of photography—the artistic—the aspirant must be guided mostly by his natural gifts; but he will find much to assist him in many advanced books on photography; but we shall give short instructions in printing, so as to enable the student to complete his picture.

Our last lesson will consist of concise instructions for the making of an emulsion and coating of plates, so that the amateur who chooses, for pure love of so doing, to make his own plates, may do so. Here, again, we intend to avoid all theory, nor shall we enter at all deeply into the question of emulsion making, as the subject has been very fully treated in two different manuals published by Messrs. Piper and Carter.

We intend to devote a chapter to the subject of lenses, and to give a few very simple rules whereby the beginner may gain some idea of the exposure which will be required under different circumstances. It is common in manuals for beginners to say that knowledge of the length of exposure can only be gained by experience. This is partly true, but not entirely. *Some* idea may be given of how long the cap should be kept off the lens under certain circumstances, and this, we believe, will greatly assist the beginner. We remember ourselves how, when we commenced the study of photography, with no assistance but what we could get from the hand-books, we sought in vain for at least some faint clue to the length of exposure, and to the factors which regulated it.

The foregoing remarks have been addressed to our usual readers. We need scarcely say that what is to follow will not be; yet we hope that even they may occasionally pick up a scrap of useful information. What we hope far more they will do, however, is to refer those of their friends whom they may know to be struggling through their first attempts at working dry plates, to these lessons.

MR. WARNERKE'S PROPOSED STANDARDS FOR LENSES.

AT the last meeting of the Photographic Society of Great Britain, Mr. Leon Warnerke read a paper in which he suggested that an attempt should be made to persuade lens makers to adopt various uniform standards in manufacturing lenses.

The first and principal standard proposed was one by which to measure the rapidity of lenses. The other had relation to the screws of the flanges.

It may be recollected that about a year ago we made a suggestion with regard to a standard of rapidity. The rapidity of a lens is governed, as doubtless our readers know, by the ratio between the aperture at which the lens works, and its focal length. To establish a standard, all that is necessary is to fix upon some given ratio, and use that as a unit—in other words, to take a lens of a certain rapidity as a standard. The unit which we proposed was $\frac{2f}{1}$, or a hypothetical lens which, as we explained, would always give an image as bright as the object to be photographed.* Mr. Warnerke proposes as his unit $\frac{f}{2}$, because he says such a lens is the rapidest to be found. He states that Dallmeyer's "baby lens" works at that aperture; but, if we are not mistaken, its power is more nearly represented by $\frac{f}{4}$.

It is not for us, however, to discuss at present in these pages the merits of one unit or another, or whether it is advisable to adopt a purely empirical standard. Mr. Warnerke makes the eminently practical suggestion that the matter be referred to a committee of the parent society, and this committee will doubtless give the matter the consideration it deserves, and will weigh accurately the claim of each unit which may be suggested. As a practical matter it is of very little consequence which is adopted. The difficulty will come, not in agreeing upon a standard, but in persuading lens makers to adopt the one agreed upon, for unfortunately the lens makers seem to be a very conservative set. Had they not been so, it would be impossible for one of the best optical firms to have issued a set of lenses nominally of the same pattern, but with their stops cut so totally without system of any kind that not only does no regular ratio exist between their rapidity when using various stops of the same lens, but stops of corresponding numbers in different lenses gave such widely different speeds as in some cases to bear a ratio to each other as high as five to one! Yet Mr. Warnerke states that by comparing seven lenses issued by the same firm, and designated by the same title, he has got the result we describe.

Whatever unit be adopted by the committee, and whether or not they succeed in putting pressure enough on the opticians to move them, all will agree that our most sincere thanks are due to Mr. Warnerke for taking the matter up in the practical manner that he has done. No man we know of could have done so with as much likelihood of bringing it to an issue as Mr. Warnerke.

After showing the desirability of a standard being adopted, Mr. Warnerke went on to consider the various methods in use for finding the equivalent focus of a lens. For comparing rapidity the back one—the one, for some unknown reason, almost always mentioned in the catalogues of the opticians—is of no use, and to find the real focus is not always very easy.

In the "single lens" it may be assumed to be *in* the lens, and this is strictly correct for the middle part of the picture. In the case of a meniscus lens having a stop at some distance in front of it, the equivalent focus of the lens is *in* the lens for the central part of the picture, but considerably *behind* the lens for the edges and corners. This does not, however, need to be taken into practical account.

In all double combinations—except the old orthoscope—the true focus is somewhere between the two combinations, and there are various ways of finding out the exact spot. One is to focus some readily movable object—a foot-rule is the best of all— to draw out the camera, and to move the object until the size of the object and of the image is the same. The distance between the object and the ground glass is then four times the true focal length of the lens. This method is not, however, so easy in practice as in theory. Ordinary cameras seldom open enough to permit of the experiment being performed, except for short focus lenses. Then, again, it will be found that a great deal of adjustment is necessary. A very small alteration in the position of the object makes a great difference in the position of the ground glass. Again, the position in question is the one at which it is most difficult of all to find the exact plane in which the image has its maximum sharpness.

A far better way than the above is the second, which Mr. Warnerke mentioned. It is as follows. Focus a distant object; measure the distance between the ground glass and the diaphragm slit; reverse the lens. Make a similar measurement, and take the mean of the two. This will be the focal length, with sufficient accuracy for all practical purposes. Another method, which was published in the last YEAR-BOOK, is to focus with the camera on a well-lighted landscape, then to measure the distance between any two well-marked objects in the image. One near each end of the ground glass is best. Afterwards remove the glasses from the lens mount, and insert in the diaphragm slit a temporary stop with a very small aperture. An image will be formed upon the ground glass, and the camera can be adjusted till the image is of the same size as it was before the lenses were removed. This can be ascertained by measuring

* Vol. xxv., page 121.

once more between the fixed points. The distance between the ground glass and the temporary diaphragm will be the focal length of the lens. This method is very easy, and is capable of very great accuracy. The degree of accuracy depends entirely upon the smallness of aperture in the temporary diaphragm that it is possible to focus with.

CAPTAIN ABNEY'S FOURTH CANTOR LECTURE.

On Monday evening last the final lecture of the course was delivered, and, so far from there being any sign of diminished interest on the part of the audience, there was, if possible, more determination shown in crowding into the room, and an increased anxiety to catch every word which was said. Our prediction that Abney's series of Cantor Lectures would be the most brilliantly successful course which has yet been delivered appears to have been abundantly fulfilled, and sincere congratulations were abundantly showered on the Captain at the informal social gathering, which took place after the lecture, at Gatti's Café, in Villiers Street; over a hundred gentlemen well known in the photographic world being crowded in and around the "Photographer's Corner" on this occasion.

Mr. Henderson's well-known moonlight picture was projected on the screen at the commencement of the lecture, the transparency not having been to hand at the previous lecture when the picture was referred to. The effect was singularly good, and the picture was thoroughly appreciated by the audience.

The reversal of the image was next brought under consideration, and practical methods by which transparency can be directly obtained from transparency, and negative from negative, were discussed.

The bromo-iodide paper was first used to practically illustrate the subject of the production of reversed images; and we may here call attention to Captain Abney's article in our last number, in which he gives the result of his most recent experience as regards the preparation and use of the paper in question. After having generally exposed a sheet of the paper to the radiations from burning magnesium wire, the lecturer moistened it with a solution of iodide of potassium, and then exposed to a positive image, which was projected on it by the electric lantern. A short exposure served to locally bleach what one may call the potential general darkening which would under ordinary circumstances have arisen from the general exposure to the magnesium light, so that on applying the ferrous citro-oxalate developer a positive picture was the result. It was next explained how this reversal of the developable image requires the presence of an oxidising agent or of free oxygen, and the matter was further illustrated by projecting the spectrum of the electric light on a similar sheet of paper, in order to demonstrate how the violet end of the spectrum is principally instrumental in effecting the reversal, the red end having but little action. The disadvantage of allowing excess of bromide to remain in emulsion is well illustrated by this experiment, as, like the iodide, it favours reversal—undoes, in fact, the work of a considerable proportion of the light, so that the useful effect is merely the difference. Eder's method of subsequently treating gelatino-bromide films with nitrate of silver was explained to be founded on correct theoretical views, and also to possess great practical value.

After this followed a demonstration of the destruction of the potential or developable image by various oxidising agents, a sensitive surface being first exposed to the rays of the phosphorescent Balmain paint, and then locally treated with each of the following agents: bichromate of potash, ferric oxalate, permanganate of potassium, ozone, bromine, and peroxide of hydrogen. On applying the developer reduction took place, except where an oxidising agent had reacted. In relation to this subject, it is a matter of much practical importance to bear in mind that oxalate or citro-oxalate developer which has absorbed oxygen may partly or entirely destroy the latent image on a bromide or bromo-iodide film; hence it becomes of primary necessity to use the solution while fresh.

That bromine is liberated during the action of light on silver bromide there can be no doubt, and in some instances the free halogen may become obvious to the sense of smell, while in the case of thick films the liberated bromine may clear or unfog the underlying portions of the film, giving rise to peculiar phenomena which have been observed from time to time. The probable practical value of a reversal method for reproducing negatives was referred to, and examples were shown on the screen. In this case a gelatine film is treated with a soluble bichromate, exposed, and developed.

Halation or blurring was explained to be principally due to reflection from the back of the plate, and this was well illustrated by projecting a powerful luminous image on a thick glass plate which which was slightly roughened on the surface. It was then easy to observe a surrounding halo which was caused by rays reflected from the back of the plate. The application of red varnish to the back of the plate changed the halo to red, while the application of a bituminous varnish like Brunswick black entirely destroyed it; thus demonstrating the value of the bitumen method which we proposed for backing plates. In the case of free films, or when paper is used, there is but little tendency to either blurring or reversal, for reasons which will now be obvious; but a film on a glass plate may be rendered absolutely secure against reversal by the presence of such a salt as potassium nitrite, the liberated bromine being immediately absorbed by this compound.

The sensitometer of Warnerke was next brought before the notice of the audience, a large model of the circular scale being used in calculating the results; after which Warnerke's actinometer was shown. These instruments are not equally applicable to bromide, iodide, and chloride plates, owing to the circumstance that the phosphorescent sulphide emits a light which is almost monochromatic from a photographic point of view; but the actinometer is of especial value for bromide work, as the rays which excite the phosphorescent sulphide correspond nearly to those which exert the maximum action on a bromide plate. The difficulties of actinometrical work are much increased by the fact that the relative proportion of the different spectral rays varies considerably.

Drop shutters were briefly alluded to, and the method of determining the rapidity of the fall by means of a tuning-fork was shown; a thin branch of a feather being attached to one limb of the fork, and this is allowed to play against a piece of smoked albumenized paper attached to the falling shutter. The number of vibrations made in a second by the fork being known, the diagram traced on the smoked paper affords an easy means of estimating the speed at any part of the fall.

The lecture concluded with a short description of Mr. Galton's system of composite portraiture, several examples of which were shown on the screen.

INTERNATIONAL EXHIBITION OF PHOTOGRAPHY.

We have received from the Photographic Committee of the *Union Centrale des Arts Décoratifs*, at Paris, a copy of a circular letter which has been addressed to all the photographic societies of France and other countries, giving an account of the plan and organization of the proposed International Exhibition. The following is a translation of the circular:—

The approaching Exhibition of the *Union Centrale des Arts Décoratifs* will, according to the prospectus, contain three distinct groups, referring to the decoration of wood, woven fabrics, and paper. The art of photography will be included in all these groups, either as respects its direct application to the decoration of wood, fabrics, and paper, or with regard to the raw materials, tools, and processes proper to it.

In inviting you to take part in this Exhibition, the Committee appointed by the *Union Centrale* to arrange specially the photographic section feels it necessary to explain, as clearly as possible, the limits under which photography can be represented. The principal object of the *Union Centrale* is to extend the application of fine art to decoration, and to promote in every way the cultivation of the beautiful in the useful. Photographers who desire to be represented at the Exhibition should keep this object steadily in view, and should select for their productions those which have really a fine-art character. Among these may be enumerated views of interiors and exteriors remarkable for decorative and architectural effects; representations of the monuments of all countries; landscapes and pictorial views, valuable as fine-art studies; portraits which may be considered works of art from particular effects of lighting, pose, drapery, or costume; reproductions of art objects, of painting, aud sculpture applied to decoration; reproductions of plants, flowers, and still-life subjects to serve as studies; photographs used for illustrating books, and the application of photography to the graphic arts. It will be noticed that ordinary photographic portraits, as well as reproductions of scientific and mechanical subjects, will not find a place in the Exhibition.

From the above account it is clear that all photographs to be exhibited must essentially have a fine art character, since it is from the point of view of their artistic application that they will be estimated, without reference to the process by which they have been obtained. Nevertheless, the nature of the method employed in producing them should in every case be stated. The committee attaches great importance to the complete realisation of the object which the *Union Centrale* has in view.

Up to the present, photographic exhibitions in France, without excluding the artistic element, have been rather exhibitions of scientific and industrial processes than of the general application of photography. Now the present exhibition is to be more especially one of fine art, and we venture to express a hope that photographers who are good enough to respond to our appeal will be able to show once more that photography has made for itself a position in the region of fine art proper, of which it has become one of the most complete and indispensable auxiliaries. Particular attention is requested to the rule by which the exhibition is opened to the photographers of all countries.

Full particulars of the exhibition and forms of applications for space should be addressed to the President of the Committee of Organisation, 20, Rue Louis-le-Grand, Paris. Works and objects for exhibition should be addressed to the Secretary of the *Union Générale des Arts Décoratifs*, Palais des Champs Elysées, from the 15th to the 25th July at latest. All the exhibits must be in order and arranged by the 30th July; nothing will be admitted after that date.

FRENCH CORRESPONDENCE.

Improvement in the Process of Zincography.

Captain Biny's Improvement in the Zincographic Process.—At page 237 of the number of the Photographic News for the 20th May last, my readers will find a description of a copying process for topography, invented by M. de la Noë. For this process it is necessary to start with a positive; but there are many cases when it would be convenient to employ directly a negative, without having the trouble of transforming it into a positive. The following is the ingenious method adopted by Captain Biny for arriving at this result:—A zinc plate, about half-a-millimetre in thickness (or more, if desired) is coated with bitumen, and exposed to the light under a negative plate. After being sufficiently exposed, it is treated with a solution which removes all the bitumen that has not been rendered insoluble by the action of light. We have thus an image formed of lines in bitumen on a zinc plate. This plate is next brushed over with gum, and then rolled up with an inked roller, as if an impression in zinco-lithography was to be taken from it. No impression, however, is taken; the only object of inking the plate is to better protect the lines, and insulate them more perfectly when the plate is coppered. Before coppering, the plate is dipped in water acidulated with 3 per cent. of nitric acid, and it is then well washed in pure water. Next it is placed in a bath of the double cyanide of copper and potassium, and left there for ten to twenty minutes, when copper will be at once deposited on it. It is then washed again in water, dried, and placed in a vessel containing pure benzine; this substance dissolves the fatty ink and the bitumen which form the image, and the lines of the picture will be seen to appear in zinc on a copper ground. After again washing the plate very copiously, it is then immersed in water acidulated with 3 per cent. of nitric acid, in order to produce a slight etching of the surface. In this bath it is left for about a minute, keeping the liquid agitated, and passing a brush along the lines of the zinc so as to clear them. The acid in the bath being highly diluted, it acts very feebly on the copper, but on the zinc its action is much more energetic, so much so as at the end of a minute to produce very marked depressions. When the etching is completed, the plate is again washed, and dried at a gentle heat. A varnish of 6 or 8 per cent. of bitumen dissolved in benzine is then passed over it, and when this is dry, the plate is transferred to a stone or to a sheet of metal which has been coated evenly by means of the roller with a layer of fine lithographic ink. The squeegee is then passed lightly over the back of the zinc plate, and it will be found that all the projections have been blackened by the ink wherever they have come into contact with the stone, while the lines constituting the drawing are free from ink altogether. This black layer which covers the bitumenised surface is intended to form a screen against the action of the light, and when the whole plate is now exposed, only the direct rays act upon the bitumen of the lines which is not protected by the blackened surface. To complete the plate, it is now only necessary to lay it on a level table, with the prepared surface upwards; it is rubbed over with a metal cube, first interposing a piece of blotting paper dipped in spirit of turpentine. In this way the whole surface is cleaned, and the zinc of the ground alone appears, while the lines covered with bitumen have not been touched, and we have a plate for which a large number of impressions may be taken almost equal to copper plate, although produced in a lithographic press. By electro-depositing a layer of copper on a sufficiently thick plate of zinc, and then submitting it to prolonged etching, lines of considerable depth may be obtained; the image may be taken on the copper surface either by means of bitumen, or by means of bichromated gelatine or gum—as in the Gobert process—and we have an engraving in copper, the cost of which has been much reduced owing to the foundation being of zinc.

Leon Vidal.

FURTHER NOTES ON ACTINIUM, AND ON THE EQUIVALENT OF ZINC.

BY DR. T. L. PHIPSON, F.C.S., &c.

Since my last communication on "Actinium" in this Journal, and my letter to the Editor stating that the new metal had been isolated from its ammoniac-chloride solution by means of magnesium, I have had little opportunity of pursuing these researches. The difficulty which I at first experienced of entirely separating all traces of zinc oxide from actinium oxide, by means of caustic soda, still subsists; so that the blowpipe reaction of oxide of actinium with chloride of cobalt is uncertain. The result is a mass of a magnificent dark emerald green, a much finer and darker colour than is seen with purified zinc oxide; but how much of this is due to one or the other metal it is impossible to say at present.

The purified zinc oxide obtained during these experiments, in a crystalline state from the soda solutions, has served me for a new determination of the *equivalent* of zinc, and the results all point very distinctly to the equivalent 32, which is a multiple by a whole number of H, and so according to the law of Prout. The method employed consisted in dissolving this purified zinc oxide in HCL, precipitating with pure carbonate of soda, washing, calcining, and converting a given weight of the oxide thus obtained into sulphide. The details will be published later.

I have also obtained a sulphide of actinium (in an allotropic form?) which is only slightly sensitive to the action of light, whereas the ordinary sulphide darkens very visibly in a few minutes, and is quite black, or slate-coloured, on being exposed for twenty minutes to the sun. This intense darkening cannot be due, as some may suppose, to the presence of silver, mercury, cadmium, arsenic, &c., because the original liquor was, in the first place, submitted to HS for twenty-four hours, and next, because with actinium compounds the action does not occur under a sheet of glass.

In the latter respect actinium is interesting as bringing out a new and curious property of glass. Hitherto the compounds used in photography have been so sensitive that the action of light, even under glass, is more or less instantaneous, and no difference has been observed. But with the ordinary actinium sulphide it requires at least twenty minutes, in good morning sunshine, to produce the dark grey tint, and in such an interval the action under a piece of plate glass about 2 millimetres thick is absolutely *nil*.

Glass has, therefore, the property of arresting a certain amount of *actinic rays*, as other transparent substances are known to arrest rays of *heat*—a property which glass possesses.

The plate glass used in these observations is slightly green on its section; but very similar results are obtained with various other kinds of white glass, even when much thinner than that mentioned. A fact which is still more curious is, that a plate of dark *blue* glass, which is supposed to allow actinic rays to pass easily, *protects* the substance in question from the sun's action just as much as a plate of *white* glass does.—*Chemical News.*

PHOTOGRAPHY BY THE ELECTRIC LIGHT.

BY H. VAN DER WEYDE.*

OVER six years ago, I was challenged, during a foggy November day, by a desperate London photographer, to invent a method of taking good photographs without daylight, or, as he jocularly put it, "Why don't you Americans bottle your daylight, and send it over to us?" and he assured me there were "milllions in it." I don't know whether it was the prospect of "millions," or the great pleasure I have always felt in overcoming difficulties, that induced me to lay aside my palette, and turn my studio into a laboratory. I think my feelings were a little mixed. I had already invented an improved model for building glass-houses, on the principle that every pane of glass visible to the sitter should face him at an exact right angle; and placing the glass in the zig-zag crossing of imaginary diverging lines from the usual sitter's place at each end of the studio, effected this.

In looking at the results of all former attempts at taking portraits by artificial light, kindly shown me by the late Wharton Simpson, who was then editor of the *Photographic News*, and, I think, a member of this Society, although I found some very remarkable, they were all, from an artistic point of view, failures; even the best results suggested a metallic or varnished surface, with glittering high lights, dense shadows, and ghastly reflections.

Instead of attempting to do anything better with artificial light, I first tried to condense the actinic rays of London daylight—when I could catch them—for which purpose I constructed a plano-convex water lens out of two large plates of glass, one bent by heat to the depth of eight inches, which had to be repolished by hand. I believe it was the largest lens ever constructed; it measured six feet and six inches in diameter, and held nine hundred and eighty-seven pounds of filtered water—and the first time I tried to fill it, not having calculated upon the immense weight of this water, although the glass was three-quarters of an-inch thick, it burst over me with a loud explosion, and I was overwhelmed, but, as you perceive, not quite drowned, though the point of one of the flying pieces of heavy jagged spears of glass pierced through my forearm, between the bones, and laid me up for six weeks; but that is only a detail in the life of an inventor. So I set at it again, reconstructed my lens, and finished this experiment with a conviction that I was on the wrong track.

I then began experimenting with artificial light, such as the magnesium and the electric light from a Grove battery. I constructed a copper reflector with a silver lining, and having had enough of the water lens, ordered the largest dioptric lighthouse lens that could be made; the reflector and lens were each over four feet in diameter.

It now occurred to me that the great difficulty to be overcome had not been an inadequate quantity of artificial light, but that the construction of the relative position of its rays is diametrically opposite to that of daylight. In daylight we are flooded with a soft embrace of converging rays giving soft-edged shadows; in artificial light we are struck with the sharp darts of diverging rays from a point, throwing sharp-edged shadows; and in trying reflectors to lessen this hard effect, we only made a war of rays around the sitter, in which the direct rays always have the best of it, and over-expose the high lights before the others have had sufficient time to perform their part. The question was not to discover a better artificial light, but to turn and twist its diverging rays from a point, so as to concentrate them, and, so to speak, make them embrace instead of strike the sitter. This was the supreme difficulty I had to conquer.

In continuing my experiments, I sought to obtain, first, parallel rays from the parabolic reflector, and then to condense them into converging rays by the dioptric lens; and I at this time adopted the most important point in my invention; it was a small saucer, or concavo mirror, about four inches in diameter, placed close to the light, so as to hide it from the sitter, and prevent any direct rays from leaving the reflector. But I found that the silvered interior of my reflector was a mistake. It not only condensed all heat rays, and baked the sitter, but it also polarised the light. So I whitewashed the interior, and from that moment I saw my hopes realised, for I produced at last an artistic portrait with tender crisp high lights, which did not need retouching, and was full of modelling and transparency in the shadows. I tried to do without the condensing lens, but found my light not powerful enough; and it was not until I used a powerful dynamo-machine, worked by an engine, that I could dispense with it.

I now went to my friend who told me there were millions in it; but he, and all other photographers in London whom I approached, were too sceptical to invest; they refused the millions or any share in them, so that I was compelled to exploit the invention myself, and with that view bought the lease of my present house, now nearly five years ago. Its slate roof, ladies and gentlemen, is still intact, and I intend that it shall remain so.

The first instance on record of gas being literally turned into electric light was at my establishment. I had my gas-engine put up, September, 1877, in direct opposition to the advice of the manufacturers of my electric machine. I never use an electric lamp, but, as you see, have invented a much more practical arrangement for my purpose. I simply bring my carbons together by a movement of the hand. The positive 20-millimetre carbon is stuck right through the saucer, and can be pushed in from time to time as it burns. The negative 15-millimetre carbon, fastened in a rod which passes through the back and centre of the reflector, is also adjustable. The saucer and positive carbon being fixed to a flexible brass rod, can be made to approach the other carbon by simply pulling the cord attached, and which passes through the back of the reflector, and over a small drum. I first designed another position for the carbons, but on the same principle, but find this better, as the reflector gets the full benefit of the strongest rays.

If there are any photographers here who wish to know whether they can make use of my invention in this country, my answer is, yes. Two of the richest members of the profession, I understand, make use of it in London, and such being the case, all others are quite welcome to it. The leading photographers on the Continent are not only using my invention, but are good enough to recognise the inventor.

So, gentlemen, I continue to photograph without daylight—in fact, I never took, and never will take, a photograph by daylight.

* A Paper read at a Special Meeting of the Society of Arts.

Notes.

We commence with the spring a series of twelve elementary lessons on dry-plate photography for the benefit of beginners and of those who are not averse to retracing a beaten path to make sure they have not missed an object here and there by the wayside.

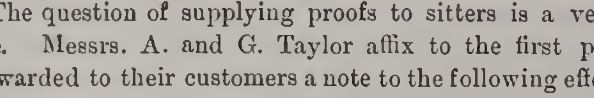
Dr. Eder has completed the first section of his Manual of Photography, treating of the chemical action of light. The frontispiece is a fine photo-engraving of Major Russell.

Mr. Warnerke has all his lenses nickel-plated; moreover, as a precaution against dust and dirt in travelling, he provides each of them with a disc of ebonite, which screws inside the lens tube.

The new bromide of ammonium, just discovered by Roozeboom, is obtained by adding a moderate excess of bromine to a strong aqueous solution of the ordinary bromide. Heat is evolved, and deep red prismatic crystals separate as the solution cools. The new salt is a tribromide, NH_4Br_3. Roozeboom thinks that even a penta-bromide may be formed in some cases, but he has not been successful in isolating this.

The question of supplying proofs to sitters is a vexed one. Messrs. A. and G. Taylor affix to the first print forwarded to their customers a note to the following effect: "This is a rough proof. Please return it promptly in enclosed envelope, as we cannot proceed with portrait until this is received back. Should you desire any modifications made in the general expression, particular lines, &c., these can be readily observed by our artist if you will please note your wishes when returning the proof."

Messrs. Sarony & Co., of Scarboro', have just produced a number of large negatives on bromo-gelatine plates measuring 54 by 40 inches, and 30 by 25 inches. Mr. T. G. Whaite, who prepared the plates and produced the negatives, has devised a simple "coater" for large plates consisting of a V-shaped trough, one side of V being thin wood, the other of double muslin, which is coated to within an eighth of an inch of bottom of V with shellac varnish. Here is a picture of it. The emulsion is sup-



plied to the trough as it is being drawn over the plate, on which it acts as a brush, "painting" the plate, free from air-bells.

Mr. Whaite says, in respect to it: "I find the above coater act admirably, but it must be very light, and easily handled with one hand, hence the necessity of only one side being wood; coating the muslin with shellac prevents too much running out over the plate; in fact, the coater acts much as the stylographic pen, the emulsion is dragged out, as it were, by drawing over the plate.

An attempt of Magatti to effect the synthesis of pyrogallic acid by treating the diazo-derivative of dimethylquinol with water was partially successful; but evidence of the formation of a pyrogallic ether was obtained. It is easy to see how these experiments may ultimately lead to a notable reduction in the price of pyrogallic acid.

Mr. William Kurtz, the well-known New York photographer, has sustained a serious loss by fire. His valuable stock of negatives was injured, and oil paintings to the value of ten thousand dollars destroyed. The fire, curiously enough, was due to the setting fire of a Christmas tree, whose needles and boughs had become dry, and therefore very inflammable.

The *Globe* so seldom talks nonsense, that one is quite vexed at its occasional want of intelligence. Under the "Iniquities of Fashion," it speaks of "the sudden rush of public opinion towards an extravagant belief in sun-pictures," and deplores that photographs should have taken the place of miniature portraits. "We now know full well," says our rosy contemporary, "that a miniature of the old-fashioned sort is far better worth the money than one of the new-fangled substitutes for it."

So that Miss La Creevy will live to see the discomfiture of photographers, after all, and when "the sudden rush of public opinion" is at an end, the weak-kneed, pink and white productions—for nine-tenths of the old-fashioned miniatures had no pretensions to art—will once more be eagerly purchased by all who would keep in mind the features of a friend. And yet we cannot help thinking that if a single little brown photograph of William Shakespeare existed at this moment, it would be more highly prized by those who love the bard than any of the numerous paintings handed down to us.

The photographer's apprentice, it seems, is not always a scientific enthusiast. The other day, the principal of an establishment in a certain town in the north, which it is proverbially unwise to carry coals to, invited his young people to a lecture and demonstration of the carbon process at the local Society's rooms. Not only did the young people respond with alacrity, but, to the joy of their principal, took their places a full hour before the proceedings commenced. "So refreshing to see lads take an interest in their work," was his admiring remark to those around. The admiration, however, only lasted till Saturday afternoon, when the studious young people presented their overtime bill, in which three hours were charged for attendance at lecture.

We hear from Dundee that many sales of pictures have been effected at the Exhibition. All the President's prints were sold the first day, and many of Mr. Nesbitt's and Mr. Diston's. If we could only make our exhibitions a better medium of publishing in this wise, their popularity would be much increased. By the way, we neglected to mention the name of Mr. Gifford in connection with the Dundee Exhibition, a serious omission, since this gentleman's labours have had much to do with the success of the gathering.

On Monday last Captain Abney again called attention to the fact that old oxalate developer was an oxidising agent, and as such, may perfectly destroy the latent image; now, as the double sulphate of iron and ammonia is well known to form a much more stable solution than is the case when simple ferrous sulphate is used, Berghe's proposal to use the double salt in making the oxalate developer is worth noting.

IODIDE IN EMULSIONS—THE THIRD CANTOR LECTURE—PRICE OF HYDROKINONE.

BY CAPT. ABNEY, R.E., F.R.S.

In your issue of last week, you have an interesting article on the reciprocal displacement of the halogens. The first part I read with the greatest pleasure, collecting together as it does the information which is to be found scattered in various chemical literature. The reference to Potilitzin's experiments are particularly welcome, since, as far as I know, they are only to be found in full in a German periodical. The affinities of the halogens for silver are placed in the following order in your third paragraph: chlorine, bromine, iodine, fluorine. This is most certainly the correct order of the affinities, and it must be confessed that I was a little staggered to find in your last paragraph the following words:—"Since chlorine and *iodine* have a stronger affinity than bromine for silver, without doubt the chloride or iodide of silver will first be formed, even although, as is usual in emulsion making, the soluble bromide should be in excess. It is doubtful, however, if the finished emulsion contains any chloride or iodide at all, for a prolonged digestion in presence of excess of soluble bromide would, according to the experiments of Field described above, convert the small amount of chloride of silver into bromide."

Luckily, the experiments of Field, which are to be found in nearly all comprehensive works on chemistry, are quoted. Thus, in the last paragraph on page 73 of the article, the experiments are enumerated in which it is shown that *silver chloride is completely* decomposed by potassium bromide, and that *potassium* (or other) *iodide will completely decompose silver bromide and silver chloride.* In this statement we have a correct view of the case, and I cannot but think that there has been a slip made in the last sentence of the quotation I have given.

If soluble iodide and bromide be present during emulsification the silver iodide *must* be formed, and that if not formed at first, the double decomposition indicated by Field must take place. There can, therefore, be no doubt whatever that the presence of silver iodide *can always be ensured.* I have taken up the cudgels as one of "those who have hitherto dwelt so emphatically upon the superiority of emulsion containing a certain proportion of iodide," and have certainly no reason to doubt the presence of the iodide. In the case of the chloride your article is in every way correct, and my belief is that very few emulsions contain any chloride of silver. The only way to secure this is to use the proportion of soluble iodide and bromide exactly to convert a certain amount of silver nitrate, then to know what amount of chloride is required in the emulsion, to add that amount of silver, and then to emulsify with an excess of soluble chloride. I may state, for the information of your readers, that as rapid an emulsion can be formed this way as by emulsifying with an excess of bromide. Separate emulsification of each haloid, and then addition after washing, is not a bad plan either.

In your notice of my third Cantor lecture, it might be inferred that the ebonite I used for an experiment intended to show the sensitiveness of a particular kind of bromide to the dark rays below the red of the spectrum allowed orange and red rays to traverse it. The ebonite I used was not permeable to any but the dark rays. I am also afraid that my theory regarding the insolubility caused by alkaline pyrogallic acid development was not understood in the sense I meant it. When sulphite of soda is used with pyrogallic acid, and also when ferrous oxalate is used, no insolubility is induced, as I pointed out at the time, whilst I indicated that bromine would render the film insoluble. When pyrogallic acid and ammonia are brought in contact with bromine, a rather complex reaction is produced, which results in the formation of a compound which renders gelatine insoluble. The full details of this, however, I defer.

In one of your notes on page 78, I see that Dr. Vogel says it costs 1s. to develop an 8 by 5 plate with hydrokinone. Surely there is some mistake. Hydrokinone can be obtained now at 6s. an ounce (though I paid 12s. a drachm for it in my first experiments three years ago), and 2½ to 4 grains will develop a plate of the size given by Dr. Vogel. Exclusive of the ammonia used, such a plate should be developed for about ½d. With pyrogallic acid the cost would be about ¼d.

EXPERIENCES IN AUTOTYPE OR CARBON PRINTING.

BY W. GREEN.*

Your Secretary (Mr. Payne) has invited me to come here this evening for the purpose of giving you an account of my experiences in Autotype or Carbon printing, and it is with great pleasure that I respond to his request.

I began working the Autotype process rather more than ten years ago, and made considerable use of it for enlargements, always hoping that some day I should be able to print all my work in permanent pigments. I need not weary you by detailing all the trials and disappointments I met with in my studies and experiments, but only wish to say that I have gradually overcome the difficulties which presented themselves, and now use it entirely for my portrait work, to the mutual satisfaction of my patrons and myself. I have not prepared an elaborate lecture on the subject, but my purpose is to lay before you, as clearly as I can, those points in the working of the process which I think likely to prove interesting.

It would be impossible, in the time at my disposal, to mention all the various applications of the process, so I shall confine myself to that which bears on the production of ordinary work, such as cartes, cabinets, &c., and afterwards I will give you a complete demonstration of its practical working, from the preparation of the tissue, to stripping the finished picture in all the various stages of the process; and Mr. Payne has kindly provided for me such appliances as, I think, will enable me to carry out the work with success.

I do not mean to discuss the comparative merits of Autotype and silver printing, but will content myself by recording my own opinion that from a given negative it is possible to produce a print in pigment quite equal to silver, with the additional advantage of permanence in favour of the former.

We have been constantly told that Autotype is much more simple than silver printing; and yet, if you think of all those who bought licences from Mr. Lambert, and had the great advantage of his personal instruction (for, though I never had the opportunitty of seeing him, he was, I believe, one of the ablest workers we ever had among us), you will find that very few indeed succeeded in working the process, and still fewer were sufficiently successful to induce them to continue its practice. I think the cause of failure in many cases has been that they were led to believe that there were fewer difficulties than really exist—in fact, that the possession of the licence was almost enough to constitute them fully-fledged carbon workers; and when the inevitable difficulties cropped up, they had not gone into the work with the requisite determination to overcome them, but blamed the tissue or transfer paper, and gave up the process as too uncertain to be of value.

In theory the process is simplicity itself, and under favourable conditions it is so in practice; but as Mr. Swan can tell you, gelatine is not always of the same quality, and it requires some considerable experience to enable one to understand its varying conditions.

* Read before the Newcastle-on-Tyne and Northern Counties' Photographic Association.

I do not doubt that there are many present who are perfectly familiar with the theory of the process, but I know it has not been studied by photographers nearly so much as it deserves to be; and therefore I must ask the forbearance of those who are well informed while, for the benefit of the uninitiated, we glance for a short time at its growth in the hands of those men whose united ideas and discoveries have enabled us to achieve such satisfactory results as are now possible, as I think this course will make the practical part more easily understood.

I shall, therefore, briefly, only mention what I consider the chief landmarks, and hope so to condense the information on this point as to avoid over-stepping the bounds of your patience.

The term "Autotype" is used to indicate a particular process, by which an artist's work or picture from nature may be reproduced in monochrome, without the intervention of another hand or eye, the only means used being the natural forces of light or actinism, and chemical affinity; the material employed being any of the permanent pigments which are used by artists in oil, water colour, or crayon.

We find that Ponton, Becquerel, Poitevin, Pouncy, Blair, Fargier, &c., each added their quota to the general stock of knowledge upon this subject; but it was not until Mr. Swan had patented his improvements that pigment printing became commercially practical, and even then the nature of the process was such as to require a specially constructed factory and skilled operators to be successful so that it could not be adopted by photographers in general.

The general principles of the process will be best understood if I give a short account of the various attempts by some of those experimenters whose names I have mentioned to produce pigment pictures.

We must premise that the basis of all Autotype printing is the peculiar action which light has upon the bichromates, particularly those of potassium and ammonium when they are exposed to the actinic rays in contact with organic matter.

Mungo Ponton first observed this action when exposing to light, paper which had been immersed in a solution of bichromate mate of potassium. Becquerel showed that sized paper acted much more rapidly under such action than that which was unsized, hence the association of gelatine or gum with the bichromate in such experiments. Poitevin found that if a pigment were mixed with gelatine and bichromate before exposure to light, it was retained, and could not be removed by washing; he therefore availed himself of this property, and so succeeded in producing the first photograph in pigment. Paper coated with a mixture of albumen or gelatine, bichromate, and pigment was exposed to light under a negative; the albumen or gelatine became insoluble where the light had acted, while that unacted upon, retaining its original solubility, was washed away, leaving the pigment fixed in the insoluble gelatine to constitute the picture.

The process at this stage was, however, suitable only for pictures in line or stipple, as, for reasons which will presently appear, half-tone could not be produced. Sutton made several valuable suggestions for the application of Poitevin's patent, and Pouncy, by using gum-arabic instead of albumen, and a porous paper into which he brushed the sensitive pigment compound, produced the first carbon prints in half-tone.

It was the Abbe de Laborde in France, and Barnet and Blair in England, who explained why Poitevin and Pouncy had obtained such imperfect results. They showed that the sensitive compound became insoluble only on a surface exposed to light, and that the part partially acted upon, and constituting the half-tones of the picture, rested upon a substratum of the compound entirely unacted upon, and therefore soluble, and that to retain these half-tones this soluble substratum must be removed from the opposite side.

To effect this, they spread the sensitive compound on glass, or transparent paper, and printed the pictures through the transparent material; after exposure they washed away the soluble compound, leaving the picture attached to the glass or paper.

Fargier next spread the gelatine and pigment on glass, and covered the surface after exposure with collodion; the plate supporting it was then immersed in warm water; when the soluble gelatine was removed, the collodion film floated and acted as a support for the picture, which had then to be caught on a piece of paper.

Mr. Swan greatly improved on this process; he spread the compound on glass previously coated with collodion stripped off the compound film, which he called a "tissue." This he exposed under a negative, and afterwards mounted it upon a support before development, thus avoiding the practical difficulties of Fargier. He showed that the support might be either permanent or temporary: in the former case, the exposed tissue was at once fixed to the paper or card by means of albumen rendered insoluble by alcohol or heat. When the support was intended to be temporary, a thin coating of india-rubber solution was applied to the surface of the exposed tissue, and also to a piece of suitable paper; the two were then brought into contact under heavy pressure. The necessity for having a temporary support to carry the picture during development is very easily explained.

We have now reached a stage in the process where we have a picture by each method developed, but, unfortunately, they are inverted, unless before printing we adopt some means of reversing the negative. Mr. Swan saw that to do this with all negatives, particularly those which were valuable, would be both troublesome and dangerous, and that unless some means could be found to reverse the carbon and gelatine film after development, the process could be of no practical value. He therefore paid little attention to single transfer, but devoted his well-known ability and perseverance to perfecting the second method, since known as double transfer. He corrected the picture which had been developed on the temporary support, by laying it down on a piece of paper intended for its final resting place, which was first coated with gelatine, and treated with alum to render it partially insoluble. When dry, the back of the paper which had formed the temporary support was moistened with benzine, and this dissolved the layer of india-rubber before mentioned, and allowed the picture to be laid bare firmly fixed to the paper. Before completing his patent, Mr. Swan discovered the advantage of spreading the pigmented gelatine in a layer of defined thickness on paper, and modified the composition of the sensitive compound by the addition of sugar, thus giving us the tissue very much in its present condition, except that the bichromate salt is not generally mixed with the pigment and gelatine, but is applied to the tissue in the form of a bath, to render it sensitive as required.

It will be sufficient for our purpose this evening if we now pass on to the double transfer process patented by Mr. J. R. Johnson, of the Autotype Company in 1869, which made Autotype printing thoroughly practicable, and places it now within the reach of those photographers who wish to employ it in place of the silver process, at a comparatively small outlay.

Mr. Johnson found that by laying the exposed tissue down on the temporary support, and thoroughly scraping the air from between with a squeegee, it would adhere by atmospheric pressure alone during development, and that it was only necessary to smear the surface of the support with some fatty substance, which would prevent adhesion, to make the final transfer easy and certain.

Mr. Sawyer has now given us a flexible support which can be used instead of the rigid plate. It is most useful for ordinary printing, and by its use many applications of Autotype are easy, which before were quite impossible.

Correspondence.

ELECTRIC LIGHT PHOTOGRAPHS.

Sir,—I have much pleasure in complying with your request, and send the following particulars relative to the two photographs taken by the electric light. As I have not heard of anything similar being attempted before, I have no doubt they will be interesting to any brother photographers who may choose to call and inspect them, as proving the great power and advantage conferred on photography by the electric light. The subject is a ball in the Victoria Hall, Saltaire, Yorks, under the patronage and presence of the Earl and Countess of Bective, with a distinguished party. As the Countess of Bective has lately taken a great interest in the woollen industries of England (which materially affect this district), the event in question proved to be the prominent one of the season. When invited to try, I had very serious doubts as to whether anything satisfactory could be got, but eventually decided to do so, there being nothing to lose, whilst there was a certainty of gain, if only of experience. Having prepared myself with the most rapid plates I could obtain from Messrs. Wratten and Wainwright, I made some experiments in exposure at a lecture on electricity given by Professor Barrett, of Dublin, the demonstrations being under the control of Mr. Louis Crossley, of Halifax, an able and ardent worker in electricity. The lights at this lecture were not so powerful or steady as those used at the ball, although the same lamps were used, but this may have arisen from not being in perfect working order, owing to the short time at command. The results, however, of my attempts were so satisfactory that I decided at all events to take the ball party. I found that with an exposure of thirty-five seconds a fair negative, of good printing quality, was got, of a rather difficult assembly. The result you have in one of the prints.

At the ball it was a different affair, and it was no easy task to induce an assembly of that kind to remain stationary even for so short a time, and it was only by good fortune and favour that I got a trial. The lights used were on the Brush system (six in number), and each of about 2,000-candle power. The motive power was supplied from the works adjoining. In addition to this, I had all the gas light obtainable with a view of softening the shadows. The illumination from the lamps was very brilliant, there was not the least glare, and, so far as I could observe, no person present complained of the light being trying to the eyes. The electrical demonstration, in fact, was a great success, and gave universal satisfaction. Two exposures were made, twenty-five and thirty seconds, and whilst both are satisfactory, the longest exposed is the best negative. The lens was Ross's rapid symmetrical with open aperture. I should have liked to use as top, but dared not, on account of the lengthened exposure it would entail. The lens was very carefully shaded from the lamps, but, in spite of my care, you will observe a small halo at the bottom of one of the photographs, which I attribute to reflection of one of the lamps through the lens. The plates were developed by the formula sent with them, and came up admirably, without any trouble or forcing whatever.

I also enclose a cabinet photograph of the orchestra, taken by the same light, exposure twenty-five seconds. If they should prove of any interest or use to my co-workers, they will have served the purpose intended in sending them.—I am, sir, yours truly, ALBERT SACHS.

CHLORIDE IN EMULSIONS.

SIR,—In your leading article upon the "Reciprocal Displacement of the Halogens," you say that in the case of small quantities of iodide and chloride being employed when emulsifying in gelatine with bromide in excess, it is doubtful if the finished emulsion contains any chloride or iodide at all. I myself think that there is no doubt about the iodide, as the colour of the film, its long time in fixing, &c., clearly show. But as regards the chloride, it is a different matter. Captain Abney has said (I am told) that in the presence of ammonia the chloride, or at least part of it, will be converted. Whether this be so or not, there are some who, in making their emulsions without ammonia, weigh up their salts in a rather loose manner, and fondly believe they are working a B. I. C. emulsion. I have seen formulæ given which, if made with the same materials I get—not the pure, but ordinary commercial salts from well known houses—would certainly not contain any chloride. I have tested mine, and find, as others have, the working equivalents considerably different from the theoretical. I have made, perhaps, my best B. I. C. emulsion after the following manner. Weigh up—

Ammonium bromide	 120	grains
,, iodide	 8	,,
,, chloride	 20	,,
Potassium bichromate	... 3 or 4	,,
Pure carbolic acid (crystal)	... 15	,,
Hard gelatine	 120	,,
Nelson's No. 1	 120	,,
Silver nitrate	 200	,,
60-grain solution silver nitrate	...	*quant. suff.*

Dissolve the ammonium bromide in 4 oz. water in a bottle, and add the carbolic acid. Soak the hard gelatine in this several hours, add the Nelson's No. 1, and shake it about; when this has swollen, raise the temperature to 130° or 140°, and keep it at this for two or three hours at least. I have kept gelatine at this temperature for over eight hours without any ill effect. I attach some importance to this, as the gelatine, probably from very mixed substances and sources, and of different solubility, is by this means broken up and equalized. I now always use the whole of the gelatine from the first. The silver bromide is formed finer with less care; there are no coarse particles to filter out; and extreme rapidity can be got in a comparatively short time, for any temperature may be used without fear if this quantity of carbolic acid be used.

Reduce the temperature to 100°, and—of course in the dark room—drop in the bichromate of potash, then, little by little at first, the silver nitrate crystals, shaking well all the time. When about half the silver is in and dissolved, drop in the iodide, and shake two or three minutes; the rest of the silver may now be added and shaken till dissolved. Now carefully add a little of the 60-grain silver solution, and after well shaking put a drop on glass and examine the colour by white light; if not coloured, add more silver solution. So soon as it shows the least pink, drop in the ammonium chloride and two drachms of the silver solution; this, with the little free silver already in the emulsion, converts about 5 grains of the chloride, leaving chloride in excess. If you have tested your salts, probably a nearer approach to the weight of silver required may be weighed out at first; the above, however, gives a good margin. There may be nothing new in this, but by this method you know you have got your silver chloride in the finished emulsion.

Touching hyposulphite in the developer, many, it seems, have failed to produce any effect, or at least any beneficial effect, from the use of a small quantity of hyposulphite in the developer, as recommended by Captain Abney; those who use the hyposulphite from the fixing bath being most pleased with it. The kind of plate used has, perhaps, more effect upon the result than some suppose. I should like to point out that I believe the additional detail developed is not due to the hyposulphite *per se*, but, in the case of the bath solution, to the silver it contains being deposited on the film (free silver in the developer, in fact), and in the case of clean hyposulphite—if of any benefit—to its solvent action upon the silver bromide, which is then reduced. I see no reason why, if the developer be well restrained, it should not be used to some extent with pyrogallic. I think it probable that the use of silver in the developer may become a great power in the hands of the photographer. No doubt we have not yet found the best way to use it.—Yours truly, ALFRED J. BROWN.

THE DUNDEE EXHIBITION.

SIR,—A correspondent in your last asks (with apologies for his impertinence for which there was some need) Mr. Robinson and Mr. Jennings what they think of the awards at the Dundee Exhibition, and if they intend to accept the low-class medals awarded to them. Without recognizing your correspondent's right to put such a question in your pages, I may reply that I shall certainly accept the bronze medal, and shall always value it as the greatest curiosity in my collection, of which it will be the sixty-first. The other sixty medals were in every case the highest that my pictures competed for. To receive the lowest award at an obscure exhibition like that at Dundee, for the picture that received the gold medal when competing with all nations at Paris, is an amusing novelty, and shows clearly that there are Scotchmen who have some sense of humour. H. P. ROBINSON.

SIR,—I shall be glad if you can inform me if the judges were empowered to award extra prizes where they considered there was sufficient merit for subjects not specially mentioned in the prize list. I, for one, paid my entrance money on those conditions, and if my photographs have not been judged, I should think the entrance money has been very wrongly obtained.

I notice in the judges' report no mention is made of animal photography, which looks as though they were never judged; but if they have been judged, and the judges considered there was no merit, of course their decision is final. But it is certainly contrary to the decisions of many of the best judges both at home and abroad, whose names I could give if required, also contrary to your own report, which says: "Mr. T. J. Dixon and Mr. Hedges show their familiar but no less wonderful animal studies. Alas! the Dundee programme did not include a medal for photographs of animal life." If this report is correct, I need not say more. David Hedges.

[The Official Programme made no mention of animal studies.—Ed. P.N.]

PORTRAITS IN PAIRS.

Dear Sir,—If you think the following worth inserting, I shall be glad for you to do so, for the benefit of my brother photographers.

It often happens one has in the course of sitters a maternal couple, and they wish to be taken separately, but facing each other. This, when one has only a north light, entails a great deal of unnecessary trouble—*i.e.*, moving backgrounds, accessories, &c.; also camera end for end. Now, Mr. Editor, if your readers will just try my dodge, they will never run away from it.

Now for it, then! Mrs. A. is taken first in the ordinary way. Very good. Mr. A. wishes to face his beloved. Just sit him down in the same chair—in the same position, if you like; focus, &c. Retire to the dark room, put your plate (dry, of course) into the slide; but be sure and put it in the reverse way—*i.e.*, film side up, and back toward the lens. Allow just the thickness of the glass plate in focussing; expose, develop, and you will have as good a picture as the most fastidious can desire.

I enclose you two prints from same negative; one-half of the plate was exposed in the ordinary way; the slide is then taken into the dark room. The plate was turned over and exposed again, with the result shown.—Faithfully yours, Geo. P. Walker.

[This method of obtaining reversed negatives is already in use; but Mr. Walker takes a new view of an old subject.—Ed. P.N.]

DRAINING EMULSION.

Sir,—In the Photographic News for February 17th, 1882, Mr. J. W. Leigh advises Mr. Birrell to drain emulsion by tying it up in a bag and giving it a whirl with the hand. That is very good for a small quantity; but I advise dry-plate makers to use a small centrifugal machine, driven by steam power, or with hand, for the same purpose; a rapid whirl of a quarter of an hour would leave the emulsion almost dry. M. Duggon,

Member of the Royal Society of Photography, of Brussels.

Proceedings of Societies.

Bristol and West of England Amateur Photographic Association.

The monthly meeting was held on Wednesday, 1st inst., Mr. T. Davey in the chair. Preliminaries having been gone through,

The Honorary Secretary handed round samples of gelatine sent by Mr. Heinrichs. He (Mr. H. A. H. Daniel) also had much pleasure in presenting to the Association, Library copies of Ponting's "Photographic Difficulties," and Hunt's "Photography," neither of them recent publications, but both containing much valuable information.

The Chairman then called upon Mr. H. A. H. Daniel, who, in introducing the subject of "Lantern Apparatus," stated that he was not going to read a set paper, but to give a few notes, with experiments. He commenced by describing the mode of fixing Chadwick's gasometer and generator, and everything being ready, a charge in the form of a black cake was put in the retort; the speaker explained that the "cakes" were made by mixing together four parts of chlorate of potash and one part of black oxide of manganese with a few drops of gum, and just sufficient water to cover the mixture to mould easily; he then directed attention to the gasometer, the top of which was rising, the gas being produced very rapidly; he explained the perfectly safe style of the construction of the retort, and the great ease with which a constant supply of oxygen could be kept up during an exhibition, three charges per hour sufficing for a single lantern, the time to recharge the retort being intimated by the top of the gasometer being connected with a small egg-boiler with bell, so that on its descending to a certain point, the bell would ring. Mr. Daniel next exhibited a special kind of carrier he had made, which had a travelling endless leather band in the bottom groove, passing round a roller at each end; this alone, he said, was not new, but the great drawback to the commercially constructed ones was that the band expanded when acted upon by the heat, and would not move the slides along; he had improved upon this, and the one exhibited had a moving roller for increasing the tension, so that it could be always in an efficient state, and the tension taken off when it was not in use. This carrier was also provided with a rolling curtain which was worked by springs, and which, after the assembling of an audience, would roll up as a theatre curtain, and reveal either a crimson proscenium or a landscape, &c.; this was then illustrated, the effect being exceedingly good. The carrier also was registering, that is to say, had various points indicating the correct position of either a Woodbury, Ferrier, or York slide. Mr. Daniel then exhibited a few slides of different makes to show their different qualities, to illustrate silver and collodion slides, some of those made by the Chairman, Rev. H. B. Hare, and commercially by Mr. Harvey Barton, by the carbon process, some by Mr. E. Brightman, also some by the beautiful processes of Mr. Woodbury, and M. Ferrier, of Paris. Mr. Daniel said that oxygen was purified by passing through the water luting of the gasometer.

Mr. E. Brightman stated that he had found mixing a solution of hyposulphite of soda with the purifying water rendered the operation very perfect. He also stated that he had found a solution of cyanide of potassium rubbed over the film remove the stains of silver from a negative which had been printed from without collodionising or varnishing.

Mr. Daniel thought that a yellow colour, such as that in a transparency exhibited, was produced in a negative intensified with mercury, if, prior to so doing, the hyposulphite had not been properly eliminated.

After some further discussion, votes of thanks to Mr. Daniel for his experiments and explanations, and to the Chairman for presiding, closed the proceedings.

The ordinary monthly meeting for January was held on Wednesday, the 18th, Mr. T. Davey in the chair.

The minutes of the previous meeting were confirmed, and it having been arranged that the evening should be devoted to lantern matters, the various lanterns were erected, and the slides of different members exhibited.

The Chairman exhibited a small collection of slides from negatives taken during a run through North Wales;

Mr. G. F. Powell a few silver and collodion slides of scenery around Bath; and

Mr. H. A. H. Daniel some by the same process representing 'bits" of the beautiful scenery on the river Froom, near Bristol.

Mr. E. Brightman recommended the carbon process as most suitable for making slides, and producing a very pleasing colour, more like the Woodbury slides, if a warm tint of tissue were used.

Mr. Daniel endorsed the previous speaker's views; but considered many found a difficulty in so doing, nearly all their negatives being of too large a size for printing slides direct. He therefore recommended the course he had adopted, viz., that of buying a quarter-plate pocket camera for specially taking lantern slide negatives; if used with a walking-stick stand, and taken out always when taking a drive or a long walk, it was astonishing how quickly negatives for printing most pleasing slides from would accumulate.

The Chairman stated that in a new room he was fitting up, he had the window arranged for fitting negatives in light-tight, with a long adjustable stage for a dark slide to slide in, so that he could either make lantern slides, or enlarge, the dark-room forming for the time being a camera.

After some further discussion, and a vote of thanks to the Chairman, the meeting adjourned.

Newcastle-on-Tyne and Northern Counties Photographic Association.

The ordinary monthly meeting was held in the College of Physical Science, Newcastle, on Tuesday, Feb. 14th, 1882, at 7.30 p.m., Mr James Downey in the chair. On the minutes of the last meeting being read, Mr. Carver remarked that there appeared to have been an oversight at the last meeting, and he begged to move "that the best thanks of the members be given to the past council for their services during the year," which was seconded by Mr. Robinson, and carried unanimously. Messrs Kimmish, Readhead, H. Sawyer, and L. Sawyer were elected members.

The Secretary read the following letter which he had just received.

Dear Mr. Payne,—Will you have the kindness to express to the meeting the extreme regret I feel at being prevented, by a slight indisposition, from being present to-night? There are several strong reasons why I wished to be present, and would, if it had been possible, done myself that pleasure. I wished to have the opportunity of thanking the members of the Society for the honour they have done me in again electing me President, and I beg you to say so. But the greatest cause of my regret at my enforced absence is that I shall miss the pleasure of witnessing Mr. Green's demonstration of the working of the carbon process. I need not say how much interest I feel in the progress of that process, nor how great a pleasure it would have been to have witnessed Mr. Green's manipulations.—Very truly yours, J. W. Swan.

Mr. W. Green then read a paper on "Experiences in Autotype or Carbon Printing" (see page 91), and afterwards proceeded to give a practical demonstration of the carbon process, both by single and double transfer, commencing with the sensitizing of the tissue, and, going through the details of the process, finally presenting the prints to the audience. Mr. Green was asked many questions, and kindly gave every explanation. The chief items were: That he preferred to use powdered French chalk to the face of the opal plate, instead of the waxing solution. He never found the slightest difficulty when using the French chalk, but frequently had when using the waxing solution. He preferred to pour water over the surface of the carbon tissue, instead of immersing it in the water, as generally recommended. It was most important to allow each piece of the tissue to remain in the sensitizing solution for exactly the same length of time. He generally used a three-minute sand-glass for this purpose.

The Chairman, in moving a vote of thanks to Mr. Green, said the members owed a double debt of gratitude to Mr. Green for the very great care and trouble he had taken, and the very lucid manner in which he had given the demonstration. He spoke of the value of the permanency of carbon prints, and said that every one present must have learned something.

Mr. Mendelssohn seconded the vote of thanks, which was carried with hearty acclamation.

Mr. Green acknowledged the vote in kind terms, and the meeting concluded.

Glasgow Photographic Association.

A meeting of this Association was held in the Religious Institution Rooms on Thursday evening, 16th inst., Mr. John Parker (president) in the chair.

The minutes of last meeting were read and approved of.

The President reported that a dozen members of the Association visited the observatory, and were received with much kindness by Professor Grant, and afterwards shown the photographic and other arrangements of that important institution.

Amongst the questions in the box when opened were:—1. "Is there any varnish that may be used for gelatine plates without collodion, so that the silver will not permeate through?"

Mr. Jas. Annan said that for some time he had been using a varnish composed of three pints collodion and one pint sandarac varnish applied cold, and subsequently warmed.

Mr. Bell said that he thought this was a most important question, for he had been in the habit of collodionizing his plates previous to varnishing; but that after being printed from, minute yellow-coloured spots often made their appearance; he therefore concluded that the joint application of collodion and varnish was not a preventative, and had therefore abandoned the collodion.

Mr. Annan replied that he used his compound varnish to prevent the occurrence of these specks, and found it to answer.

Mr. Gilfillan thought that the specks were due to the hyposulphite used in fixing the negative not being completely eliminated through air-bubbles persistently attaching themselves to the plate.

Mr. Leith said, in his opinion the specks might be due to damp; he had observed the same thing occur in a plate which had got wet through exposure to a shower during the process of printing.

Mr. Dodd suggested that the members who had given their experience should bring plates illustrating the complaint to a future meeting.

2. "Can silver stains on gelatine plates be removed?" The bearing of this on the former question was pointed out by Mr. Dodd, who said the stains could be removed by applying a solution of iodine and potassium iodide, and subsequently a solution of potassium cyanide.

Mr. Urie recommended a solution of citric acid, then hyposulphite.

3. "Is it not possible to organize an Exhibition in Glasgow, similar to that now being held in Dundee?"

Mr. Dodd said that, on the authority of Dr. Nicol, the first essential requisite would be a guarantee fund of £300.

Mr. Thompson moved that a committee be formed to enquire into the matter, and to gain all information possible.

Mr. Mactear, in seconding the motion, recommended that the Committee visit the Dundee Exhibition with that end in view.

Messrs. Goodall and Steven then proceeded to give a demonstration of enlarging on gelatino-bromide-of-silver paper. Mr. Goodall, at the outset, remarked that the paper they were in the habit of making and using required only an exposure of fifteen seconds, the light being a gas jet; but, taking into consideration the adverse circumstances under which they would labour at that time, he had deemed it advisable on that occasion to employ a much slower paper, and mentioned that in his demonstration he would expose for four minutes. The developer employed consisted of potassium oxalate, saturated solution, 6 ounces, ferrous sulphate saturated solution, 1 ounce, and ammonium bromide, 60 grains in 1 ounce of water. Messrs. Steven and Goodall were eminently successful in demonstrating their process of enlarging up to 18 by 20.

Mr. Thompson then read a paper on "The Romance and Reality in Photography" (received too late for insertion this week), and was listened to with much attention.

Mr. James McGhie read some extracts from a letter which he had received from Mr. Moryson, anent his demonstration as follows:—"On the Chairman asking questions, I find that there was a doubt whether the process of intensification would do for an over-exposed plate. If the plate has any gradation of tone in it, however slight, by a judicious use of No. 2 solution the plate can be made to produce pictures equal to a properly-timed plate. Use No. 1 until proper density, No. 2 not more than five seconds; afterwards a plunge for about three minutes in hyposulphite (saturated solution, 1 ounce; water, 1 ounce). No. 2 acts on the high-lights, hyposulphite for clearing the shadows.

A dozen beautiful photographs, presented by Mr. James Annan, were then balloted for amongst the members present, after which the meeting closed with votes of thanks to Messrs. Goodall and Steven for their instructive demonstration, to Mr. Thompson, and the Chairman.

Thursday Evenings for Photographers.

Mr. W. E. Debenham occupied the chair at the meeting held on the 16th inst.

The negatives, and also prints from them, taken by Mr. Darlow's light at the last meeting were exhibited, an interesting discussion taking place. The results of the various experimental exposures seemed to show that very little, if any, advantage is gained by the use of three separate points of light.

Mr. Turnbull, in answer to a question from the box, said that he had suffered very much through the use of the alkaline developer, but could not say whether it was the pyrogallic or bromide which was injurious. He was recovering slowly from an attack which commenced about four years ago by a small irritating spot on the back of the hand; a number of small pustules next appeared, which spread rapidly up the arms to the shoulders; they next appeared in his legs, especially under the bend of the knee.

He had consulted several physicians, among others one in Edinburgh, who made skin diseases his special practice. He knew many others who suffered equally with himself. He had not, since the appearance of the disease, touched the alkaline developer.

Mr. Henderson said that during the late summer he had suffered in much the same manner as described by Mr. Turnbull, and had consulted the same physician, and, in his case, the treatment was successful.

Mr. Coles said there was a skin-disease caused by the use of bromide, called "bromide spots."

Mr. Turnbull thought that some constitutions, as with bichromate of potash, were more susceptible to the poisoning than others.

Mr. Haddon exhibited a silver print, the hyposulphite from which had been eliminated by a very short washing in a few changes of a weak solution of eau de Javelle. This print, with others treated in the same way, and others washed in the ordinary manner, had been sent to a warm, moist climate, the result being that, while there was no perceptible change in those treated with eau de Javelle, the others rapidly faded.

Talk in the Studio.

South London Photographic Society.—The next monthly meeting of this Society will be held on Thursday next, March 2nd, at 8 p.m., in the rooms of the Society of Arts, Adelphi. Mr. E. Dunmore will read a paper on "Common Objects of the Studio," and the judges' awards for last year's artistic competition be announced.

Society of Arts.—We would remind our readers that the Exhibition of Photographic Appliances will close after Saturday next, the 26th.

Photographs of the Ultra-Violet Spectra of Elementary Bodies.—Professor Hartley commences an interesting paper on this subject in the current number of the Journal of the Chemical Society, and when the remaining part is published, we shall lay all essential points before our readers.

Artificial Light for Photography.—A special meeting held on Thursday evening at the rooms of the Society of Arts was well attended, and those present evidently appreciated the excellent points of Mr. Van der Weyde's method of applying the electric light to portraiture. About a dozen plates were exposed, the times ranging from three to six seconds. In every case sufficient, or perhaps more than sufficient, exposure had been given, Mr. Van der Weyde expressing his conviction that two seconds would have been enough in every case. The paper read will be found on page 89. Other artificial lights were also shown and tried, among which may be mentioned Sugg's 200-candle burner; several magnesium lamps, Swan's biaxial electric lamp, and Mr. Bottone's new arrangement as described in our Year-Book; and an interesting discussion took place, in which Mr. Foxlee, Mr. Cobb, Mr. Archer Clarke, Mr. Trueman Wood, and others took part. Most of the above-mentioned gentlemen exposed plates. With reference to the early use of a magneto-electric machine driven by a gas-engine for photographic purposes, Mr. Woodbury reminds us that he had such an arrangement in use for printing relief no less than ten years prior to the date mentioned in Mr. Van der Weyde's paper.

Stealing Negatives.—Joseph Ward, a photographic printer, was charged with stealing nine negative plates, valued at £2, the property of Mr. W. J. Byrne, his employer. Mr. Lay, in opening the case, said Mr. Byrne extremely regretted being compelled to take these proceedings. The prisoner entered his service five years ago, and the prosecutor had reposed the greatest trust in him, but from circumstances which came to his knowledge, his suspicions were aroused, and he discovered that the prisoner, who was receiving £150 per annum, had been systematically robbing him for some time past, and making use of his property to carry on an extensive business on his own account. The prisoner pleaded guilty to taking the negatives, but asserted that the prosecutor allowed him to take the photographs as specimens. A priest from St. Mary Magdalene's, Mortlake, said he had known the prisoner intimately for the past five years, and he had always borne an excellent character. The magistrates sentenced him to three months' imprisonment with hard labour.

Sudden Death of Mr. Stringfellow in a Railway Train.—The *Derbyshire Courier* reports that, on the arrival of the 4.42 train from Sheffield, on the afternoon of Friday last, at Chesterfield Station, it was found that one of the passengers was dead. It appears that when the train was nearing Dronfield, a person in one of the carriages seemed to be taken suddenly ill, and the communication cord was pulled. The train drew up at Dronfield Station, and the passenger died two minutes after the train was brought to a standstill. The body, which was found to be that of Mr. Stringfellow, photographer, of Sheffield, and late of Vicar Lane, Chesterfield, was brought forward to Chesterfield, and conveyed to the Railway Hotel, to await an inquest.

Indignant Mother: "Surely you don't mean this for a likeness of my son? Why, the boy looks like an idiot."—Photographer: "I'm very sorry, but I can't help that, ma'am."—*Every Week*.

To Correspondents.

⁎ Erratum.—Some Calotype prints, exhibited at Dundee by Mrs. Hill and others, were erroneously called collotypes in our last issue.

J. C. H. Balmain.—Algæine paper should be obtainable from any house having relations with Germany. The upper picture is cemented to the glass by the encaustic paste, the lower print is not.

More Light.—The proportion of glass to slates which you propose will be found to answer very well, but it would probably be an advantage to pitch the roof a little higher than it is represented in your diagram.

K. Phillips.—See an article on page 14 of the present volume.

J. B. B.—The whitest parts.

Ghost.—So many causes contribute to such a result, that it would be useless to suggest one or two without knowing how you work. You had better call on one of the makers, and ask him to go through the process with you.

H. F. Gros.—1. The ashes of unfixed prints usually contain not less than half their weight of silver, while in the case of fixed prints the amount of metal is so small as to be unimportant. 2. The crude silver chloride, prepared as you describe, should yield about two-thirds of its weight of silver.

Tiger.—One part of Nelson's opaque gelatine should be dissolved by heat in five parts of water, after which one-third of a part of powdered bichromate of potassium is stirred in. Use like ordinary glue, and it will become insoluble in the course of a week or so, even if light should be excluded.

F. O. D.—No alteration is necessary in this case.

Pyro.—We should advise you to carefully rinse your hands in warm water immediately after.

R. H. McKenzie.—1. Not sufficiently to be of importance. 2. It depends entirely on the tint which is required. 3. Yes, if you wish to obtain uniform results. 4. It often deposits as a dark-coloured precipitate. 5. Add all the materials, and then allow the solution to settle; or you may filter it. 6. Ordinary whiting answers well.

Experimenter.—Try Butler and McCullock, of Covent Garden Market; and Potter, of Farringdon Street.

W. H. Sedgwick.—Perhaps you are not sufficiently careful as regards the light in the dark room; also take care that no extraneous light enters the camera.

B. B.—Shake up some pieces of wet paper in the bottle until the deposit is removed, then dry and burn the paper.

J. Berryman.—Next week.

Light.—1. It is quite possible that your views as to the distance required between the glasses may be more correct than those of the maker of the instrument; but you must remember that he stands rather high as an optician. 2. Probably a clumsy imitation.

M. J. E.—Most ferric salts are reduced to the ferrous state when exposed to light in contact with organic matter, and this circumstance has been made the basis of the process you refer to. Details in the Year-Book.

T. Weston.—If you expect that your progress will be facilitated by trying such a large number of slightly different formulæ, you are much mistaken. Stick to the first on your list, it being as good as any.

F. L.—1. It is not usual to make any charge for hire under the circumstances. 2. Yes, provided the goods are not in any way damaged. 3. Not unless some mutual understanding was arrived at when the transaction took place.

Gelatine.—1. You might adopt the plan of adding citric acid, as recommended by Mr. Cowan. One ounce of pyrogallic acid requires about 60 grains of citric acid. 2. No doubt from the presence of traces of greasy matter on the plates.

Nottingham.—Such apparatus as you describe possesses but little commercial value when secondhand. You might make the things up into lots, and either advertise them in the Photographic News, or send them to Stevens' sale rooms, King Street, Covent Garden, W.C.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1226.—*March* 3, 1882.

CONTENTS.

COATING PAPER WITH PHOTOGRAPHIC PREPARATIONS.

Few operations are of much greater importance in connection with photography than the application of uniform layers of various more or less viscous preparations to the surface of paper, and in illustration of this, we need merely refer to albumenized paper, carbon tissue, the various kinds of transfer paper, and the sensitive sheets used for photo-lithographic purposes.

There is every reason to believe that before long a gelatino-bromide or a gelatino-chloride paper will come into very general use for printing purposes, not only on account of the rapidity and ease with which prints may be obtained, but also on account of the fact that such pictures are likely to be much more permanent than the ordinary prints on albumenized paper. We are aware that many correspondents have experienced much difficulty in covering the paper with satisfactorily uniform layers of the sensitive mixture, and we therefore propose to now consider some of the methods which are in general use for covering paper with thick or viscous preparations, and to detail some experiments which we have made on the best methods of coating paper with a gelatinous emulsion.

One of the oldest and simplest methods of covering paper is by brushing, and this proceeding answers well when a mucilaginous substance of the nature of gum-arabic is to be applied, as the brush lines flow together rapidly; and by exercising a little care a uniform and bright surface can be easily insured. In other cases application with a brush must be followed by a subsequent polishing or burnishing with a long-haired badger-hair softener, this being held so that only the tips of the badger hairs touch the surface to be worked upon. This method of subsequently polishing with a badger brush or softener is of almost universal application in the preparation of enamelled paper and cards, the ordinary enamels consisting of flour paste as a basis; a white or tinted pigment being also present, and ordinarily a small proportion of gelatine or glue. Enamelled papers are extensively used for the reception of the collotypic impression.

The well-known method of floating finds extensive application in the manufacture of abumenised paper and numerous other photographic preparations, and it is an excellent process when a thin coating is required, and the preparation is sufficiently viscous not to run down towards the lower end of the sheets after they are pinned up. It is, however, not very suitable in the case of gelatinous solutions, because these must be used while warm; and as the paper becomes heated through during the time of floating, the tendency of the gelatine to set rapidly is diminished; when, however, the paper is rapidly drawn over the surface of the gelatinous solution, as in the manufacture of carbon tissue, the case is different, as the paper is not sufficiently long in contact with the surface of the warm gelatinous mixture to acquire its full temperature, the consequence being that the film is cooled to an appreciable extent by the paper itself, and it is usually more or less solidly set at a distance of six or eight feet from the coating trough. Makers of carbon tissue recognise the fact that the more quickly the paper is drawn over the surface of the pigmented gelatinous composition, so much thicker is the resulting film, a circumstance which the above-mentioned considerations explain.

For coating paper with gelatine emulsion, there can be no doubt that one of the usual forms of tissue coating machine would be the most suitable appliance; but as the simplest arrangement of this kind is somewhat complex and troublesome to manage, we may describe two methods founded on the same principle, and which we have found to answer very well on a small scale. The emulsion is made rather thicker than is usual in ordinary cases, and is poured out into a porcelain dish to a depth of about two inches. A strip of paper, which is about an inch less in width than the longer dimension of the dish, and about six feet long, is now taken and rolled up as compactly as posible, the smooth side being outwards. The free end is now held while the coil is gently placed on the surface of the emulsion in the dish, after which the end is rapidly and steadily drawn upwards so that the coil unrols on the surface of the emulsion, after which the coated sheet is hung up to dry. Care must be taken that the coil does not come in contact with the sides of the dish during the process of coating, and the speed with which the operation is performed determines, as before intimated, the thickness of the gelatinous layer. A little practice and care suffice to enable one to obtain the most satisfactory results by this mode of proceeding; but if any difficulty is experienced, the paper may be rolled on a tolerably heavy metal roller, and the quantity of emulsion in the dish should be so adjusted as to rise only to a height equal to one-third of the diameter of the roller. In this case the method of working is the same as before, only the roll sinks instead of floating, and the operation of coating must be performed so rapidly as to render it impossible for the emulsion to run to the back of the paper by way of the ends.

Such expedients as coating waxed glass with emulsion, and then stripping the film on paper, are hardly sufficiently rapid and easy for the preparation of a paper to be used for printing or enlargements, but it is quite possible that an adaptation of the "roller" method, largely used in the application of the vulcanising solution to India-rubber fabrics, may be found useful. In this case a small roller rapidly revolves in a trough of the solution, and the fabric is led across the top of this, but in a direction contrary to its movement. This apparatus has long been in use in the rubber factories, and we remember seeing it in action at the Silvertown Works two or three years ago. A special apparatus founded on this principle, and intended to be used in coating plates, has been patented.

A neat way of coating paper, due, we believe, to Mr. Woodbury, consists in placing two sheets back to back, and rapidly drawing them through the preparation; and we have but little doubt that the simple and easily-constructed arrangement of Mr. T. G. Whaite, which we described in our issue of last week, will prove of considerable value in coating sheets of paper with emulsion.

THE TECHNICAL EXHIBITION AT THE SOCIETY OF ARTS.

This exhibition, which was closed on Saturday last, marks an era in photographic history, and as, a few weeks ago, we took a general survey of the arrangements, and noticed the principal exhibits, we may now pass on to the study of several classes of exhibits which deserve a few words.

Pictures, apart from the illustration of processes, were not shown, excepting in three or four instances, as in the case of Mr. Pointer's admirable series of photographs of cats; these deservedly occupying a post of honour in the lecture room.

As illustrative of modes of lighting, posing, and of special methods of working, several pictures may be mentioned. A 15 by 12 portrait of Mrs. Gladstone, and a similar picture of Mr. Gladstone, taken in the open air, possess in a high degree many of the characteristics of studio work. Then, again, we have a photograph of a *basso-relievo* carving in ivory, exhibited by Mr. Woodbury, and the circumstance of its having been lighted from the top causes the photograph to appear cut out or *intaglio* when placed upside down. A girl on a swing, and a boy in the act of leaping over a post, taken by Messrs. Ross and Pringle, in 1864; De Gray's magnificent instantaneous seascapes, taken in 1854; and Mead's "New York Harbour," on a Daguerreotype plate, serve as illustrations of successful instantaneous work in the old time; and Mr. W. E. Debenham exhibits some interesting examples intended to show how far the drop shutter is applicable to portraiture in a well-lighted studio, rapid gelatine plates being used. The platinotype method is illustrated by a complete set of apparatus and materials, together with a series of prints showing the successive advances in the process, and the gradual elimination of silver, gold, and lead. Three good examples of the direct full-sized reproduction of oil paintings are sent by the Berlin Photographic Company, and several exhibits elucidate special modes of colouring both over and under true photographic image.

The applications of photography to meteorological research is well illustrated by work sent from Kew and Meudon; this latter observatory contributing a very fine and sharp enlargement of a solar spot and granulations, together with many other objects of interest, including some collotypic reproductions.

Microscopic photography is well represented, apparatus and examples being shown by Mr. Warnerke and Mr. C. J. Killick, while some of the well-known work of Mr. E. Viles is hung on the staircase. Backgrounds and the general accessories of the studio are not extensively represented; but Messrs. Avery and Co. show specimens of their Empire opaque cloth which is equally servicable on each side, two tints or designs being thus available. A portable background and stand, which packs into a box under eight feet long, and about six inches square, is calculated to be of considerable value to portraitists who have to execute work at a distance, and to amateurs.

Daguerreotype and Talbotype apparatus and work are well illustrated, and an inspection of some of these old appliances reveals the idea of several new specialities which have recently been introduced in connection with the gelatino-bromide process.

Dr. Gladstone contributes a series of photographs intended to show the somewhat abnormal results obtained by photographing fluorescent bodies, his experiments having been described in the Photographic News some ten or twelve years ago; and, no doubt, many of our readers were gratified in seeing Mr. Swan's simplified electric lamp and shunt as especially constructed for photographic use, and described on page 9 of our present volume.

It may be mentioned that almost all the new forms of apparatus which have been recently described in the Photographic News are shown. Our valued contributor, Mr. J. Spiller, shows his dark box or slide as made thirty years ago, and his examples of the first preserved plates possess considerable interest now that the dry plate method has attained such a considerable importance. Photographs of the solar eclipses of 1858 and 1860 are also shown by this gentleman. Mr. Spiller, some time ago, introduced what may be called the carbon process in writing, but the faded condition of the notices of his exhibits shows that he, like many inventors, does not always adopt his own methods. Mr. Spiller's method of producing permanent writing in unalterable carbon consists in writing with very dilute sulphuric acid, to which a little sugar has been added. When writing executed with this mixture is warmed before a fire, the acid becomes concentrated and clears the sugar, depositing carbon in its pores, all trace of free acid being then neutralized by fuming with ammonia. Permanent writing possesses as much importance from an historical point of view as permanent photography, and those interested in the conservation of records would do well to study Mr. Spiller's method.

The scheme of Mr. Trueman Wood has already received the flattery of imitation, as we hear that an extended exhibition of all matters relating to photography is being projected in connection with the Westminster Aquarium.

THE CHEMICAL ACTION OF LIGHT.

BY DR. J. M. EDER.*

Dissociation and Decomposition Caused by Light.—An aqueous solution of hydrogen peroxide decomposes in the sunlight (Downes and Blunt). Chlorine water is decomposed in the light with evolution of oxygen and formation of hydrochloric acid, but in the dark this decomposition will not take place even at a temperature of 100° (Berthollet, Gay-Lussac, and Thénard); it occurs more rapidly under the action of the more refrangible rays (Davy), and under white than under yellow glass (Torsewicz). The decomposition depends on the intensity of the light and on the temperature, but when once set up it continues also in the dark, though less actively (De Saussure and Draper); heat promotes the action, but does not start it. According to Millon, hypochlorous acid is also formed during this decomposition, and it has been proposed to use chlorine water for actinometric purposes. Bromine water behaves in a similar way, though it is not so sensitive to light as chlorine water (Eder). Iodine water undergoes no chemical change (H. W. Vogel), though the alcoholic tincture of iodine is decomposed by light.

Concentrated nitric acid turns red in the light, oxygen being given off, and hyponitric acid formed (Scheele and Berthollet); this takes place most rapidly under white, blue, and violet, but not under red glass (Seebeck). The same change is brought about by raising the temperature (Gay-Lussac and Thénard). Gaseous hydriodic acid kept in absolute darkness, and preserved from contact with the air, undergoes no change, but is decomposed in the sunlight; in this reaction the blue rays have the greatest energy. Aqueous solutions of hydriodic acid, not exposed to the air, can be kept in the sun without decomposing;

* Continued from page 8.

but if the air be admitted they rapidly undergoes oxidation even in the dark (Lemoine). If potassium iodide, cadmium iodide, and lithium iodide, are dissolved in dilute acids and exposed to the light, the iodine will be set free, but in different proportions, depending on the kind of iodide and acid employed; with hydrochloric and sulphuric acid, this photo-chemical reaction is much more energetic than with the organic acids. The decomposition takes place more rapidly under blue than under red glass (Leeds), and advantage has been taken of this phenomenon as the principle for the construction of a photometer. Iodine is separated in the light from a solution of potassium iodide in the presence of oxygen, and carbonic acid or sugar in the solution promotes the reaction; iodide of potassium paper and ozonometer paper behave in the same way. Crystallized iodide of ammonium, exposed to the air, turns yellow, especially in blue or violet light, less rapidly in yellow light (Eder); solid potassium iodide is in the dry state unaltered by the action of light (Vogel).

Hypochlorous acid gas in the sunlight splits up into chlorine and oxygen (Balard); dry gaseous chlorous acid into perchloric acid, chlorine, and oxygen; hypochloric acid behaves in the same way (Millon). Chloride of lime is decomposed in the light more quickly than in the dark, with evolution of oxygen (Döbereiner and Schweinsberg). Phosphuretted hydrogen is decomposed in the sun with separation of phosphorus (A. Vogel), and loses its power of spontaneous inflammability as the liquid hydride contained in it is decomposed (Thénard). Sulphide of phosphorus becomes cloudy in the sunlight (Böttger). Bisulphide of carbon turns a dark colour when exposed to the sun, and a brown precipitate is thrown down.

The chromates by themselves resist any influence of light, but in the presence of organic bodies the light produces rapid reduction. This is especially the case with the bichromates of potassium and ammonium on paper (Ponton, 1839), linen, &c., and in the case of the same salts mixed with gelatine, albumen, gum-arabic, dextrin, cane-sugar, grape-sugar, glycerine, casein, alcohol, &c. Such mixtures turn brown when exposed to the light, chromic oxide (E. Kopp) and finally pure chromium tri-oxide (Eder) being formed; and they are more sensitive to light in the dry than in the wet state. Fox Talbot discovered that a mixture of glue with a chromate not only changes colour owing to the action of light, but that it also loses its solubility in hot water, and its property of swelling up in cold water; gum and albumen became insoluble in cold water, and sugar less soluble (Poitevin). A mixture of glycerine and potassium bichromate turns green and thickens (Schnauss), while gum, dextrin, and sugar become less hygroscopic. Gelatine with potassium chromate is from twenty to fifty times less sensitive than with the bichromate, but ammonium chromate is equally sensitive as ammonium bichromate: free chromic acid renders glue insoluble even in the dark. Chromated gelatine which has been rendered insoluble by the action of light consists of a combination of chromic oxide with unaltered gelatine, and some admixture of formic acid; gum, after being exposed to the light, forms arabate, or more probably metarabate, of chromium (Eder).

The vanadates of the alkaline metals, when in contact with organic substances and exposed to the light, turn green or blue, and if the substance be gelatine, it also becomes insoluble in water. According to Phipson molybdic acid dissolved in dilute sulphuric acid turns blue in the sunlight, but recovers its colour in the dark; but Eder maintains that this change only takes place in the presence of organic substances.

Ferric chloride in contact with organic substances, and exposed to the light, is reduced to ferrous chloride; this occurs with the alcoholic or etheric solution of salt, and more especially under white and blue glass. On paper, or mixed with tartaric acid, glycerine, alloxantin, or oxalic acid, the salt behaves in the same way; Eder has shown that while the reduction of a solution of ferric chloride mixed with oxalic acid is $=100$, that of one with citric acid is $= 19$, and with tartaric acid $= 25$. Mixtures of gelatine, ferric chloride, and tartaric acid are insoluble in the dark, and only became soluble by exposure to the light. Ferric oxalate dissolved in water, and acted on by light, is at once converted into ferrous oxalate and carbonic acid (Döbereiner, Suckow, and Reynolds), and in producing this change the indigo blue rays of the spectrum are most active. The ferri-potassic, ferri-sodic, and ferri-ammonic oxalates undergo change under the influence of light, both in the solid state and in aqueous solution (Bussy); if the air is excluded in this reaction, ferro-potassic oxalate and carbonic acid are formed; if the air is admitted, also basic ferric oxalate (Eder and Valenta). Herschel and Draper found that ferri-citrate and its double salts are very sensitive to light, and Herschel and Schoras have found the same with the tartrate; the blue and violet rays act most energetically with these salts of iron. Sulphocyanide of iron, either in an aqueous, an alcoholic, or an etheric solution, pales under the influence of the green-blue rays, but regains its red colour in the dark (Grotthus).

(To be continued.)

JOTTINGS.

BY MAJOR J. WATERHOUSE, B.S.C.
Assistant Surveyor-General of India.

Use of Celluloid.—It struck me some time ago that if flat sheets of transparent celluloid could be obtained, they would form an admirable basis for collotype printing, combining, as they would, the respective advantages of glass and metal, transparency, admitting of sunning at the back, and non-liability to fracture. It seemed probable, too, that the opaque variety of this subtance, known as xylonite, might be a good substitute for lithographic stone or zinc plates for printing from, as its surface can either be highly polished, or grained. Having ascertained that celluloid was manufactured by the British Xylonite Company, I visited their works at Homerton. I found that the only description ordinarily available was the opaque white xylonite, in sheets of various thicknesses, and chiefly used by the Company for making combs. This would be a most useful material for carbon transfer work and other photographic purposes; but in large pieces it is almost impossible to get it perfectly flat and free from an obstinate tendency to buckle, a defect which would render it useless for lithographic or zincographic printing. Mr. Merrian, the manager, showed me, however, a small printing block made of the xylonite, and also an etching, which could be printed in the copper plate press. The transparent kind is not often made; but Mr. Merrian kindly looked up two small samples for me. These were, however, so very distorted and uneven that it was useless to try them for collotype. Their strong yellow colour was against their employment in photographic work as a support for negatives, and this is a serious objection, for however colourless the plates might be at first, they would be sure to turn yellow in course of time, as stripped collodion negatives do. Notwithstanding these defects, if the manufacture of celluloid could be so improved as to admit of perfectly flat sheets being produced, there is no doubt that it would be of the greatest value to photographers all round.

Spontaneous Ignition of Papyroxyline.—Photographic pyroxyline is usually considered non-explosive, and, as such, stored in a dry state without any special precautions. Two cases of spontaneous ignition which have recently come under my notice show the danger of this practice. A small quantity of papyroxyline was put away dry in a wooden cupboard, and had been left there for about a month. One morning, on a holiday, a servant going to clean the room found the cupboard smouldering. On opening it the papyroxyline was found to have ignited spontaneously. The ignition does not seem to have been attended with any violent explosion, because the doors of the cupboard were not forced open. A body of flame sufficiently intense to fuse the edges of some pewter plates lying on the top shelf had forced its way upwards, and set fire to some paper labels on the top of the cupboard. There were a lot of chemicals and apparatus inside the cupboard, but, luckily, no damage was done to them, beyond every article being coated over with a resinous-looking substance having a strong empyreumatic smell. The second case happened with the same papyroxyline. A jar containing about a pound of it had been made over to the photographers for adding to the collodion. When given over it was in a moist state, but was allowed to get dry; after some holidays this also was found in the cupboard burnt out. It seems to have burnt itself away quite quietly, a large quantity of charred residue being left in the jar, and did no other damage. By a most lucky chance, little actual damage was done on either of these occasions; but the possibilities are serious to think of with ether and other inflammable chemicals in the neighbourhood. These cases show that pyroxyline should be kept in a moist state, and never be left carelessly about when dry. In the latter condition it is exceedingly liable to decompose and spoil, even though it may not become dangerous. Well moistened with distilled water, it will keep in good order for a long time, and can be dried again with very little trouble.

Removing Mercury Stains from Glass.—After glass plates have been used once or twice with the usual map-copying intensifier of bichloride of mercury and hydrosulphate of ammonia, the surface becomes badly stained, and it is difficult to get clear negatives. In working with the Eder and Toth's lead intensifier some time ago, we found that it was also useful for removing these stains from the old glasses. In noticing this method on a former occasion, the soaking of the glasses in the solution was recommended. It is now found better to allow the salts to dry on. The solution used is:—

Ferricyanide of potassium ...	10 parts
Nitrate of lead	7 ,,
Water	200 ,,

This is applied to the glasses on both sides with a sponge, allowed to dry on, and left for at least a week. When required for use, the powdery coating is removed by rubbing the surface well with a damp cloth. The glass is then well washed and drained for use in the ordinary way.

Engravers' Tracings on Copper.—The following simple method of obtaining designs on copper may be of use to engravers for making traces of intricate drawings, &c., on their copper plates. The copper plate ready for engraving, having been coated with the usual sensitive solution of bitumen, is exposed to light under the drawing to be copied, and developed with turpentine in the usual way. When fully developed, the lines of the drawing will be seen in bare metal on the asphalt ground. If, now, a tuft of cotton be wetted with a little platinum solution and rubbed over the plate, the lines will turn black. The asphalt ground being removed with benzole, the drawing will be seen in a clear, fine, black colour on the bright copper ground. Other metallic solutions may be used, but the deep black of the platinum is perhaps the best, and the copper plate is not perceptibly etched by it. The method is only suitable for drawings in line. The same principle may be applied to the ornamentation of metal and glass for decorative and other useful purposes. For bitumen work I have found Husnik's solution of purified bitumen answer very well. It is sold ready prepared, and only requires dilution with turpentine or benzole.

A PARIS PHOTOGRAPHIC LAWSUIT.

Our Paris correspondent writes:—

About two years ago Mademoiselle Sarah Bernhardt conceived the strange idea of having her portrait taken, lying at full-length in a coffin edged with white silk. Monsieur Mélandri, a Paris photographer, was charged with the execution of this duty, which was all the easier from the fact that the model simulated very successfully the immobility of death. The *cliché* was without reproach, and Mlle. Bernhardt was fairly enchanted with its success.

"Now, I will make a bargain with you," said the artiste; "promise me not to dispose of a copy till after my death."

"After your death!" exclaimed the photographer.

"Oh! that will be sooner than you think for; I engage to die within a twelve-month—"

"You are joking—"

"No, it is a presentiment I have, and presentiments never fail me. Moreover, if in a year's time I am still in this world, I authorize you to print as many copies as you like, and sell them at any price you please."

The photographer consented to the strange compact, and for the space of a year not a single print went out of his studio. But Mlle. Sarah Bernhardt had no intention of carrying out her promise; she remained as lively as ever. Tired of waiting, Monsieur Mélandri wrote to the celebrated actress that she had not carried out her contract.

"A little patience, please," was her reply; "as soon as I have carried out my engagements in America I will certainly attend to your little matter."

Another year passed, but without result. Monsieur Mélandri wrote again to Mlle. Sarah Bernhardt, telling her that since she had failed to keep her promise, he was no longer obliged to abide by his, and that he should put the coffin portraits in circulation at once. Mlle. Bernhardt hastily telegraphed that she had promised to create three new rôles in Paris, and that when she had done this, no obstacle in the world should prevent her executing her terrible promise. This does not seem to have suited Monsieur Mélandri, for he has now brought an action before the *Tribunal de Commerce*.

Such is the history of the latest eccentricity of the famous Ex-Sociétaire of the *Comédie Française*.

By-the-Bye.

WHAT PHOTOGRAPHY DOES FOR SCIENCE.

Fifteen years ago it would not have been difficult to enumerate within the space of this article the chief duties photography discharged in connection with science. She was a species of upper-servant then, performing valuable services enough, but rather of a light order. To-day she is a maid-of-all-work, put upon, on every occasion, to discharge all sorts of functions, whether menial or high-class. Unlike her domestic sister, she is always to be trusted, and hence the most responsible, as well as the most servile offices, are relegated to her domain. Nor is it only, as in former days, a few of the sciences that employ photography; men conducting researches of vastly different character unite in their desire to work photography; and among astronomers, meteorologists, surgeons, physicians, geologists, chemists, physicists, and botanists, the camera is regarded as one of the most useful of investigating apparatus.

Photography helps science in two ways: it is employed in the high office of investigation, and in the subservient one of simple record. The best illustration we have of its use as a mere recorder is that to which it is put at the Kew and other observatories. Day and night, unceasingly, photography watches the fluctuations of the barometer, the rising and falling of the thermometer, and the delicate pulsations of the swinging magnet which tell of the sudden bursts of magnetism that vivify the earth at intervals. All the changes, whether they be weak or strong, that take place among the observing instruments, are written down accurately by photography, hour after hour, and thus a most trustworthy record is secured for after-comparison and study. Not only are the labours of assistants thus spared, but, what is of far more moment, the records obtained are infallible, and beyond the reach of human error. The daily pictures taken of the sun at Kew and Meudon (we mean, of course, when the orb is visible), are other instances of the value of photographic records, of which we could multiply instances without number.

It is, however, when photography is used as a means of investigation that more interest attaches to the subject, and within the past two years especially there have been some wonderful discoveries made through the medium of our art.

To commence with surgery—for, as Pope very truly says: "The proper study of mankind is man"—we may mention the important research of Dr. Koch, now of Berlin, which formed the subject of one of our earlier "At Homes." Dr. Koch was on the look-out for bacteria, those tiny organisms which invariably attend decomposition (if they do not represent decomposition itself) in animal tissue, for, although the presence of these noisome animalculæ in diseased flesh was pretty well established, no one had been able to point them out with even the most powerful microscope. Dr. Koch, in the course of his researches, bethought himself of photography, and he was delighted to find that the camera showed to the world something which had previously been invisible. He found not only bacteria present in animal tissue, but he found, too, by taking pictures of the tiny organisms, that their shape and form varied with the nature of the disease by which the animal tissue had been attacked. Thus he discovered that the tiny bacteria responsible for gangrene, the deadly disease before which all hope for the patient begins to fade, were shaped like tiny currants or grapes hanging clustered upon fine cobwebs, while tissue cut from an animal suffering from relapsing fever showed, when photographed, the presence of thin hair-like organisms. As these organisms were not visible under the microscope, to photography alone is due their discovery.

This amply suffices to show the value of the camera as an investigating apparatus in medicine. Another instance, almost as interesting, is the research on the action of the pulse and heart by Dr. Ozanam, Dr. Lucs, &c. Dr. Ozanam, it may be remembered, established dicrotism, or double beat of the pulse, by photography; while Dr. Diamond, Dr. Wright, and others, have also proved over and over again how valuable photography is in studying mankind in health and disease.

Coming next to the science of chemistry, a recent example may be quoted to show how photography can help the investigator here; we refer to its aid in the analysis of iron and steel. Messrs. Parry and Tucker maintain that theoretically, at any rate, a well-focussed photographed spectrum of any iron or steel is an unerring index to its composition, and although in practice this is not absolutely true, still the lines in the photograph tell us more than we could otherwise divine. The question whether two steels are of the same quality can be settled in half-an-hour by photographing the spectrum of each side by side on the same plate, supposing the two metals to be homogeneous. "There is something so absolutely certain in a photographed spectrum," says Mr. Parry, "that it is most desirable to establish photography as the basis of all spectroscopic work."

And this brings us to the important use made of photography by the physicist, the astronomer, and the meteorologist. By merely photographing the spectrum, as Draper, Abney, Vogel, Waterhouse, and many others have shown, there is much to be learnt both at the red end of the spectrum and at the violet end. In the case of the latter, indeed, it is simply impossible to study the phenomena without the assistance of a camera. Dr. Huggins' pictures of the stars—or, rather, of the spectra of the stars—may be cited as a wonderful investigation only rendered possible by intelligent photography. M. Janssen's pictures of the sun's orb, again, in which he has been able to secure half-tone for the first time, therefore giving us an insight of the sun's mass—of the limb we had already learnt much through the camera—may be quoted as a further example of astronomic investigation by skilful photography, to say nothing of the many camera pictures taken during eclipses, which have made us familiar with solar phenomena whose presence was not dreamt of twenty years ago. Another no less remarkable lesson is afforded by a comparison of photographs of the sun with the photographic records kept of magnetic disturbance. It may seem strange at first sight that any such comparison could furnish data of importance, and yet the most specious results have been deduced therefrom. The recurring presence of sun spots, as shown by the solar pictures, answers to the recurrence of magnetic disturbances, as shown by the photo-magnetic records, and hence a relation one to another is here established which cannot be gainsaid. Mr. Warren de la Rue's moons, which were afterwards eclipsed by Mr. Rutherfurd's stupendous pictures of the same orb, are further proofs of the value of photo-astronomical observations. In short, in the realms of physics, astronomy, and meteorology, the aid of the camera has now become indispensable.

In conclusion, we may cite also the study of anthropology and geology by means of the camera as interesting examples of scientific photography. The clever plan of measuring skull sections recently adopted is singularly useful. A black scale with white marks is set up against black velvet and photographed, but instead of developing the plate, this is used in the camera a second time, to depict a skull; the latter is put in the plane previously occupied by the scale, so that no fresh focussing is necessary. The plate, after the double exposure, then shows the skull with the scale running through it. A series of pictures taken in this way are said to furnish most important information either for study or instruction. In respect to geology, one of Mr. Whymper's Chimborazo pictures furnished an excellent illustration of the aid photography may lend to the subject, for it demonstrated the thickness of the ice crust deposited at a specific altitude. The height of certain objects in the vicinity permitted a comparison of the crust, which, as the picture clearly showed, was of very uniform thickness.

We repeat, however, it is in the more delicate applications of photography to science that most interest attaches, where the results are due almost as much to the skilled worker as to the art itself; and it is well for those interested in photography to look back occasionally upon the difficulties surmounted and the discoveries made, which, but for the existence of our art-science, would have still remained stumbling blocks in the path of progress.

The "At Home" next week will be "Messrs. J. Valentine and Sons at Dundee."

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

The Regulation of Exposure—The Exhibition of Specimens—Photographing Mr. Gladstone—A Question of Procedure.

The Regulation of Exposure.—Instantaneous shutters are now so numerous that there is scarcely need to ask inventors to set their wits to work to devise another. So far as quickness of exposure is concerned, there is no lack of shutters which provide this quality to perfection. In one respect, however, all shutters are deficient, and that is in regard to some means of ascertaining the exact time of exposure. We hear of exposures varying from one second to the hundredth part of a second or even less, but in most cases these durations are not the result of exact calculation, but are mere guess-work, and consequently misleading. To remove this uncertainty an apparatus has been devised by a Col. Sebert, and described by him to the Paris Société d'Encouragement. The apparatus is contained in a small box which can be easily adapted to any camera. There are two shields, one above the other, controlled by springs which tend to lower one and raise the other. A chronometric counter is in the front part of the box, and presents its disc below the objective. The act of bringing the index to the time of exposure required, applies two catches, one of which holds the first shield raised and closes the camera, and the other holds the second shield down, but ready to rise at the right moment after the first has gone down. The index of the counter is liberated by an ordinary pneumatic attachment. As the index moves round the disc, it at once liberates the upper shield without shock, so opening the camera, and when it reaches zero, it liberates the other shield, which closes the camera. It is said that with this apparatus the time of exposure can be regulated to a fraction of the hundredth of a second. A diagram lately was given in *La Nature.*

The Exhibition of Specimens.—Not the least important branch of a photographic business is the exhibition of specimens; but we fancy that, as a rule, photographers do not pay the attention to it which its importance demands. We refer more particularly to the frequent change of specimens. Railway stations are as good places for exhibiting as can well be found, for rarely do passengers who have to wait a few minutes on a platform fail to stop in front of a frame of photographs, glad of the chance of seeing something in the way of a relief from glaring and monotonous advertisements. But when you are a regular traveller, and see the same photographs in the same frame day after day, week after week, and month after month, you grow to loathe the sight of the faces which are presented eternally to your view. We can call to mind, in a certain suburban railway station which it is our lot to travel from three or four times a week, a case of photographs which we once looked upon with interest, but which we now hurry by as soon as possible. It contains at least a dozen pictures, some very good, the centre one being a cabinet sized portrait of a child. Photographically speaking, nothing can be said about the portrait. But the child, by no means pretty itself, has such a scared expression about the eyes, and has its mouth pursed up in so nervous a fashion, evidently showing that it was in a state of mortal terror when its photograph was taken, that to be obliged to look at it day by day is nothing short of an infliction. And the worst of it is, that when you hate a thing it is pretty sure to fascinate you. We are certain that the public who use this station would be deeply grateful for the removal of the objectionable picture, and for some slight change in the others, yet it never occurs to the photographer to do either. And what is true of this railway station is true of a dozen others, and also of the specimens exhibited at the majority of photographers' residences. Variation is the exception, and staleness the rule. The mistake generally made is the exhibition of too many specimens. To arrange a dozen cartes so that one harmonious whole shall be presented is no easy matter, and everyone who has tried it is familiar with the difficulty of getting a dozen silver prints of exactly the same tone, of well-balanced subjects, and where the faces shall be pleasant to look upon. A single inartistic picture is sufficient to spoil the effect. Therefore we would say, be content with a smaller number, and, what is more important, change them frequently. In the pride of obtaining a faultless negative, photographers often overlook the subject photographed, and will exhibit a positively ugly face, simply because the negative happens to be a good one. This we hold to be a total blunder. If it be true that a thing of beauty is a joy for ever, it is equally true that a thing of ugliness is an eternal torment. We therefore reiterate the advice: exhibit only pleasant pictures, few in number, and change as often as possible.

Photographing Mr. Gladstone.—Mr. Gladstone is not like the late Lord Beaconsfield; he has no objection to being photographed. How many times the Premier has had his portrait taken it is impossible to tell, but he must run Her Majesty pretty hard in the matter of photographs, which is saying a good deal. It must not, however, be supposed that Mr. Gladstone delights in dawdling away his time in a photographic studio. For instance, in reply to an application from Mr. Walker, of Regent Street, lately, he said he would call on a particular day and give the artist fifteen minutes. Accordingly, he was punctual to the minute, and, with his watch on the table, posed for the stipulated quarter of an hour. It goes without saying that Mr. Walker was as "spry" as the circumstances would permit, and as he took fifteen separate negatives he cannot be charged with having lost any time. We assume that gelatine plates were used. With collodion the task would have been impossible. More advantages in the use of rapid dry plates—economy of the time of a great statesman, and convenience and profit to the photographer. One of these photographs, it may be mentioned, is said to be exceedingly good, and has been engraved for Harper's Magazine.

A Question of Procedure.—It would be interesting to know what power the general body of the Photographic Society have apart from the Council. Is the Council in the position of a managing committee, whose decisions must be ratified by the body of members, or is the Council all supreme, and able to veto any resolution adopted or decided upon at a general meeting? There is not the slightest antagonism, that we are aware of, between the members and the Council, and therefore the question can be discussed dispassionately; but from a little incident which occurred at the last meeting, it would seem as if there was some doubt on the point, and it would be as well if the exact relations were better known than they are. In the discussion which followed Mr. Warnerke's remarks on the necessity for a standard of rapidity for lenses and for uniformity in apparatus, Mr. Warnerke himself asked whether some notice might not be inserted in the Journal inviting the opinions of the members. "Certainly not," replied the President; "the matter must come before the Council." Mr. Warnerke said no more, nor did any other member take up the question. But supposing the reverse had been the case, and some obstinate gentleman (and there are many such in the world) had pressed the point to a division, and a resolution had been passed approving Mr. Warnerke's suggestion, what would have happened? To this we can only reply in the words of a Speaker in the House of Commons, who, when asked what would follow the solemn formula of "naming names," said despairingly, "Heaven only knows, for I don't."

NOTE ON PITS IN GELATINE.

BY ALF. J. BROWN.*

All who have made gelatine dry plates have noticed that when the emulsion has set—really, as it is setting—depressions are formed, which have come to be called pits. It is common, almost universal, to ascribe these pits to grease in the gelatine; why, I don't know, as I have never heard any reason given.

I say grease has nothing to do with them, as I shall endeavour to show. I made up 3 ounces of a 20-grain solution of Henderson's gelatine; a plate was coated with it and marked No. 1. It is not so clear as it should be, because it was not filtered. I then added to the solution a drop—more than a minim—of flask oil, and coated No. 2. No. 3 had two drops of oil, No. 4 had four, No. 5 ten, and No. 6 sixteen drops, the solution the while of course getting less as the plates were coated, but not very much. It was well shaken after each addition. There was no increase in pitting, but as they dried the gelatine appears to have squeezed the oil out, for it is principally upon the surface, and may be smeared or rubbed off. Under the microscope, when these globules are rubbed away, are left little beds where they have rested, some smaller globules being still in the film. I next made two ounces of a 20-grain solution of Nelson's No. 1, and coated a plate No. 7; twelve drops of oil were then added. This gelatine seemed to take more kindly to the oil, and really formed an emulsion. The acid in Henderson's would perhaps account for any difference. No. 9 was then coated. No. 12 is the same solution after being kept one-and-a-half hours at a temperature of 130°; they look the same to me. You will see that the last two are like ground glass, but the oil is still principally upon the

* Read before the Thursday Evenings for Photographers.

surface, and may be rubbed away. The oil caused no extra pitting, and nothing which could be mistaken for it. I then took a little old emulsion which had been knocking about for tw o or three months, filtered it, and coated a couple of plates, Nos. 13 and 14. They pitted a great deal. I then added oil to it, shook it up well, filtered it again, and coated 15 and 16. There is nearly a drop of oil in each of those quarter plates. There was absolutely no sign of a single pit. I don't advise you to add grease to your emulsions to get an even film, but I intend myself to make an emulsion containing neats-foot oil, to see how it affects the development. You shall know the result.

Now, if it is not grease, what is it? I have examined quite a number of plates and spots with the microscope, the dull spots in the dried film, which Mr. Denbenham has aptly termed freckles, showing where was a pit when wet. Particles of dust will cause them, or the slightest filament cast from the clothes of the worker, but these you will find in the centre of the spot. They appear to exercise a repellent action upon the gelatine; this action, indeed, forms the basis of, I think it is Major Waterhouse's invention of getting "grain" by the use of sand or fine powder. But dust is not the cause of the large majority of pits. It is too common in everyday practice to take for granted that gelatine is a homogeneous mass. Nothing is farther from the truth; the many and varied sources from which the raw material is obtained will expel that idea if you only give the matter a little thought. More than this, if the skin, gut, hoof, or bone, &c., were taken from one animal only, it would not then be alike in all its particles. The work of decay and reparation which is ever going on makes this impossible, the newly formed being more tender than the mature. I say it is these harder particles of gelatine that underlie and cause the pits; they contract sooner than the bulk of the mixture, are really set sooner, and expel part of their moisture, which is taken up by the surrounding more fluid film.

Damp a plate that is freckled with a soft brush and water, the surrounding parts will rise much quicker and higher than the spots. Why? Because they can't, at a low temperature, absorb enough water to do so. Coat your plates at a low temperature, and the pits are gone, or may be nearly so. Why? Because these particles are already contracted and will dry, level with the mass; at least, this is my experience. This is why, I think, that 15 and 16 lost their pits, the second shaking and filtering having reduced the temperature very much.

Moral:—Raise your gelatine to a high temperature, break it up as much as possible, and coat at as low temperature as you can.

You may dispute my theory—I may be wrong—but I think I have shown at least, that pits do *not* arise from grease.

INTENSIFICATION OF GELATINE NEGATIVES OR POSITIVES WITH SILVER.

BY H. HOULGRAVE.*

TOWARDS the close of the past year, I was asked by a friend to make him a series of lantern transparencies from a number of photographs and engravings with which he provided me. As I have for a long time past worked exclusively with gelatine plates, I had no choice of a process by which to do them. With me it was a case of either gelatine or nothing. Unfortunately, in my hands at least, gelatine transparencies are rarely entirely satisfactory. The faults I have to find with them are that they are apt to be too thin and of bad colour. If an attempt be made to overcome these objectionable qualities by pushing the development, the lights of the picture are almost sure to suffer, and if recourse be had to silver intensification (at least, by any of the published methods) matters are often rendered worse rather than better, owing to the difficulty there is of avoiding staining or veiling, more or less, what ought to be the clear portions of the picture.

As I had plenty of time allowed me for the work, I tried a number of experiments in order to find out, if possible, some means of overcoming the above-mentioned difficulties; and I have at last hit upon a method of working which, though differing only very slightly from the usual plan of proceeding, yields me results incomparably better than any I have hitherto been able to obtain.

The following are the baths and solutions which I use:—

1.—*Iodine Solution.*

Iodide of potassium	2 drachms
Iodine	1 drachm
Water	3 ounces

* A communication to the Liverpool Amateur Photographic Association.

2.

Nitrate of silver	20 grains
Distilled water...	1 ounce

3.—*Iodine Bath.*

Alum	2 ounces
Hydrochloric acid	2 drachms
Iodine solution	1 drachm

Dissolve the alum in hot water, and then add the acid and the iodine solution.

4.—*Iron Bath.*

Sulphate of iron	2 drachms
Citric acid	2 ,,
Glacial acetic acid	1 drachm
Alcohol...	1 ounce
Water	9 ounces

Dissolve the iron and the citric acid in hot water, and then add the alcohol and acetic acid.

As this bath improves very much with age, it will be found a good plan to mix two bottles of it, one of which must be used as the stock bottle and kept constantly filled from the other, and when this second bottle is empty, a fresh supply must be made.

The iodine bath undoubtedly deteriorates with use, and must consequently be renewed from time to time. Having prepared the above solutions, the following is the way in which they are to be applied. But first let me say that the intensification may be proceeded with whilst the picture is still wet, either before or after fixing, or after it has been allowed to become dry, and each of these methods has its own peculiar advantages. Should the plates be rather too thin and transparent, it will be better to intensify before fixing, because density can be more easily obtained at this time; but with thick, opaque films, such as are now generally used, the operation is best performed after fixing, because the effect can then be so much better seen and judged. Should, however, the plate be at all inclined to frill, it will then be necessary to defer the intensification till after it has become dry, because when once it is dry, all danger from frilling will cease.

And now let me suppose that it is desired to intensify a picture after fixing, as this is the case that will most generally occur. The following is the plan of procedure:—After removing the plate from the hyposulphite bath, wash it thoroughly for four or five minutes in several changes of water; then, having poured a portion of the iodine bath into a flat dish, plunge the plate into it. Rock the dish gently for about half-a-minute, after which remove the plate to a dish of water, wash for about a minute in three changes of water, and it will now be ready for the iron bath.

In all the printed instructions for applying this which I have seen, one or other of two methods is invariably prescribed. The first is to pour a little of the iron solution into a flat dish, add a few drops of a solution of nitrate of silver, and then plunge in the plate. This having been done, observe what takes place. Unless the dish be chemically clean—a not too easy state of things to bring about—the silver will expend its energies in blackening it, and will finally convert the solution into a muddy mess, which, if the operator be not very careful, will cause a deposit to settle on the film, and ruin the negative. The other plan is this:—Having attached the plate to a pneumatic holder, pour the solution on and off from a developing cup until the required density is obtained. This may appear a delightfully simple operation in theory, but in practice it is quite the reverse, because a gelatine film is so repellent that it is almost impossible to get an aqueous solution to lie nicely upon it. Fortunately, both these difficulties may be entirely avoided in the following way:—Pour a portion of the iron solution into a flat dish, and in this immerse the plate. Next pour into a developing cup a little of the same solution, and from ten to twenty drops of the nitrate of silver solution; for a 5 by 4 plate two drachms will be sufficient. Now take the plate out of the dish, and, holding it either by one corner with the fingers, or on a pneumatic holder, immediately pour over it the contents of the cup. The solution will flow up to the extreme edges of the plate, which may now be kept evenly covered without the slightest difficulty.

Should the picture only require a little additional density, this will be quickly obtained; but if, on the contrary, it be much too thin, it will gain strength very slowly, and the operator will require to use all his patience and a liberal allowance of silver as well, to obtain what he seeks, and possibly be obliged to resort to mercury to finish with. But, even in this case, the previous treatment with silver will not have been wasted, as it will furnish a foundation for the mercury to build upon, and it will now be easy to gain an amount of density which the mercury alone would not have given. Should the intensifier become turbid in the course of the operation it must be immediately rejected, and the plate flushed with a small quantity of the iron solution, but on no account with water. The intensification may then be continued with a fresh portion of the iron and silver solutions. As soon as the operation is completed the plate must be washed until the water will lie smoothly upon it, and then be plunged a second time in the hyposulphite bath, in which it should be allowed to remain for about a minute, after which it may removed to a dish of water and washed in the usual way.

Before closing these remarks I feel as if a word of apology were due from me for having occupied the time of the meeting with a matter which most of you may consider trivial and, possibly, not new. My excuse is that I certainly had no intention to have done so, and I should have remained quietly in the dark had not our indefatigable Hon. Secretary most unexpectedly unearthed me and dragged me into light.

Notes.

The Duke of Edinburgh officially opened the Electrical Exhibition at the Crystal Palace on Saturday, but many of the exhibits are still conspicuous by their absence

The Post Office and the War Office contribute a most interesting show, the latter displaying examples of the applications of electricity to warfare. Unfortunately, these examples do not include the one of all others most likely to interest photographers, that of copying plans and maps by the electric light in the field. Our readers are well aware that one of the principal duties of military photographers accompanying an army corps is to reproduce, by the aid of the camera, any plans or reconnaissance sketches made by staff officers; and that this work may proceed as quickly as possible, the photographers are put in a position to go on with their labours at night by using the electric light. They are not only able to take a negative, but also to produce prints, either for collotype printing or photo-lithography, and thus hundreds of *fac simile* copies of any important sketch are forthcoming the very morning after it has been placed in the hands of the army photographers.

It is pleasant to find the Photographic Society once more in a solvent and flourishing condition, with a few hundreds in the bank. But it has taken many years to rise from its insolvency, the turn of the tide dating from 1870, when most of its Council became life members, and in this way raised the necessary funds to enable it to clear off its obligations.

Mr. Francis Bedford prefers to extract the silver from old hyposulphite baths by means of liver of sulphur, while Messrs. Valentine and Sons precipitate the precious metal with zinc plates. In a laboratory experiment, we found the former method to be the most exhaustive, the proportions recovered by sulphur and zinc being as five to four. On the other hand, in favour of zinc, there is the circumstance that the smell is not so objectionable, while the silver is not recovered in the form of sulphide, but in a metallic condition. The experiences of these gentlemen should, in any case, cause all photographers to exhaust their waste hyposulphite solutions in one way or the other.

The first number of another German photographic journal appeared last month, the *Photographischen Rundschau*; it is the organ of the Schleswig-Holstein Society.

On the other hand, we are sorry to hear that the *Zeitschrift für Praktische Photographie*, a journal published in Munich, has ceased to appear. It was issued by the Munich Photographic Society.

Another item of news from Germany is scarcely so important. An International Photographic Association is announced as having been founded at Guben by Herrn. Groll and Pfeiffer, under the grandiloquent name of the "Victoria" Society. If only there had been one other founder, we should have had an instance of history repeating itself in connection with the three tailors of Tooley Street. Guben, we believe, is in Prussia, but we are not quite sure.

The Alexandra Palace authorities wish to secure some instantaneous pictures of the multitude that usually honours that place of entertainment with their company on Easter Monday. An announcement elsewhere shows that medals and money prizes are offered for the best negatives taken on that occasion; but photographers should note that they part with "all copyrights" when they part with their negatives.

We stated the other day that the Empress of Germany was one of the few in this world who strenuously object to being photographed. She has but once been pourtrayed in the camera, and that was only at the earnest solicitation of the Queen; but the Empress of Austria, it seems, has never been photographed at all.

In the *Graphic* last week was a fine group picture of the Empress of Austria surrounded by ladies of the Court, and hers was the only portrait not taken from a photograph. The other high-born dames of Austro-Hungary were depicted from photographs taken in the Adèle Studio at Vienna, and Herr Koller's studio at Pesth, both of which establishments have recently been the subject of an "At Home" in these columns.

It is sometimes handy to know how to revive a piece of apparatus that has been French-polished. Here is a mixture which must be applied with plenty of elbow grease;—

Pale linseed oil	2 pints
Strong distilled vinegar	½ pint
Spirits of turpentine	¼ ,,
Hydrochloric acid	1 ounce

Chemistry is a wonderful science, but there are some problems it cannot solve, and to tell the difference between cane-sugar and beet sugar is one of them. Nevertheless, there is a marked difference, and one easily perceived, if not by man, by the moth; for entomologists find that to attract these at night by "sugaring" tree trunks with beet-sugar is well nigh impossible, and only when cane-sugar is used does the device succeed.

The finest portrait in Mr. Abel Lewis' collection, which took the gold medal at Dundee, is that of a lady leaning against the trunk of a tree. An upright tree stem of this nature is one of the most simple, useful, and, for out-door costumes, most appropriate accessories the photographer can have. With gelatine plates, a model requires hardly any other support. Mr. Mendelssohn, of Newcastle, has a fir trunk in his studio, but the silver-birch, an ivy-grown oak, or the stem of an ash, would be quite as suitable.

Herr Klic, of Vienna, has been successful in selling his very perfect photo-engraving process in France, Prussia, and Bavaria. MM. Goupil et Cie. have acquired the right of working the process in France, and the other two purchasers are the Berlin Photographic Company, and Herr Bruckmann, of Munich. Neither in Great Britain nor America has any one yet come forward to treat for the sole right, although Herr Klic has received several applications for licences.

The president of the Chemical Society, and president of the Institute of Chemistry, are to hold a "reception" at the Crystal Palace on the 22nd inst.

The gathering takes place in connection with the International Electric Exhibition, which sanguine people hope to see complete by Midsummer. No less than one thousand gentlemen are expected, the hosts on the occasion being Professor Roscoe, F.R.S., and Professor Abel, C.B., F.R.S.

Our readers will remember the account we gave in April last in these columns of Professor H. Dufour's chemical actinometer. In pursuing the investigation, he has made an observation of some importance. In a word, he is in a fair way to discover a photometer that will speak, or, at any rate, emit sounds. It is well known that a mixture of chlorine and hydrogen gases diluted with air or oxygen combines slowly in light. Without air the mixture is exploded by exposure to white light, the chemical rays being most efficient. M. Dufour has examined the behaviour of this mixture as to its power of yielding radiophonic and photophonic sounds when illuminated by intermittent beams of different kinds, as in the researches of Graham Bell and Tainter. He finds that the loudest sounds occur when violet and ultra-violet rays are employed, no sound whatever being produced by red rays. It will interest photographers, therefore, to know that it is only actinic rays that speak.

At the Photographic Club, the conversation recently turned on the subject of alum and chrome alum employed both for "tanning" gelatine plates and carbon tissue, the opinion being generally in favour of the latter. There is no doubt that chrome alum does not possess the same tendency to "crystallize out," which is so frequently remarked when ordinary alum is used, causing the surface treated to be covered with white powder when dry. Moreover, chrome alum is a more trustworthy substance than that sold as common alum.

The Meteorological Society have been mulcted by Government of the price of the "Saladin" balloon, which was lost together with Mr. Powell, M.P. Those who desire in future to make experiments in balloons, whether in connection with meteorology, photography, or other purposes, are not likely to take passage in a Government equipage in these circumstances.

M. Léon Vidal sends us his new volume, *Cours de Reproductions Industrielles*. It is a most interesting work, containing, as it does, not only a description of the graphic and photo-graphic arts, but also examples printed by their means. Photo-lithography, photo-gravure, Woodbury-type and its recent improvements, collotype, &c., &c., are all described in detail; but perhaps the most remarkable feature is the illustrations anent photography in colours. M. Vidal gives examples of the Ducos du Hauron process and of his own, not only exhibiting finished prints in colours, but also printings of the different tints, which, when superposed, make up the photograph in colours. We heartily congratulate our Paris correspondent on his most useful and attractive work.

It is difficult to understand for the moment how photography can assist memory, but the present generation affords a trite illustration that it does so. A man of eight-and-twenty or thirty, who possesses portraits of himself in childhood, has a much keener recollection of himself, his habits, and his surroundings, in those days, than the man or woman who was never photographed early in life. The child's dress in the picture has no doubt much to do with this greenness of memory, but it is the circumstance of his being able to look back at the portrait again and again, as time goes on, the picture forming a landmark always fresh and familiar, that makes it so valuable a line with the past.

Another value—for it is a valuable quality—of old portraits is that the "young people" enjoy the opportunity on seeing their parents and elders when they too were young "The old frump," or "antiquated baboon," as vain youth sometimes stigmatizes old age, the youngster finds as sprightly and good-looking as himself in the portraits take long ago, and he wisely puts a bridle on his tongue hence forth; while our elders, again, are reminded by their youthful pictures that they, too, were young once, and are so disposed to be less harsh towards youth in consequence.

Some people have an idea about making their family albums as smart as they can. The old yellow portraits are weeded, and bright and elegant ones substituted. Portraits highly burnished, and with plenty of magnificent furniture, are slipped in, and those with antiquated balustrades and stony columns are slipped out. Never do this; it is a woeful mistake. Commence a new album, if you like, but let the old portraits be; and, when you have kept them for years and years, you will find your reward in a book whose every page has upon it a sweet remembrance or a touch of pathos.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. 1.—Selection of Apparatus.

The first thing that the photographic beginner has to do, after he has made up his mind that he going to take up the fascinating art-science, is to determine what size of "plate" he will work—that is to say, how large his pictures are to be. As a matter of course, he should begin work upon the smallest plates which he can buy, as the first few results are sure to be far from perfect, and the cheaper the plates spoiled the better. This does not, however, bind him to the smallest size. All photographic cameras are made so that several different sized plates will fit into them, and after the first difficulties are over, the tyro is sure to aspire to the production of something larger than the well-known "card" or carte-de-visite.

In considering size of plate to be worked, it must be borne in mind that the larger the plate the greater the weight to be carried into the field, the greater the difficulty of manipulation, and the heavier the expense at every turn. This being the case, we would suggest to our friends as a good size that known as "half plate"; this is a plate measuring $6\frac{1}{2}$ inches by $4\frac{3}{4}$ inches. This allows of pictures being taken of the popular cabinet size, and the apparatus necessary can very easily be manipulated in the field. A somewhat larger size can easily be carried by an active man; but we should recommend that, at any rate, nothing greater than "whole plate," or $8\frac{1}{2}$ inches by $6\frac{1}{2}$ inches, should be attempted. The smallest size of plate offered for sale is the "quarter plate," measursng $4\frac{1}{4}$ inches by $3\frac{1}{4}$ inches, and, as we have said, the beginner should confine himself to this size till he has become somewhat familiar with the different operations involved in the taking of a negative.

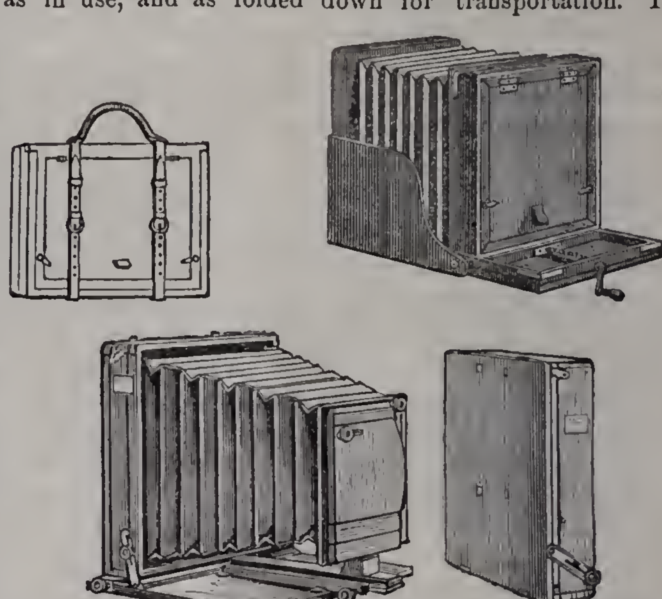
Having decided the size, the next thing to consider is in what manner to purchase the apparatus; and here we must say emphatically that the only way in which to be sure of getting reliable photographic requisites is to go to a first-rate dealer, and to purchase them new from him. There is a general idea in the mind of the non-photographic public, probably gained from seeing numbers of old cameras and lenses exposed for sale in pawn shops and such like, that great bargains are to be made in second-hand photographic apparatus, and that the beginner may "pick up" what he wants very cheaply by a little looking about. There can be no greater mistake. The experienced photographer *may* occasionally pick up an article very cheap; but the man without technical knowledge will be sure, if he attempts to do the like, to find on his hands goods which will be useless to him when he has somewhat advanced in his art.

Having thus advised our reader where to purchase his apparatus, there still remains the question, "How? Is it advisable to go in for a complete set, or to buy each article separately?" The beginner will be best advised in this matter by the state of his funds. The "sets" made up by most of the chief photographic dealers are most excellent and complete; but the sum charged for them is greater than many are willing to lay out at once. These may buy at first only those articles which are absolutely necessary to begin with, and may add to their store from time to time, as they think fit. We give a list of the articles most necessary for working quarter plates, and afterwards shall say a word on such of them as seem to us to call for special description:—

A camera.
A lens.
A tripod stand.
Three flat dishes or trays of porcelain or other material.
A graduated measure, holding $\frac{1}{4}$-ounce.
A graduated measure holding 4 ounces.
A dozen gelatine quarter plates.
A dark-room lamp.

A photographic camera is, as probably everyone knows, a sort of box, at one end of which is held the sensitive plate, and at the other end of which is held the "lens"—which latter throws an inverted image of any object in front of it on to the plate—and that there is a means of adjusting the distance between the lens and the plate, or of "focussing" the camera. Every camera has, besides this, a piece of ground glass, which can be put in the exact place to be afterwards occupied by the plate, and upon which the image can be seen so as to facilitate focussing. It is also fitted with a "dark-slide." This is a sort of case in which a sensitive plate may be fixed. After this camera has been focussed, the dark-slide is placed in the position before occupied by the ground glass, which latter is removable. The "shutter" or sliding door of the dark-slide is then removed, and, on taking the cap off the lens, the image falls on the plate. As many dark-slides as are desired may accompany a camera, and thus a number of plates may be carried into the field. Slides are also constructed to hold two plates each, and are called "double dark-slides." These are by far the best and most convenient to use for dry plates. Three slides are a common number to accompany a camera. This enables half a-dozen plates to be carried out. Each dark-slide should be fitted with a set of "carriers." These enable plates smaller than the largest size for which it is constructed to be placed in it.

All modern cameras for use in the field are made so that they can fold up into small compass for ease in carrying, and have "bellows bodies," that is to say, can be drawn out and in like a concertina. We illustrate two of the best modern forms of camera, showing in each the camera as in use, and as folded down for transportation. In



purchasing a camera, the photographer should get one which will open to a considerable distance—if possible, as much as twice the length of the largest size plate which it will work. In some part of his career the amateur is sure to aspire to the taking of portraits. His attempts in this direction are almost certain to be failures, and to cause great pain to his friends, but nothing is surer than that the portraiture fit will attack him. When it comes to this, he will find a camera which opens to a considerable length a great advantage.

There are various adjustments attached to modern cameras which, although of little use in the hands of the beginner, will be found of great convenience to him when he is more advanced. These are chiefly a vertical and horizontal adjustment of the front on to which the lens is screwed, and what is called a "swing back." This latter provides a means of varying to a certain extent the angle between the sensitive plate and the axis of the lens. A leather case into which the camera and the dark slides can fit, should be provided. The lens is the next most important piece of apparatus, even if it is not the most important of all. As we intend to devote a special chapter to lenses, we shall not go much into the question just now, but shall merely advise that what is known as a "single achromatic" lens of such a length of focus as to enable the largest plate which the camera will hold to be covered should be purchased. The lens should be bought direct from some reputed maker. The particular form of lens known as the "wide angle landscape" lens is the best.

The tripod stand calls for little special remark. Its general form is known to all. In those of modern construction each leg folds into two, so as to make the whole more portable. The only requirements of the camera stand are that it should be light, should be easy to fit up and take down, and should be quite rigid when fixed up.

The flat dishes or trays—or, as they are sometimes called, flat baths—are for use in the operation of developing, fixing, &c., to be described in a future chapter. Such dishes, made of so-called porcelain, can be had for a few pence each, and we should recommend that such be purchased for quarter-plate work. When the photographer advances to larger sizes, he may indulge in the more expensive and more convenient dishes made of ebonite and other light material.

The dry plates can be bought from any photographic dealer. They are extensively advertised in the NEWS; but we cannot take upon ourselves to recommend one make in preference to another. We have found all excellent, the cheap as well as the more expensive.

The dark-room lamp will be described when we come to the chapter on the "dark-room."

INTERNATIONAL PHOTOGRAPHIC COMPETITION.

THE Council of the Edinburgh Photographic Society invites photographers throughout the world to take part in a photographic competition for the most suitable pictures for presentation prints to members of the Society.

The following prizes are offered:—

1st. The handsome Gold Medal of the Society.					
2nd Silver Medal from same die, and			£5	0	0
3rd.	Do	do	3	0	0
4th. Bronze do		do	2	0	0
5th.	Do	do	1	0	0

The Council wish to restrict competitors as little as possible, but suggest that the size of print should be not less than $8\frac{1}{2}$ by $6\frac{1}{2}$ inches, nor larger than 16 by 12 inches. The subject is left entirely open, but it is essential that competitors comply with the following conditions, which will be strictly enforced:—

1. The negatives must be suitable for producing not less than 500 prints by a permanent process at a cheap rate, and lent to the Society for this purpose.
2. Competitors, if required, must forward negatives for inspection prior to the award.
3. Prize prints to be the property of the Society, and the negatives to remain in the custody of its curator until after the required prints are issued to the members.
4. Pictures to be unframed, and, if mounted, must be on cardboard only.
5. No lettering, whereby the competitor can be identified, will be permitted upon the picture or mount, beyond a simple sign, number, or motto, each picture to be accompanied with a sealed envelope bearing this mark outside, and within the name and address of competitor.
6. Competitors to forward their pictures, carriage paid, not later than 30th September, 1882, adressed to the curator, Mr. J. M. Turnbull, 19, St. David Street, Edinburgh.

It is proposed to hold a public exhibition of the pictures sent for competition.

The Council will take the utmost care of all works submitted, but they will not hold themselves under any responsibility.

Unsuccessful pictures will be returned, if desired, at the competitor's expense.

NOTE.—Competitors may supply permanent proofs from their negatives, and enclose in the sealed envelope an estimate for producing 500 similar prints, but this matter will be considered entirely apart from the award.

FRENCH CORRESPONDENCE.

DARK RED NEGATIVES FOR THE BITUMEN PROCESS—IMPROVEMENT IN THE METHOD OF TRANSFORMING NEGATIVES INTO POSITIVES—A SOLVENT OF SILVER CHROMATE—NEW PHOTOGRAPHIC WORKS.

Dark Red Negatives for the Bitumen Process.—When negatives are taken from line drawings, for the purpose of engraving chemically, it is necessary to have a ground of perfect opacity. This result can be obtained by means of the following formula, which gives a red ground, and one completely impermeable to light. In the first place, a rather weak negative must be taken; it may even be a little grey in the ground. This is then fixed, and washed in plenty of water, and then plunged in the following bath:—

Water	... 1,700 grammes
Red prussiate of potash ...	... 65 ,,
Pure nitrate of lead ...	... 100 ,,

It is then again thoroughly washed, and, afterwards, an 8 per cent. solution of yellow chromate of potash, mixed with one-third of ordinary ammonia, is flowed over it. After this it is very carefully washed a third time. This method of intensifying is very well adapted for plates of plans and maps, and for the reproduction of any kind of line drawing.

Improvement in the Method of Transforming Negatives into Positives.—Captain Biny has improved his process for directly transforming a negative into a positive. He develops with a solution of lactate of iron, and then he exposes to the light, at the same time keeping up the action of the developer. After this he washes the plate, and plunges it into a weak solution of bichromate of potash, the manipulation being subsequently continued as previously described. Lactate of iron seems to produce excellent results as a developer of gelatino-bromide plates. It is dissolved in hot water up to the saturation point, and then allowed to cool. When it is used, two parts of the oxalate are mixed with one of the lactate, and the mixture is filtered. The image comes out beautifully with this developer.

A Solvent of Silver Chromate.—Another method recommended by Captain Biny depends on a mixture which he has discovered for dissolving silver chromate. This mixture consists of:—

Water	... 100 parts
Nitric acid	... 5 ,,
Alcohol	... 15 ,,

Alcohol in the presence of nitric acid and of an insoluble chromate seems to cause the formation of acetate of chromium and of malate of ammonium, which, if they are not soluble in, are at least carried off by water, and are thus rendered incapable of injuring, during the subsequent development, the image formed of salts of silver. A gelatino-bromide, therefore, which contains chromate of silver will give up its chromium to the alcohol and the nitric acid, so that by this means it will become neutral. From the peculiar action of this mixture, Captain Biny thinks that a method may be deduced of distinguishing directly whether a gelatino-bromide contains an excess of nitrate of silver. Such a bichromatised gelatino-bromide, after being dried, and the whole of its surface exposed to the light, will, when dipped into a solution of oxalate of iron, become completelely blackened. On the other hand, a gelatino-bromide which has been perfectly bichromatized, but is absolutely neutral, will, after exposure, not be blackened by the oxalate of iron.

New Photographic Works.—Two special works have just been published. The first; "L'Aide Mémoire de la Photographie pour 1882," by M. Fabre, a photographic annual in which there is always given a clear résumé of the progress effected during the past year. The second is, "Le Cours de Reproductions Industrielles," an account of the principal graphic processes of reproduction. Being myself the author of this work, I can do no more than mention its publication, and will only add that it contains the courses of lectures which I have delivered every year at the "Ecole Nationale des Arts Décoratifs."

LEON VIDAL.

ON PLATINOTYPE PRINTING.

BY W. COBB.

WHAT! another short paper on gelatine plates? Oh! please, Mr. Editor, don't be too exacting. It strikes me that fiddling so long upon one string, however harmonious at first, may become like "sweet bells jangling out of tune and harsh." Besides, having had so much to do with gelatine emulsions, I am beginning to think seriously that, as like begets like, my brain has acquired the faculty of setting like such emulson, and so refuse to flow with the necessary ideas. Recognising this as a possible fact, I think it is high time to strike another chord, and if I can succeed in making it reverberate to some good purpose, I shall feel inclined to dance with joy to music of my own making. Gelatine emulsions and plates have had a very large share of attention given to them for a long time past—doubtless deservedly so, considering the very important part which they now play in our system. But there is another element in the photographic economy, which, recognising its bearing upon our future prospects, is, in my humble opinion, of sufficient importance to warrant us in giving to it a greater amount of attention than we have ever yet done: I refer to our method of printing. There is quite as much necessity for a revolution there, as ever existed in the negative department. Is not that a positive fact? There may be—indeed, I will admit that there is—a great charm and richness about a well-toned silver print; and so there is about the rich autumnal tints of nature, or the silver gray of the luxuriant appendages which man is sometimes vain enough to pride himself so much upon; but I must confess that all these have more or less a depressing influence upon my mind, for—

"Tho' rich and charming in their way,
They bear the impress of decay."

Regarding all this as inevitable, there is yet no reason whatever why we should not put a check upon it when we can—in fact, as a rule, we do. Then let us set to work and secure more permanent prints from our negatives, especially as existing means for doing so are now so ample and easy. I think it is a great pity that the public do not more frequently—

Ring in our hearing the doleful cry—
These shadows how fleeting—how soon they fly!
They pleasantly greet us, then bid us good-bye.
Our turn will come next: we'll stop the supply.

Ah! that would do it! If they only laid a finger upon our bread and butter we should see the necessity for immediate action, and treat them more fairly in this matter. I am very pleased to find that there is a growing feeling on the part of the public generally in favour of platinotype printing, and it seems to me that if there could be more concerted action amongst photographers it might be made a popular method of perpetuating our productions. It is something new to them, and there is always a charm in novelty, apart even from its intrinsic value. It is worthy of note that the Platinotype Company have very recently adopted a much more reasonable policy than formerly characterised their proceedings, and, if I mistake not, this will prove a benefit alike to themselves, to photographers, and the public. I would very strongly urge upon the members of our fraternity, who have not already done so, the desirability of giving this process a fair trial, and introducing it to their customers. The working details are very simple and interesting, and the proofs themselves are stated upon highest authority to be unquestionably permanent. The only difficulty I have found in working this method is, that of keeping the paper absolutely dry, which, in order to secure the best possible results, is of vital importance. In support of this fact allow me to state that only a short time since, I had occasion to make a large print from a very intense negative. After taking, as I thought, all necessary precautions against the influence of damp, I placed the printing frame containing the negative and paper in the open air to print. Result No. 1 was a poor, weak, muddy-looking proof. Knowing the paper to have been in perfect working order only a day or two before, and the atmosphere being as free from humidity as could reasonably be expected at this season of the year, I was puzzled, and made a second attempt under similar circumstances, but with a similar result. I then took the printing frame, negative, and pads, and thoroughly warmed them before the fire, and tried a third time, making the exposure in an apartment heated with hot air. The result proved all I could wish. Here, then, was a case where, if the conditions of success had not been in a measure understood, the process itself might have been put down as the delinquent. There is every reason to suppose that many of the failures which have arisen in working this beautiful process are directly traceable to the same cause.

I would just add that, as a medium for working upon, the paper as prepared lends itself most admirably to all the requirements of the artist, whether it be for colour or black and white.

ROMANCE AND REALITY IN PHOTOGRAPHY.

BY C. S. THOMPSON.*

THE subject I have chosen for my paper this evening necessarily gives it a somewhat miscellaneous character. That photography has its romantic side few will deny, but that romance is of such an erratic order that it is hard to say when or where it may be found. There may be romance in the subject—a subject teeming with the pure and lovely freshness of youthful vigour; but, at the same time, it may defy all the skill of the magician of the camera to reproduce the same upon his plate. On the other hand, the subject may be real and ordinary when as such the photographer wishes to secure it, but that tantalising spirit creeps in where least expected.

Perhaps the foregoing may be explained more clearly if we ask again the oft-repeated question—"Can photography be classed amongst the fine arts?" Painting and photography are undoubtedly sisters, but the similarity in their disposition and temperament is still an open question. One man may be able to take a good photograph, and another may be able to produce a correct drawing of a table or chair; but not one or the other of these could from their works be ranked as an artist, and, therefore, not one or the other would be able to infuse the slightest trace of romance or sentiment into his works. For my own part, I believe that unless a man be somewhat of an artist, he will be nothing more than a mechanical photographer.

There is one great distinction between art and photography, forming a barrier that is often overlooked. To the painter a certain amount of licence is always granted. His conception of a picture bears the stamp of his own personality. The treatment and touch of his work give him the opportunity of throwing life and spirit into a subject which may perhaps lack both. The photographer's case is different. He has to deal with things provided already, and, not having the same power to modify them, it is only by judicious selection, aided by a mind carefully trained in the study of lights and shadows, that he will be able to cause any of his own individuality to enter into his works.

The early photographs, on the whole, bear little artistic merit with them, especially in portraiture. Who was to blame for this? I know not; but my impression is that on it being discovered that a correct delineation of any object could be produced in a photograph, then that very fidelity became its own drawback. The general public also contributed—and do so now to a great extent—to destroy all romance in portraiture. The average sitter would not be satisfied with a picture that did not reproduce all his pet peculiarities. He wants everything to come out well. Perhaps he has had his hair cut and carefully oiled for the occasion, his handkerchief neatly folded square and emerging from his pocket to be in keeping with a gorgeous array of shirt

* Read before the Glasgow Photographic Association.

front, and his coat left unbuttoned so that his watch guard may be visible to his admiring friends. These are only a few of the traits of the "every-day young man" who does his best to bring photography down to a very low level.

But, unfortunately, the blame does not rest with his class alone. People in good positions, well educated, and, who, therefore, should know better, are almost as bad. As a rule they don't appreciate artistic portraits, and most likely will refuse to take them if they are offered. Of course if a person sits for his portrait, he should get a portrait and nothing else. I don't mean to say that the figure should be subservient to the accessories in the composition of the picture—far from it; otherwise beautiful pictures are often spoilt from this cause alone.

Why furnish a picture with articles that have no connection with the figure or the pose? But, apart from the furnishing of a picture, there is generally something about the arrangement of the figure that proclaims aloud the fact—"I am having my likeness taken!" This may in a measure be accounted for by the sitter having for some time previously been studiously experimenting to discover what style or attitude will suit him best, and having selected one, he desires the photographer to take him so. The most probable result of this will be the total loss of all the characteristics of the man. It is a most difficult thing to persuade people to allow their portraits to represent them in their everyday life; but this is, I am afraid, an evil for which the photographer has no remedy.

However, the same excuse cannot be made for pictures of actors or actresses taken in costume. For instance; an actor represents a certain character in a certain piece. Now there are few, if any, plays upon the stage that are not full of attitudes and situations incidental to the piece, and characteristic of the character; but often when the photograph is produced it is as much like one character as another. Why, then, throw all individuality on one side and give us nothing but a portrait of a person in some fancy dress?

It is here that the forethought and conception of the photographer are required to get life and animation into his work, so that it may tell its own tale. It is here, also, that the artistic training of the operator will tell him what is required, and combining this with his technical knowledge, he will be able to produce results which are faithful portraits, when, at the same time, the crudeness of stern reality is toned down by a touch of romance or idealism.

In some cases, though where feeling plays the most important part in a subject, the camera fails utterly. I may mention, in illustration of this, a deathbed scene—a single figure, encircled by sorrow-stricken relatives. What are the feelings such a scene as this would stir up in our breasts? And what feeling would we have on viewing a photograph of the same? Some people might approve of it, but others (and I think they would be in the majority) would say it was a desecration of the most solemn page in the history of life. Where is the romance in the photograph of a battle-field? What becomes of—

"All quality,
"Pride, pomp, and circumstance of glorious war?"

You may find them on the easel, but not in the camera. Therefore, as far as certain subjects are concerned, photography cannot (at least at present) raise itself up to the level of her sister of the brush. Many, I have no doubt, will be ready to contradict this assertion of mine; nevertheless, I believe it is true.

But if photography be denied certain most important facilities, such as I have just mentioned, she has others which in some measure help to compensate for these deficiences. In quiet, sunny, rural scenes; a mirrored lake, surrounded by hills, in all the luxuriant vesture of glorious summer; a yacht, with a cloud of snow-white canvas raised to catch the first passing breeze; or some wild glen or rugged mountain side only partially revealed between the driving clouds of mist. In such scenes as these (and there are many like them) the camera has equally as much, if not more, power than the brush. Take, for instance, some of the beautiful landscapes and studies now before the public. They are full of artistic feeling, and appeal more directly to our minds, because they faithfully represent scenes in our everyday life.

In using the word "romance," I am not sure if it fully express that feeling of mind and conception which is necessary. Some people may use other words that appear to them more applicable; but it matters little what word is used, for it will all result in an attempt to define that almost mysterious connection between mind and matter. I feel that what I have said this evening falls far short of what it was my wish to say, could I but frame the thoughts that are in my mind.

The two sides of the subject are so much alike, and yet so very dissimilar, that to draw inferences from one without touching upon the other is a most difficult and perplexing task; but it is a subject that demands the attention of every photographer, no matter if he be professional or amateur, or his work landscape or portrait. There is too much of the cut-and-dry style at present in vogue, which should be done away with as soon as possible. And now that we have rapidity of gelatine plates, and lenses of great "depth of focus," we have a far better chance of producing pictures that will compare more favourably with the work of the painter than in the early days of photography.

I may mention, in conclusion, a very curious case that has of late occupied the attention of judges in the law courts of Brussels, and which bears directly upon the subject of this paper. A Belgian artist, M. Van Beers by name, has recently painted a picture entitled, *Le Syrene*, or *Le Premier Pas*, which, on being exhibited, called forth the censure of the critics, one of whom boldly declared that the artist used photography as the foundation or base of his pictures. M. Van Beers very naturally resented such an an assertion, and forthwith entered an action against his accusers. On the case being decided there was little favour for the artist in the finding of the judges, who gave it as their opinion that M. Solvay (the newspaper critic) had not overstepped the bounds, and that his statement was quite justifiable. This verdict does not, however, settle the question that will have most interest with artists generally. Whatever may be the case, this painting has certainly a very photographic appearance about it. If it be not a coloured photograph, then M. Van Beers has in his treatment and drawing managed to get that very fault into his work which is the greatest drawback in ours, namely, too much reality and too little romance.

Photographers as well as painters should, if they have any artistic knowledge at all, be able to see more in a subject than there really appears to be on the surface, and they should not have it said of them, as was said of a certain man, that—

"A primrose by a river's brim
A yellow primrose was to him,
And it was nothing more."

Now, gentlemen, here is an engraving from the picture in question, so you may judge for yourselves how much the photographer has assisted the artist in the production of *Le Syrene*.

Correspondence.

A PHOTOGRAPHIC SOCIETY FOR THE NORTH OF LONDON.

Dear Sir,—Judging from the reports which appear periodically in the News, I almost envy those of my brethren who are privileged to attend the very interesting and instructive meetings of the different societies of which they are members. I take this occasion of asking whether in the North of London (where a society once existed) there is not sufficient material to form a society? There are the adjacent districts N.W. and N.E., containing several photographic establishments. Perhaps there are others, who have felt the same want as myself, anxious to come forward in the matter.—Yours very truly,

North London.

SULPHITE OF SODA DEVELOPER.

Sir,—I have been surprised that so little notice has apparently been taken of Mr. Berkeley's sulphite of soda developer. I tried it some time ago, and, since doing so, have abandoned all others for it. I am sure it will prove a boon to those who, like myself, have always preferred pyrogallic to ferrous oxalate, and I am writing in the hope that others will be induced to give it a trial.

The quality of a plate developed by pyrogallic and sulphite of soda is very closely akin to that of one developed by ferrous oxalate. There is none of that yellowness caused by plain pyrogallic. The colour is such as to produce excellent transparencies for the lantern, and even prints upon opal glass. The printing qualities, too, of the negative are much superior to those produced by plain pyrogallic. I find also that it is far easier to obtain the requisite density with the sulphite than with other developers.

A picture on a properly exposed plate usually, with me, begins to appear in about half a minute, and the development is generally complete in from four to five minutes, thus allowing ample time to make any modification the development may indicate.

I may add that I use $1\frac{1}{2}$ grains pyrogallic, and 6 grains sulphite of soda (neutralized) in every ounce of developer, to this I add from $\frac{1}{2}$ grain to 2 grains ammonium bromide, and from 2 grains to 3 grains ammonia according to the requirements of the plate.—Yours truly,

Vero C. Driffield.

EMULSION MAKING.

Sir,—In your leader (page 73) you say that it is doubtful if the finished emulsion contains any chloride or iodide at all. If you look by daylight at cloths that have been in contact with an emulsion containing an iodide, you will observe that they are of a deeper yellow than when only bromide is used, and, if there is any chloride in the emulsion, it soon gets of a purple colour, proving the presence of chloride, as neither bromide nor iodide gives this colour; and if a plate covered with an emulsion containing chloride is put behind a negative in a printing-frame, a picture will make its appearance in a few minutes, and this picture remains even after all the bromide and iodide is dissolved in the hyposulphite bath. It is a noteworthy fact that the chloride is far more sensitive than when in combination with albumen, and, although the image is faint, no doubt its vigour would increase in proportion to its increase in the emulsion.

I may add that the emulsion I use contains only 10 grains of chloride and 120 grains of bromide. Any one can be satisfied of the truth of what I state by an experiment.—Yours respectfully,

William Birrell.

THE DUNDEE EXHIBITION.

Sir,—Your correspondent, "Due South," is dissatisfied with the awards of the Dundee jury, but you declare your conviction as to the integrity of the judges—a most proper view. There can be no doubt this medal-giving business causes great heart-burnings and jealousies to spring up, and when a man once obtains a medal he appears to expect the highest awards at every exhibition to which he may contribute for the term of his natural life. I should say Messrs. Robinson and Jennings would consider it a great impertinence to be asked such a question as "Due South" suggests; both these gentlemen have more medals than they can comfortably stow away, and would certainly not object to a few going to the "second and third-rate men." Indeed, Mr. Robinson's window gives one more the impression of an engraver's than of a photographer's, such is the plentitude of the numismatic display.—I am, sir, yours obediently,

Southron.

ERUPTIONS CAUSED BY THE ALKALINE DEVELOPER.

Sir,—In your report of the Thursday evening meetings in last week's News, there is a statement by Messrs. Henderson and Turnbull, regarding the ill effects of the alkaline pyrogallic developer on the system; and as I am at the present time suffering from the same symptoms as there described, I can fully corroborate their statements. I have worked gelatine plates for the last three years, and have always used the alkaline developer. In June last the first spot appeared under the joint of my left knee, first being very small, but gradually spreading in a circle to the size of a shilling, itching a great deal at times, and when rubbed, watery matter exuding; the next one appeared on my left hand, between the knuckles, which I thought at first was a heat bump, and knowing that ammonia allayed the irritation, I applied some; but as the place gradually grew bigger, I tried numerous remedies, none of which did any good, and it was not until I went for my holidays that there was any improvement, when the place on my leg got quite well, and the one on my hand nearly so; but I had not been back to business more than two or three days when my hand was quite as bad again, and just about Christmas another appeared on the back of my right hand, which is still very bad. It was not until about three weeks ago that I began to suspect the real cause, as I then noticed that if I did not develop any plates for a few days the places would be decidedly better, but directly I did so they were worse again. I think this a matter that deserves investigation in the interest of the profession, and hope you will take the matter up in your valuable journal. For my own part, I am trying the ferrous oxalate, and mean to try and banish altogether the alkaline pyrogallic.—I am, yours, &c.,

Frank H. Berry.

ELEMENTARY LESSONS IN PHOTOGRAPHY.

Sir,—The writer of this is quite overjoyed to read that elementary lessons are to appear in the Photographic News. Having some leisure, he would like to occupy it by photograppic amateuring. Sensible of slowness of comprehension, and being somewhat dull of understanding, he ventures to beseech that the lessons which are about to be given may be carefully adapted to the very meanest capacity for receiving instruction, through their author being mindful to point out every inch of the ground he traverses. For the sake of the densely stupid, let him not, in desiring to avoid becoming too voluminous, err in the opposite direction, and be at all chary of furnishing the very fullest painstaking explanations on all points whatsoever.

The undermentioned will owe him much gratitude, if he will kindly condescend to describe with the utmost minuteness and distinctness of language each single separate step, *seriatim*, of not simply what is to be done, but exactly how it is to be done, and in what order and manner, stating all the little (apparently) insignificant minutiæ of manipulation and arrangement which are essential to success, and which those who know how to practise them find so valuable in yielding perfect results.

It is exceedingly difficult for an instructor who can do anything skilfully, to analyze what he does, take it to pieces, and show how perfection is gradually arrived at. The method has become so much a matter of course to himself, that it seems to him as if the same degree of knowledge and power he possesses must come to others by the light of nature, and not through his brain being taught to work, and his habits being trained and formed. A teacher commonly assumes that his pupils have far greater intuition than they really possess. But how likely it is that even highly-intelligent persons may easily overlook what is obvious, appears from the story of Sir Isaac Newton not seeing that there need not be two holes in his door for his dog and his cat.—Faithfully yours,

Chesterfield Junior.

Proceedings of Societies.

Thursday Evenings for Photographers.

At the meeting held on the 23rd ult., Mr. J. A. Harrison occupied the chair.

Mr. A. J. Brown read a paper entitled, "Notes on Pits in Gelatine" (see page 102), and a discussion followed.

Mr. Henderson said that pitting had been attributed to the admixture of two gelatines of different setting powers, but he was of opinion that it was partly due to the presence of carbonic acid gas; he had found that an emulsion giving pits when freshly made, if kept for twenty-four hours in a liquid state did not then give pits.

Mr. W. E. Debenham thought Mr. Brown's experiments were very interesting and useful. In his experience, thinking grease might be the cause, he had washed the sheets of gelatine with ether, and this not having the desired effect, he had dissolved it and agitated with ether, but all without success, thus showing that grease was not the culprit.

Mr. Mackie suggested that it would be interesting if the experiments were repeated, using a solid fat such as suet. He showed several negatives having iridescent stains on them, more especially near the edges and in the shadows; this he found could be cured by immersing the plate in a solution of pure cyanide of potassium.

Mr. Debenham attributed the stain to gas fumes in the air.

Mr. Brown thought it was a deposit of metallic silver caused by contact with the air.

Mr. Reimann had, when developing a negative, observed a stain very similar to that shown by Mr. Mackie, but found that he could rub it away with his hand.

Mr. Haddon said that when chloride of calcium was used in drying-cupboards, if placed in an ordinary beaker, after a time it becomes inert by being covered with moisture, and he showed a modified arrangement he had devised to overcome this difficulty; this consisted of a perforated inverted cone fixed in a saucer-like trough so that the moisture drawn from the air by the calcium percolated through the holes in the cone into the trough beneath.

Mr. Ashman had noticed that if a negative was brought into the sunlight after being fixed, and previous to washing off the hyposulphite, it becomes much-reduced in density.

Mr. Debenham had noticed the same effect if the plate was slightly washed first.

Mr. Henderson thought it was not so much caused by the sun as by the action of the air in the presence of hyposulphite, and instanced the fact that if a plate is removed from the hyposulphite, and left without washing, in a very short time it will be dissolved away; whereas if a negative is left for some days in the hyposulphite solution it will not be much reduced.

A question from the box was read, viz., "Is there any means of toning a silver print with gold after it is fixed?"

Mr. Henderson suggested the old hyposulphite and gold formula.

Mr. Debenham said that Mr. England's pictures of the 1851 Exhibition were all toned by being placed in a solution of hyposulphite till yellow, and then removed to another of hyposulphite and gold 1 to 6.

Mr. Henderson had also adopted this method in consequence of noticing that the prints did not commence to tone till the chloride had been removed.

Liverpool Amateur Photographic Association.

The monthly meeting of this Association was held on Thursday evening, the 23rd ult., at the Free Library and Museum, Mr. E. Roberts (President) in the chair.

The minutes of the preceding meeting having been read and confirmed,

The Chairman announced that a picture of Meyringen, by Mr. W. England, had been selected by the Council for enlargement as the presentation print for 1881. He (the Chairman) then read the following rules which had been drawn up by the Council for the regulation of the annual competition :—

1. That pictures for competition be sent in not later than 6.30 p.m. on the day of the meeting of the Association in November, addressed to the Honorary Secretary, Liverpool Amateur Photographic Association, Free Public Library, Liverpool.

2. That each picture shall bear a private mark or motto only, and be accompanied by an envelope bearing a similar mark or motto outside, and contain within the proper name and address of the competitor.

3. That the subjects for the annual competition be chosen by the Council, and announced to each member on the circular summoning the November meeting.

4. That certificates of honour and prizes be awarded by three judges, to be selected by the Council.

5. That each picture be mounted on a separate mount.

6. That only one picture by the same member be submitted for competition in each subject.

7. That the competing pictures must have been taken during the year preceding the adjudgment of the certificate or prize, and that the development, printing, and toning must have been the *bona fide* work of the competitor.

8. That a certificate of honour be given annually to the producer of the best picture illustrative of each subject.

9. That a prize be given annually to the producer of the best series of competitive pictures.

10. That a prize be given for the best picture of the year, not necessarily a competitive subject.

11. That a prize be given annually to the producer of the best picture, on any subject, on plates or films entirely prepared by the competitor.

12. That all exhibits become the property of the Association.

The following had been selected by the Council as the subjects for 1882:—Landscape, with Distance; Country Lane; Waterfall; Flowers, Fruit, or Ferns; Relics of the Past; Instantaneous; Human Figure Study; Winter.

The Secretary read portions of a letter from Mr. J. H. T. Ellerbeck, announcing that he proposed to be "at home" on each alternate Tuesday evening from 7 to 9 p.m., at his address, No. 7, The Elms, Peel Street, the Dingle. These "at homes" are "open to all or any members who wish for information, or a quiet chat on matters photographic."

The Chairman referred in complimentary terms to Mr. Ellerbeck's most kind offer, and, on behalf of the Society, accepted it very gratefully. He thought that it could not but be of the greatest assistance to the members, and especially to those who had newly joined the Society, to receive the benefit of Mr. Ellerbeck's experience and advice.

The Hon. Secretary read a paper, by Mr. H. Houlgrave, "On the Intensification of Gelatine Negatives or Positives with Silver" (see page 103). The paper was illustrated by a number of negatives and positives, intensified by Mr. Houlgrave's process. These were greatly admired by all, as among the most perfect and beautiful specimens of photographic work which had ever been exhibited.

A unanimous vote of thanks was accorded to Mr. Houlgrave for his most useful and interesting paper.

Mr. A. Pumphrey, of Birmingham, then gave a detailed account of the modes of exposing, developing, and drying his new films. The filmograph, with its appurtenances, was exhibited and explained in every particular, and Mr. Pumphrey answered fully numerous inquiries put to him by the members present.

A vote of thanks to Mr. Pumphrey was proposed by the Chairman and seconded by Mr. W. H. Kirkby, and was carried by acclamation.

Mr. Knott then gave a lantern exhibition with the lime light, the slides having been supplied by himself, the Rev. A. T. Scott, Mr. Boothroyd, the Hon. Secretary, and others.

A vote of thanks having been accorded to Mr. Knott, the meeting, which was largely attended, adjourned till the last Thursday in March.

Talk in the Studio.

Leeds.—A meeting of the amateur and professional photographers in the Leeds district will, we are informed, be held at the Mechanics' Institute on Thursday, March 9th, at 8 o'clock, to receive the report of the committee, and make arrangements for the organization of the proposed photographic society.

A New Drama.—The *Daily News* says: "Mr. Baden Pritchard has dramatised his novel entitled 'Dangerfield.' The variety of character and the intrinsic interest of the story would seem to fit it well for the stage; and it is to be hoped that the author will, in spite of the defective state of our copyright laws, be permitted to enjoy the fruits of his own invention. 'Dangerfield' is a comedy-drama in three acts."

Metallic Designs on Glass obtained by the Aid of Photography.—An ingenious method of obtaining mirror-like designs on glass has been devised by Leclerc. The glass, having been silvered by the chemical process, is coated with a thin and uniform layer of sensitive bitumen, and this is exposed under a transparency, the next step being to wash away the unaltered bitumen with oil of turpentine, so as to leave the bituminous design on the silvered glass. The application of moderately strong nitric acid removes the silver, excepting where it has been protected by the bitumen, so that the metallic design shows like a mirror from the reverse side of the glass. The plate may be backed by paint or any other suitable material.

Mr. Sala on Art.—In distributing the prizes at the West London School of Art, Mr. Sala said that within the last thirty years there had occurred five distinct boons for which lovers of art ought to be grateful. The first and second were the purchase by the Government of the Elgin marbles and the series of international exhibitions which followed the Great World's Fair of 1851. For the third boon they had to thank two very different and conflicting influences, the great fire which destroyed the Houses of Parliament, and the remarkable religious revival then called Puseyism, and later Ritualism, which was awakened by the "Tracts for the Times." The burning of the Houses of Parliament led to a Royal Commission for the encouragement of the fine arts, and to the adoption of the Gothic style by Sir Charles Barry, aided by that wonderful draughtsman the elder Pugin, which not only necessitated the application of a good architectural style, but brought in the decorator, the maker of stained glass, the modeller, the carver, and the manufactures of encaustic tiles and brass work. The religious revival led to the cultivation of mediæval art, to a kind of pictorial Puseyism, encouraging at least in one direction the art of illumination which had been dead for centuries. The last boons, he said, were the spread of Japanese art in this country, and of photography. He could not help recognising the numerous lessons they owed to the Japanese, beautiful symmetry and design, and true sympathy and brilliancy of colour. As to photography, the mighty artists scorned it; yet it enabled them to contemplate exact representations of the great works of ancient art, the originals of which were only to be seen at Rome, Pisa, and other places on the Continent.

Photometrical Standards.—Last week Professor Dixon read an interesting paper on this subject before the Chemical Section of the Society of Arts. After alluding to the (apparently) insurmountable difficulties in fairly estimating light, owing to its composite nature, the various standards and methods of photometrical working were described, and, in most cases, experimentally illustrated, it being demonstrated that such methods were but ill adapted for comparing lights of differing qualities, as, for example, candle light and the arc electric light. A demonstration of Arago's polarization method of determining the equality of two lights excited considerable interest. The rays from two sources were decomposed by passage through prisms of Iceland spar, and the ordinary ray from one source was made to fall on the same spot as the extraordinary ray from the other source, three luminous images being thus obtained. When both sources were adjusted to equality, no polarization existed in the case of the light resulting from the superposition of the two equally polarized rays; the observation being made with a selenite or quartz plate, while the two remaining light spots were, of course, completely polarized.

Death of Professor Marreco.—It is our melancholy duty to record the death of Professor Marreco, which took place last night at his residence, Westmorland Road, Newcastle. The learned professor had been ailing for some time. Last summer he felt far from well, and in writing to Principal Aldis, with whom his relations were of the most affectionate character, he said a holiday would be absolutely necessary. From some cause or other this holiday was not taken. The Professor worked on until the close of the year, but from that date his strong life-energies began to droop, and he has at length succumbed to his malady. A. Friere Marreco, M.A., F.C.S., was born at North Shields. His father was a Portuguese merchant, his mother, Miss L. Harrison, was daughter of Mr. John F. Harrison, originally of Somerset House, a family ably represented in Newcastle by the eminent engineer of the name. At a comparatively early period the exigencies of commerce took Mr. Marreco's father back to his native country, and thus it was that in Lisbon the departed Professor laid the foundation of that extensive knowledge of chemistry by which he was distinguished. Although his connection with England was temporarily broken, while he was yet a youth he returned to Northumberland, and perfected his chemical knowledge amidst its manufactures. From 1859 until 1867 he performed the chief portion of the duties of reader in chemistry in Durham University, acting generally during that time as the deputy of Dr. Richardson. Ultimately he succeeded to the office of lecturer, and in due course became demonstrator in the Medical School in connection with the University. Professor Marreco was one of the original members of the Newcastle Photographic Society, and was also a member of its council.—*Newcastle Chronicle*, February 28th.

To Correspondents.

David Hedges.—You desire an answer, not from the Editor of the News, but from one of the Dundee judges; unfortunately, the latter is not in a position to reply, much as he might wish to do so.

W. H. Cheesmann.—Neither the exhausted alkaline pyr gallic developer, nor the iron oxalate solution, contains any silver or other substance worth saving. If you were working on a very large scale it might pay you to wash off the films from spoiled plates and to extract the silver.

F. Stanley.—The starch is free from hyposulphite, and we would recommend you to use plain collodion in preference to iodised. Such an experiment as the following would be sufficiently conclusive for founding a claim upon. Cut a print into three parts, one of which should be unmounted, the second mounted on a reliable sample of card, and the third on the doubtful sample, then keep all three in a damp cellar. It is, we believe, an established matter of law, that when a material is sold for a specific purpose, there is an implied guarantee as to its suitability for such use.

W. B.—There can be but little doubt that in the town which you mention there will be abundant facilities for disposing of good views of the neighbourhood. Situated as you are, it would probably answer your purpose to employ some photo-mechanical process, as Collotype or Woodburytype. We shall have pleasure in giving you any information in our power.

W. W.—The second formula (B) is to be preferred, and the use of hot water should be avoided.

H. A.—The value of negatives is so variable and so much influenced by special circumstances as to make it difficult to estimate. If the views you enclose have no special interest attached to them, and are merely to be regarded as photographic scraps, it is probable that you will not obtain more than 20s. each.

J. T. C.—Mere exposure to the air would not cause the blacking you refer to, and we are at a loss to account for the phenomenon. You might cut two small strips from the border, and try the effect of hyposulphite of soda on one, and of weak cyanide on the other. If you succeed in restoring the print, you had better secure as perfect a copy as practicable.

J. Berryman.—Of course we cannot say with certainty what is the cause of the defects which appear on developing your plates, but we have found a similar coloured fog to arise from either one of the following causes: 1. The use of dirty or porous vessels capable of contaminating the emulsion with decomposed remains of previous batches. 2. Partially decomposed or unsuitable gelatine. The "opaque gelatine" sold in packets by the grocers is often unsuitable and causes red fog; but we have always found the selected or "X opaque" gelatine sold by Messrs. Nelson and Co. to be satisfactory. 3. The use of imperfectly purified ammonia. The *liquor ammoniæ* sold as made from volcanic ammonia is generally pure. 4. Fumes of putrescent matter in the preparation or drying rooms.

F. Cowley.—1. Very good results have been obtained by the process you refer to, and you will find particulars in back numbers of the News. 2. The use of pink or white albumenized paper is a matter of taste; but you will find that comparatively few high-class photographers use pink paper except in rare cases. 3. Occasionally, but not often. *Second letter*. 1. We have no doubt that Mr. Henderson would send you a copy if you were to write to him. 2. Yes. The process is very easy, and plain directions will be found in previous volumes of the News or the Year-Books, and also in Captain Abney's Instructions. 3. About three-sixteenths of an inch is a convenient thickness. 4. It is a kind of mineral pitch which is found in many parts of the world. You can obtain it from Hopkin and Williams, of Cross Street, Hatton Garden, E.C. No definite formula can be given, as samples vary very much as regards solubility. 5. They will be printed in the Journal of the Society of Arts during the summer, and probably be reprinted in the Photographic News. Thank you for your kind wishes and suggestions, and rest assured that no number of questions will weary us as long as they arise from a sincere desire for information.

Thomas.—We should prefer No. 1.

G. M.—Considering everything, you would probably find the second most suitable for your purpose.

J. R. X.—We would advise you not to use acetate of lead at all, as it is practically impossible to prevent the formation of traces of the insoluble sulphate or the carbonate, and these easily become blackened by traces of sulphur compounds.

Bradford Experimenter.—It is a colourless and invisible gas, but when it comes in contact with the air it absorbs oxygen, and red fumes of the mixed tri-oxide and the tetra-oxide are formed.

T. Braid.—The single thickness of yellow-glass, like sample, will serve very well, provided you take great care not to expose your plates unnecessarily to the light.

K. L. Johnson.—The operation requires some care and experience, but by observing the precautions given in the paper referred to, and avoiding dampness during the process of laying the film, you ought to succeed.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1227.—*March* 10, 1882.

CONTENTS.

ABSORPTION OF LIGHT IN THE ATMOSPHERE.

The blue colour of the atmosphere on a cloudless day has, like very many of the other familiar phenomena which nature presents to us, been for a long time the subject of scientific investigation by physicists, and the enigma of meteorologists; and many speculations have been advanced respecting the cause, not only of the blueness of the sky, but also of the bluish haze which appears to veil dark shadows and distant objects.

Originally it was supposed that this tint was caused by the presence of exceedingly minute particles floating in the upper atmosphere, rendering it turbid, and reflecting chiefly the rays of smallest wave-length, owing to their very minute size. Nor is this theory without foundation, for many similar phenomena are known to be produced by matter in a finely-divided state. Professor Tyndall has performed many experiments, showing the action of vapours on light; and, by passing a beam of light through tubes containing air mixed with various organic vapours, he was able to produce artificial blue clouds. As the result of his experiments, he concluded that the blue colour of the sky was due to the existence in the higher regions of the atmosphere of excessively fine particles of water or of some other substance, so finely divided, indeed, that their wave-lengths form but a small fraction of the length of a wave of violet light. This theory is strengthened also by the fact that both the light emitted from his artificial blue cloud, as well as that from a blue sky, is polarised in a direction at right angles to the axis of the rays.

More recent researches, however, have thrown additional light upon this subject, and have led to the idea that the cause of the blueness of the atmosphere is to be found in the absorptive power of ozone. Nor can we deny the fact that it is extremely difficult to believe that the extraordinary transparency of the distance, on many occasions when the sky is bluest, could exist when the air is filled with innumerable particles of solid matter, however small they might be; for in that case we should expect increase of blueness to be accompanied by greater haziness of the atmosphere.

At no very remote period it was doubted whether ozone existed in the atmosphere at all; for, unfortunately, the tests for its presence are ambiguous unless applied with the greatest care. But, although our knowledge of its actual amount and variation is still far from being perfect, recent researches prove conclusively not only that ozone is present in the atmosphere, but also that it plays a very important part in the absorption of solar rays.

It is found that a column of air a square centimetre in section acquires a full sky-blue tint from the presence of only 2·5 milligrammes of ozone, and a very considerable quantity of air assumes a blue colour even when not mor than about $\frac{1}{700000}$ of its volume of ozone is present. Now this amount has been determined by Houzeau to be present under ordinary circumstances in the atmosphere. Hence it is extremely possible that ozone may be the cause of the blueness of the sky.

It has been shown by Hartley, who recently contributed to our columns the account of some interesting photo-spectroscopic observations, that if the absorptive power of gases and vapours causes this colour in the atmosphere, the other constituents of the air cannot play any important part in the phenomenon; for ammonia, water-vapour, and carbonic acid are all perfectly diactinic, even in considerable quantities. The only other substance capable of absorption of solar rays would be the oxides of nitrogen; but Hartley shows conclusively that it is impossible for these substances to have much effect in this respect; for if present, these substances would probably exist in the atmosphere as nitrate and nitrite of ammonium, which in minute quantities he found to be quite diactinic. Even if present in a free state in sufficient quantities to absorb the visible rays, the sky would not be blue at all; for photographs of the spectrum transmitted by the oxides of nitrogen show that these gases absorb just those rays which ozone transmits.

Now it is without doubt that the solar spectrum, as transmitted by ordinary air, is limited by the absorptive power of some constituent of the atmosphere, nor is this constituent invariably present in the same proportions; for Cornu has shown that the limit of the spectrum varies considerably with different meteorological conditions, the actinic rays being transmitted in greatest quantity at noon and at high elevations.

These facts, coupled with the extraordinary power which ozone possesses of absorbing the ultra-violet rays, seem to prove beyond doubt that Hartley's views are correct, and that the ozone present in the atmosphere causes the limitation of the solar spectrum.

Thus the amount of ozone present in the air acquires a peculiar interest to photographers, by directly influencing the actinism of the sun's rays. Unfortunately, however, it is extremely difficult to determine with accuracy the variations which it undergoes. In the opinion of some chemists the proportion of ozone in the air is constant; but the experiments of Houzeau and Reiset seem to prove that it increases in quantity at high elevations and with the prevalence of S.W. winds. Nor is it probable that its amount depends entirely upon the electrical conditions of the atmosphere, for it is produced in considerable quantities during the evaporation of water, and is probably derived from this source rather than from aerial discharges of electricity. Its absence from the air above great towns is explained by the fact that it is reduced by organic matter and sulphurous acid to the state of ordinary oxygen: but probably the ozone in the higher regions of the atmosphere would remain unaffected.

At a recent Thursday evening meeting the question was discussed, whether fog in the atmosphere cuts off the actinic rays of light in the same proportion as it does the luminous rays. The opinion was, that on account of the absorption of actinic rays by the yellow colours of the fog, the more refrangible rays were cut off in even larger proportion than the luminous rays. It is well known that smoke and volatile hydrocarbons are quite capable of extraordinary actinic absorption. In the opinion of Professor Hartley the presence of dust, such as carbon or finely-divided opaque matter, has no other effect than to intercept the light and to weaken the whole spectrum; but the presence of even a minute quantity of benzene or napthalene is to cut completely out a portion of the spectrum, so that no increase in the length of exposure would supply the missing rays.

It is gratifying to learn, however, that in most cases absorption does not increase in proportion to the quantity of the absorbing body present, but that generally a maximum effect is produced, beyond which any additional increase is without any appreciable effect. But it is without doubt that very large numbers of the imperfections in negatives produced by errors of exposure, on days when the conditions of light were apparently well understood, have their origin in atmospheric absorption of actinic rays. In all cases photographers should guard themselves against the fallacy that a clear sky is necessarily accompanied by the maximum actinism of light.

ELECTRIC LIGHT IN THE DEVELOPING ROOM.

A leader which appeared in the Photographic News, during July last, served to call prominent attention to the necessity for making some provision for ensuring a proper change of air in the dark-room; and in illustration of this point we referred to some calculations which we had made with regard to the amount of oxygen consumed by an ordinary gas jet, or by a paraffin lamp of similar illuminating power. Such a flame was found to consume an amount of oxygen corresponding to complete removal from no less than 40 cubic feet of air per hour; such a consumption of the vital element being approximately equal to the amount of oxygen absorbed in the lungs of an average man during two hours. Thus the lamp would possess a vitiating power corresponding to that of two men; but in making a comparison one must not lose sight of the fact that the lamp is likely to burn in the dark room for a longer time than that during which it is actually tenanted by the photographer or his assistants. Another point that must be remembered in connection with the lamp is the fact that unless the air-way through it is sufficiently large to insure the most perfect combustion, we have not only carbon dioxide formed—this in itself acting as a narcotic poison—but also carbon monoxide, this latter possessing, even when present in a minute quantity, a direct physico-chemical poisonous action on the blood. There can be but little doubt that many of the cases of injury to health (which have been attributed to fumes of ammonia or to pyrogallic acid) ought really to be laid at the door of carbon monoxide. It should be remembered that carbon monoxide is invariably formed when a e rbonaceous fuel burns with an insufficient supply of air, and in taking precautions to prevent the escape of light through the air-ways of the lamp, the photographer is making arrangements by which this singularly poisonous gas is generated to a dangerous extent.

When we were making experiments on the use of the Swan incandescent light for portraiture, we tested the value of the lamp in question for illuminating our dark room, the bulb being placed in a vase of ruby glass and covered over at the top. The result was most satisfactory, and our only regret was the impracticability—at any rate in our own case—of always having at hand a source of sufficient electric energy to keep the carbon thread at the required temperature. Since then we obtained some very small incandescent lamps in which a platinum wire replaces the carbon thread of Swan; and as these lamps—which are made by Messrs. Becker and Co., of Maiden Lane—can be worked by three or even two cells of a bichromate battery, we immediately proceeded to experiment on their suitability for dark-room illumination. In the first place, one was carefully painted over with a suitable red varnish, and suspended in a convenient position by two thin insulated wires, a small piece of tin-foil serving as a reflector and eye-shade. A button for making and breaking contact was fitted to the edge of the table, and three pint cells of Bunsen's battery were charged, and placed in a convenient position out of doors. This arrangement was found to possess most important additional advantages over ordinary lamps, as a touch on the button serves to re-light or to extinguish it, and the light can pass directly downwards without obstruction. As the lamp is no larger than a small walnut, and it hangs quite freely from the flexible conductors, it can be slung up on a hook against the wall, or suspended directly over the developing-dish, as may be required. The three cells of Bunsen's battery served us off and on for more than a fortnight, although, at one time, the acids were somewhat weakened by rain falling into them. An experiment was next made with a hand Gramme-machine as a source of electricity; but the first few turns caused the platinum wire to fuse, the current being too powerful. When, however, another lamp was set up, and the machine was turned slowly, the result was most satisfactory, the power required to drive the machine being quite trifling. We should suggest that a very small Gramme-machine, mounted on a sewing-machine treadle-stand, would be about the most convenient arrangement, and a little extra would gearing enable the machine to be actuated by either foot or by hand, the odd boy of the establishment supplying the motive power.

Others can now adapt and vary our idea of the application of the incandescent lamp to dark-room use, by making the lamp of ruby glass, or its immersion in a red liquid; and possibly a thermo-electric battery might with advantage supply the small amount of electricity required.

THE LATE M. POITEVIN.

This distinguished chemist has just died at Conflans, in France, whither he retired some time ago, after many years of arduous work in connection with photographic investigation. His labours were chiefly confined to the elaboration of permanent printing processes, and to him we owe in a very great measure the success that has attended carbon printing and the production of photographs in greasy ink.

As far back as 1855, M. Poitevin recognized the property possessed by gelatinous, gummy, and other similar bodies, when impregnated with a solution of bichromate of potash, and exposed to light, of taking up and retaining a greasy ink, and succeeded in applying the discovery to the perfection of a photo-lithographic process.

By covering a lithographic stone, grained in a suitable manner, with a coating of gum or albumen, mixed with a solution of bichromate of potash, and allowing the same to dry, a sensitive film was obtained, on which a picture was produced by means of a negative. Prints were then obtained by the ordinary lithographic process, the ink adhering to those parts only which had been rendered insoluble by the action of light. On the publication of his process, M. Poitevin pointed out that the employment of the bichromate compound might serve for the production of metallic plates in *relief* or in *intaglio*, applicable for use in the arts of engraving and typography, as a film of the material in question, after exposure to light under a negative, was found to resist the action of water in those parts which had been modified by the light; whereas the unaltered portions became swollen when moistened, thus forming a perfect design in *relief*, from which a cast could be prepared.

M. Poitevin, as a pioneer in the matter of photo-lithography and collotype printing, received the Duc de Luynes' prize—or, rather, the greater portion of it—in 1867. The total amount offered was 10,000 francs, and of this, something more than 8,000 was awarded to M. Poitevin, who was considered to have most nearly solved the problem for which the prize was instituted—the production of permanent photographs.

M. Poitevin, notwithstanding his success as a photographic experimentalist, was far from being a successful man. At the time he received the Luynes prize, he was obliged to support his family by accepting the humble situation of chemist in the small town of Ahun, in the department of the Creuze. Fortune smiled on him somewhat afterwards, but he never was in affluent circumstances. He was the most modest of men, albeit in later years a little soured by reason that so little pecuniary benefit had come to him. We believe he only took out one patent, which was sold to MM. Tessié de Mothay and Maréchal for £400, and upon which may be said to be founded collotype printing.

To those who were intimate with him, he was a warm and sympathising friend; but to the outside world his demeanour appeared grave and retiring. He had not occupied himself with photographic research for some time, his last contribution being a printing process combining the use of iron and silver salts, and which will be found published in our columns in January, 1880.

Although he had been suffering for some time, his death (which occurred on the 4th inst.) was so sudden that a scheme projected by M. Léon Vidal and others to invest the funeral with a semi-official character by inviting delegates from the various photographic societies, unhappily fell to the ground. M. Poitevin was 63 years of age.

At Home.

MESSRS. JAMES VALENTINE AND SONS AT DUNDEE.

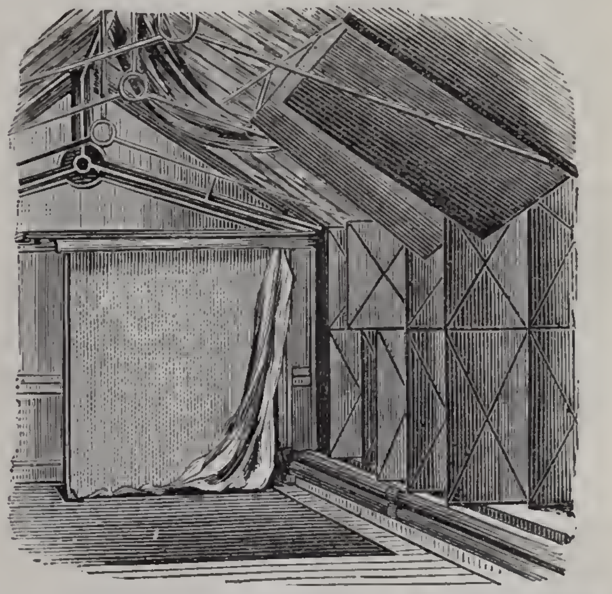
The largest photographic establishment in Scotland, and one of the largest in the world—that of Messrs. James Valentine and Sons—takes very high rank indeed. Mr. James Valentine himself died two years ago, just as he had completed the re-organization of the vast undertaking which bears his name; but his sons (Mr. W. D. Valentine and Mr. George Valentine) have shown themselves in every way equal to the task of carrying out their father's designs. As many as forty employés are to be found in the establishment of Messrs. Valentine, and it says something for their administrative ability that this number of hands is engaged all the year round. The work is so well regulated that, both summer and winter, there is plenty to do, in one department or the other.

Perhaps the best idea of the extent of work done is to be gathered from the fact that 3,000 prints a day is not an unusual number to produce, while upon the printing-tables may be found, at any rate in dull weather, as many as 700 frames. The principal work is the production of views of Scotland, Mr. W. D. Valentine being responsible for the negatives, which, as our readers know, include the most delightful scenes that have ever been taken of that delightful country. Every phase of Scottish scenery is here. A cluster of dark granite boulders, strewn with brown seaweed, and beaten by angry waves, whose white foam is tritely characteristic of their spent wrath; a placid loch, with stately craft floating calmly on its surface; a solitary lighthouse of silver grey, rising from a clump of black rocks, and surrounded by turbulent waves flecked with white—a very painting; lichen-grown crags, sweet forest glades, delicate fern gardens, bowery foliage—in a word, nature in every shape and mood is here represented.

The Messrs. Valentine also enjoy high reputation as portraitists, and it is, indeed, into the portion of the establishment devoted to portraiture that we are first led. A hall tastefully furnished leads to the reception-room, whence again a corridor takes us through the dressing-rooms to the studio. We may mention here that it is in the reception-room that the only open fire in the whole establishment is found, for, following the example of Mr. Marshal Wane, of Edinburgh, Messrs. Valentine employ hot-water piping throughout. They make use of Keate's boiler and coil, which is found to be exceedingly economical, for upwards of forty rooms are heated by its means, at an expenditure of between six and seven shillings a week. Gas cinders only are required for consumption, perhaps the most economical fuel one can use.

The studio itself, which is forty-six feet long, was most agreeably warmed (and this, too, albeit our visit was in February). Studios are apt to strike chilly in our experience, and if a sitter has to divest him or herself of any garments, a cold glass-room is not only unpleasant, but adds to the difficulties of the photographer. In Dundee, no doubt, cold is a greater enemy than in most towns; but still, the example of Messrs. Valentine is one well worth following. Moreover, the system of heating obviates many winter difficulties. "The snow never lies on the roof here," says Mr. W. D. Valentine, "for there is always warmth sufficient to melt it as it falls."

Curtains are almost unknown in Messrs. Valentine's glass room. Side light, and light from the roof is tempered by means of upright zinc shutters on hinges. The height of the lower range of shutters is 3 feet 6 inches, and of the upper one 2 feet 6 inches, their breadth being about 20 inches, the same as the sash. They are painted on the inside (that next the glass) of a pure white, and when opened more or less, reflect light upon the model at the end of the studio. Our sketch will give some idea of their construction.



Not only the end of the studio, but also the angle farthest from the glass, is fitted up as a background. The angle, indeed, forms a rustic arbour, tastefully arranged with fragments of cork bark, ivy, &c., so that with but little trouble it is constituted an apt and unconventional background for groups, &c. A change from the ordinary flat background is at times very welcome, and by simply turning the camera, this is here secured.

We pass through the retouching room, noting on our way two little points. The one is a plan of concentrating light upon negative or print; the ordinary plan, which we have already pointed out, is to have a spherical decanter of water near at hand, which condenses the light upon any spot on which you desire to work; but Messrs. Valentine employ, instead of water, a weak solution of sulphate of copper, the greenish hue of the latter being less trying to the eyes. "It is what jewellers always use," explains Mr. Valentine. The other point is that of employing a developed gelatine plate instead of pure glass to support the negative during retouching; the brown tint of the former is also preferred, as being less injurious to the eyes.

There are no doors to the darkrooms. Mr. Valentine holds them to be not only unnecessary, but positively harmful. They give rise to dust, and they are always in the way. They are, too, easily done without. The passage leading to the dark-rooms is only lighted from the top, the panes of the skylight being reddened. In these conditions of lighting from above, all that is necessary is to place inside the entrance of the dark-room a broad barrier, or partition, round which you must walk to get into the room. In one of his dark-rooms, by-the-way, Mr. Valentine showed us a huge pane of ruby glass, which, after but two years' exposure to light, had lost more than half its original colour. Photographers, therefore, will do well to look after their windows occasionally; fortunately, most of them begin by working in a light that is far more subdued than is actually necessary.

But we must pass on. We go downstairs to the printing department. This occupies the whole of the basement, the principal portion being a long room, in which there are no less than twelve tables ranged side by side, each measuring about 9 by 2 feet. It is the biggest printing room we have ever seen. At each of the tables stands a girl with printing frames, and her duty is simply to open each frame, withdraw the print, provide a fresh piece of paper, and then to push the frame through an open window to the printer. For, opposite each table, there is a window of this kind, opening directly into the yard, so that all the girl need do is to carry her freshly-filled frames to the side, and the printer, by putting his hands through, reaches them without difficulty. In the same way, the frames are afterwards returned. In all photographic establishments, the difficulty is with new hands; but the Messrs. Valentine, by thus subdividing the work, get over it very well; that is to say, those inside the printing room need have very little experience compared with those occupied with the actual printing, who number among them the most skilled employés of the establishment.

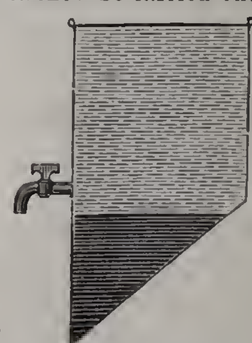
The printing is done in the open air or under shaded glass, according to the season of the year. Many of the pictures require skies printing in, and this of course necessitates double work. Mr. W. D. Valentine arranges with the head printer what sky negative shall be employed for a particular picture, and then the printing frame containing this, instead of being returned to one of the ordinary changing tables, is taken to a separate department, where the sky negative is adjusted and a suitable mask fitted.

The sensitizing of the paper takes place in a compartment at the end of the printing room. Three baths are employed, large enough to take a whole sheet, each bath provided at the end with a glass bar or rod, over which the sheet is dragged after being lifted from the liquid. There is no draining of the sheet; the glass rod has removed the spare liquid from the surface, and immediately afterwards the paper is pressed between blotting-paper. It is half dry by this time, and requires to be hung but a very short time to be completely desiccated. Nevertheless, Messrs. Valentine contemplate drying still more quickly by means of hot water boxes, over which the paper will be stretched on net-work. The regulation time of floating the paper is two minutes; the strength of the baths, fifty-five grains of silver nitrate to one ounce of water.

It is one man's duty to fold the sheets of sensitized paper and to cut them, a knife fixed hinge-wise to a board serving to do this very rapidly. "By this means, our prints have always clean-cut edges, a matter of much importance when it comes to toning and washing," says Mr. Valentine.

We have not time to speak of the negative rooms—all negatives in use being racked, while reserve and stock plates are packed in paper—but must pass on to the washing room. Here, raised in the centre of the long apartment, are a number of baths; there is, in fact, a double row of seven, so that two sets of assistants, facing each other, can work at the same time. The prints are first put into No. 1 bath, rinsed, and then placed in No. 2, whence they are conveyed to No. 3, and so on until they get to No. 7. Above the baths are hanging india-rubber tubes, which supply both warm and cold water; and each bath is supplied with an outlet that empties it rapidly. The water from the first four baths runs off into a residue tank in the yard, but the other washings are thrown away. Each print is taken separately in hand, and handed from one assistant to another. After toning and fixing, a washing even more thorough ensues, for after rinsing all night in tanks, in which each print is nipped separately between laths to prevent conglomeration, the prints are put one by one on a glass plate, and subjected to the action of falling water, both warm and cold.

Messrs. Valentine have given the question of residues careful study. The tanks are placed in the open yard, in the full glare of daylight, for they find that the deposition of the chloride takes place much more rapidly out-of-doors, than in. In summer the deposition is very rapid, while in winter it is comparatively slow; but still there is no danger of losing suspended particles by drawing off liquid that has stood twenty-four hours in their tanks. Moreover, with the washing arrangement we have just described, the assistant cannot throw away valuable washings, but the liquids must of necessity run into the tanks. The bottom of these is wedge-shaped, so that when emptied of liquid the residue cannot be carried off.



Section of Residue Tank.

The old hyposulphite baths used for fixing prints are collected in a separate tank. The most economical plan is to treat them with so-called liver of sulphur, and thus extract the precious metal in the form of sulphide. But, practically, Messrs. Valentine find it best to throw down the silver in the metallic form by means of zinc. Fragments of old zinc will do—sheeting, water-spouts, &c.—and from these the black deposit is brushed from time to time, and collected. "The silver collected from our hyposulphite washings fetched thirty pounds last year," said Mr. Valentine, in reply to our question as to whether it paid.

We are next led into the mounting room. The mountant employed is gelatine soaked in water, and then dissolved in hot spirit. But they are very particular about the brushes employed, since most of these leave "brush-markings." A brush two inches broad, of red sable, is the only instrument permitted in the establishment, and the price of these, we were told, was no less than fourteen shillings. The tables here are all covered with linoleum, not only to protect them from wet, but also because the soft character of this material is not likely to injure any albums or finely-bound books that come into the place.

Our allotted space is full, and yet we feel we have done but scanty justice to this magnificent establishment. Still one thing more we must mention—the burnishing by steam, which is a sight of itself. We believe Messrs. Valentine is the only firm in the world in which steam power is employed for the purpose, the apparatus having been specially designed by Mr. J. C. Cox, the president of the Dundee Photographic Society. The to-and-fro movement of the burnished plate under the roller, due to a very clever reversing action, is exceedingly smooth and regular, the rate at which the burnishing goes on being 350 pictures in the hour.

The "By-the-Bye" next week will be "Photography in its capacity of Clerk and Draughtsman"; the following "At Home" will be "Herr Obernetter in Munich."

A FEW COMMON OBJECTS OF THE STUDIO.

BY EDWARD DUNMORE.*

I WILL this evening devote a little time to a chat about what may be termed some of the common objects of a photographer's work-room. For that purpose I will get you to imagine an apartment where are the objects to which I shall allude, and enter it with me.

The first common object that strikes the eye, in more than one sense, upon entering, is dust. Dust varies as greatly in its composition as in its effects; it is, in fact, unattached matter, wandering about, seeking a lodgment, which, when effected, at once changes its designation from dust, and becomes dirt, and dirt, we are told with truth, is matter in the wrong place, and, being so, is the cause of much anxiety and annoyance to the photographer. When working out of doors in hot dry weather, especially where the soil is in great part composed of chalk or limestone, the dust penetrates every chink and cranny of tent and camera, getting on to the films and into the baths. If the wind happens to be gusty, so much the worse. The manipulation of coating the plate with collodion and getting a spotless film is an extremely difficult matter. By the time the day's work is over, the nitrate bath will badly require filtering, and the apparatus generally will be in a dirty condition. The evil results will, however, be but small—a few unimportant specks on the negatives, perhaps none. The reason for this immunity is, that the dust, though plentiful, was almost inert, being in a great measure composed of powdered flint aud chalk, or limestone, with comparatively little organic matter; and if the precaution is taken of sensitizing the plate with the film side down, little harm accrues.

In speaking of wet plate work out of doors, I may, perhaps, be considered by some, in these days of rapid dry plates, to be talking of an exploded process, but there's life in the old bath yet; and there are qualities in the negatives made by it of some subjects that gelatine plates cannot touch, let alone the permanency, which in the gelatine process has not yet been sufficiently tested, and of late a new trouble has been talked of—spots that appear after the negatives have been used some little time, and go on increasing until the negative is spoiled. The reason given for them is dust on the film when collodionizing or varnishing. These specks of dust being of a repellent nature, the collodion or varnish does not make a perfectly homogeneous coating, but leaves small holes, through which the silver from the paper penetrates and does the mischief, especially when the printing is carried on out of doors in damp weather. I have examined these spots with the microscope, and they present the appearance of an opaque nucleus with concentric rings of different degrees of opacity. I am not, however, prepared to say that this is the true solution of the difficulty; there are certain peculiarities in the case, that make one hesitate to endorse this idea in its entirety as the true and only explanation of the fault; at present, however, it is the most feasible theory advanced for the occurrence of a very serious drawback.

Dust in the studio is in a great measure dependent upon the carefulness, or rather carelessness, of those engaged therein, and may consist of powered hyposulphite of soda, pyrogallol, silver nitrate, ferric sulphate, &c., &c., mixed with organic and inorganic matter in uncertain proportions. It may, in fact, and does, consist of particles of any solid substance that has been used or handled in or about the premises. Solutions of solid substances being spilled about is a prolific source of chemical dust; the solvent evaporates, and the solid matter is left to be ground and powdered by passing footsteps, and wafted into the air, in which it remains suspended, to be finally deposited on any surface that may present itself, slowly or rapidly, according to its specific gravity or the fineness of its particles, the characteristics of this dust of course being governed by the preponderance of that chemical that has been most liberally wasted. Bearing in mind the energetic nature of this chemical dust, care ought to be exercised that our daily occupations are conducted with as little "flustering" as possible. I think this word conveys the idea as well as any I could use, that no unnecessary currents of air should be caused by violent or rapid movements calculated to disturb objectionable dust that may have accumulated unnoticed. These violent movements in some measure account for the fact that some operators are so much more troubled with faults on their negatives than others, when working with the same chemicals under apparently similar conditions. A continual source of supply of chemical dust is from the boarded floors of rooms where chemicals are stored or used. The boards in course of time become impregnated with substances that get spilled or dropped upon them; the friction of the feet is sufficient to loosen or grind off some of this mischievous matter, which currents of air impartially distribute. As a precautionary measure, the floor of the laboratory or operating chamber should be kept slightly damp during working hours, and dust prevented from accumulating as much as possible; when it does, remove it in a sensible manner, not merely whisking it off one thing to settle on another—doors and windows carefully closed the while—but where slightly damp cloths are admissible, use them; and when not, open the window and carefully remove it with a dry duster, getting as much as possible out of the premises. There seems to be, judging by ordinary observation, comparatively few people who know how to dust; if they know, they seldom put the knowledge into practice. Watch the generality of employés who have to sweep a room out—the dust raised is something alarming; the prevailing idea seems to be that all that is necessary is to raise the dust; where it goes to is no matter. Ofttimes business commences before the dust has time to settle, and if it happens to be a busy day with a warm dry atmosphere, the number of negatives slightly defective from dust specks are numerous. The special and particular cleanness of gelatine dry plate films is in a measure owing, I believe, to the special care bestowed in avoiding dust during the process of manufacture; afterwards dust is certainly of less importance.

I have here a small quantity of dust gathered from unconsidered places, ledges, tops of doors, corners of rooms, &c., &c., in fact, anywhere where it had been accumulating for some little time, and it consists, no doubt, of an immense variety of substances—organic, inorganic, and chemical—with in all probability some slight amount of metallic particles. I now sensitize a small piece of albumenized paper with a solution of silver nitrate, and, before it dries, sprinkle a little of this dust upon it; the result is, as might be expected, spots and stains wherever the dust adheres, and chemical action is set up. Of course this is an exaggerated case, but when we substitute the infinitely more sensitive surface of our negatives, what surprise can be felt at their being rendered useless for picture making, if dust has access to them? Or would it not be surprising if the nitrate bath did not get out of order when such deleterious matter is introduced? Dust is perhaps one of the most insidious and troublesome things with which photographers have to deal, and, consequently, no pains ought to be considered too great to avoid its interference with our especially delicate and complicated chemical processes. So much, then, for dust, a subject, by-the-bye, upon which I might enlarge very considerably, but the time at my disposal will not permit it. The next common object to which we will turn our attention is silver nitrate. All photographers are acquainted with this metallic salt in some form or another, and there is scarcely a photographic business carried on without its aid, so although common, it is very important. It is an easily-manufactured simple salt obtained by dissolving silver in dilute nitric acid, and crystallizing as we usually see it; in flat, tabular crystals of unequal size. At one time there were many complaints of the impurity of this salt, and acidity was frequently laid to its charge. For my own part, I have not had under my observation an acid sample of nitrate for many years. When purchased of respectable refiners, its purity can generally be relied on. Acidity is a fault that might suggest itself on account of the method of its manufacture, it being

* Read before the South London Photographic Society.

crystallized from an acid liquid, and merely dried, the salt being anhydrous, heat will drive off any acid that may cling to it, and the result is a neutral salt. Recrystallization from its solution in distilled water will undoubtedly remove any acid that is left from imperfect drying in the first instance, and remove any dirt or accidental impurity that might be contained in the first crystallization. For very delicate experiments it is, perhaps, as well to use recrystallized salt, although for ordinary purposes the first crop of crystals is sufficiently pure. That impure nitrate is sometimes offered for sale, there is no doubt, and the impurity may be either accidental or intentional. With regard to intentional impurity—or, I should, perhaps, say, adulteration—as far as my experience goes, it is of rare occurrence; and, as a rule, the purchaser gets his money's worth for his money. The moral obliquity sometimes charged to chemists and refiners is, I think, unfair so far as supplying adulterated silver nitrate goes. I have a sample here of a sophisticated nitrate, the adulterant used being potassium nitrate, which it contains to the tune of about 25 per cent. If the sample of silver nitrate is, either from its appearance or behaviour, suspected of impurity intentionally added, it is one of the most easy matters in the world to ascertain the fact by quantitive analysis.

Take (say) ten grains of the suspected salt, and dissolve it in half an ounce of distilled water, then from a dropping tube add very carefully as much solution of a soluble chloride (the strength of the solution so calculated that half a drachm precipitates a grain of silver) as is needed to precipitate all the silver; the amount of chloride solution then being read off, the exact amount of silver is at once ascertained, and the exact weight of the adulterant used. Impure nitrate of silver, not intentionally sophisticated, is sometimes obtained when the source from where the metal is derived contains much sulphur—say from photographic residues that have been precipitated by means of sulphuret of potassium. It is extremely difficult to thoroughly get rid of the sulphur from the metal and nitrate made from it, as it is apt to be contaminated in a degree sufficient to interfere with the proper working of the nitrate bath. Sulphur is the source of many photographic troubles. It has been shown by Mr. Spiller that sulphates may exist in the nitrate bath owing to the pyroxyline from which the collodion was made being insufficiently washed, and then it is a source of pinholes. This is the effect of the silver nitrate when it contains sulphur in combination—pinholes, and generally unsatisfactory films. Testing silver solution for purity is a laboratory experiment, and requires close watching, but the behaviour of this salt when treated with ammonia is more easily shown. We often now have, in making our gelatine emulsions, to form an ammonia nitrate solution by adding strong liquor ammonia to a solution of silver nitrate, until the precipitate, which is voluminous and of a dark brown colour, is redissolved. Thus you will observe the instant the ammonia is added, the precipitate forms; but should it happen that a *trace* of nitrate of ammonia is contained in the liquor ammonia, although no perceptible difference is formed in the result, the difference in its apparent action is most remarkable, and may cause some perplexity. I will now add a trace of nitric acid diluted to the ammonia; no perceptible difference is made; it smells equally pungent, and remains equally colourless and clear; there is, of course, a small portion of nitrate of ammonia formed, which remains in solution, and this slight addition has the curious effect of preventing any precipitate being formed when it is added to the silver nitrate solution. You will observe the mixed solution remains apparently unchanged; no precipitate whatever forms; but the chemical action takes place all the same, and the nitrate is converted into the ammonia nitrate. This may be ascertained by the sense of smell, for until all the nitrate is changed, the added ammonia loses its pungency; but as soon as this is effected, the fumes of the ammonia remain, on account of no further combination taking place. The result is practically the same as when the precipitate was formed. In one instance the eye was the guide as to the right quantity of ammonia, and the other, the nose. If, however, too great an excess of the ammonia has been added, it may be easily remedied by heating the solution a short time, which will drain off the excess of ammonia. There is, however, a danger that fulminate of silver may be formed by a great excess of ammonia, so it should be carefully added. This experiment shows what very slight causes may affect delicate processes, and lead to confusion unless understood; *e.g.*, a glass measure that has been used for measuring nitric acid, and not thoroughly cleansed before using for the purpose to which I have just alluded, might produce this peculiar effect, and puzzle the operator considerably.

The next common object is a glass measure. It is as well to verify the graduations on glass measures before taking them into regular use, for they are frequently inaccurate. This may be easily done by placing the vessel in a scale and weighing in definite quantities of distilled water, observing if they agree with the graduations. In choice of them, select those that are made of thin, clean glass, rather tall and with heavy feet, as being more easy to use, and less liable to get knocked over. A thin glass cylindrical measure is somewhat inconvenient to use for small quantities; those tapering to an obtuse point outside are infinitely more usable, a correct quantity being much more rapidly measured—the liability to error increasing in proportion to the area of the surface of the fluid in the measure.

The next matter to which I shall call your attention can scarcely, perhaps, be called a common object, it being invisible. Its effects are, however, calculated to produce many uncommon objects, and challenge very particular notice—I allude to gases and deleterious fumes and vapours, of which, perhaps, those containing sulphur are the most objectionable. Ammoniacal fumes are by some considered very prejudicial in their effects upon wet collodion plates. In making this remark, I must say that from my own experience my plates have not to my knowledge suffered any deterioration in working from this cause. But a well-known skilful photographer told me he once had a commission to photograph some buildings in course of demolition located near to some slaughter-houses, from which ammoniacal fumes emanated, which were so pungent as not only to be very offensive, but by the time he had taken two or three plates, his bath became unworkable, and from stains and markings on the films he had to discontinue. Each day he found it the same, and had to go supplied with a new bath, morning after morning, whilst the job was in hand. Whether this upset of the bath proceeded from ammonia or from other gases, engendered by decomposing animal matter, I cannot say. This gentlemen, at any rate, attributed the difficulty to ammonia. That sulphur in any of its combinations in a gaseous form is very prejudicial to our work, none can doubt—sulphuretted hydrogen at once reducing a solution of salts of silver. If wet and newly-sensitized albumen paper is hung up to dry in an apartment to which dangerous fumes have access, there is little doubt but that the paper will be partially spoiled—its whites degraded, and the toning interfered with. A similar effect is produced if a trace of hyposulphite gets into the water in which the prints are washed previous to toning; a yellowish metallic appearance covering the whole surface is soon apparent. Precisely the same chemical effect takes place if sensitized paper is fingered with fingers contaminated with hyposulphite, only in this case the marks are definite and local, and much more intense. An escape of ordinary illuminating gas in the laboratory or sensitizing room is undoubtedly prejudicial to the work. It affects the nitrate bath by causing a scum to accumulate on the surface, which is somewhat troublesome to remove, and gives rise to markings on wet collodion films; also staining dry emulsion ones. Sulphur in any of its combinations is to be guarded against as being most insidious and destructive—an agent, even if very diluted, having the power of thoroughly decomposing and rendering powdery the leather bindings of books or leather in any form. Subjected to its influence for a moderately long time suggests at once a danger to gelatine negatives that may be stored in a place to which it has access, the insoluble gelatine of the films being somewhat analogous to leather, and is affected by the same agencies.

The use of coke as a fuel is another source of danger, unless the fumes are perfectly carried away, for it must be borne in mind that the changes caused are not, save in particular instances, immediate or easily detected. A special instance to which I have already alluded is newly sensitized paper. I have here a piece of that substance, and whilst it is yet wet with the silver solution I will submit it to the action of a gas containing sulphur. The results are immediately visible; of course this is applying the objectionable fumes in a concentrated form; if diluted, the effect would be the same, only a longer time would be necessary to produce so decided effect. A general yellowing of the paper scarcely, or perhaps not at all, noticeable in the light in which paper is generally prepared, is produced, but quite sufficient to impair the quality and colour of the finished proof. Obnoxious vapours may exist in an apartment of which we may be quite unaware until some substance for which they have a special affinity is introduced. Then chemical action is at once set up, and their existence clearly demonstrated. As a rule, these obnoxious gases and vapours are in so dilute a state that some time has to elapse before their presence is manifested. It is well known that a person entering a room direct from the fresh air will detect an odour of which the occupants are quite unconscious.

In some few instances ocular proof may be obtained of the existence of a gas, but, as a rule, delicate chemical tests have to be resorted to, to determine it—with some, the humidity of the atmosphere, which is condensed by the gas as a white vapour, and becomes visible; with others, a combination may take place, and a solid may be found in a fine state of division; for example, we will suppose hydrochloric acid exists in the room in an invisible state, the introduction of ammoniacal gas will at once show it by the formation of hydrochlorade of ammonium. I will pour a few drops of liquid ammonia on to this piece of paper; the atmosphere surrounding it remains perfectly clear and transparent; but when the vapour of hydrochloric acid is allowed to escape and mix with the ammonia vapour already existing, dense white fumes are the result, the vapours in this case neutralizing each other, and forming a definite salt.

Drains are always a source of danger, not only to the householder on the score health and comfort, but to the photographer on account of his occupations; so great care should be taken that they are properly ventilated and trapped.

In conclusion, I can only recommend careful supervision over all sources from which deleterious vapours or gases may proceed from drains which perhaps are most important to bottles accidentally left uncorked or carelessly stoppered. I have in this paper alluded but to a few of the common objects of interest to photographers, and the few experiments I have made are of a nature permitting of easy observation, and not requiring that patience and careful attention that are characteristic of the majority of chemical reactions daily brought under our notice, and which are entirely unsuitable for illustrating a paper of this kind, although they may be infinitely more important. It may be borne in mind that although the experiments I have shown exhibit concentrated violent action, the same alterations take place in our every-day work, but in a much slower manner, necessary time being allowed for the action of, as I may term it, the diluted forces—time being a most important factor in most of the processes with which we have to deal.

I trust I have not trespassed too long upon your patience by this somewhat dry paper, which, as the title indicated, has treated of a few common objects, such being, by their very nature, removed from the realms of that novelty which in the present day is so attractive that papers deficient in this element are looked upon as inflictions to be tolerated, but disliked. I however, bearing in mind the difficulties of securing papers for our meetings, trust the want of novelty will be forgiven, and be my apology for reading one that treats of no new processes, nor demonstrates any new invention.

Notes.

A photographic journal in Spanish has appeared, the *Boletin Fotografico*; it is published not in Spain, but in Havannah.

Mr. J. W. Swan lectures to-night at the Royal Institution on "Electric Lighting by Incandescence." The Swan Light Company make the welcome announcement that henceforth the price of their lamps will be but five shillings each.

At a meeting of the Solar Club on Monday last, Mr. W. Ackland and Mr. W. B. Bolton were elected members.

On Monday, Mr. Muybridge, of San Francisco, will be present at the Royal Institution to exhibit and explain his well-known photographs of galloping horses and other animals in motion. The lecture will be at 5 p.m., instead of the usual hour of nine, tickets being obtainable through members of the Institution, as in the case of the ordinary Friday evening lectures.

We regret to announce the death of M. Poitevin, which took place on the 4th inst., at his residence in Conflans. M. Poitevin was sixty-three years of age.

M. Poitevin was certainly the most noted of our living photo-chemists, not only in France, but in the whole world; and although for the past ten years he took no active part in photographic investigations, the work he had done was of such paramount importance that it never faded from the mind. The value of Mungo Ponton's discovery as to the use of the bichromates in photography was at once appreciated by Poitevin, and his investigation into the behaviour of these substances in connection with gelatine paved the way both to carbon printing and collotype printing. In connection with permanent printing processes, indeed, the name of Poitevin must always be highly honoured.

A monster album! His Royal Highness the Prince of Wales has requested the portrait of every member of the Savage Club for his album of literary and dramatic celebrities, the size chosen being the cabinet picture. It looks as if the Prince were in league with the photographers.

M. Van Beers, the Belgian painter, having lost his lawsuit, about which we have heard so much of late, will lodge an appeal before the Brussels Tribunal.

The lawsuit, our readers may remember. was brought by the painter against a critic who accused Van Beers of employing photography as a basis for his paintings. Although the critic was unable to show that "The Syren"—the picture immediately criticised—was in any way due to the camera, it seems he brought evidence to prove that M. Van Beers sometimes did employ a photograph whereon to apply his pigments, notably in a picture representing two donkeys and their driver. It was not an action to decide whether a painter is or is not justified in employing photography, but whether the critic in this instance had spoken maliciously of the painter. The Tribunal seems to have decided there was no malice.

Speaking of the Van Beers case, Mr. Woodbury, who is just now in Brussels, says:—"A new style of photography has sprung up since the the trial, which one might call Van Beers-type. The portrait, with a white or plain background, is printed in carbon, and transferred to a ground covered with tints, as in the many colour systems that have from time to time appeared (patented or not). The picture is then given to an artist who paints in a suitable background in oil. The effect is very good though one would imagine that the vigorous touches of the artist on the background would kill the more delicate tints as seen through the carbon print. Still, such is not the case, the results being very effective."

Mr. Woodbury further says :—"M. Geruzet, who, by-the-bye does nothing but carbon, has shown me some charming pictures produced in this way, and I can recommend the idea to our own photographers in search of a novelty. A Woodbury print would answer as well, if not better, but would not be suitable for single copies."

Mr. Bedford's plan of sensitizing albumenized paper should be noted, for it is one of the most trustworthy that can be employed, especially when the sensitized paper is to be kept for some days before use. He floats the paper first of all upon a 60-grain silver bath, perfectly neutral, then a second time upon a bath containing 30 grains of silver and 30 grains of citric acid to 1 ounce of water, the paper being drawn over a glass rod in the end, and dried. The longer it is floated the better the paper keeps, and any slight discolouration that may arise after ten days or a fortnight disappears in the fixing bath.

The suggestion of Mr. Warnerke to tightly roll up sheets of sensitized paper one within the other, if desired to keep it long, is also a practical hint to be noted. The outer sheets may get discoloured in time, but these protect the rest from the noxious influence of the atmosphere more effectually than ordinary wrapping paper. Mr. Warnerke speaks of having kept sensitized paper good in this way for a space of two years.

Gustave Doré is going to try his hand as a sculptor, the attempt being to produce a bronze statue of Alexandre Dumas. A numerous series of photographs has already been collected by the eminent painter, who has never concealed his ideas of the value of photography as the handmaiden of art. Doré was a frequent visitor to Rejlander's studio, and that artist's portrait of the French master is probably the best ever taken. Gustave Doré's model will be cast in wax, by the so-called *cire perdue* process; that is to say, the metal will destroy the mould in the process of casting, and nothing will then remain behind but the bronze statue.

The photograper and the sculptor seem intimately connected. A series of profile pictures, giving the salient lines of a model, are invaluable to the sculptor, and upon photographs of this kind was based, our readers may remember, the process of photo-sculpture which the late M. Claudet brought before the public. Since the photographer has to study modelling and lighting after the manner of a sculptor, art-training in a sculptor's studio would doubtless form the best education for a photographer. M. Adam-Salomon's success as a photographer was due simply and solely to his art-training and experience as a sculptor.

M. Guérain, the photographer to the Paris Observatory, proceeds to Egypt in May next, to take photographic observations of the solar eclipse. For some years past the existence of certain intra-Mercurial planets has been mooted in France, and the evidence of photography is now to be invoked to assist in setting the point at rest.

Mr. Aitken has been studying the blue colour so characteristic of the Mediterranean and the Lake of Geneva, and his conclusions are embodied in a paper presented last month to the Royal Society. Mr. Aitken begins by saying that two solutions have been offered of this puzzling problem—the one explained the colour as due to reflection of small suspended particles which did not reflect the lower rays of the spectrum, and the other that the colour was the result of the absorbent action of the water itself upon the white light, before and after reflection of these particles. The latter theory Mr. Aitken holds to be the true one. The smaller the number of white-reflecting particles, the darker or greener the water appears to be, Mr. Aitken having been successful in turning the still green water of Lake Como into a bright blue by scattering finely-divided chalk in the middle of the lake.

The Paris photographers—or, rather, that goodly number of them who belong to the Photographic Syndicate—have made it their custom lately to hold an annual dinner in the French metropolis. The festive gathering for this year has been announced for the 14th inst. When will their English confrères, we wonder, follow so excellent an example?

We shall shortly print some notes by Herr Fritz Luckhardt, of Vienna, on the subject of constructing glass roofs, a matter to which that gentleman has recently given some attention.

Photography is said to interfere with the sale of autographs. Letters, manuscripts, and signatures, however well authenticated, do not realise the high prices at sales they used to do five years ago. We can hardly understand this, as an original sign manual must always possess intrinsic value. The fact that the great men or great women have pressed the sheet with their hands, and their living energy has traced the letters before you, must always remain a consideration, since it is a distinct link between their lives and the present moment. Photography cannot rob a document of its personal character.

At the same time, it must be conceded that the camera, by creating a fac-simile of any characteristic writing, becomes an important factor in a consideration of the kind. Instead, however, of reducing the marketable value of a rare manuscript or autograph, it should be the means of enhancing it. The owner is in a position to sell the original as before, and also authentic photographs of it.

And here is a hint that some of the "Society journals," at a loss for a novelty, may like to have. Why not publish every week an example of the writing of our famous literary men, past and present? A chapter from *David Copperfield*, in the author's own hand, and with all his original corrections; half-a-dozen verses of Byron, photographed from the original manuscript; some of Oliver Goldsmith's *Vicar of Wakefield*, or *Deserted Village*, if the manuscript is still extant; a leading article in Mr. G. A. Sala's neat handwriting, as it is sent in to press—all these (to quote a few instances out of many hundreds) would be of interest to the public; while their faithful reproduction by photo-lithography entails no trouble whatever.

Mr. Alexander Ayton, of Londonderry, sends us two prints, treated in the same fashion as blotting paper which is to be converted into vegetable parchment; that is to say, they have been immersed in diluted sulphuric acid. In the one case, the matt appearance produced is permitted to remain, and in the other, a brilliant surface is imparted by enamelling with varnish. The effect of both pictures is decidedly pleasing.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. 2.—CHEMICALS.

AFTER the photographer has provided himself with the necessary appraatus and plates, his first consideration must be the purchase of the chemicals which he will require to convert his plates into negatives. We give a list of those which he will need, stating after each about the quantity which we think it desirable that he should possess himself of at first. Afterwards we give a few words describing the general properties of each substance, but not entering into the chemical composition. Each chemical, whether liquid or solid, should be kept in a bottle which should have the name distinctly labelled on it, if possible in print.

We ought to have enumerated in our last lesson, amongst the necessary apparatus, a small balance such as apothecaries use for weighing out medicines. This should be provided with the usual set of "apothecaries weights." The chemicals required are as follows:—

Pyrogallic acid	1 ounce
Ammonia of specific gravity ·880 ...	3 or 4 ounces
Bromide of ammonia	1 ounce
Sulphite of soda	4 ounces
Neutral oxalate of potash ...	½ pound
Sulphate of iron	½ pound
Citric acid	1 ounce
Hyposulphite of soda	1 pound
Alum	½ pound
Methylated spirit	½ pint
Negative varnish	A few ounces
Bi-chloride of mercury	½ ounce

A couple of books of test papers, one of blue litmus and one of red litmus.

Pyrogallic acid is a white, feathery, and extremely light body. It is exceedingly soluble in water. It is a powerful absorber of oxygen, especially when alkaline. When a solution of it has absorbed oxygen, it turns brown.

The ammonia used in photography is the strongest solution of ammonia which it is possible to make in water at atmospheric pressure. It is the well known hartshorn. It is a perfectly transparent and colourless fluid. It is powerfully alkaline. When the stock has been purchased, it is advisable to pour it at once into a bottle holding exactly double the amount of the ammonia, and to fill up the bottle with water. If this is not done, the stopper of the smaller bottle may be blown out by the pressure of the liberated ammonia gas when the weather is warm. This will destroy the whole, as, on exposure to air, the liquor ammonia rapidly becomes weaker from the ammonia gas escaping.

Bromide of ammonia is usually found as a white powder, looking very much like ordinary table salt. It is very readily soluble in water.

Sulphite of soda is a white crystalline body. It is readily soluble in water.

Neutral oxalate of potash is a white crystalline body. It is readily soluble in water. It ought to have neither an acid nor an alkaline reaction; but often that sold as neutral is somewhat alkaline.

Sulphate of iron or "copperas" is a greenish crystalline body. It is very soluble in water, but requires considerable time. Its solution decomposes very readily if it be at all exposed to the air, on account of its absorbing oxygen; after this it is useless for photographic purposes. It should therefore be kept—after it is dissolved in water—in a closely stoppered bottle.

Citric acid is met with either as clear colourless crystals, or as a powder. It is soluble in water.

Hyposulphite of soda is a clear colourless crystalline body, and is somewhat deliquescent—that is, if left exposed to the air it becomes damp. It is readily soluble in water.

The alum used may be the ordinary alum sold by grocers, and may be either a potash or a soda alum. As it is intended to be dissolved in water, it should be bought in the form of a powder. It does not dissolve in very large quantities in cold water, and dissolves somewhat slowly.

Methylated spirit calls for no particular notice, as it is well-known to all. That sold as "finish" is not suitable for photographic purposes.

Bi-chloride of mercury is a whitish crystalline substance. It is sparingly soluble in water, and is strongly poisonous. It is commonly known as corrosive sublimate.

Negative varnish in appearance is very like the ordinary spirit varnish used for varnishing wood, but differs from it in the resins used to manufacture it. It can be bought from any photographic dealer. That sold as "dry plate negative varnish" is the most suitable.

The test papers are for discovering whether a liquid such as a solution of any salt is neutral, acid, or alkaline. To use them, proceed as follows. Suppose you have a solution of whose condition as regards acidity or alkalinity you are ignorant. Dip a small piece of the blue litmus paper into the solution. If the paper changes its colour to red at once, or after a short time, the solution is acid; if no change in its colour takes place, the solution is either neutral or alkaline. In this latter case, dip a piece of the red litmus paper into it; you will now know its exact condition. If the red litmus becomes blue, the solution is alkaline; if no change takes place, it is acid.

We have now enumerated and shortly described the necessary chemicals, and shall give instructions for mixing one or two of what are called "stock solutions." These are solutions which may be kept for some time, and which the photographer should always have by him. The ones we now describe are those to be used in the first lesson in development, which will appear shortly.

No. 1 bottle to be labelled "Solution of Oxalate of Potash" in large letters, so that it may be read in a very dull light. Place the whole half pound of neutral oxalate of potash in a bottle capable of holding from ten to twelve ounces. Fill up the bottle with warm water, place in the cork, and shake. A part, but not the whole, of the white crystals, will dissolve. The liquid will be what is called a "saturated solution"—that is, the water will have taken up as much of the salt as it is capable of doing. When any of the solution is used, the bottle should be again filled up with water, and this may be done repeatedly till all the crystals are dissolved, when more oxalate of potash must be purchased. This solution must be tested in the manner described above to discover whether or not it is alkaline. If it is, enough citric acid must be added to make it neutral or very slightly acid.

No. 2 to be labelled "Sulphate of Iron Solution." Place about a half of the sulphate of iron in a half-pint bottle, and proceed exactly as with the last stock solution. It is very necessary in this case to keep the bottle always full of solution, and well corked, as the oxygen of the air, if it come in contact with the liquid, very rapidly spoils it.

The solution should be of a bright green colour. If it get red, it is useless.

No. 3. *Ammonia-Bromide Solution. One per cent.*—Weigh out twenty grains of ammonia bromide. Place in a four-ounce bottle, and make up to four ounces with water. The percentage is not exactly correct, but is quite near enough for the purpose.

No. 4. *Alum Solution.*—Place three or four ounces of the alum in a pint bottle. Fill up with warm water. The whole of the alum will probably dissolve, but some of it will be thrown down again as crystals when the solution becomes cold. As long as these last, more water may be added from time to time, as the solution is used. When they are all dissolved, alum must be added.

No. 5. *Fixing Solution.*—Place five ounces of hyposulphite of soda or "hypo" in a pint bottle, fill up with warm water, and shake till all is dissolved.

Common tap water may be used for all these solutions, which, stated briefly, are as follows:—

No. 1. Saturated solution of oxalate of potash.
No. 2. Saturated solution of sulphate of iron.
No. 3. Ten per cent. solution of bromide of ammonia.
No. 4. Saturated solution of alum.
No. 5. Twenty-five per cent. solution of "hypo."

ON THE RAPIDITY OF PHOTOGRAPHIC LENSES.

BY LEON WARNERKE.*

For some years past I have endeavoured to arrive at greater precision in the use of the various influences and adjuncts we have to deal with in photography; such was my attempt when I measured the intensity of light by my actinometer, and the sensitiveness of plates by my sensitometer. But we have still another adjunct playing a very important part in all photographic manipulations; that is, the rapidity of photographic lenses.

The thorough knowledge of every element and apparatus employed tends to secure certainty in manipulation and excellence of ultimate results; but of the failures occasioned by imperfect knowledge of the tools used, none is more common than that produced by ignorance of the rapidity of lenses.

The object of my communication this evening is to examine the question mentioned, and to demonstrate the utility, nay, necessity, of some definite unit to permit us to measure the rapidity of lenses. We must congratulate ourselves that, although the photographic art has not reached its maturity, the manufacture of lenses has attained to such perfection as to leave very little to be desired. We have lenses constructed with special objects dictated by the requirements of the art. There are more than a dozen different classes of lenses in use at present: every class has special qualities, special advantages, and weak points; these are described in treatises, in descriptive catalogues, or learned by practice, so that the peculiarity of every class, as regards quality, are sufficiently known.

But when we wish to arrive at a knowledge of rapidity—and this must be done with precision—we find ourselves in a great difficulty. In the first instance, the rapidity of every individual lens, in a certain class, varies: there are diaphragms to each lens, which influence the rapidity; and we look in vain for any information as to the value of that influence. We find consecutive numbers stamped on each diaphragm, in some lenses having only an approximate relation, but none whatever in others.

Before I proceed any further, I wish to define what constitutes the rapidity of a lens. This rapidity depends partly on the colour of the glass, the number of glasses in the combination, the number of reflecting surfaces; these we shal not take into consideration, but depend mainly on the aperture of the lens, and its focal length.

It is evident that, other things being equal, the intensity of light in the image depends first on the quantity of light admitted, and, secondly, on the area over which it is distributed. It varies, therefore, directly as the aperture, and inversely as the size of the picture.

But the size of the picture given by a lens varies directly as the square of its equivalent focal length; and the area of the aperture, or diaphragm, varies as the square of its diameter. Therefore, the time of exposure varies directly as the square of the equivalent focal length, and inversly as the square of the stop.

Let us have—

f, as the equivalent focus of a lens;
a, its aperture;
f', focus of another lens;
a', its aperture.

Let us suppose that—

$$\frac{f}{a} = 4 \text{ and } \frac{f'}{a'} = 8$$

The time of exposure will be $4^2 = 16$ sec. for the first lens, and $8^2 = 64$ sec. for the second. Therefore, the first lens is four times more rapid than the second.

Now, all this useful information is not to be found except by calculation and troublesome measurement, which will not be undertaken by one person out of ten; but without it the photographic lens remains a *terra incognita*.

I consider that a correct calculation of the rapidity of the lens is as necessary an appendix as the brass mount, the diaphragms, or the cap, and that it must be attached permanently to the lens. The best plan would be by means of engraving on the brass tube or on the diaphragms.

Moreover, this rapidity must be expressed in some absolute unit alike for all lenses.

The choice of this unit is a matter of considerable importance, and, therefore, it must be discussed and decided by persons more competent than myself. The urgent necessity of the adoption of some system to express the rapidity of lenses is sufficiently demonstrated by numerous proposals to adopt various units, and by many articles in the photographic journals. This subject is, therefore, worthy the consideration of this Society; and a committee, if nominated by the Council, would not have a more important and useful work to accomplish than to decide what unit to adopt, and what measures to take, in order to secure the general adoption of a system for future lenses, as well as for application to those already existing.

For my personal use I adopted a certain unit, and have tested its utility during the last eight years. I can, therefore, confidently recommend it as the first suggestion for future deliberations. The following is a short description of it.

In the first instance, accurate measurements of the equivalent focus and aperture must be secured. I use two methods to find the equivalent focus; the first (which is absolutely accurate) consists in obtaining, in a copying-camera, the image of a geometrical figure the same size on the ground glass as the original. The distance between the original and ground glass divided by four represents the exact equivalent focus.

The second method is an approximate one. I take for this purpose a point anywhere on the mount of the lens, and, obtaining an image of the sun, with the front lens facing the sun, I note the distance from the chosen point to the screen on which the image is produced. I then repeat this experiment, only turning the lens so that the back lens is facing the sun, and again measure the distance from the chosen point to the screen. The mean between these two distances is the approximate equivalent focus.

For the measurement of the working aperture of a double-combination lens, I do not know any better system than that proposed by Mr. Dallmeyer. The camera is directed towards the horizon, and a distant object is focussed. The focussing screen is then replaced by a cardboard with a small round hole pierced in the centre. A candle in the dark-room is put as close as possible to the hole. The beam of rays passing through the diaphragm will produce on the front lens a luminous circle, the diameter of which is the required working aperture of the lens.

Having now these data, in a very few minutes I am enabled to make all the calculations as above described. But now I come to the important point. As a unit in which to express the rapidity of the lens, or, what is equivalent, the time of exposure, I adopted the lens having $\frac{f}{a} = 2$, or having an aperture equal to one-half of the focal length. Or, in other words, admitting that such a lens requires an exposure of one second, all the other lenses and diaphragms are calculated by comparison with this particular lens.

A lens of this description does exist; it is the quickest lens made; but the point whether such a lens exists or not is of no importance.

* Read before the Photographic Society of Great Britain.

As you can observe by the data given below, the time of exposure, calculated on this basis, is as nearly as posible that required by the ordinary wet process in an average light; this was one point which decided me to adopt it. The wet process was not condemued at the time when I adopted this unit; but even now, when the era of gelatine is in full swing, I do not think any advantage is to be gained by adopting a larger unit: a fractional number for quick lenses is very inconvenient. It is for this reason that I oppose the unit already proposed by other investigators, as it drives us into extremely large numbers.

To complete the description of the modes of calculation, I take one of my lenses—the patent stereoscopic by Dallmeyer.*

Equivalent focus, $f = 0{\cdot}13$.

Largest aperture, $a = 0{\cdot}0296$.

$$\frac{f}{a} = \frac{0{\cdot}13}{0{\cdot}0296} = 4{\cdot}4. \qquad \frac{f'}{a'} \text{ for unit lens} = 2.$$

Dividing $(4{\cdot}4)^2$ by 2^2 I found number 5, which is the absolute rapidity for this lens and aperture. All other diaphragms of the same lens are expressed as follows† :—

Number of Diaphragm.	Diameter of Aperture.	$\frac{f'}{a'}$	Absolute Rapidity.
1	0·0296	4·4	5
2	0 0253	5·1	7
3	0·0207	6·2	10
4	0·0182	7·1	13
5	0 0148	9·1	21
6	0·0109	12	36
7	0 0074	17·6	77

The focal length and the numbers of absolute rapidity are engraved on the lens mount, or on every respective diaphragm. A single glance at such a lens conveys at once a full idea as to the photographic value of the lens, and, coupled with a knowledge of the rapidity of the plate, enables the operator to fix his exposure without failure. From the acquaintauce I have made with a great many lenses found either in my own or my friends' possession, I found that the rapidity must be calculated for every lens separately, aud caunot be applied even with tolerable accuracy to a whole class of lenses. To illustrate this, I give here data calculated for several lenses of different focal lengths, but belouging to the same class, viz., portable symmetrical:—

Approximate Focus.	5-in.	6-in.	7-in.	8-in.	8¼-in.	9-in.	10-in.	13-in.
Diaphms. 1	64	79	100	100	78	81	69	101
2	81	90	169	162	100	110	112	154
3	169	160	222	268	191	210	198	306
4	462	281	340	529	196	552	354	...
5	1056	924	930	819	300	1560	1008	...

Here is another table for several lenses of the rapid rectilinear class :—

Approximate Focus.	6⅜-in.	6¼-in.	8¼-in.	10½-in.	12¼-in.
Diaphragms. 1	18	16	20	17	14
2	22	25	30	29	22
3	28	30	36	36	28
4	53	64	72	72	...
5	100	121	143	150	121
6	257	267	289	324	240

I conclude these remarks with reiterating my proposition; viz., consideriug that only a complete knowledge of the lens is arrived at when its rapidity is known, I express the desire that a unit for the measuring of this rapidity may be adopted, and that the rapidity of every leus and diaphragm may be calculated, and in a prominent manner marked on the lens mounts or on the diaphragms.

This measure will be doubly beneficial if universally adopted; but, in order to ensure that, some great influeuce is necessary, and this can be arrived at by the aid of this Society, through its Council.

Before I leave this room, permit me to express a feeling shared by everybody who uses the camera, either as a hobby or otherwise, of the immeuse annoyance occasioned by an endless variety of the threads, the size of screws, and lens flanges. Every maker makes his own thread distinctly different from the thread of other makers. Let me express a wish that the example of adopting a uniform thread, so successfully carried out by microscope-instrument makers, may be followed by the makers of cameras and leuses; and let us hope that if the nomination of the Committee to consider my first proposal can be realised, the same Committee may try to arrive at this desirable end also.

* All measurements are made in metres.

† Absolute rapidity is expressed in round numbers

ENAMELLING, AND A RECENT DISCOVERY FOR FIXING SILVER PRINTS.

BY ALEXANDER AYTON.*

Gentlemen,—As I announced at last meeting, I shall have somethiug to say to-night on the finishing and enamelliug of photographs; but in addition to this, I now propose giviug you some other experiences, and as the subject of dry plates is eugrossing so much iuterest at present, a few remarks in connection with them may uot be out of place.

I had my first experience with dry plates about twenty-five years ago. They were, I believe, those called collodio-albumen, and hearing a great deal of their efficiency I obtained a supply of them. Receiving an order, shortly after, to photograph some very interesting limestone caves, I started one bright summer morning in high spirits at the prospect of a successful day's work without the paraphernalia of the wet process. Arriving at the place, I exposed a good many plates, varyiug the exposures from thirty minutes to an hour, and in the interim, amused myself by searchiug for ferns. Returuing home in the evening, I began the development, which was contiuued till far iu the morning, hoping against hope for something to appear, but all that became visible was a piece of white rock or a peep of sky. Thoroughly disgusted, I had nothing more to do with dry plates till the advent of the gelatine process, and, thanks to the disinterestedness of such men as Dr. Maddox, Mr. Charles Bennett, Mr. R. Kennett, &c., we now enjoy the benefits of it, untrammelled by patent rights or any other hindrance to its practice.

My first plates were made by Messrs. Wratten and Wainwright, and I had considerable success, especially with pictures of children. By-and-bye the rejected plates began to accumulate to such an extent that the question arose: What is to be done with them? and after a good deal of consideration I determined to make my own emulsion and re-coat them. This was more easily resolved upon than accomplished, but after many discouragements I made a beginning, and so I then considered that half the battle was won.

When I began, it was the very hot summer of 1880, and the first difficulty I encountered was with the gelatine not setting, it being Nelson's No. 1 or 2, so that the first two or three batches of seven ounces each were complete failures. I theu discarded the washing process, and after boiling, precipitated the emulsion with alcohol, using, instead of Nelson's gelatine, Swinburne's patent isinglass. I was then able to use my own plates, and since theu have bought none. Increasing my batches to twenty ounces, I coutinued in this way till I had filled all the jars and bottles in the house with waste alcohol, and began to wonder if I could not manage to do without "the liquor." By this time the weather had become colder, and I then had no difficulty with the boiling and washing process, and this I have continued to use ever since.

I have latterly adopted a somewhat different method of emulsifying from any I have seen published, which I shall endeavour to describe, and to put the matter, as it were, in a nutshell. I prepare the material for tweuty ounces by the alkaline process (that is, with ammonia nitrate of silver), and twenty ounces by the acid method, boiling for ten or twelve minutes; neither of these emulsions, so treated, would separately yield a rapid plate, but by mixing both together with the excess of gelatine, allowing it at night to set, and afterwards washing thoroughly, I obtain an emulsion of the very highest sensibility aud certainty. I have used with very great success the formula of Dr. Eder, and latterly that of Mr. Bolton, containing iodide aud chloride; plates by this method are well adapted for making transparencies, the deposit of silver being very fiue. I have also made several batches, using ammouium bromide for the alkaline method, and potassium bromide for boiling; by mixing both together with the full quautity of gelatine, I obtain what I think the best results. Examples of work done on these plates I shall show you by-and-bye in connection with another matter.

In reference to the place where I carry on my operations, I appropriated a room about niue feet square, and employed a joiner to put up a wooden partition, with a door and window, dividing the room into two unequal parts, the larger being six feet by niue, called the dark-room; in the window I have two thicknesses of ruby glass, and upon the door a spring lock, which cannot be opened from the outside but with the key.

Before the ruby glass in the outer room I have a gas jet to illuminate the dark-room. This can be raised or lowered at will by a tap inside, so that while there are a number of plates

* Read before the Edinburgh Photographic Society.

setting upon the glass slab, I can lower the gas and retire, all the light being excluded from the outer room. In front of the window I have a wooden sink about three incees deep, with a water tap, and near it a Bunsen's burner with a saucepan. Across one end of the room there is a glass slab for receiving the plates after being coated, and at the opposite end I have my drying boxes. The first one I constructed was on the plan of that recommended by Mr. England; but owing to the size of mine, I had two iron tubes with gas jets inside of one as in his box. However, this arrangement was not satisfactory, as the plates nearest the tubes became over-heated and in some instances melted. I then had another box made to fit on the top of this one, and by putting two zinc pipes outside the previous iron ones, allowed them to pass outside the top of the second box, and by drilling numerous holes, connected the two. The upper one has become all that could be desired; the heat from the tubes being more genial, and the plates, having the benefit of the hot air from the lower box, dry more evenly, and are less liable to frill. Carrying out this idea, I mean to have another box constructed below, simply for heating the air to supply the two above.

In reference to frilling, I see that tannic acid is recommended to prevent this; but with alkaline pyrogallic, the cure is worse than the disease, as you will see by the plate I now show. It is stained a reddish yellow in the shadows. Microscopists use a solution of tannin with ammonia to stain tissues, and I presume that this compound is formed in the gelatine film by much the same means, but, fortunately, with ferrous oxalate, the plates develop out quite clear.

Hoping that these few hints may be found useful, I now pass to the process of enamelling.

My first ideas of enamelling were obtained from photographs of H.R.H. the Princess of Wales, done in Copenhagen, and sold in this country at the time of her marriage, in March 1863. I thought that, when it was possible to transfer one of the old positive films to patent leather or black paper, I could transfer a film of plain collodion to paper; and in putting this into practice, I coated a piece of patent plate glass with collodion, and, with a weak solution of gelatine, floated the print upon it, and when dry, repeated the same operation with the card mount. This method I see described in the present Year-Book, and, if carefully performed, it is tolerably successful; but I soon discarded it for one I accidentally discovered, and which I have practised less or more since that time. In looking among some old negatives, I observed one with a mask which had been gummed on to the varnish, and had become partly detached; on raising it up I discovered that the paper was beautifully enamelled with the collodion and varnish of the negative.

I was not long in acting upon this suggestion, and, without going into all the details of the experiments I made, I may say that the method I now use is this. Cleaning the plates in the usual way, and finishing with wash leather, no talc or French chalk being used, they are coated with plain collodion about the consistency of that for negatives, and put upon a rack till dry, when they are varnished with a white lac varnish. I prepare a stock of these plates, and so have them always ready for use. Another method, and one which I think the best for larger sizes, is to prepare the glass with French chalk, coat with a thick collodion, and afterwards coat with gelatine as you would an emulsion plate, and allow to dry. Plates coated at night are usually dry next morning. This process has been published many times before. The first to publish it was Herr Liesegang, in the Photographic News, Sept., 1860, also by J. Beattie and others in 1863.

The prints, we shall now suppose, have been washing all night, and are tolerably free from soda; but we know to a certainty that, even with enamelling, some of them, at least, will not last. I now propose, in a great measure, to obviate this by the following treatment:—After drying I immerse them one at a time, with a glass rod, in a solution of 2 volumes of sulphuric acid to 1 of water, or I think it is safer to dilute the acid one-half with water; this changes the tone from the usual brown to black. They are then returned to the washing trough, and thoroughly washed, adding a few drops of ammonia to the last water, which, to a great extent, restores the former brown. The black tone they assume in the acid may be occasioned by sulphur toning, and, if so, it seems to be removed by the action of the ammonia. I have also tried the immersing of them in a weak solution of caustic potash, which effectually removes all trace of the previous black tone; but I find that with some albumenized papers it turns them yellow. I may say that of the papers I have tried, that called "double coagulated" seems to be the best. In looking at these prints, it is very apparent that the whites have become more pearly and the shadows more velvety, and, if finished plain, present a matt surface not unlike a platinotype thus removing the (so-called) vulgar glare of silver prints upon albumenized paper. Those I now show you will illustrate this, particularly the views by Mr. Valentine.

The action of the acid upon the size of the paper is to convert it into a jelly, which is washed out, the paper appearing, when wet, like blotting-paper, and, when dry, like parchment.

By thus changing the paper we get rid of any remains of soda, and between the delicate silver composing the image we interpose, as it were, an impervious medium, thus saving it from any deleterious matter that may be in the mount.

As you will see, the silver forming the image has not been acted upon in any way injuriously.

The prints so treated, and which are to be finished with a matt surface, having been cut to the proper size before toning, are now placed one over the other, and mounted while wet with gelatine (starch paste is no use), and if desired can be burnished in the usual way, the same as the one I now show. "Carte" sized prints for enamelling I coat on the back with gelatine, and pin up till dry, when they are cut to the size and mounted upon a thin Bristol board, by damping the card and passing through a lithographic machine. They are now ready for having the spots touched up and any defects rectified with Indian ink, or, if any are to be coloured, they are now in a fit state for this operation; the colours used are the ordinary water-colours, but without gum or any other medium. When this is done, they are coated with thin collodion, and the next operation is to soften with hot water, and float with a weak solution of gelatine on to the varnished plate, which sets immediately. They are then put up in an airy place till the next morning, when they are dry, and may be stripped off the glass.

Prints of a larger size cannot be so treated. In taking them out of the water, they are laid face upwards on a piece of glass, and raising the edge, a line of gum is put all round to keep them down. The defects are then made good, or, if desired, they may be coloured and afterwards coated with collodion; this done, they are squeegeed with hot water on the plate previously prepared with gelatine, and after being allowed to set for some time, the mount is floated on in the usual way with gelatine, or, if preferred, they may be stripped off the glass in the thin state, and mounted with the machine by simply damping the card, enough gelatine being left on the back to make it adhere; the effect is much the same as if printed on double albumenized paper.

Another method which I have lately tried is this. After the prints are touched up or coloured, they are floated upon the enamel glasses in the way previously described; they are then impregnated with Canada balsam, thus rendering them perfectly impervious to moisture. They have now become semi-transparent, and the next operation is to coat the back with collodion and varnish mixed, which, when dry, gives a beautiful white coating of cotton. This method of depositing cotton I discovered years ago, in my early experiments with enamelling. I see Mr. Woodbury draws attention to it in the present Year-Book. It only now remains to give a back upon this, and, when dry, to strip off the glass. Or, instead of coating with collodion and varnish, I have roughly coloured a print previously treated with the sulphuric acid, and floated it with gelatine on to the semi-transparent one already on the glass; this has the effect of giving greater depth to the colouring. They may also be treated with wax instead of Canada balsam; but in the use of either of these the tone of the picture is very much reduced. I think I obtain a much better effect by rubbing the paper from the back of the print with sandpaper, till it is quite thin and nearly transparent. I show you a specimen done in this way, and you will observe how translucent it has become. Another method is to coat a piece of plain paper with a film of gelatine, which, when dry, is again coated with a film of albumen, with the proper chlorides. We have now albumenized paper on a substratum of gelatine, which is sensitized, printed, and toned in the usual way, when it is squeegeed upon the enamel glass, then immersed in hot water, and the paper backing removed; it is then treated with bichromate of potash and exposed to light, which, as you know, renders the gelatine insoluble. It only now remains to float a card upon the back of this and allow it to dry, when we have an albumen print resting upon an insoluble film of gelatine, and with a film of gelatine and collodion on the face. The specimen I show you is very rough, but it will serve to show the practicability of the process; and when I tell you that the gelatine was spread upon the paper with my finger, and the albumen afterwards by the same means, you will understand the cause of the heights and hollows. Perhaps some of our manufacturers of albumenized papers, on reading this, may be induced to manufacture a few sheets for experiment. I hope by some of these methods to secure permanency, and thus remove a stigma which has long disgraced our art; or, if the source of fading is in the albumen itself, I am afraid we must fall back upon the carbon process, or upon the lately-suggested gelatine-chloride process.

I should now like to draw attention to a few useful applications of the same principle. As you are aware, for some of the mechanical printing processes a reversed negative is required, and having an order a short time ago for negatives for that purpose, they were done by the wet process, varnished as usual with negative varnish, and then coated with a film of gelatine. One of these I have brought to show you how beautifully it leaves the glass.

The next application is one which I think might become very useful. Taking a positive on glass in the usual way, it is varnished, and a piece of chocolate-coloured paper is floated on to it with gelatine, and when dry may be stripped off and mounted in the way previously described. This is a far more artistic production than the new species of positives on tin.

The last application has reference to collodion transfers. They are taken in the usual way and varnished, after which a piece of rough crayon paper is applied with a squeegee and gelatine, and when dry are stripped off and mounted. A specimen done in this way I now show you.

I have been led thus extensively to go into the subject through a visit we have lately had from a gentleman professing to teach enamelling, and claiming besides to make his prints absolutely permanent. This permanency he professes to obtain by saturating the prints with wax, as you can see from the print I now show, done by one of his licensees. There is nothing very new or extraordinary in this; we know that the late Adam-Salomon did this with his prints many years ago, and made no secret of it, and we are now asked to buy this process, and only find out when too late that we knew all about it years ago. Our dealers ought to be very careful who they introduce to their clients.

While upon this subject I cannot refrain from expressing my dislike to secret processes, whether genuine or otherwise; it has not been by secrecy that photography has progressed so far, nor will the process-monger add much to its progress in the future.

Lately we have had a startling advertisement, "The Missing Link;" this was announced as an intensifier of wonderful efficiency; and when it comes to hand what do you think it contains? No. 1 solution is an iodide of mercury, and No. 2 is cyanide of silver, both of which were recommended by Monckhoven. These two solutions are to be had in nearly every studio, and can be prepared at less than 1s. each; they are now vended under the garb of secrecy at 10s. 6d., and when the carriage is added they cost 12s. This has also been extensively puffed up and sold by those who ought to know better. I shall leave the further elucidation of this subject to Mr. Tunny.

By these remarks I endeavour to repay in some measure the many useful hints I have received from this and kindred associations.

Correspondence.

DECOMPOSITION OF PYROXILINE.

Dear Sir,—Major Waterhouse mentions in your last issue two cases of spontaneous ignition of papyroxyline. This statement is so contrary to my experience with this substance that it would greatly interest me to hear from Major Waterhouse which formula he uses.

It is now nearly twenty years that I first made papyroxyline, and use it in great quantities, and I have never had an opportunity of stating either spontaneous ignition, nor even deterioration in keeping it even in a dry state in tin cases. The process I use for making it is very simple. I mix equal measures of sulphuric acid and nitric acid, and after the mixture has cooled I fill the vessel with thin paper, of which I enclose a sample. I leave the paper in the acids for about five hours, when I take a small piece out of it; this I wash in water, and after drying put it into a mixture of equal parts of ether and alcohol. If it dissolves quickly, I take the whole lot out and wash it; if it does not dissolve, I leave it a few more hours and try again. Papyroxyline prepared in this way (*i.e.*, in cold acids) gives as much intensity as cotton prepared in hot acids. Dr. Dawson, who tried it, says, "This is the first experience I have ever had of the capability of collodion made from any kind of pyroxyline extracted from cold acids to yield intense negatives. But might there not be more contained in Dr. Liesegang's practical experience than is 'dreamt of in our philosophy?'"

The above given formula I recommend to the attention of photographers in places where they may have difficulties to buy collodion or pyroxyline.—Yours faithfully,

Dr. Liesegang.

DRYING CUPBOARDS.

Sir,—It seems to me that Mr. England's drying cupboard is still the best form that has been published, and photographers therefore owe that gentleman a debt of gratitude. Is the cupboard to be purchased, may I ask, ready made? Of course, I know very well that any carpenter I applied to would at once express himself willing and anxious to construct one, and no doubt there is little difficulty in doing so; but I do not want to give a carpenter a job: I want a drying cupboard. Can you tell me of anybody who has already constructed a trustworthy drying cupboard after Mr. England's design?—Faithfully yours,

Gelatino Amateur.

[We dare say Mr. England will give our correspondent the desired information.—Ed. P.N.]

MISSING LINKS.

Sir,—There has been more than a hubbub north of the Tweed, in consequence of some recent sensational announcements. One gentleman says he has found the "missing link" with regard to the intensification of negatives. Another gentleman, from the other side of the Atlantic, says he has discovered another missing link, namely, giving absolute permanency to photographs. A gentleman resident in the Northern Capital announces at the Photographic Society's meeting that he has discovered the American gentleman's mode of securing permanency, viz., by subjecting the prints to diluted sulphuric acid. I hope your readers will be on their guard not to risk putting a print they may attach any value to into such a mixture, as rapid deterioration would ensue upon such treatment.

With regard to the American discovery, it is nothing more nor less than one of the old methods of rendering the prints transparent, and painting them on the back. This, as your readers are aware, has been once or twice patented in England. Some have proposed oil, some wax, some varnish, and some paraffin. The latter is always to be preferred. The method of the new discoverer is either wax or paraffin, either of which will give great transparency to the print. The secret of applying the colour to the back and front of the print has been so often described that it is surprising to think how many take the last announcement as new. Let your readers post themselves up in the back numbers of your valuable paper, and they will have the advantage of knowing at once what is new what is true, and what is false.

H. B.

THE DUNDEE EXHIBITION.

Sir,—As you were one of the judges, and do not feel in a position to answer my question, perhaps the Secretary will do so. I simply want to know if the judges were empowered to award extra prizes for merit, for subjects not mentioned in their prize list. I shall then be satisfied. And they surely cannot object to give me an answer if things have been carried on in a straightforward manner, as I was induced by the committee to compete under the above conditions.

David Hedges.

Proceedings of Societies.

South London Photographic Society.

The ordinary monthly meeting of this Society was held on Thursday, March 2nd, at 8 p.m., in the rooms of the Society of Arts, Adelphi, Rev. F. F. Statham (President) in the chair.

The minutes of the preceding meeting having been read and confirmed, Mr. Alexander Mackie was duly elected a member.

The Chairman, in alluding to the Artistic Competition, said the judges—Messrs. Vicat Cole, E. Warren, and S. P. Jackson—had made the awards for last year, Mr. E. Dunmore being the recipient of the medal, and Mr. T. B. Blow of the diploma. The Committee had been considering the matter, and had come to the conclusion that this year four subjects only would be given out, two for figure and two for landscape. The titles would be announced at the next meeting, and competing pictures would have to be sent in before the opening of the Exhibition in Pall Mall, due notice of which would be given. The Chairman also said that the secrecy clause would be done away with. The Chairman said he had been asked to call attention to a lecture to be given by Mr. W. K. Burton, on March 9th, at the Society of Arts, on "Practical Hints on the Manufacture of Gelatine Emulsion and Emulsion Plates." Tickets, no doubt, could be had of Mr. Wood.

Mr. E. Dunmore then read a paper on "Common Objects of the Studio," and demonstrated various points described in his paper.

The Chairman, in the course of some remarks, alluded to dust as being, in some cases, an important factor in diseases; the thorough cleansing of vessels was, he said, an important item, as shown by the failure of one of Mr. Dunmore's demonstrations, through not having time to properly wash out the vessel. The Chairman alluded to sulphide of hydrogen as playing an important part in a household, and said many unpleasantnesses were caused, both photographically and otherwise, by not thoroughly washing down drains.

Mr. Bolas said the moral of Mr. Dunmore's paper was, "Down with the dust!" and he had often heard the same cry from the Treasury Bench, Mr. Bridge often crying, "Down with the dust!"

Mr. Cole said many failures were caused, perhaps not so much by wilful adulteration, as by insufficient attention in storing chemicals.

Mr. Brooks said nitrate of silver was adulterated with baryta, mostly in small crystals, causing black spots to appear in emulsion plates when dry.

Mr. Foxlee said that impurities often arise from weighing different chemicals in the same scales without thoroughly cleansing them first.

The Chairman called attention to the fact that Mr. Dunmore's remarks alluded not so much to adulteration as failures from accidental vapours and other matters.

Mr. Cobb said that in his early days, great care in respect to dust was insisted upon; but in his experience of work at the Woolwich Academy, the cadets certainly made the dust fly about by the pranks they played, yet he had seen some of the cleanest and most perfect negatives turned out.

Mr. Nesbitt observed that it seemed as if those who took the most pains to free their dark rooms from dust got the dirtiest results. Perhaps this was owing to the fact that the dust was always in a state of agitation.

Mr. Edwards agreed with Mr. Nesbitt, and thought it was best to let sleeping dogs lie.

Mr. Foxlee said the best means of removing dust was by a damp wash-leather.

The Chairman remarked that Professor Tyndall had proved that light was caused by reflection from particles of matter floating about, so perhaps it was as well all dust could not be removed, or we should have possibly no light.

After some few further remarks had been made, a vote of thanks was passed to Mr. Dunmore for his paper.

Mr. A. Cowan passed round a little wire tray for holding gelatine plates during development, to avoid putting the fingers into the pyrogallic, as doing so caused, in many cases, bad sores. It consisted merely of a piece of flat tin on which the plate rested, and, at each side, a circular piece of wire, placed perpendicularly to the surface on which the plate rests, these acting as handles to raise the apparatus.

Mr. B. J. Edwards passed round some transparencies made upon gelatino-chloride plates.

Mr. Nesbitt asked if the sensitiveness was as great as with ordinary gelatine emulsion.

Mr. Edwards said the chloride emulsion was much slower, but could be developed as rapidly as nitrate; and also it could be developed in a much more brilliant light, and, therefore, more comfortably. Mr. Edwards then promised to read a paper at the April meeting, on "Gelatino-chloride Pictures by Development;" he also said he would develop various pictures, and explain the process.

The meeting then adjourned.

Edinburgh Photographic Society.

The fifth ordinary meeting of this Society was held in 5, St. Andrew Square, on the evening of Wednesday, the 1st inst., when the President occupied the chair. The minutes of the previous meeting having been approved of, the following gentlemen were unanimously elected ordinary members of the Society:—Messrs. A. A. Campbell Swinton, Joseph Lennie, W. Jamieson, David Gordon, John C. Rodgers, James Fairbairn, and Wm. Ireland.

The Secretary then read the rules and recommendations drawn up by a sub-committee and adopted by the Council, in reference to the presentation print competition (see page 107, in our last).

Mr. Alex. Ayton read a paper entitled "Some Photographic Experiences, including Enamelling and a Recent Discovery for the Fixing of Silver Prints" (see page 123).

The President heartily congratulated the members present on the mass of valuable information they had just received from Mr. Ayton, and proposed a cordial vote of thanks to him.

Mr. Tunny, in seconding the motion, said he had great pleasure in expressing his appreciation of the paper. He was sure that many present would be initiated into mysteries of which they were quite ignorant until that evening. He felt that all interested in photography would be indebted to Mr. Ayton for several of the ideas which were certainly original, and of very great value; he reciprocated the sentiments anent the process-monger, and especially the one particularly alluded to. Vote of thanks accorded by acclamation.

Mr. G. G. Mitchell was grateful to Mr. Ayton for the mass of information he had brought before the Society. He was specially struck with the simplicity of the mode for transferring films of collodion. He noticed that a question was asked as to the best way to reverse the gelatine film. He found that by putting the negative aside immediately it was removed from the hyposulphite bath, until all the superfluous moisture had drained off and evaporated, the film acquired a toughness which allowed it to be pulled off the glass without injury if reasonable care were employed. He had repeatedly employed the method, and invariably with success. The chief thing to avoid was the folding or creasing of the film while floating in the water, or before it was finally placed on its permanent support, any fold or crease being indicated by a perceptible line when the negative was dry.

Mr. J. M. Turnbull was much obliged to Mr. Ayton for his important contribution, and for the very thorough way in which he had entered into the various details. They were of so much value because they were the outcome of the accumulated experiences of many years, and he deemed it a very generous thing in him to have given so full an exposition of his peculiar mode of enamelling, in which process it was well known Mr. Ayton was *facile princeps*.

Mr. W. T. Bashford said he had taken advantage of the hint thrown out by Mr. Ayton at last meeting, and had made a few experiments in the direction indicated. With the sample of paper he had employed he could not succeed in parchmentizing the prints without at the same time so materially injuring the photographs as practically to make the method valueless; at the same time he considered that if any benefit accrued from a bath of sulphuric acid, a much weaker solution would suffice than is necessary to parchmentize the paper. He, as well as others, was much impressed with Mr. Ayton's announcement; but on calmly thinking over the matter, he felt that, so far as shown, he could not accept the assertion that silver prints treated with sulphuric acid were rendered permanent. Of course time might prove the claim correct, but it must be remembered the acid introduces that arch-enemy of permanency, sulphur, in a very active state, into intimate contact with the atoms of silver composing the print. That sulphur in this stage does react on the silver is evident by the marked change of tone due to sulphurization; that sulphur does not of necessity cause fading is proved by the historic fact that many old sulphur-toned prints are among the most permanent in existence; yet it must be acknowledged that the presence of sulphur tends to instability. If the print is not perfectly freed from hyposulphite prior to the sulphuric acid bath, what takes place? The acid decomposes the salt, sulphurous acid is liberated, and sulphur is precipitated. If we take a quantity of water containing hyposulphite and add a few drops of H_2SO_4, we shall notice by the smell that sulphurous acid is disengaged, and we shall see by the opalescent cloud that sulphur is liberated, and in time falls as a precipitate. It is an analogous action that takes place when a silver print containing traces of hyposulphite is subjected to H_2SO_4; the sulphurous acid would be removed by washing in water; not so, however, the atoms of insoluble sulphur that are entangled in the pores of the paper and albumen; these remain in intimate contact with the atoms of silver forming the print, so that there may be a reasonable fear that it is not more stable than prior to the acid bath. Mr. Ayton had given a most beautiful, simple, and original method of enamelling, and had also brought prominently forward several other methods of isolating the silver print, but the speaker feared that a coating of collodion, gelatine, wax, or varnish in any of their varieties, singly or collectively, would not certainly ensure its permanency if the print were originally of an unstable character. During the past few weeks a person had claimed to make photographs permanent by saturating them with a wax, and one of his dupes finds that before a month is out the print done as a sample by the process-monger himself shows unmistakable signs of fading.

Mr. J. G. Tunny intimated that two bottles had been placed in his hands for the purpose of ascertaining the active photographic ingredients they contained. He said: "These solutions are sent out, I understand, for strengthening or giving density to negatives. No. 1 is an old friend—or, rather, I should say, an old enemy—under a new name. It is a mercuric iodide in an excess of potassic iodide. I shall put a little of the solution into this test-tube. I add a few drops of the bi-chloride of mercury, and now you see the bright scarlet colour of iodide of mercury. In this other test-tube I shall put a little of the No. 1 solution, and now add a few drops of nitrate of silver; there you see the yellow precipitate of iodide of silver. This, then, is the active principle of the bottle No. 1. No. 2 bottle contains cyanide of silver. In order to prove so, I shall place in this tube a small quantity of it. A drop or two of muriatic acid added instantly forms a white curdy precipitate of chloride of silver. In this other tube I shall add to the No. 2 solution a few drops of nitrate of silver; this, you will see, instantly forms a heavy precipitate of the cyanuret of silver. This is exactly the solution that Monckhoven, more than two years ago, gave to the public for the intensifying of negatives. Those who wish to make these solutions for themselves will find the following formulæ answer admirably:—No. 1. Bichloride of mercury 20 grains, iodide of potassium 60 grains; grind up these in a mortar with a few drops of water, put into a 20-ounce bottle, and fill up with water. No. 2. 30 grains of nitrate of silver dissolved in 2 ounces of water, 60 grains cyanide of potassium in two ounces of water; when dissolved add the two together, filter into a 20-ounce bottle, and fill up with water. But, for my own working, I prefer bromide of potassium instead of the iodide that is used in No. 1 solution, using 30 grains of the bromide instead of 60 grains of the iodide. Gentlemen, in conclusion, the note of warning cannot be too often or too loudly sounded. Beware of using mercury in any form for the strengthening of negatives; many valuable ones have been lost by it. It is a powerful and valuable agent if unalterable permanency could only be obtained. Recently I have subjected all intensified negatives by it to a bath of saturated sulphate of iron. So far as these have been tested there seems to be no change after an exposure of some weeks to the little sun that has been available recently.

A vote of thanks proposed by Mr. Dobbie was heartily accorded to Mr. Tunny for his interesting demonstration.

The meeting, which was unusually large, terminated at a late hour without overtaking all the items on the billet.

Glasgow Photographic Association.

A meeting of this Association was held in the Religious Institution Rooms on Thursday evening, 2nd inst., at 8 o'clock, Mr. John Parker (President) in the chair.

The minutes of last meeting were read and approved.

Mr. David Service was elected a member.

The question-box was opened in the usual course, but nothing of importance resulted from its contents.

Mr. Lusk showed some negatives illustrating a question which was discussed at last meeting, anent certain yellow spots which frequently make their appearance on gelatine plates that have been printed from.

Mr. Robertson exhibited a drop-shutter that had been made by Dr. Paterson twenty years ago, and which proved that the principle of some of the modern shutters is not novel.

Mr. James Paton then gave a lantern demonstration of "Three Days on Loch Lomond with the Camera, and Specimens of Instantaneous Photography," which was much appreciated by the members and friends present.

Photographers' Benevolent Association.

The Board of Management held its monthly meeting at 181, Aldersgate Street, on Wednesday, the 1st inst.

The minutes of the preceding meeting having been read and confirmed, the following gentlemen were duly elected as members of the Association:—Messrs. A. J. Brown, C. R. Brown, H. Garlick, J. Smith, and H. N. P. Warren.

The other business having been disposed of, the meeting adjourned until April 5th, at 8 p.m.

The balance-sheet, with reports for the past year, is now ready, and will be forwarded upon receipt of application to the Secretary.

Thursday Evenings for Photographers.

At the meeting held on the 2nd inst., Mr. A. Mackie occupied the chair.

The subject of blood poisoning by the use of the alkaline developer was again discussed, and Mr. Henderson read a letter from a country photographer from which the following is an extract:—"The statements of yourself and Mr. Turnbull have taken me by surprise, and enlightened me about myself. I am in a dreadful state, seemingly from the same cause. I have six great sores now on the right knee, and two on the left, besides about twenty others; the doctor has been, as he said, quite unable to account for them. I cannot sit for them on my buttocks and thighs, and scarce do any work. If you will write me I shall feel greatly obliged, as I have not been able to get any cure."

Mr. A. J. Brown said that since last meeting he had been experimenting by rubbing the skin of the arm near the bend of the elbow with the various solutions. Four days' rubbing with a strong solution of bromide caused no apparent effect, the mixed developer only gave a slight stain, but a solution of pyrogallic had caused a very red mark, which he said itched very badly, and pustules were now appearing.

Mr. W. M. Ashman said he had found a beneficial result by using a nitrate of mercury ointment.

Mr. A. Cowan spoke of a gentleman whose fingers had been so badly poisoned as to disable him for over six weeks, and he exhibited a plate-holder he had devised to place in the developing tray and obviate the necessity of touching the solution with the fingers; it consisted of a thin frame of tin, having wires at the sides to raise it by; the plate being placed in this holder could be carried through all the stages of developing, &c., without being touched by the hands.

The Chairman announced that Messrs. Avery and Co. had presented the meeting with a "Patent Empire Cloth Background" and fittings; for which the thanks of the meeting were tendered.

Mr. Henderson exhibited a negative very much under-exposed, which showed a great deal of green fog; this negative was backed up with black varnish and copied, the copy being a transparency, and showing much more pluck and detail than could possibly have otherwise been obtained from such an imperfect negative.

The Chairman passed round two plates prepared with "Kennett's Pellicle" in 1873; these being interesting as showing how great a density was obtainable with so thin an emulsion.

Mr. Cowan showed three prints of a group taken by electric light at the Society of Arts, the previous Thursday.

Mr. Brown showed a print from a negative of a pantomine scene, taken during the performance, with an exposure of about four minutes; he also exhibited an actinometer, constructed after Messrs. Mucklow and Spurge's plan, from pill boxes and perforated zinc.

In reply to the following question from the box, "Is not the use of soap in burnishing prints very likely to hasten their fading?"

Mr. Henderson said he thought it had a deleterious effect and had long since abandoned its use in favour of a preparation of beeswax and parraffin dissolved by heat, and a small quantity of spike oil of lavender, then adding alcohol.

Mr. REIMANN asked if there was any method of reducing a negative intensified with mercury and ammonia.

Mr. COWAN recommended "Ozone Bleach."

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

THE sixth ordinary meeting of this Association for the session was held in Lamb's Hotel, on Thursday, March 2nd, Mr. JAMES C. COX (President) in the chair. The Vice-president, together with the other office-bearers, mustered in full strength, and numerous other members testified their interest in the proceedings.

The HON. SECRETARY (Mr. C. Johnson) read the minutes of the previous meeting, which were duly confirmed.

Messrs. Birnie and A. C. Milne were then admitted members of the Association.

Mr. JOHN ROBERTSON (Vice-president) afterwards read a paper entitled, "Dark-Slides *v.* Changing-Box." Mr. Robertsou brought a good deal of experience and useful details into his paper, the whole bearing generally in favour of dark-slides. An animated discussion followed, in which the terse, sharp questions and answers showed the keen interest taken in the subject. On the motion of the President, a vote of thanks was awarded to Mr. Robertson for his contributiou to the Society's records.

The next business on the programme was the nomination of office-bearers for the ensuing year, when it was unanimously and cordially resolved that Mr. James C. Cox be again invited to accept the office of President. The request was accompanied by a well-earned tribute to Mr. Cox for the courtesy, talent, and zeal he had shown since the formation of the Society. The Vice-presidents, Treasurer, Secretary, and Council were duly nominated for election at the next general meeting in April.

It was most generally remarked that the Exhibition continued to be a success, and that the officers immediately conuected with it deserved the highest praise for their efforts.

The usual vote of thanks to the Chairmau closed an animated meeting.

HALIFAX PHOTOGRAPHIC CLUB.

THE monthly meeting was held March 6th, at the *Courier* office, Mr. W. C. WILLIAMS (vice-president) in the chair.

The SECRETARY (Mr. E. Gledhill) read the minutes of the last meeting, which were confirmed.

Mr. WHITELEY then exhibited several very good negatives and prints from them. He had prepared the plates from some emulsion made from a sample of gelatine seut to the Club by Mr. Heinrich. He said he had some difficulty in squeezing the emulsion through the meshes on account of its being so strong.

Mr. W. C. WILLIAMS then offered some remarks on Captain Abney's enlarging method on paper.

Mr. MYOTT exhibited a half-plate camera lens and stand, bellows body, and very portable, with one double dark slide specially made for dry plates by Mr. J. Lancaster. Mr. Williams also spoke of a plan he had adopted for preserving emulsion for future use, which he thought would keep it for several weeks. He placed the emulsion in a canister, and heated it to drive out the air, and then sealed up the aperture.

For the next monthly meeting Mr. Williams promised a paper on "Photo-Eulargement," and its illustration with practical experiments.

Talk in the Studio.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next meeting of this Society will be held in the Gallery, 5A, Pall Mall East, on Tuesday, March 14th, at 8 o'clock, when the following papers will be read. "Relation of the Human Eye to the Photographic Camera," by William Peek; aud upon "A New Method for Obtaining Clearness and Intensity in Gelatine Negatives," by William Willis.

THE ROYAL BRIDE AND BRIDEGROOM.—We hear that Mr. J. Thomson, of Buckingham Palace Road, was honoured with sittings by their Highnesses the Princess Helen, of Waldeck, and the Prince of Waldeck, prior to their departure; as also by his Royal Highness the Duke of Albany.

JUMBO.—Our issue this week would not be complete without some allusion to Jumbo; so we are very glad to acknowledge from Messrs. Briggs and Son, of St. John's Wood, two capital likenesses of the elephant and his castle of children, as he appeared, we are assured, "two days after his attempted removal for America."

INSTANTANEOUS PHOTOGRAPHY.—A case interesting to Manchester photographers was decided by the Attorney-General on Saturday afternoon. The late Michael Noton, who was a member of the Manchester Photographic Society, in the year 1879 communicated to the Society his invention of an instantaneous shutter. Mr. Noton died in 1880, and subsequently, in June, 1881, Mr. Sands, of the firm of Hunter and Sands, of London, applied for letters patent for the shutter. The issue of the fiat for the sealing was opposed by the surviving brother of the inventor, on the ground that the late Mr. Noton had freely given his invention to the public, as was his custom in respect of his many ingenious appliances. The opponent was represented by Mr. Edward K. Dutton, of Manchester; and the applicant for letters patent by Mr. T. Aston, Q.C. It was acknowledged that the applicant had added a ratchet wheel with a detent and a scale to the instrument. The Attorney-General decided that the claims under the patent to be granted must be cut down so as to cover only the additions to the instrument made by the applicant, and that the title must be amended.

To Correspondents.

W. PARRY.—There is so much competition in that particular line just now, that an excellent article can be obtained from any dealer in photographic apparatus; and it would be impossible for us to particularise unless informed as to whether you wish to burn candle, gas, or oil. Also see our leader in present issue.

T. L. M. C.—It is intended that the paper negative should be waxed in the ordinary way.

T. B.—Why not send it to us for publication?

W. G. H.—Probably the most convenient method will be to develop carbon prints on waxed and collodionised glass, and then to squeegee down over the print a wet sheet of gelatine loaded with a white pigment, as oxide of zinc or sulphate of barium. When dry the sheet of gelatine will readily separate, bearing with it the print.

J. C.—One part of ammonia citrate of iron and one part of ferricyanide of potassium should be dissolved in six of water, and paper is saturated with it. Exposure should be about as for a silver print, and mere washing for fixing.

CARBON.—1. A moderate fee would be required in most cases. 2. From two to three guineas.

LEO.—There can be no doubt that the gelatine putrefied, and that minute bubbles of gas were formed.

GRIT.—1. An increased proportion of gelatine should be used during the boiling. 2. We think not, but you might print the number with a set of India-rubber stamps. 3. The proceeding would hardly pay unless in the case of very large cards. 4. Probably not worth more than old paper price.

Z. X. Y.—1. Fasten up some large sheets of white material behind the window, and at an angle of 45°, so as to obtain an uniform reflection from the sky. This having been done, paste one or two thicknesses of tissue paper outside the window over the white and blue parts. 2. A gelatine plate, certainly, but coat the reverse side with Brunswick black in order to prevent halation.

SUBSCRIBER (Merton).—It is merely a makeshift expedient, and will in all probability lead to future trouble and annoyance.

SHIRE-HALL.—It is probable that the addition which you refer to will not make any difference either for better or for worse; but the fact of using the solution after prolonged exposure to the air will certainly make a very considerable difference, and must lead to certain failure.

F. O. T.—If the circumstances are exactly as you describe them, you would no doubt be quite justified in refusing to give up the pictures.

T. RICHARDS.—1. The oxide of zinc merely serves to give the film a moderate degree of opacity. 2. Two drachms of glycerine is quite enough in such a case. 3. Yes. 4. Dissolve it in a few drops of water before adding it to the gelatinous mixture. 5. Not less than 130° F. 6. Only by carefully straining through muslin.

B. ANDREWS.—Although it is much better done at the time, there is no reason why you should give up the task. A preliminary soaking in dilute acetic acid will serve to remove all traces of lime, and then you can proceed as before.

ST. ALBANS.—1. It merely consists of carbonate of lime in a finely divided state. 2. About eight grains to each ounce. 3. Rather less time than an ordinary silver print. 4. No.

THE PHOTOGRAPHIC NEWS.

CONTENTS.

MR. MUYBRIDGE AT THE ROYAL INSTITUTION.

Before a distinguished audience, which included H.R.H. the Prince of Wales, the Princess of Wales, and the three young Princesses, the Duke of Edinburgh—a distinguished photographer, it may be remembered—the Poet Laureate, the President of the Royal Society, and most of the managing body of the Royal Institution, Mr. Muybridge, of San Francisco, gave, on Monday, his first public demonstration in this country. Mr. Muybridge might well be proud of the reception accorded him, for it would have been difficult to add to the *éclat* of such first appearance, and throughout his lecture he was welcomed by a warmth that was as hearty as it was spontaneous.

Mr. Muybridge wisely left his wonderful pictures to speak for him, instead of making the occasion the subject of a long oration. He showed his photographs one after another on the screen by the aid of an electric lantern, and modestly explained them in clear but plain language. In this way the demonstration was at once rendered entertaining as well as interesting.

Mr. Muybridge first explained his plan of securing such rapid pictures of animals in motion. He showed a representation of his "studio" to begin with; it was like that portion of a race-course to be found opposite the grand stand. This latter building was, in effect, a camera stand, and a very grand one, into the bargain, for it contained twenty-four cameras in a row, the lenses a foot apart, all looking on to the course. As the animal passed, these cameras, with their instantaneous shutters, were fired off one after another by electricity. Thin linen threads, breast high, and a foot apart, were stretched across the course, and as the animal broke these threads, they, being connected, each of them, with a camera, brought about the exposure. The instantaneous shutter in each case simply consisted of two little planks, one to move upwards, and the other to move downwards, in front of the lens by rubber springs; the tension of these latter is very great—equal to 100 lb., Mr. Muybridge said—and the exposure was calculated to be not more than $\frac{1}{5000}$ of a second. Whether this calculation is correct or no, certain it is that the spokes of a trotting carriage shown were very sharp, and there was hardly a movement visible in any of the animal pictures.

We may mention here that all his photographs were taken on wet plates, for they were secured four years ago. Iron was employed in their development, and no additional care or particular method was had recourse to.

Mr Muybridge, by way of comparison, first threw on the screen a series of artist's sketches of the horse in motion, some of them old-world designs of the Egyptians and Greeks, some very modern, including the principal animal from Rosa Bonheur's well-known "Horse Fair." In no single instance had he been able to discover a correct drawing of the horse in motion, and, to prove his statement, he then threw on the screen several series of pictures representing the different positions taken up by a horse as he walks, trots, ambles, canters, or gallops. One thing was very plain from Mr. Muybridge's pictures, namely, that when a horse has two of his feet suspended between two supporting feet, the suspended feet are *invariably* lateral; that is to say, both suspended feet are on the same side of the animal. This, no painter—ancient or modern—had ever discovered. Then the amble was found to be different from the canter, and the canter very different again from the gallop; although most people imagined that, to perform all these, the horse used his legs in the same fashion. Mr. Muybridge was at some difficulty to describe the amble, and it seemed at one time as if it would be necessary to call upon Mr. Tennyson to give a definition of it in his well-known lines: "Property, property, property!" but he succeeded subsequently in defining the step very satisfactorily afterwards by means of his pictures.

After Mr. Muybridge had shown his audience the quaint and (apparently) impossible positions that the horse assumes in his different gaits, he then most ingeniously combined the pictures on the screen, showing them one after another so rapidly, that the audience had before them the galloping horse, the trotting horse, &c. Nay, Mr. Muybridge, by means of his zoepracticoscope, showed the horse taking a hurdle—how it lifted itself for the spring, and how it lightly dropped upon its feet again. This pleasing display was the essence of life and reality. A new world of sights and wonders was, indeed, opened by photography, which was not less astounding because it was truth itself.

After these life-like pictures, it needed not Mr. Muybridge's dictum that to use a mild term it was "absurd" to see a galloping horse depicted with all four feet off the ground, a simple impossibility. And if this held good of one horse, what must be said of ten horses, thus painted, as was the case in Frith's "Derby Day," which Mr. Muybridge projected on the screen by way of comparison, and which the clever photographer described as a miracle.

Mr. Muybridge modestly calls his series of animals in motion—they include horse, dog, deer, bull, pig, &c.—simply preliminary results. They contain little or no half-tone, and are only proof of what may be done. What he desires now to secure, if he only receives sufficient encouragement, is a series of photographic "pictures," and these, with the experience he has now acquired, and with the gelatine process to help him, should be well within his reach. We only trust this encouragement will be forthcoming, and that Mr. Muybridge will be tempted to carry on the difficult work he has commenced with such genuine success.

THE RETURN OF SPRING.

The numerous bright gleams of sunshine which have flashed out from time to time during the past fortnight or ten days will probably act as an incentive to many amateur and professional photographers to make preparations for out-door work, and doubtless many who have only practised the wet process will adopt the gelatino-bromide method at this juncture. Old apparatus will now be overhauled or altered, while new will be purchased; and many amateurs are, doubtless, busy in carrying out plans for new dark-rooms or modified apparatus. As the gelatino-bromide process now is one of the chief methods of making negatives—if, indeed, it is not actually the most important—the dark-room of the past requires considerable modification. The old-fashioned cupboard, only just large enough to stand in, and provided with extemporised yellow blinds, will no longer serve, either as regards the safety of the light, or the space available for work; and those collodion workers who intend to adopt the gelatino-bromide method during the approaching season will do well to thoroughly refit, and, where possible, enlarge, their laboratories; while those who have already practised with gelatine emulsion should carefully test and thoroughly examine all windows, as a medium which has proved sufficiently non-actinic during the dull months may not be safe in the face of the powerful light of spring and the early part of summer.

Our readers will bear in mind that the entry of extraneous light into the dark-room is by no means easy to detect, unless the observer acclimatises his eyes by remaining in the dark for a considerable time; and a mirror should be used in examining those parts of the room which can only be looked at from remote corners—often, indeed, the very corners which are selected as being suitable places for laying plates aside during a few minutes.

Slides and cameras which have been placed aside during the winter will require special examination, as glued joints will often open, and the leather may be cracked, separated from the woodwork, or rendered defective by the attacks of insects. In connection with this matter, we may mention that the woodwork of cameras and slides is often so thin as to form a very imperfect protective against the direct rays of the sun, or even the long-continued action of ordinary daylight.

The question of lenses naturally occurs in conjunction with our present notes concerning the recommencement of out-door work with the camera, and we may remind those who have so loudly predicted that the portrait lens will soon become a thing of the past, that the objective in question is still prized by those who wish to practically realize the full value of the gelatino-bromide plates for instantaneous work, and, although an objective of the rectilinear or symmetrical class is certainly superior when it can be used, there are many cases in which a judicious photographer will arm himself with a portrait combination, even for outdoor work.

A SIMPLE PNEUMATIC FILTER FOR GELATINE EMULSION.

The following method of filtering emulsion is as simple as it is satisfactory. It is the result of a number of experiments in search of a thoroughly efficient filter, and has been in use for about three years. The articles used in the construction of the filter are a gallipot, and a piece of chamois-leather about four times the diameter of the mouth of the pot. The leather should be well dressed, and, as nearly as possible, of uniform thickness. It should be thoroughly washed in soda and water, and all trace of soda afterwards removed by repeated changes of water. The final rinsing should be effected in distilled water, after which the skin, while wet, is laid over the mouth of the pot, so as to form a hollow receptacle for the fluid emulsion.

When the emulsion to be filtered is poured into the hollow, the skin should be gathered up in the operator's hands, and pulled tight over the mouth of the pot. By this means the air in the pot becomes partially exhausted, and the emulsion is forced through the pores of the skin, leaving the grit and refuse behind.

This simple pneumatic filter may be improved by fixing the leather into a wooden ring large enough to enable the operator to increase the pressure used in stretching the membrane over the mouth of the pot. In our practice, however, the simple sheet of leather has been used, owing to the facility it affords for washing.

It should be borne in mind, in using a filter of this sort, that the leather, after each operation, should be washed in the dark-room, and preserved in a jar of distilled water. Should the washing be conducted in daylight, some of the particles of silver bromide remaining in the skin will be affected by the light, and passed through into the next batch of emulsion, greatly to the detriment of the resulting plates.

This filter may be employed for a great variety of purposes, as, for example, in straining soups and jellies, as well as for manifold operations in the laboratory. We have great pleasure in placing it at the disposal of our readers.

PROOFS AND RE-SITTINGS.

Opinions are divided on the subject of sending out proofs to sitters. There is only one class of photographers, we believe, to whom the difficulty never occurs—those, namely, who bargain to supply a single picture for a stated sum. Thus Mr. John Fergus, of Largs, for example, supplies one cabinet portrait for a guinea, and then charges half-a-crown a-piece for every succeeding copy; while Herr Koller, the leading Pesth photographer, to take an example from the South, gives a single promenade portrait for eight florins, and charges a florin and a-half apiece for copies. But this arrangement is only applied, we believe, to larger portraits, so that even these gentlemen have the proof problem to solve in the matter of carte pictures.

Some of our English photographers forward untoned and unmounted prints to their customers, and so, do not provide these latter with a picture gratis, nor give themselves a great deal of trouble in case the portrait fails to please. Others, on the contrary, make it a practice to take as much trouble over retouching and finishing a proof copy, as over the supply.

Again, there are those who charge for the proof, and those who do not; those who require the first impression to be returned, and those who are indifferent on the subject. To stamp in red ink the words "proof copy" is a plan occasionally adopted to prevent a sitter who only wants one copy getting it for nothing.

As we have said, it is a subject on which many opinions exist, and for that reason we have asked some of our friends to express their ideas on the subject. This is what they say:—

One whose name is a household word among British photographers writes:—

I send out my specimens as good and complete as I can make them. Customers do not understand photographic technicalities, and will give a better order from a perfected specimen than from an untouched, untoned, or unmounted print. I not only retake, if a customer wishes it—first destroying the prints already taken—but I will not allow a customer to give an order if I find that he does not quite like the proofs. I insist on having all the proofs returned, but if any are kept, full price is charged for them. Sometimes when I have sent half-a-dozen proofs to a sitter he will give his order from one of them, and will try to buy the others at a greatly reduced price. "They are of no use to you," is his argument; but I never relent. Full price or destruction is my invariable rule.

A firm of "Photographers to the Queen" says:—

For over twenty years we have always supplied finished proofs of the number of positions ordered, and they have been counted in the number given for the price paid at time of sitting. If the proofs are not liked, another sitting is given free of charge.

A voice from Baker Street says:—

Our practice has always been, and I think it is the wisest with our connection, to submit at least two properly finished proofs for each sitting, whether carte-de-visite, cabinet, or larger sizes. A client then knows exactly what will be received in execution of an order, and I should expect endless little troubles to arise from submitting untouched proofs. We invariably obtain our fees at the time of sitting, and do our best to please our clients, but never give more than one re-sitting; if dissatisfaction still exists, we make an extra charge of 10s. 6d. for the third sitting, but such a necessity seldom happens. The following is a small paper which we send with all proofs:—"Messrs. Pyro and Hypo have the pleasure to enclose proof prints from the negatives recently taken, and will be obliged by their being returned as early as convenient, with the number of copies required written on the back of each."

Another voice from Baker Street says:—

I have adopted the only method open to me, viz., supplying perfect proofs in all cases; this being the result of an experience of nearly thirty years. Proofs approved are counted as part of order.

A Bond Street House writes:—

I have always treated proofs as of no value intrinsically; my terms are for the time devoted to the creation of the negative; the mere pieces of paper and cardboard which are called "proofs" are, in my estimation, of no value; I therefore send them liberally, and ask that they may be returned with all directions written on the back; if they are not, I do not charge for them, but send the required number in addition. I have never considered that I have sold carte-de-visite and cabinets at so much per dozen. The value of the work has been in the negative, as in the case of a doctor or barrister, who do not charge for the paper upon which their opinions are registered, but for the opinions themselves. This, I consider, is the proper spirit in which proofs should be viewed.

A "Successful Photographer's" opinion about supplying proofs is the following:—

Proofs should be thoroughly finished, and fewer re-sits will be the result. I make an extra charge of two shillings on the set of cartes, which entitles the customer to re-sit until satisfied. At the same time, I compel the client to return all the unapproved copies, thus preventing the parties from being retaken for the sake of more positions. At a rough calculation I have about one re-sit in a dozen; this makes an average of twenty-four shillings for every re-sit. I send the following with my proofs: "The photograph enclosed herewith is sent for inspection, and, if approved, must be sent back marked with a X. *All other copies that may have been taken must be returned at the same time, or the order cannot be completed*, as only one position will be given. If the portrait is not approved, another sitting will be given, free of charge, any fine forenoon, before 12 o'clock. Should the proof be considered rather dark, or too light, this can be altered without a re-sitting."

Glasgow says:—

When we submit proofs, we expect that they should be paid for. Except in special cases, we do not charge for second sittings; but we think, were the profession to adopt that rule, it would be a good thing to do.

Bristol says:—

I think it very necessary that proofs should be forwarded for approval; but I make it my practice to send *rough and untoned proofs*, enclosing the following intimation:—"Mr. Protosulphate begs to forward *rough and untoned proofs*, which should be kept from a strong light as much as possible, otherwise they will discolour." During my experience (twenty-one years) I have tried all the many ways of sending *finished proofs*, but have come to the conclusion that my present system is the most satisfactory on the whole. Doubtless I have to re-take some negatives that perhaps I should not have to do if finished pictures had been sent, owing to the untoned proofs having to bear the test of comparison with finished prints. On the other hand, my experience has proved to me that the majority of re-takes are by sitters who are *not pleased with their expression, style of garment, badly fitting dress or coat, and, it may be, the position.* If a negative contain any of these shortcomings (which are quite out of the photographer's power to alter), all the time expended on such negatives and prints is lost, however lovely they may be in a technical point of view when finished. With an established photographer, his patrons are aware of the class of work he produces, and if they are satisfied with the expression and position, rely upon his reputation for the finish. "With untoned proofs" you can promise them the following day (should time be of consequence, even the same day); but with finished proofs two or three days must elapse before the sitter know the result. "With rough untoned proofs," should a re-sitting be required, you go about the re-taking with better grace than had you expended considerable time, trouble, and material in producing what the photographer himself considers a thoroughly perfect photograph, but the sitter does not like, on account of expression, &c.

Liverpool says:—

It has always been my practice to supply proofs—finished copies—and I have found that in doing anything that could satisfy my patrons, I could never discover that they considered themselves too well treated. They generally dispose of such proofs as they think best, unless requested very particularly to return them for further purposes of the work to be done, &c. I may here introduce a remark which has probably more meaning than at first sight would appear. I have invariably found that the best and otherwise most artistic productions are seldom, if ever, selected; almost always the worst productions are accepted as the best, and, as a sequence, re-orders follow from the same inferior negative. Any attempt at not supplying proofs would be resisted by the public, and met by the forcible observation "that every one supplies proofs." I need not trouble you with charges, and so on; nearly every photographer has a different scale of prices. I have never altered mine for more than twenty years—in fact, ever since the introduction of the magic carte-de-visite. I am not aware that experience gained, time and money lavishly expended, entitle the public to a lowering of prices. I may be mistaken, and I have probably suffered in consequence, but such is my impression.

A firm in the S. W. district writes:—

We always send out proofs untoned and unmounted, simply trimmed with care. In this way, it is generally possible to forward pictures by the evening post. An unmounted proof, everybody knows, is only a rough picture, and although a finished photograph is on the whole more pleasing, the untoned impression has a softness and charm that are not at all disagreeable. We do not charge for a re-sit, but we should grumble if called upon more than twice to take a sitter to whom we had given our best attention.

A Gold Medallist writes:—

In reference to sending out proofs and giving re-sittings, I think no rule can be laid down to regulate the whole trade; it will always remain a personal matter with the photographer, according to ability, circumstances, &c., upon what principle he conducts his business; there will always be a certain percentage of the public who are attracted, and are continually on the look-out for something cheap. These have to be catered for as well as the other portion who are willing to pay a fair price for a good article. I think for the ordinary small photographs, such as cartes and cabinets, where (as a rule) a number of copies are required, the public have a right to demand proofs before ordering; and if a reasonable charge per dozen is made, the profits will admit of this, and also of occasional re-sittings, should they be required. I must confess that re-sittings, as a rule, are annoying, and sometimes the demands of our patrons in this respect most unreasonable. Still I think we should not grumbe at having to take a few extra negatives. We certainly reap the full benefit from a portrait that gives entire satisfaction; and from an experience of over twenty years I know that very few copies are ordered if the picture is not liked, however good the quality of the work may be. In my own practice I charge the same price for one copy (carte) as for half a dozen; consequently, I never have to take negatives for single copies. If asked the price for a single carte, I say, ten shillings and sixpence, but you can have six copies for the same price, or a similar sum for three cabinets. I experience no difficulty in the matter, but others differently circumstanced might.

Newcastle says:—

The amount of energy daily wasted in the thankless task of finishing a series of portraits for mere approval is beyond estimation. Six, nine, twelve sittings for a few cartes or cabinets, are, I know from daily contact with my customers, quite usual in many establishments. The best of these are submitted, to stand or fall, not on their merits, but oftener on unscrupulous whims, changing fancies, and unjustifiable lack of appreciation. Alas! poor artist, placed in the power of a capricious sitter; his only protection is an appeal to the purse strings—give nine, twelve, a hundred proofs if desired, but let each one be paid for. But far better, sweep away the whole system; it was all very well years ago, when the many vagaries of the art were constantly obtruding, when uncertainty of effect was prevalent; but now, artist and sitter alike are so conversant with the details of form, colour, light, and shade, as to alter the whole face of the matter. There is no occasion for so many trial sittings, one or two, as a rule, being sufficient. As a matter of fact, for some considerable time I have exposed only one negative (with occasional exceptions) on each position ordered; but I don't expose until confident the result will be a success. With experience, one rapid comprehensive glance of the eye immediately preceding exposure will estimate the composition as a whole, and the niceties of detail in posing, lighting, and expression. The sitter, not having had time to be wearied, is thus benefited by the resulting natural portrait, and the photographer, through concentrating his skill on the one production, is also the gainer. No proof need be shown, and an occasional re-sitting, which rarely happens, is charged a sum equivalent to the price of an extra position. Of course, there are instances where several negatives are an advantage, and where proofs are imperative; in such cases a fixed charge is made for each. It is a mistaken and injurious notion to suppose that a high-class establishment must of necessity submit proofs. Quite the contrary is my opinion; for the higher the repute of the artist, the more reliance will the public place in him, and be guided completely, if he will only take the reins.

THE CHEMICAL ACTION OF LIGHT.

BY DR. J. M. EDER.*

The iron salts are used for many purposes in photography. Ferricyanide of potassium is decomposed in the light, and ferrocyanide is formed (Vogel), the violet rays being twice as energetic in producing this phenomenon as the red rays (Chastaing); besides the ferrocyanide, prussic acid and soluble Berlin blue are also formed (Eder). Ferricyanide of potassium on paper is sensitive to light, even in a dry condition (Herschel, Niepce, and Burnett), and the presence of gelatine promotes the reaction (Gintl). Potassium ferricyanide mixed with chloride of iron turns blue on exposure to the light (Herschel). A solution of ferrocyanide of potassium decomposes slowly in the light, turning a darker yellow colour, while potash and prussic acid are separated (Schönbein); on paper it becomes a bluish colour (Herschel). Manganese ferrocyanide also turns blue under the action of light (Arche). From a solution of sodium nitro-prusside a precipitate of Berlin blue is thrown down in quantity proportionate to the intensity of the light to which it is exposed, and this decomposition is quickened by the presence of iron chloride; the latter mixture is decomposed twice as rapidly under blue as it is under yellow or red glass. Prussian blue fades in the light—especially when kept in a vacuum—with the loss of cyanogen or hydrocyanic acid, but in the dark it takes up oxygen again, and recovers its blue colour (Chevreul). According to Schoras the colouring matter is precipitated from a solution of prussian blue on exposure to the light, but this is denied by Böttger.

From a solution of uranium chloride in ether (Gehlen), and from one of uranium nitrate (Becquerel and Chastaing) or of uranium sulphate (Ebelmen) in alcohol, the green oxide of the metal is precipitated by the action of light; the presence of glycerine (Botton), or of tartaric acid (Niepce and Boivin) has a similar effect. Nitrate of uranium on paper is converted into the green oxide in the light (Burnett and Niepce). Many of the organic salts of uranium are rapidly reduced by exposure to the light—for instance, the double oxalate of uranium and ammonium, the acetate, citrate, formate, tartrate, &c., of uranium; in producing this result the blue and violet rays are the most active.

* Continued from page 99.

Cupric chloride dissolved in ether and alcohol is reduced by the action of blue and white light to cuprous chloride. According to Fehling, an alcoholic solution of the alkaline tartrate of copper is also decomposed by light; Fehling's normal solution separates in the sunlight from 30 to 40 times more cuprous oxide than in the dark, and the solution diluted with about six volumes of water, which in the dark is very permanent, is rapidly decomposed in the light (Eder). The double oxalate of sodium and copper blackens in the light (A. Vogel), and in the presence of oxalate of iron metallic copper is separated (Ehrmann).

The brown peroxide of lead, produced by the oxidation of the monoxide under violet glass, loses colour again when exposed to the light under yellow and red glass, and forms minium. Lead iodide in contact with a damp atmosphere gives off iodine under the influence of light, and becomes converted into the oxide and carbonate; a mixture of lead iodide and starch turns blue on exposure to the sunlight (Schönbein, Roussin, and Schmid). If kept for a long time in violet or green bottles, lead iodide undergoes no visible alteration, but if it is then mixed with starch it causes the blue colour to appear much quicker than is the case with the same salt which has been kept in the dark or in red bottles.

Mercury chloride in an aqueous solution is decomposed into mercurous chloride, hydrochloric acid, and oxygen (Boullay and Davy), but the presence of hydrochloric acid or of ammonium chloride prevents this decomposition. Solutions of the same salt in ether or alcohol are decomposed much quicker; mixed with oxalic acid this salt also decomposes (Planché and Becquerel), but in this photo-chemical reaction the formation of mercurous chloride, and the escape of carbonic acid gas owing to the hydrochloric acid being set free, soon decreases (Marchland), while in the presence of ammonium oxalate the action is more equal (Eder). Both these mixtures are used for actinometrical purposes. The addition to a solution of corrosive sublimate of formic, tartaric, succinic, citric, or malic acids, or of cane-sugar or tannin, also promotes the decomposition under the influence of light.

Bromide of mercury behaves similarly to the chloride, and the iodide of the same metal on paper turns brown (Hunt), more especially in the blue rays. Moist mercurous chloride becomes grey in the sunlight. Both the red and the yellow oxides of mercury are darkened on exposure to the light with the loss of oxygen, and they are converted into a mixture of the suboxide and metallic mercury; the violet rays are most active in producing this effect. Moist subiodide of mercury also discolours in the light, and turns almost black, giving off hydriodic acid—especially in blue or violet, also in green light (Chastaing).

Many other compounds of mercury are sensitive to light—the nitrate, carbonate, and chromate, the basic sulphate and sulphite, the hyposulphite and its double salts; many of the double compounds of mercury and ammonium; also the oxalate and suboxalate with their double salts; the tartrate, pyromucate, and benzoate of mercury, all darken when exposed to the light. Iodide of mercury produced by dipping a film of iodised collodion on glass in a bath of mercurous nitrate will receive, after a short exposure, an image, which can be developed by a solution of pyrogallic acid and silver nitrate; bromide of mercury will not act in the same way (Schnauss).

(To be continued.)

By-the-Bye.

PHOTOGRAPHY AS CLERK AND DRAUGTHSMAN.

In employing photography in the capacity of a clerk or draughtsman, there is always one inestimable advantage: you can rely implicitly upon the truth and correctness of the result. And this quality, we believe, is likely to cause photography to be employed in years to come to a very great extent in the bureau of the statesman, the counting-house of the merchant, the office of the lawyer, and the workshop of the engineer. True, we have now-a-days many clever autographic copying processes—the gelatino-glycerine cake is one of the simplest and best—by means of which a writer may take one or more copies of his manuscript; but these, if they render photography unnecessary in certain instances, do not restrict the usefulness of the art in any degree.

One of the first, if not the very first, record we have of photography undertaking the duty of copying clerk is that cited by Professor Alexander Herschel. He has told us how his father, the late Sir John Herschel, made use of photography with iron salts—the blue process—for copying his calculations and intricate tables. These cost so much trouble to produce, and represented such valuable investigations, that he was exceedingly loth to trust them out of his hands. For many reasons it was necessary to prepare a copy or copies of his work, and as he could not rely implicitly on anybody's figures but his own, he himself had the trouble of writing them out. To photography, then, he turned at the first opportunity; he could trust it, obviously, even better than himself to copy the elaborate calculations, and could rest quite sure that not a single error crept into the mass of figures during their reproduction.

The blue process, which gives white figures on a blue ground, is still frequently employed, especially by scientific men who want simply a rough copy of their work; but it naturally has the disadvantage that the ground is not white. Still the paper is so exceedingly easy to prepare, and the process so simple, that it will long command attention where occasionally a valuable MS., an intricate calculation, or an elaborate plan has to be copied. The ink of the original should be as black as possible—Indian ink is best: and for printing, the document is simply placed above the prepared paper, the two being kept flat by means of two plates of glass held together by clips or other simple contrivance. The process is already well known to our readers, but it may well be repeated in Profesfor Herschel's own words:—"The solution for treating the copying paper is as under:—

Citrate of iron (or ammonio citrate)	...	140 grains
Ferricyanide (red prussiate) of potash	...	120 ,,

dissolved together in two fluid ounces of water. The solution can be kept in a glass stoppered bottle, well wrapped up in a dark cloth, or shut up in a dark cupboard, for any length of time. It is applied to the paper by means of a brush, or tuft of cotton wool, and the surface dried in the dark. Two or three minutes' bright sunshine suffices, if the original is on thin, or tracing paper, for printing, and the fixing is done by washing in clear water for a few minutes."

The "Pellet" paper, a patented article, which may be readily purchased in any large town, is better than the above process, for the reason that the copy is in blue upon a white ground. But the manipulations, on the other hand, are a little more elaborate, and the method is more costly. Where much copying is done, the Pellet paper is largely used, as, for instance, in the engineering departments of the Great Eastern and other railways. The use of photography in such connection is very obvious. Here is one example. The Company desire to purchase some engines; to do this as moderately as they can, they put out the work to tender, and supply any firm desirous of contracting with an elaborate plan showing every minute detail. Formerly, tracings were made of the original approved plan, and these were supplied to would-be contractors. Of course tracings are comparatively easy of production, and with a little care there should be no mistakes in copying; but by bringing photography to bear, the expense of copying is reduced as nearly as possible one-hundred fold, while the chance of error disappears altogether.

Among diplomatists and lawyers, photography as an accurate copyist is also beginning to be appreciated, but here it is desirable to have a reproduction in black, and for this reason we think that the process of nigrography, to which attention has recently been called by Captain Pizzighelli, is likely to find favour. The ordinary autographic copying processes to which we have alluded, and which give from one copy to two or three score, handy as they are, do not suffice to satisfy the lawyer and diplomatist's wants. In the first place, the document to be copied may have been written ages ago, or it may happen that it cannot be copied until it is signed, and when this takes place, the writing has lost its virtue to copy in the ordinary way. In these circumstances the photographic art is singularly useful. Copying by hand is out of the question, for even if done correctly, the copy may lose all its value by not being a facsimile. Here is an instance of what we mean. A Russian document was recently submitted privately and confidentially to a foreign minister; it was impossible to leave the pamphlet—for it was of several pages—in his hands for more than a few hours, and yet the minister urgently desired a copy. There were clerks in his office who understood French, German, and Italian thoroughly, but Russian characters were too many for them. In a fortunate moment the chief clerk bethought himself of photography, and suggested it to the principal; the pamphlet was unstitched, spread out upon a drawing board, and within a few hours there lay another similar volume in miniature, upon the minister's desk, produced by means of photography, and fit for translation and perusal at leisure.

Diplomatic enclosures, which are generally confidential, are now frequently repeated by photography, either by the aid of the camera, or by simply printing through, while lawyers also employ the art for making facsimiles of authentic documents. A photographic copy is held in a court of law, now-a-days, to be as good, almost, as the document itself, for a witness can swear to the handwriting and style just as well as if he had the original before him. Any intelligent man, too, can do the work of copying after a little practice, whether it is the blue process, Pellet process, or nigrographic process he makes use of. The last is more elaborate than the blue process, but with a little practice is soon acquired, while it yields most excellent results. Paper thoroughly sized is floated in a darkened room upon a solution of—

Gum-arabic	... ...	25 parts
Water	... ...	100 ,,
Bichromate of potash	.. ...	5 to 7 ,,
Alcohol	... ...	1 part

Or the mixture may be applied with a broad camel's hair brush. Dried, and kept in a cool dark place, it will remain fit for use a long time. It is exposed in the same manner, and for about the same time as in the blue process, and is then put into cold water for twenty minutes to wash out the unchanged bichromated gum. When dry, a dozen or more prints may be taken at a time and treated with the black colour, made up of—

Shellac	... ...	5 parts
Alcohol	... ...	100 ,,
Finely ground lamp black	...	15 ,,

This is applied with a sponge. Afterwards the papers are laid in water acidulated with sulphuric acid (containing 2 or 3 per cent. of acid), when the superfluous black colour is removable by a brush, and the writing or design appears in fine black lines upon white paper.

Another process, which has been recently worked out by Captain Pizzighelli, also yields capital prints. Thirty volumes of a solution of gum-arabic (water five parts, gum one part), are mixed with eight volumes of an aqueous solution of citrate of iron and ammonia (water two parts, double salt one part), and to the mixture is added five volumes of an aqueous solution of perchloride of iron (water two parts, iron one part).

The mixture appears limpid at first, but soon grows thicker, and it should be used quickly after mixing; it is applied to well-sized paper by means of a brush, the paper being dried in the dark.

Any design, drawing, or tracing may be employed as negative, and, after printing a few minutes, the development is proceeded with. A solution of ferro-cyanide of potassium (water five parts, ferro-cyanide one part) is applied with a brush, and the picture appears almost instantly as a dark-blue positive. As soon as every detail has appeared, the print is quickly rinsed, and then put into a dish containing dilute hydrochloric acid (water ten parts, acid one part) when the image becomes clearer and brighter, the ground gets white, and the gum-iron film is removed. After further washing the print is dried.

There can be little doubt that prepared photographic paper will soon be found in every large office where valuable documents abound. The labour saved, as well as the accuracy assured, are already important points, and when to these is added the circumstance that a *facsimile* is the result, firms of many kinds will not be slow to avail themselves of the advantages of photographic copying. With a camera at one's disposal, it is possible, of course, to do yet more, for huge manuscripts may in this way be reduced to small dimensions, while their intrinsic value yet remains. But to use a camera again, more photographic skill is required. Very little knowledge, on the other hand, is required for simple photographic printing of the nature we have mentioned, and with its aid the duties of clerk and draughtsman may often be advantageously discharged.

The next "At Home" will be "Herr Obernetter at Munich"; the following "By-the-Bye" "On Buying and Selling a Business."

PRACTICAL HINTS ON THE MANUFACTURE OF GELATINE EMULSIONS AND PLATES FOR PHOTOGRAPHIC PURPOSES.

BY W. K. BURTON.*

This paper will, I imagine, be read before a mixed audience, some of whom have a complete knowledge of photographic processes, whilst others may not even know the meaning of the word "emulsion." I shall, therefore, try to explain accurately what we mean by the term, and shall then glance rapidly at the history of emulsions generally, so far addressing myself specially to those who have no knowledge of photography. I shall then enter more particularly into the question of the manufacture of a gelatine emulsion, demonstrating the process; and in this part of my paper I shall address more particularly those whom I shall suppose to have at least some photographic knowledge.

In all our modern negative processes, the object which we have in view in preparing a plate is to spread evenly on a surface, usually of glass, one of the silver haloids. Those which are used are the bromide, the chloride, or the iodide. Any one of these can be made by combining nitrate of silver with the corresponding soluble haloid. For example, bromide of silver is formed by combining nitrate of silver with any soluble bromide. As an example, I have here a solution of nitrate of silver in water. I have also a solution of bromide of ammonia in water. I pour the one into the other, and a dense white precipitate is thrown down. This is bromide of silver. Now, in the manufacture of every photographic plate, this process takes place. It may either take place on the surface of the plate, in which case we have what is known as a bath plate; or it may take place before the film is spread over the plate, in which case we have an emulsion plate.

To explain this matter rather more fully, I have here a certain slightly coloured transparent fluid. This is what is called "iodised collodion." It is a soluble iodide, dissolved in collodion. Collodion is a substance which will form a thin film over a glass plate. If, therefore, I pour this iodised collodion over this plate, I shall have a film in which there is the substance necessary to form iodide of silver with nitrate of silver, and you will see, that when I drop this plate into a bath containing nitrate of silver solution, it will lose its transparency and become white and opalescent. In fact, iodide of silver is formed on the surface of the plate, and a "bath plate" has been prepared.

Now this is a very beautiful process, and one which is most pleasing in many ways, but it has its drawbacks. You have seen that, for one thing, some delicate manipulation is required. Not only that, but we are working with two most fickle substances. In practising the wet process, the bath is continually going out of order. If the bath is right, then the collodion is wrong. Then the film itself is of such delicacy that a touch will destroy it; but the great difficulty is, that the plate must be prepared within, say, half-an-hour of the time it is to be used, and when once exposed must be developed within a few minutes, so that the photographer must have the whole paraphernalia necessary to manufacture the plates wherever he means to work them.

Very long ago, it suggested itself to photographers that the two substances, the iodide and the nitrate of silver, might be combined in the collodion before it was poured over the plate, so that the whole process of manufacturing the plate should consist in pouring the collodion over it. I need not enumerate the unsuccessful attempts that were made; suffice it to say that, in 1864, Messrs. Sayce and Bolton succeeded in suspending bromide of silver, in a fine state of division, in collodion, which had afterwards only to be poured over a glass plate. This process I now demonstrate. I pour an alcoholic solution of nitrate of silver into a bromised collodion. You perceive the bromide of silver formed in a fine state of division. All that is necessary is to pour this over the plate, to wash the latter, and an emulsion plate has been prepared, and is ready for the camera. You see that the process is far simpler than the bath process, but the very great advantage of it is that, whereas the bath plate had to be used immediately after preparation, the "collodio-bromide" plate may be kept for a lengthened period, either before or after exposure.

The collodio-bromide plate was about the same in sensitiveness as the wet plate, and for long was the dry plate of the day.

It began, after a time, to suggest itself to the minds of various photographers that, possibly, some other vehicle than collodion might be used to hold the bromide of silver in suspension. In 1871, Dr. Maddox suggested gelatine as a medium, and experimented in it, getting good results. He prepared bromide of silver in a solution of gelatine of such a strength that it was liquid when hot, but in the form of a jelly when cold. He spread it over plates when warm, and allowed it first to set as a jelly, and then to dry.

In 1873, Mr. R. Kennett took out a patent for a "pellicle," which was simply emulsion prepared as by Dr. Maddox, but afterwards dried. It had to be re-dissolved in warm water, when plates could be coated with it.

It was not, however, till 1878—when Mr. C. Bennett published the fact that if a gelatine emulsion be kept warm for a number of days, the sensitiveness increases enormously—that gelatine plates came to the front. Mr. Bennett's experiments demonstrated the fact that in gelatine plates there might be a sensitiveness never before dreamt of by photographers—five times, ten times, or twenty times what they had been used to. It was afterwards shown that if the emulsion be boiled instead of only being kept warm, a very much shorter period of time sufficed to gain the sensitiveness. It was again shown that if the emulsion be kept warm in the presence of ammonia, the process goes on with great rapidity. In 1879 was published a process in which boiling is recommended, but in which it is advised that a very small quantity of the gelatine necessary be introduced before boiling, the rest afterwards. This process is due to Mr. W. B. Bolton. It must be understood that a very considerable quantity of gelatine is required to make a solution which can be spread over glass, and which will "set" as a jelly on the plate: but that a much smaller quantity of gelatine is enough to keep the bromide of silver in suspension while it is being boiled. The advantage to be gained is that only a small proportion of the gelatine goes through the ordeal of boiling, which is one liable to decompose it.

I have not, up till now, touched at all on the subject of washing an emulsion. I have pointed out that by combining bromide of ammonium with nitrate of silver, bromide of silver is formed; but we must recollect, also, that nitrate of ammonium is formed, and that this, if left in the emulsion, would be most hurtful. I here give the equation:—

$$Ag\,NO_3 + NH_4\,Br = A\,gBr + NH_4\,NO_3$$

* Read before the Chemical and Physics Section of the Society of Arts.

Besides the nitrate, there is another consideration. It is quite impossible in practice to weigh out such accurate quantities of each of the two salts that they shall exactly convert each other. We must have a little of one or the other over, or, as it is said, we must have a slight "excess." This might be either nitrate of silver or bromide of potassium; but as an excess of nitrate of silver is found hurtful, the proportion of the two haloids are always so adjusted that there shall be an appreciable excess of soluble bromide, or if the emulsion be one to contain a chloride, of soluble chloride. Now, it is necessary, after emulsification and boiling, to get rid both of this excess of soluble haloid and of the nitrate. This is done by washing, and to the washing process gelatine lends itself admirably. A gelatine solution, in the form of a jelly, is quite insoluble in cold water. All, therefore, that is necessary, is to break up the emulsion when in this form, and to allow it to soak in running water. The nitrate, which is soluble, and the soluble bromide, will each diffuse away.

Now, to pass on to the actual manufacture of an emulsion. The process which has worked best in my hands is the acid boiling process, and this I intend to demonstrate to-night. By working exactly as I am now about to do, I obtain plates of the very highest sensitiveness, and, at the same time, of good quality.

I need scarcely say, that the operations which I now perform in bright gas-light must, when an emulsion for practical use is wanted, be carried out in the deepest ruby light, and very little of that. To begin, then, here is the formula:—

I.

Nitrate of silver	400 grains
Water	8 ounces

II.

Bromide of ammonium...	220 grains
Iodide of ammonium	15 ,,
Chloride of ammonium	15 ,,
Gelatine (Nelson's No. 1)	80 ,,
Water	8 ounces

Hydrobromic acid, enough to make the solution just acid.

III.

Autotype gelatine	450 grains

soaked in water, and afterwards squeezed to get rid of as much of the water as possible.

A few remarks on the formula.

Iodide is recommended by Captain Abney, and I find that it adds greatly to the quality of the plates. Although chloride of ammonium is used in the preparation of this emulsion, it is not intended that there shall be any chloride of silver in the emulsion. The bromide and iodide are just estimated to convert the silver, using Warnerke's practical equivalents. The reason for using the chloride at all is that I believe a greater degree of sensitiveness is gained by boiling in presence of an excess of chloride than with an excess of bromide. I have not myself been able to find that any advantage arises from the presence of chloride of silver in the emulsion.

The amount of gelatine used in emulsification is somewhat greater than is sometimes recommended. I believe the quality of the plate is thereby improved. It may be asked why I do not give a definite quantity of acid; it is because the chemicals themselves are frequently acid. I believe that the success in getting a very sensitive, and, at the same time, clear emulsion, greatly depends on the amount of acidity of the solution. It should be just acid enough to show by litmus paper. If this is the case when the salts are first dissolved, nothing more is wanted. If not, add very dilute hydrobromic acid, till the solution will just turn blue litmus paper red. If it has been neutral at first, about one drop of strong hydrobromic acid will suffice.

I have found the autotype gelatine the best for the bulk, as frilling, in my experience, never occurs with it. It is very hard setting, but, at the same time, does not repel the developer as some gelatines do. Somewhat more than the quantity given may be used, if it be desired.

To emulsify, I pour the solution No. 2 into a glass bottle (when at home I use a hock-bottle); I afterwards add, little by little, the nitrate of silver, both solutions having been raised to a temperature somewhere approaching the boiling point. The whole is then poured into a large beaker or jelly-can; this is covered with a cover consisting of a wooden dish, and placed in a saucepan. The lid of the latter is put on, and the whole is allowed to boil. I coat a plate with the emulsion newly made. It will be seen that, on looking at a light through the plate, the light appears ruby red. The emulsion is said to be "red by transmitted light." As the process goes on, however, the colour changes, and at last it becomes blue. It is difficult to say exactly when the whole of the bromide of silver has been converted into the blue variety, but it may be discovered by gently drying a plate coated with the emulsion. The blue bromide and the red bromide will separate into patches. When all is converted to the blue, the boiling may cease. The time taken in boiling seems to vary considerably with different manipulators; with me it is generally somewhere between one and two hours; but I have frequently boiled for several hours without producing fog, and have, in fact, never reached the fog-line, so long as the emulsion was kept distinctly, but slightly acid. The bulk of the gelatine is then added, and the whole poured out in a flat dish to set.

When it is set quite stiff, it is cut up and placed in the "squeezer." It is pushed through wire gauze into a hair sieve held under water. This cuts it into very small particles, and, if water be allowed to run through the sieve for half-an-hour, the soluble salts will all be washed away.

After this, the sieve is allowed to stand a short time, for some of the water to drain off. The emulsion is then heated, is filtered through two folds of a pocket handkerchief, and is spread on the glass. For this I use a small teapot as a pourer. I used at first to measure the emulsion for each plate, but can now guess the quantity with great accuracy. My teapot holds four ounces, and this will just coat a dozen, or rather eleven, half-plates. I pour the emulsion on the plate while the latter is on the levelling shelf. I then take a glass rod in the finger and thumb of each hand; dip this rod into the pool of emulsion on the plate—the emulsion runs by capillary attraction along the rod to the edges of the plate, but no further. I lift the glass rod about a sixteenth of an inch; the emulsion rises with it. I pass it rapidly first to one end of the plate then to the other, guiding myself by keeping my thumb and finger on the levelling shelf, and the plate is absolutely evenly coated. It is never removed from the levelling shelf till it is set. The plates are slightly warm to begin with. The plates, after they are set, are reared on ends in racks, the design for which I got from Mr. G. F. Williams; they are then placed in the drying box to dry.

Plates prepared as I have described are quite as rapid as the average of the so-called instantaneous plates sold commercially. Captain Abney first pointed out that an emulsion got more rapid by keeping it cold after it was washed. In my experience, this only happens when the emulsion is alkaline, or at least not acid. If to the emulsion, made as described above, about eight drops of strong ammonia be added to the pint, it will be found that after a week's keeping, the plates made from it will be from two to three times quicker than before, and such are quicker than any commercial plates that I have used. This adding of a few drops of ammonia simply to neutralise any acidity which may be in the emulsion must be by no means confused with the process where digestion is carried on in the presence of one to two per cent. of ammonia before washing.

I must say a word on a point that is often discussed; "Is it worth while for an amateur to make his own plates?" I certainly think it is not, if he expects to economise by it. If, however, he is such an enthusiast as to make plates for the pleasure he will derive from working those made by himself, instead of those purchased, then by all means let him make them, but do not let him suppose that everything is to go quite smoothly, and that he is to have no trouble—at least, if he is aiming at rapid plates. It is easy to make a moderately rapid emulsion, and to make a number in succession with uniformity, but it is not so easy to make the plates. It is on the coating and drying of the plates that the difficulty comes. Then, if an exceedingly rapid emulsion is required, the difficulties increase, and, in fact, become very great; the amount of light admissable is so small, that manipulation must be performed more by feeling than by seeing.

We often hear people grumbling at the quality of commercial plates. My own surprise has been at the uniform excellence of the plates issued by all the leading manufacturers. If any amateur reaches the quality and uniformity of any of our first manufacturers, he may be well pleased with himself.

ON THE BEHAVIOUR OF IODIDE OF MERCURY IN CONTACT WITH HYPOSULPHITE OF SODA.

BY DR. J. M. EDER AND G. ULM.*

The solubility of iodide of mercury has been investigated, with the result, that one molecule of the iodide was found to require

* Communicated to the Imperial Academy of Science in Vienna.

for its solution two molecules of hyposulphite of soda. This solution is decomposed either on standing for a long time, or on evaporation in a vacuum, or by warmth, a precipitate being disengaged of a yellowish to cinnabar red colour; this precipitate is composed of variable quantities of sub-iodide of mercury, sulphide of mercury, and free sulphur partly soluble in bisulphide of carbon and partly insoluble. In the presence of an excess of hyposulphite of soda, the precipitate contains no free sulphur. Iodide of potassium and iodide of mercury combined behave in the same way with hyposulphite of soda.

The yellow precipitate, so freely liberated from the solution of iodide of mercury in hyposulphite of soda, is by reason of its containing subiodide of mercury sensitive to light; it becomes black on exposure. Indeed, the solution itself is sensitive, for on exposure to light 1·03 to 1·012 more precipitate is formed than in darkness. The precipitate formed during exposure to light contains appreciably more free sulphur than that obtained in the dark, while the amount of subiodide of mercury and sulphide of mercury remain pretty well the same. Alcohol precipitates from the solution $HgS_2O_3\ (Na_2S_2O_3)_2$ and $HgI_2\ (NaI)_2$ remain in solution.

Metallic silver becomes iodide of silver with simultaneous precipitation of subiodide of mercury.

From these reactions, the authors deduce the conclusion that a double salt $HgI_2(Na_2S_2O_3)$ is formed by the solution of iodide of mercury in hyposulphite of soda, and this is contained in the solution.

Alcohol only exerts a decomposing action, without precipitating the respective component substances.

[The above investigation has a material bearing on the matter of intensifying gelatine plates with mercury.—Ed.]

Notes.

The late M. Poitevin was a Chevalier of the Legion of Honour.

Dr. J. M. Eder was on Tuesday elected an honorary member of the Photographic Society.

"Photography with Emulsions," Captain Abney's new work on the subject, was published on Monday last by Messrs. Piper and Carter.

Mr. T. G. Whaite has devised a simple and very perfect plan of coating paper with gelatine emulsion. We hope to publish particulars of it next week.

Dr. Huggins informs us that he has been successful in photographing the spectrum of the nebula of Orion, and has found therein a new line in the ultra-violet. It is not so long ago that to photograph a star was something wonderful; since then Dr. Huggins has told us how he has been able to photograph the spectrum of a star, that is to say, to secure an impression on a photographic film, not from the full light of a star, but only from such minute portion of it as can pass through a slit $\frac{1}{350}$ of an inch in diameter, the image being distended on the plate to the extent of half-an-inch.

Dr. Huggins has now photographed the spectrum of the nebula of Orion, the small luminous patch which puzzles astronomers to this day. Some nebulæ, like the Milky Way, for instance, are found to consist of tiny stars when looked at through the telescope, but the nebula of Orion baffles the most powerful instrument, and appears to the eye as a luminous cloud. It is of this that Dr. Huggins has now photographed the spectrum, showing a new line in the ultra-violet, a result, the importance of which will be appreciated, since it is the first to teach us something definite about this strange phenomenon. Dr. Huggins communicated his discovery to the Royal Society yesterday evening.

Vienna has followed the example of London, Paris, and St. Petersburgh, and now possesses an electric studio. It was opened by Herrn Stagel and Eckel on the first of this month, being fitted up upon the Van der Weyde system. A Siemen's machine giving a light equal to 5,000 candles is employed, worked by an eight-horse-power engine. A concave mirror reflects the arc light, whose direct rays are screened by means of a little saucer from the sitter; the latter is posed about seven feet from the light.

Levitsky at St. Petersburgh prefers to employ the wet process in his electric studio, and, strange to say, it is used also in Vienna. The exposure given for a carte-de-visite bust portrait is from five to six seconds. In Vienna, the studio is open from dusk to 10 p.m.

Dr. Julius Schnauss, the well-known chemist of Jena University, has just issued a photographic dictionary. It is a most complete work, treating of the chemistry, technics, and optics of the art, and contains 536 pages.

House agents have for a long time past recognized the value of photography, and it may be worth while to note the fact that Her Majesty the Queen made up her mind to take the Châlet des Rosiers, at Mentone, after receiving a fine photograph of the house and grounds.

A committee on lenses has been nominated by the Council of the Photographic Society, at the suggestion of Mr. Warnerke. Its principal aim will be to get opticians to agree upon some system to express the rapidity of various lenses that are made: to establish, in fact, a "unit" of rapidity on which all shall agree. The Committee is composed of Mr. Warnerke, Captain Abney, and Messrs. Darwin, Wortley, England, Dallmeyer, Cowan, Bedford, Davis, Brownrigg, Heaviside, and Stuart.

Major Waterhouse brought before the Photographic Society a new photo-engraving process on Tuesday. A latent image is produced on a bromised copper plate—the sensitiveness of which has of late been overlooked—and development is then brought about by using the ordinary dry-plate developers, either alkaline pyrogallic, or ferrous oxalate. Subsequently the plate is etched. Major Waterhouse, anent the subject of etching liquids, promises to communicate to the News a list of those he has found effective.

The Home Office has ordered the police to secure photographs of "bodies found" in all cases where foul play is suspected, so that not only indentification may follow of the deceased, but, if possible, of the means that led to death. The body of the murdered man found in Finchley Wood has been photographed in accordance with this order. The Paris police have adopted this course for some time, and are provided with a well-fitted movable laboratory, in shape and exterior like our police vans, so that a picture may be taken, when necessary, of the spot where the body is found, ere this is removed.

"I should like to see your boxing pictures," said the Prince of Wales to Mr. Muybridge on Monday at the Royal Institution, when the galloping horse, the running deer, the trotting bull, the halting pig, and the racing dogs had successively crossed the screen in life-like measure. "I shall be very happy to show them, your Royal Highness," responded the clever photographer; and promptly there was thrown upon the screen two athletes, who pounded away at one another right merrily, to the infinite delight of the audience in general and the Prince of Wales in particular.

Mr. Muybridge, in this case, had taken rapid successive pictures of a pair of boxers as they assumed one fighting position after another, and then these photographs were as rapidly thrown on the screen in the same order by means of his zoepractiscope. Thus a boxing-match was reproduced in all its photographic reality. "I don't know that these pictures teach us anything very useful," said Mr. Muybridge, "but they are generally found amusing."

Mr. Muybridge's "Boxing Match" may call to mind the steam engine in motion, of which we ourselves secured a photograph in 1870, when working with Sir Charles Wheatstone. Sir Charles had invented an instrument similar to Mr. Muybridge's zoepractiscope, and asked our aid to furnish the necessary pictures. We produced two series, one of a steam-engine, and another of an infantry soldier going through the bayonet exercise. Our work, however, was very simple compared to Mr. Muybridge's. To secure the steam-engine in motion, we merely had to produce thirteen photographs; the engine was at rest, and we simply turned the fly-wheel one-thirteenth of a revolution between each picture. The result many of our readers may have seen; the engine moved, but rather slowly, as if it were slackening speed.

Captain Abney lectures to-night at the Royal Institution, on "Spectroscopic Work with the Infra-red (Dark) Rays of the Spectrum."

A new edition of the late M. Poitevin's work—"Printing without Silver Salts"—was announced a short time since. Its appearance will not be delayed through the author's death, for M. Léon Vidal, our Paris correspondent, was entrusted with the work of preparing it for the press some months ago. It would have been some satisfaction, however, if the distinguished chemist could have lived to see this new issue of his valuable book. The first edition, we hear, is completely exhausted.

Perhaps the most striking experiment shown by Mr. Swan, last Friday, at the Royal Institution, was that in which he demonstrated how much more economical it was to employ a strong current of electricity than a weak one in his incandescent lamp. Thus he showed how a certain quantity of electricity gave no light at all; how twice the same quantity gave a light equal to two candles; while three times the quantity produced a light equal to thirty-five candles.

As to economy in using the Swan lamp, we may refer once more to our experiments published in November of last year, in which we showed that a low resistance lamp (52 Ohms) gave a much brighter light than one of higher resistance (58 Ohms), the same quantity of electricity being used in both cases. The low resistance lamp marked 23 on our photometer, while the high resistance lamp only marked 20. When a large number of lamps are employed, and the current is a powerful one, this difference may be of little importance; but where single lamps are used—and we soon hope to see them in our dark-rooms—the "resistance" offered by the lamp to the electric current is an element of considerable importance.

There is some prospect of a course of Cantor lectures being delivered at the Society of Arts, upon the manufacture of optical instruments; we hear that a gentleman well known in photographic circles is likely to be the lecturer.

A deputation representing most of our largest towns waited on Earl Spencer, last week, to urge upon the Lord President their right of being permitted to share with London, Edinburgh, and Dublin, the art treasures purchased by the country out of the proceeds of the 1851 Exhibition, and which are to be found, for the most part, at South Kensington. Earl Spencer promised, in reply, to assist with specimens from South Kensington any local exhibition that might be established, and stated that during the past year the item spent in photography for reproducing works of art had been increased by £250. "Photography," said Lord Spencer, "was a most important means of educating art students," and he thought, by still further employing the art, local museums could be furnished with much valuable information.

Applications of photography to science are numerous enough, but painters are prone to deny that it can be applied to the cultivation of the fine arts. But now Mr. Muybridge has exhibited to the Royal Academy, at its own invitation, his photographs of animals in motion, perhaps we may hear it admitted that photgraphy can help the painter as well. At the time the "Roll Call" was exhibited, artists without number fell upon the lady painter because a horse was shown, it was averred, with its legs in an impossible position. Mr. Muybridge's series of horse pictures proved on Tuesday to the Royal Academy and its followers that a moving animal assumes many more positions than were ever dreamt of in their philosophy.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. 3.—The Dark Room.

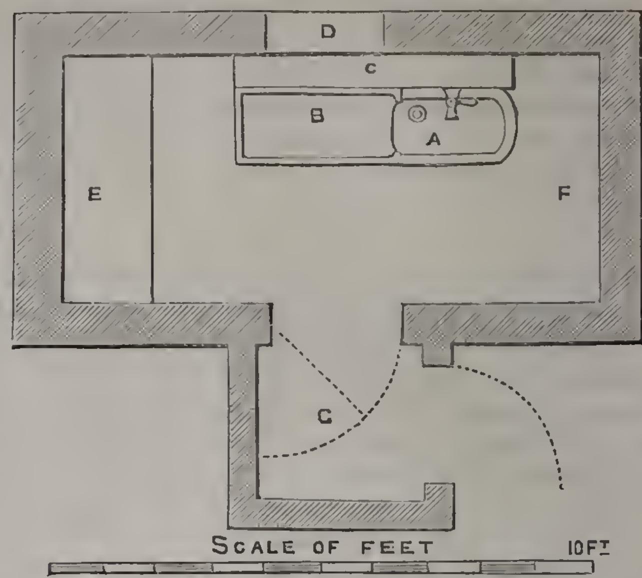
Our young friends will understand that the plates which they are about to work with are of the most "exalted sensitiveness;" that is to say, a very small amount of light allowed to act on them will produce a change which may be made visible. We must explain, however, that it is only certain rays of light which have the power of making the change which we mention. All our readers who have a little knowledge of physical science, know that white light is in reality a combination of light of all the beautiful colours which we see in the rainbow, and that if we pass a ray of white light through a prism, it will be broken up into all these colours. The order of them is—violet, indigo, blue, green, yellow, orange, and red. Those at the beginning of the list are called rays of high refrangibility, those at the end, rays of low refrangibility. Now, it is a curious fact that the photographic change which is worked in a sensitive plate is worked entirely by the rays of high refrangibility, principally by the violet and the blue, which are said to be "actinic;" whilst the red, which is said to be "non-actinic," has no effect at all. Were it not for this peculiar fact, photography would be almost impossible, because we could find no light in which we could manipulate our plates without their being affected and consequently destroyed. As it is, however, we only require to secure some place illuminated by those rays which do not have any photographic action, and we can work quite freely. In other words, we want a room lighted with only red light in which to work.

Photographers give such an apartment the name of "dark-room," although the term is a misnomer. In the dark-room, then, we propose to give what hints we consider necessary for the beginner.

It is scarcely to be expected that the young amateur, taking up the subject of photography for the first time, will have the power of obtaining the exclusive use of a room of considerable size, to convert into a dark-room; but, on the contrary, he will probably have to put up with some temporary arrangement; nor is it at all necessary even when he advances considerably that he should have a permanent dark-room unless he intends to make his own plates. Any room or closet from which all the outer rays of light can be shut off may be converted into a dark-room in which plates may be changed and developed. If a room having a sink and water tap—say the pantry—can be "annexed," the trouble will be greatly reduced; but it is quite possible to make shift with a pail for a sink, and a water jug instead of the tap.

We have said that it is necessary to shut out entirely all outer light. This pre-supposes the use of artificial light for illuminating the apartment with the necessary red or non-actinic light. We consider that until such time as the student sees his way to fitting up a permanent dark-room, he will find it best to work with artificial light. There are lamps constructed especially for the purpose of giving "safe" light sold by all dealers in photographic apparatus. These use either gas, oil, or candles, and all consist of an arrangement whereby the air necessary to support combustion is introduced by passages which will not allow white light to find its way out, the colour of the light being modified by funnels of ruby glass, or shades of ruby paper or cloth. The gas and oil lamps are much to be preferred to the candle arrangements, as with the former it is possible to raise or lower the light at will.

All, then, that the photographer has to do, is to find some small room or closet, which he can make quite dark, in which he can have a plain deal table to work upon, and to purchase a "dark-room lamp" from a photographic apparatus dealer. Our description of dark-rooms would not, however, be complete, unless we say something about the fitting up of a permanent photographic room in which all the operations, including the manufacture of the plates, may be conducted. We give here a sketch of such a room.



D is a window whereby the necessary light is introduced. It should be about two feet long, by one foot six inches high, and should be glazed with one thickness of ruby, and one thickness of orange glass. On the inside there should be a blind of red Turkey cloth, which can be raised and lowered at will. This is to reduce the amount of light when the sun shines direct on the window, or when the process of plate manufacture goes on.

A is a sink made of glazed stoneware. The top edge should be about two feet six inches, or two feet eight inches along the floor.

B is the operating table. It should be covered with sheet lead, should have a very narrow and low ridge round all the sides except that next to the sink, should have a very slight incline in that direction, and should have the sheet lead "dressed" over the edge of the sink, so that all spillings may find their way into it.

C is a narrow shelf about four inches above the level of the table and sink, and extending along the whole length of both of them. On it is placed the lamp when artificial light is used, as when working at night, and the bottles of solutions actually used for development. The lower edge of the window should be an inch or two above this shelf. There should be a shelf about six inches below the operating table, on which the flat developing dishes may be kept.

E is a table on which the levelling slab may be placed when the manufacture of plates is commenced. Above it —or, in fact, along all available space of the walls—shelves may be fixed for carrying bottles, &c.

A space is reserved at F for the drying cupboard, used in manufacturing plates. Above it, and with its lowest edge about three feet higher than the floor, should be fixed an ordinary cupboard, with a door closing light-tight. In this may be placed plates or anything sensitive to light, which would be destroyed if left about, for it must be understood that even light of the deepest ruby red will in time act upon a sensitive plate.

G is an arrangement of double doors, whereby the photographer may go out or in without letting any light enter.

Provision must be made for ventilating the room without letting in light. There should be at least one common gas jet for lighting up the room when no sensitive plates are about, so that solutions, &c., may be mixed with comfort, and there should be provision made for attaching several rubber tubes with the gas pipes for connecting with Bunsen burners, &c.

The photographer will in all probability not *build* a room, but will adapt one already built to his purposes. In this case he will have to exert his ingenuity to allot his space to the best purpose. We have enumerated all the appliances for which room ought to be reserved.

FRENCH CORRESPONDENCE.

Death of Poitevin—M. Braun's Emulsions—Another Shutter—Measuring the Velocity of the Shutter—A New Use of Celluloid—Society for the Defence of Copyright—Warnerke's Sensitometer.

Death of Poitevin.—As was announced in the last number of the Photographic News, Alphonse Poitevin died at Conflaus (Sarthe) at the age of sixty-three years, surrounded by all his family. He leaves a wife and four children, the eldest a son, aged eighteen years, and three daughters, one of twelve years, the second of nine years and a-half, the third of twenty months. He lived at Couflans on a small estate which he had inherited from his father. The rents which he drew therefrom were very small, and scarcely sufficient to maintain and educate his children. This limited income caused him great anxiety, and I have no doubt that to his trouble on this account, added to the wear and tear of his constaut work, was due to some extent the softening of the brain, the first symptoms of which became apparent about two years ago. Those who, like myself, were in constant relatiou with him, could not but perceive the gradual weakening of his mental powers, but we were far from supposing that the catastrophe was so near at hand. To tell the truth, his scientific work, great and brilliant as it was, was accomplished some years ago, and latterly his ideas seemed only to come to him occasionally, and then he was able for a short time to discuss the further researches which it might be possible for him to undertake. More especially the question of printing in salts of iron was an object to which he intended to turn his intention, but the effort was not of long duration; his energy failed him iu consequeuce of the brain disease, and for the same reason he felt it impossible to undertake passing through the press a second edition of his work, "On Photographic Printing without Silver Salts," although the first edition is completely exhausted. I had offered him my assistance in this uudertaking, notwithstanding my numerous other pressing occupations, and I had intended, in concert with him, to complete each of the chapters of the work by an appendix, giving a general account of the practical and industrial applications of those principles which had been discovered and described by Poitevin. The work was in full swing when I was so painfully surprised by the news of the death of my friend—a man with a universal reputation, to whom science is largely indebted, and whose memory will, I trust, be honoured iu a manner worthy of it.* I hope not only that some commemorative monument will be erected to Poitevin, but also that the French Government, and also the lovers of the art for which he has done so much, as well as all those who have benefited by his discoveries, will agree to do something for his family, in order that they may not suffer in a worldly point of view by the loss which they have just undergone. Poitevin has left no fortune, and it will be dreadful to think that his four children will not be assisted by his country, to whom he has been an honour, and by the whole of the photographic profession, which owes him so much. I feel convinced that every one will take a part in fulfilling a duty which we owe to the memory of Alphonse Poitevin.

M. Braun's Emulsions.—The last meeting of the Photographic Society of France was a particularly full one. M. Fernand Braun, photographer of Angoulême, read a paper on his process of preparing gelatino-bromide emulsions. The prints which he exhibited as the results of this process are valuable proofs of its efficacy; they are, in fact, worthy of special notice. Among them he showed some prints from instantaneous negatives, of very large size, and really faultless. A full account of the details which he communicated would greatly exceed the limits of this letter; but I hope to be able to send the complete text of the paper itself to the Editor of the Photographic News, to be published in some future number, if he should think fit. We have by no means heard the last of gelatine emulsions; the question is still in course of settlement, and it is necessary to follow the subject closely, in order to select from all the processes and formulæ those which go to make up a really reliable method.

Another Shutter.—Instantaneous shutters still occupy a great deal of attention. At the meeting above mentioned, one was shown by M. Liskferme consisting of four discs which move simultaneously from the centre to the circumference. This idea is not a new one, and the way in which it is applied may be almost called rudimentary. However, it will probably soon disappear with a heap of other shutters into the arsenal of neglected instruments, whence, perhaps, it may be drawn forth some day by anyone who is looking for a more valuable invention.

Measuring the Velocity of the Shutter.—Colonel Sébert, who is well kuown for his methods of chronometric observation, proposes to verify by a graphic process the duration of the exposure obtained with the shutter of M. Paul Boca. He has endeavoured to prove that the length of the exposure will be really that which is registered beforehand by the needle on the disc of the instrument. The result of his observations, which have been very skilfully arranged, is that, subject to a few minor corrections, the instrument will register perfectly correctly exposures of from $\frac{2}{50}$ second up to $4\frac{1}{2}$ seconds. M. Sébert points out that the instrument is capable of being made to register exposures of hundredths of a second. In the present state of the photographic art these very short exposures are often necessary. This demonstration is without doubt very interesting, but I should like to see brought within reach of the public a more simple method of verifying the rapidity of the shutter. It seems to me that a simple method of realising this idea would be by means of a disc graduated into 100 degrees, over which a needle cau travel iu the space of one second. It will then be only necessary, when trying the shutter, to photograph the needle in movement, and the number of degrees registered on the photograph would indicate the duration of the luminous action. This remains to be seen.

A New Use of Celluloid.—With laudable perseverance M. David is still engaged in the study of the use of celluloid in photography. At the meeting of the Photographic Society he presented some sheets of gelatine, coated by means of a brush with a film produced from the liquid from which celluloid is obtained. By means of this coating the gelatine is rendered impermeable and impervious to the action of water, or of other photographic substances.

Society for the Defence of Copyright.—There has lately been established at Paris, at the instigation of the *Cercle de la Librairie*, a society for maintaining the right of property in literary work abroad. The Photographic Society has already affiliated itself to this newly-established Society, and the *Syndicate de la Photographie* intends also to join.

Warnerke's Sensitometer.—M. Marion, on behalf of Mr. Warnerke, exhibited the sensitometer which has already been so highly spoken of in the English journals. The idea of this instrument is excelleut. A plate of some phosphorescent substance receives the highest possible impression (which is, therefore, a fixed quantity), and it is then allowed to act upon sensitive films whose degree of sensitiveness can be correctly determined by means of this luminous plate. The application of the process is carried out in a frame suitably arranged. Burning magnesium is used to render the phosphorescent substance luminous, but, no doubt, any other source of light capable of producing the maximum vibration of the phosphorescent particles would serve the same purpose, and allow of the same degree of accuracy being arrived at. Leon Vidal.

* The book itself will shortly be published by Gauthier-Villars; it will be illustrated with a portrait of Poitevin printed in phototypie by Berthaud.

RAPIDITY OF LENSES.

BY W. H. WHEELER.

I venture to trouble you with a few remarks on the subject of Mr. Warnerke's paper, printed in your last number, in the hope that they may prove generally interesting.

We shall all agree that a ready and accurate knowledge of the rapidity of our lenses is most desirable. It would be well if every photographer knew by heart the focus and aperture of every combination, and of each individual lens in his possession, that he knew the diameter of every stop, and could at once, after estimating the proper exposure with that which he most frequently uses, calculate that of any other lens and stop that he thinks best for his immediate work. It is not my desire to criticise Mr. Warnerke's plan, but to suggest a few considerations which may help others in doing so.

There is no doubt that the manufacture of lenses has now reached a high excellence, and probably theory has not much more to suggest in the way of practical improvements. I think, nevertheless, that there is still much to be done by the optician. But a more intelligent demand must precede supply, and accurate knowledge of photographic optics must become more general before photographers will adequately appreciate, and intelligently select and use, the instruments with which opticians do or might furnish them.

With one of Mr. Warnerke's suggestions I cordially agree, namely, that on the brass tube of every lens should be engraved the value of its intensity with the full aperture, and on each diaphragm the intensity with that stop. But I venture to think the number engraved should be the denominator (with decimals as required) of a fraction whose numerator is unity, which fraction should thus express the equivalent solar focus of the combination, divided by the diameter of the direct pencil as it passes through the front lens. Much must still be left to individual judgment. That, whereas, with full aperture the intensity of the light degrades from the centre to the edges of the plate, while a stop tends to equalize it; and that the increased conjugate focal length of a combination with a near object reduces the whole intensity; are variations, which, like that of the light and subject, cannot be provided for by any simple general rule. This leads me to a cause of error which Mr. Warnerke has not alluded to. Though the fraction $\frac{\text{aperture front lens}}{\text{equivalent focus of combination}}$ accurately represents the intensity; yet $\frac{\text{aperture stop}}{\text{equivalent focus}}$ is not accurate, at least in any ordinary case, and this may be seen by measuring the largest skeleton stop, which allows full aperture, though its opening is smaller than the diameter of the front lens. For, as a pencil of rays of any diameter has generally a less diameter at the stop—being reduced by convergence—the intensity of the combination must be greater than that fraction, the effective aperture of the stop being practically increased in the ratio which the distance from front lens to stop bears to the whole focal length of that lens by itself, and this often makes a material difference in the calculation for exposure. Now with near objects this focal length is of course the conjugate focus for the distance of the object, and must obviously increase much more rapidly with its proximity than the conjugate focus of the entire combination, thus rendering accurate calculation distinctly troublesome, probably far too much so for practical use. To apply this reasoning to cases of enlargement, where the lens is reversed, the back lens of course becomes the front, and according to the scale of the enlargement, the correction may pass through the zero point, and change its sign. It is enough to point it out as a cause of complication.

In the use of single lenses, generally, an allowance should be made for the saving in absorption of light, and in reflections at the surfaces of the lens being avoided. In measuring the focal length of deep meniscus lenses by a distant object, the distance from lens to plate will be found greater when the convex side is towards the plate, than when turned towards the object. The relation, too, between the focal length and the scale of the image is not invariable, except in combinations perfectly free from distortion. In single lenses it will obviously vary considerably according to the diameter of the lens, the distance of the stop from it, and the place of the stop, whether before or behind the lens, for the two former causes affect the value, and the last changes the sign of the distortion. Now, the distortion of a lens is simply the inequality of the effect of its refraction on the axes of oblique pencils, the whole effect of which refraction goes to alter the scale of the image, and of course the relation which that scale bears to the focal length of the lens. For all these reasons simplicity of method, and accuracy of result, in estimating the intensity of lenses, are not so readily attainable as may at first sight be supposed.

But the importance of an authoritative engraved value for the intensity of a lens with and without the stops supplied is great, because then the reputation of the maker is distinctly pledged to its accuracy, and careful measurement may be relied on. In my experience the smaller stops of even first-class lenses sometimes very inaccurately follow the scale intended by the maker, and accurate measurement is much easier to him than to the photographer.

Allow me, in conclusion, to mention a convenient plan which has for many years made me independent of variety of threads in the screws of the flanges. Each brass flange is attached to a square slab of mahogany, all of uniform size, and each slab slips on or off a fitting on the front of each camera. Thus any lens, large or small, can at once be attached to any camera in my possession.

Correspondence.

THE DUNDEE EXHIBITION.

Sir,—Mr. H. P. Robinson has not been well treated by the people at the "obscure Exhibition" at Dundee. They don't understand the "eternal fitness of things," photographically speaking, as the council of the Parent Society in London understands them. To award Mr. Robinson a poor bronze medal for a picture that takes gold medals at Paris and London is too infamous.

As an old member of the "Parent Society," I am aware that it has been stated pretty often that it is useless for provincial photographers to compete for medals at the exhibition of the Parent Society, as they are usually bespoke—that a certain clique is sure to get the gold and silver medals.

The audacity of the judges at an "obscure Exhibition like that at Dundee," as Mr. Robinson politely calls it, must be something remarkable, and they seem to have forgotten the fact that the editors of both the photographic journals are also members of the council of the "Parent Society," and can lend their valuable aid to remedy the judgments of the "obscure Dundee judges," and to help their brother members of council—Mr. H. P. Robinson and Mr. Payne Jennings—to a proper recognition of their claims to the gold and silver medals at all exhibitions—whether obscure or otherwise.

As an occasional exhibitor at the exhibitions of the Parent Society, at Pall Mall, I would add that I have some experience of the mode of hanging the pictures at the November show, and am aware of the treatment often experienced there by the unprotected provincial photographer by the so-termed "hanging committee."

Trusting to your known impartiality for insertion of this letter, I am, sir, faithfully yours,

Not a Gold Medallist.

[Our correspondent has evidently forgotten for the moment that Mr. Robinson is a "provincial" photographer, and so many would consider Mr. Payne Jennings. It would, we fear, puzzle our correspondent to mention "the clique" by name who have received from the Parent Society "the gold and silver medals," since for years past nothing but bronze awards have been made.—Ed. P.N.]

A DRYING CUPBOARD.

Sir,—I think "Gelatino Amateur" is right when he says that Mr. England's drying-box is the best; but I have made a slight modification, which answers the purpose well. A description may be of use to him and to other amateurs who dabble in photography.

Having a carpenter at work on the premises just at the time I was thinking of manufacturing a drying cupboard, and not being myself very handy with the saw, I got him to put together a cupboard—size about 4 feet high, 3 feet wide, and 1 foot deep, with a well-fitting door, a rabbet being affixed round the inside. A candle introduced, the door shut, and the gas extinguished, soon told me where the light would penetrate. This was soon obviated by pasting brown paper over the places. The door was the worst; but I got over that by fixing some list round the rabbet. I attached four short legs to the bottom, which was raised from the floor about half a foot.

I now bored a number of holes into the bottom, and one large one about four inches in diameter through the top, to which I attached a piece of tin pipe, three inches high, and four inches in diameter, and over this I fitted another pipe or chimney, about three feet high, which could be slid over the short piece. A small gas jet was placed inside the short tube, connected by a rubber tube to a gas bracket.

Now for the bottom. To each side (lengthways) I nailed a strip of wood, and over these a piece of tin-plate, covering the whole area, excepting the ends, through which the air would pass. The object of the tin was that by placing a couple of night-lights underneath, it would get heated, and warm the air which would pass through either end, and the gas jet lighted at the top, a current of warm air would be constantly circulating. For the shelves, I tried wires extending from side to side; but they were too unstable, and after a dozen plates had tumbled from top to bottom, I replaced these wires by strips of wood, which were capable of being taken out, as each end rested on strips attached to either end. This, then, is the unvarnished description of an amateur's drying cupboard, and one that answers in every way; but in this, as in everything else, one must use his ingenuity.

I always burn two night lights of nine hours each underneath, so that, by lighting them at night, they burn till next morning, to be replaced by others.

I always see that the film has well set on the glass slab before transferring the plates to the box, so that there is not so much need to have the shelves perfectly level; but I always make a rule of thoroughly warming the box by placing a lamp inside an hour or so before using.—I am, yours truly, W. H. Plaister.

Dear Sir,—In answer to your correspondent "Gelatino-Amateur," in the last number of the News, I do not know of any firm who manufacture or keep in stock a drying box on the same principle as mine, but if he finds any difficulty in getting one made, on sending me his address I will forward him the name of the carpenter who made mine.—I remain, dear sir, yours faithfully, W. England.

7, St. James's Square, Notting Hill, W.

PROCESS-VENDORS.

Sir,—"Tit for tat" is fair play (at least, so the world says), and as my intensifier has been called in question by a Northerner, I intend to question the same gentleman's "accidentally"-found-out process of varnishing the collodion film before enamelling. In the first place, that the analyist found certain chemicals in my intensifier I will not deny, but I wish it to be known that there are other chemicals in the same; what they are I will keep to myself, although my honesty is involved. As there are some doubts of the stability of mercurial intensifying, I can prove that such doubts, if the chemicals are made up in the manner in which I make them, are without foundation. I will submit a dozen cabinet negatives intensified by myself some six years ago, if desired, for inspection.

Now for the "tit for tat." Let me tell Mr. Northerner that his accidentally-found-out process of varnishing upon the collodion in the process of enamelling has been known to me for upwards of six years, taught me by my respected principal, with whom I served my apprenticeship. This I can substantiate, which is more than Mr. Northerner can when he says that my process of intensifying is the same as "Mouckhoven's."

As to the dislike for "secret process vendors," I would ask the question of the photographic fraternity, "Which of the two men is to be more respected—the process-vendor, or the process-hunter?"—Faithfully yours,

L. A. Moryson.

Proceedings of Societies.

Photographic Society of Great Britain.

The monthly meeting of this Society was held on Tuesday, at 5, Pall Mall East, J. Glaisher, Esq. (president) in the chair.

The President announced that the Council had elected Dr. J. M. Eder to be an honorary member of the Society. Messrs. A. Dismoor and F. Imd were also elected.

Lieut. Darwin (hon. secretary) read a paper by Major Waterhouse on "Photography on Copper." Major Waterhouse's first experiments were made with bitumen. A copy of a print, or the print itself, was laid on the bitumenized copper, and exposed to light, and the image developed by turpentine. This plan answered well, but was only suitable for line reproduction. His next efforts were directed towards obtaining half-tone, and in this he succeeded by employing either a bromised silver or bromised copper surface, and developing by alkaline pyrogallic or ferrous oxalate. The resultant picture, when rubbed, had the effect of a Daguerreotype.

Captain Abney referred to the fact that among the patents of Mr. Fox Talbot was one for a method of obtaining an image in iodide or bromide of copper in the camera, the development being by mercury. In some experiments he (Captain Abney) had made some time ago, he had succeeded in obtaining pictures on copper by using sulphate of copper and sea salt, thus depositing chloride of copper on the plate.

Mr. W. Peek then read a paper on "The Relation of the Human Eye to the Photographic Camera." He said he had taken up the subject in an entirely opposite view from that adopted by a member of the Halifax Club, who last year read a paper endeavouring to prove that this relationship existed. Mr. Peek contended that the eye was only able to focus at one time one point in any plane, but that the rapidity by which the focus was altered, prevented any sensation of blurring. The photographic lens, on the contrary, had an unchangeable focus, and could only represent that which was on one plane. He thought that if the photographer could take pictures in which the whole of the objects were in focus, he would approach much nearer to nature than by producing pictures when the principal object alone was sharp. As an instance of what he meant, he referred to a recent photograph representing Mr. Ruskin leaning against a background of leaves, in which the latter were quite sharp, and yet did not distract the attention from the figure. Mr. Peek also spoke approvingly of Mr. H. P. Robinson's picture, "When the Day's Work is Done," for the same reason.

Col. Wortley protested against the principles laid down by Mr. Peek, that the whole of the objects in a picture should be in the same focus. Such a doctrine was contrary to the principles of art.

Mr. S. Davis said there was an important distinction between the human eye and a photographic lens. In the crystalline lens of the eye there is greater density in the centre than in the margin, and by this means spherical definition is obtained. In photography this can only be accomplished by the use of a combination of lenses.

Mr. Spiller said that in the Photographic News of December 23, 1859, appeared a paper by himself, entitled "The Eye as a Camera-Obscura." The experiments he then undertook with Mr. Dick were to ascertain what was the actinic structure of the eye. It was known that the visual rays passed through the various elements of the eye, but it was not certain that the actinic rays did so. This he, Mr. Spiller, proved by scraping a portion of the back of a bullock's eye uutil only a very thiu film remained, which allowed the rays to pass, and with the collodion and Talbotype processes he was enabled to take pictures, thus showing that the chemical rays did absolutely pass through the eye.

Col. Wortley, adverting to the artistic side of the question, said he was sure Mr. Robinsou would not endorse Mr. Peek's remarks.

Capt. Abney held that from a scientific point of view Mr. Peek was right. You could only see one print when you looked at a landscape in nature, and you could do no more when you looked at a picture. He could see no difference between the two.

Mr. Bird said Mr. Peek's views appeared to be those held by the pre-Raphaelites.

Mr. Peek having replied,

Mr. Willis read a paper entitled "Suggestions for Improving the Clearness and Printing Qualities of Gelatine Negatives." Mr. Willis's method consisted of the application of a ferric oxalate developer until the image was whitened to the back of the plate. The latter was then to be rinsed well, and the ferrous oxalate developer applied, when the image became of a rich brown. He had endeavoured to use potassic chloro-platinite for intensifying, but had not found it answer, owing to the affinity which platinum had for gelatine.

Mr. S. Davis read a Note bearing on the subject, in which he detailed some experiments he had made with phosphate of soda. If the plate, after immersion in a solution of this salt, one ounce to twenty ounces of water, was developed with pyrogallic of double strength, it never fogged. But to prevent staius it was necessary to use fresh hyposulphite for each plate.

Captain Abney said he had lately been experimenting with hypophosphite, and found that it was an admirable preventive of green fog.

Mr. Berkeley said that he had used hypophosphite in combination with the hydrosulphite developer some years ago, but found its action very slow, contrary to Captain Abney's experience. He then used collodion plates.

Captain Abney observed that in combination with the hydrosulphite developer this might be the case, but when used alone he had found the hypophosphite with pyrogallic instead of ammonia remarkably energetic.

Mr. Maxwell Lyte referred to the use of glucic acid as a developer. He thought this substance possessed properties which rendered it worthy of attentiou for photographers. When used in iron it would intensify.

The President then announced that a committee to enquire into the relation of rapidity of lenses, suggested at the last meeting by Mr. Warnerke, had been formed, consisting of the following gentlemen: Messrs. Warnerke, Abney, Darwin, Wortley, England, Dallmeyer, Cowan, Bedford, Davis, Brownrigg, Heaviside, and Stewart.

The meeting then adjourned.

Society of Arts.

On Thursday, the 9th inst., Mr. W. K. Burton read a paper on "The Manufacture of Gelatine Emulsions and Plates for Photographic Purposes" (see page 134), before the Chemical and Physical Section of this Society. Mr. John Spiller occupied the chair, and a large gathering of gentlemen well known in photographic circles were present, several of them joining in the discussion which followed the paper.

Dr. Maddox briefly alluded to the considerable advances which had been made since he originated the process, leaving him far in arrear.

Mr. Kennett referred to the early history of the gelatine process, and said that the heat required for evaporating the emulsion in order to produce a dry pellicle served to exalt the sensitiveness just in the same way as the modern process of digestion.

Mr. England spoke highly of the ammonia process of Dr. Eder; and Mr. Cowan found that this method gives the clearest, quickest, and most certain results, especially when a large excess of bromide is used.

Mr. H. Trueman Wood congratulated Mr. Burton on the thoroughly practical nature of his demonstration, and referred to the present eveuing as forming an appropriate occasion for the discussion of points which Captain Abney could not include in his recent course of Cantor lectures. He had found it advantageous to adopt the plan of dissolving the gelatine in the least possible proportion of water, and diluting the silver as much as practicable. Canvas seemed to him to be the best material for breaking up the emulsion, as one could take a fresh piece for every batch; and as regards preparing one's own plates, he thought the only real gain was the self-satisfaction resulting from such a proceeding.

Mr. Maxwell Lyte referred to the fact that the advance of science depends on photography, and entered into a brief discussion with Mr. Millar Thompson as to the conditions under which one might expect chlorine in silver chloride to become replaced by bromine or iodine.

The discussion was continued by Messrs. Cowan, Monson, Howard, Cobb, Bolas, and others, after which Mr. Burton made a few additional remarks. He had found that the acid digestion process would give plates fully as rapid as any he had tried, some given to him by Mr. A. L. Henderson alone excepted. He strongly objected to the use of canvas for breaking up the emulsion, as it often served to introduce impurities. The plates should not be dried at a higher temperature than 65° F., unless the temperature of the general atmosphere was over this. The effect of the acid during digestion appears to be physical, and, within a wide range, any acid will answer well.

Bristol and West of England Amateur Photographic Association.

The ordinary monthly meeting was held as usual at the Studio, Portland Street, on Wednesday, 1st March, Mr. W. Radcliffe in the chair. The minutes having been confirmed,

Mr. H. A. H. Daniel said that one or two of the officers of the Association found the first Wednesday in the month an awkward day for the meeting, one of the Vice-Presidents, for instance, having, on account of fixed business engagements, to miss four of the meetings during the year. He would, therefore, either give notice to propose at the next meeting a definite resolution altering the day, but would get all the separate opinions on the subject possible in the meantime, and frame the resolution accordingly, so as to meet the convenience of the majority.

The Chairman then exhibited one or two articles of interest. Firstly, the new easily-fitted and perfectly-effective swing-back invented by Mr. Smith, of the Sciopticon Company. He explained that it was simply fitted with a roller and socket joint, tightened by a turn of a screw, all of which revolved in a slot, giving every movement possible to a swiug-back. Secondly, the Chairman exhibited a very ingenious lengthening cone for the camera, also the invention, to a great extent, of Mr. Smith. It was made of a light black opaque material, and had four sides, the two perpendicular ones having inside light wood flaps opening against them, which served to keep the cone extended, and prevent its drooping with the weight of a lens, the whole being exceedingly light, and folding quite flat

Mr. H. A. H. Daniel remarked that both were most useful little pieces of apparatus, the side flaps on the cone being the chief novelty in its construction; the cone would also form, when not in use, a very good view-meter.

The Chairman said that the addition of a few diaphragms would make it perfect for that purpose. He had been attending Captain Abney's lectures, which, he would remark, by the way, had been listened to by overflowing audiences, to whom, by experiments, Captain Abney had brought home facts often before heard of, but seldom thoroughly realised. For instance, most clearly had he demonstrated the benefit to be derived by mixing chlorides with the gelatine emulsion.

Mr. Daniel enquired what chlorides Captain Abney recommended.

The Chairman replied that the ammonium bromide and chloride were used. The lecturer spoke with some stress as to the destructive power free bromide exerted upon the sensitiveness of the plate, and illustrated it by drawing a brush dipped in a solution of bromide across a sensitive surface, thereby producing a perfectly insensitive band.

Mr. E. Brightman said he understood that it also had a definitely destructive effect upon the picture. He also believed that iodide was more sensitive to the violet end than bromide to the red end of the spectrum.

The Chairman considered that it was the iodide which was the most sensitive to the red end of the spectrum. Regarding the subject of luminous tablets for using with sensitometers, this speaker stated that Mr. W. B. Bolton used the following method for making them. He melted solid paraffin in a cup, and added sulphide of calcium thereto, melted and mixed up, pouring it out upon levelled and warmed plates, and keeping warm till it had perfectly settled down, then allowing to cool, and placing another plate of glass at the back for protection.

The proceedings shortly afterwards closed.

The Hon. Secretary announced that at the April meeting the President, Colonel Biggs, would read a paper.

Manchester Photographic Society.

The ordinary monthly meeting of this Society was held at the Mechanics' Institution, on Thursday, March 9th, 1882, Mr. Alfred Brothers, F.R.A.S. (vice-president), in the chair.

The minutes of the previous meeting were read and passed, after which Mr. J. Bolton, of Ashton-under-Lyne, was duly elected a member of the Society.

The Chairman, in the name of the Society, presented to Mr. John Warburton a magnificent album with a suitable inscription, as a slight acknowledgment for services rendered in connection with the late Photographic Exhibition.

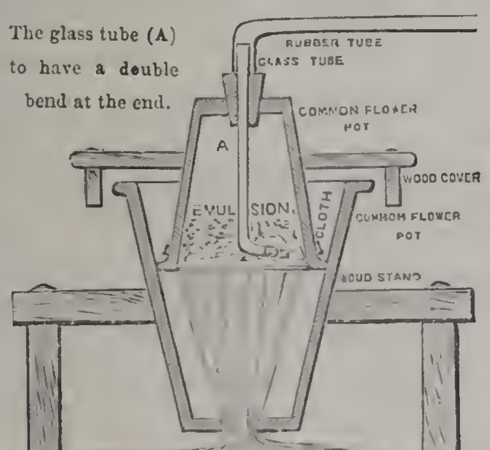
Mr. John Warburton returned thanks in a short and appropriate speech.

Mr. John Kershaw exhibited an ingenious apparatus for facilitating the filtration of gelatine emulsion, consisting of a glass vessel containing the emulsion to be filtered, and at the bottom of which wash-leather was tied, and at the top a pneumatic ball and pipe with valve was attached, acting as a pressure pump; thus by squeezing the ball a pressure is put upon the emulsion, and forced through the wash-leather.

Mr. Atherton said he had used wash-leather for a long time, and had never found any difficulty in filtering through it, and he therefore saw no necessity for the apparatus.

Mr. Bainbridge exhibited a double-cased tin can, the inside of which was filled with hyposulphite of soda, and soldered up. When heated to a certain temperature by placing the apparatus in hot water, the hyposulphite dissolved, and afterwards kept hot for a long time. He used it to keep the gelatine emulsion hot, and he said it was very effectual.

Mr. John Schofield explained a gelatine emulsion washing apparatus he had contrived, and produced a drawing (see figure).



To drain, turn off the water, and disconnect the tube from the tap only.

Mr. J. W. Leigh exhibited a series of about thirty prints from 11 by 9 collodio-albumen negatives, illustrating a walk from Bettws-y-Coed to Ponty Pant. These were very much admired, and proved objects of great interest; and amongst answers to many questions, Mr. Leigh said they were nearly all taken with a Dallmeyer single landscape lens, and that they were the work of more than one trip to Wales.

A vote of thanks was passed to all the members who had brought objects of interest.

A communication from Mr. E. K. Dutton was then read, on a recent legal decision relative to instantaneous shutters.

The formal meeting terminated, a very enjoyable lantern exhibition of members' slides followed.

Mr. Percy Collis showed some excellent portrait transparencies on gelatine plates.

Messrs. Greatorex, Woodward, Wade, Blakeley, Coote, and other members also exhibited.

The members adjourned about ten o'clock, after spending a very interesting evening.

Photographic Society of Ireland.

The annual Lantern Exhibition of this Society was held on Friday, the 10th inst., in the Lecture Theatre, Royal College of Science, Dublin.

This year there was a departure from the usual custom, inasmuch as—with one or two exceptions—no photographs were placed upon the screen which were not the work of members. This fact gave additional interest to members and their friends, which resulted in a large and influential gathering.

Despite the many advantages of gelatine, all the transparencies were upon collodion films. The majority of the pictures were from "Home" subjects, some very fine Continental scenes by Messrs. Thos. Mayne and E. P. Johnson being also exhibited. Mr. Russell's instantaneous views of yachts, taken with the "Gun Camera," were very interesting, as were also Mr. J. L. Robinson's architectural views in Worcester and vicinity. Views taken by the following gentlemen were also shown:—Messrs. Saml. Baker, Alex. Conan, J. R. Fleming, Thos. Mayne, S. W. Nugent, Herbert J. Penrose, Greenwood Pim, Professor J. E. Reynolds, John V. Robinson, John Russell, Joseph H. Woodworth, Chas. W. Watson, and others. Mr. Thos. A Bewley kindly described the pictures, the lantern being managed by Mr. Woodworth and Mr. Watson.

The next meeting of the Society is intended to be held April 14.

Thursday Evenings for Photographers.

At the meeting held on the 9th inst., Mr. C. B. Cutchey occupied the chair.

Mr. Henderson exhibited some prints that had been exposed in his show-case at the door for about three years, unprotected by any sun-shade; they were coated with a preservative solution of one ounce gum-dammar to three pints of benzole, and the only change which had taken place was that they had become of a slightly more purple colour.

Mr. Brown said he found a varnish of Chinese wax and benzine a good preservative from fading.

Mr. Henderson had used wax, but found that it caused the prints to turn slightly yellow. He then passed round some gelatine plates that had been kept about fourteen days in a cupboard with saucer of water, and also others from the same batch that had been kept in a dry atmosphere; those kept in the damp were covered with minute pinholes.

Mr. Brown again exhibited the sensitometer shown by him at the last meeting, in which he had made slight alterations, and he also passed round a plate that had been exposed under it; it was made in duplicate, so that a plate of a known rapidity would be exposed with the one to be tested. He also showed a plate-holder for use in developing; it consisted of four pieces of metal bent at one end for the plate to rest on, and joined together at the top by means of a spiral spring, something after the form of a pair of tongs or tweezers.

In answer to the Chairman, he said that the pain and inflammation of his arm caused by the application of the pyrogallic acid had much increased since last meeting, but he had obtained slight relief by the application of linseed meal.

Mr. Debenham exhibited his actinometer, which was so constructed that twelve two-inch plates could be exposed simultaneously, the medium through which the light was filtered being various thicknesses of the best "Foreign Post," soaked in paraffin; but he said he thought the principle of a number of holes was the better plan. He used the light from three paraffin candles, at three feet distance, giving an exposure of ten seconds and always exposed a standard plate from a batch of known rapidity at the same time as those he was testing.

Mr. Haddon thought that the plates ought not to be all developed for the same time, but allowed to have the full action of the developer, as some samples of gelatine were so much more absorbent than others.

Mr. Cowan showed a chloride plate developed by Captain Abney's "developer," the tone being a rich brown.

Mr. Cobb showed a print from group taken by the electric light at the Society of Arts, without any reflectors, and a stereo lens, with an exposure of about fifty seconds; several prints from negatives taken at the same time by Mr. Trueman Wood were also passed round.

In reply to an inquiry whether he had experimented if it was the air in conjunction with the hyposulphite of soda which had the reducing action on gelatine plates, Mr. Ashman said he thought it was not.

Mr. Coles said he had exposed a plate one half of which was washed, and the other half unwashed, to light and air, and found no difference; he used sulphite in the developer.

Mr. Mackie found no difference in the effect if sulphide was used.

Mr. Haddon thought that the action of light liberated free bromine, which in combination with the hyposulphite acts as a very energetic solvent.

A question from the box was then read, viz., "Is it customary for operators to keep specimens of their work?" The opinion of the meeting seemed to be that decidedly it was neither customary nor right, and several gentlemen stated that they had been victimized by this means.

Mr. Debenham said he would on no account give an operator specimens, but made no objection to lending same.

It was then proposed by Mr. Reiman, seconded by Mr. Henderson, and carried unanimously, that a soiree and ball should be given in aid of the funds of the "Photographers' Benevolent Institution, and a committee was formed to make the necessary arrangements.

Bolton Photographic Society.

The March meeting of this Society was held at the Baths, on Thursday evening, the 2nd inst., Mr. R. Harwood in the chair.

Mr. J. R. Bridson and Mr. Leach were elected members of the Society.

Jarman's electric light—medium size apparatus—was exhibited, and photographs taken by means of it, by Messrs. Parkinson, Dalton, Banks, and Taylor, with more or less success.

The meeting closed with a vote of thanks to Messrs. Cussons, of Southport, who had lent the apparatus for exhibition.

Sheffield Photographic Society.

The usual monthly meeting of this Society was held at Freemason's Hall, on the evening of March 7th. Thomas H. Morton, M.D., presided.

After the minutes had been read and confirmed,

The Chairman said it was his duty—and a painful one for him—to refer to the loss the Society had sustained by the death of its able Treasurer (Mr. John Stringfellow). He had known the deceased intimately several years, and could testify to the interest he took in the Society's proceedings, and in everything connected with photography. He was known to the members as an expert photographer, and a thorough kind-hearted man—one who was always ready to impart the information he possessed. Mr. Stringfellow would be greatly missed by the Society, and also a large circle of friends. He (the President) wished to move that a letter of condolence be sent by the Secretary (Mr. Taylor) to Mrs. Stringfellow. The motion was seconded by Mr. Dakin.

Mr. J. D. Leader, F.S.A., in supporting the same, said he endorsed the Chairman's remarks. He had frequently availed himself of Mr. Stringfellow's kind assistance in photographic matters.

Mr. Rawson and Mr. Given also spoke in high terms of the late treasurer.

Mr. Firth proposed and Mr. Hadfield seconded, that a suitable portrait of the late Mr. Stringfellow be placed in the album.

Mr. Hadfield was unanimously elected treasurer, *pro. tem.*

The subject of Photographic Exhibitions was discussed, and some good suggestions offered by several members. Attention was directed to the summer excursions, and it was agreed that the first outing should be to Haddon Hall, on April 27th.

The meeting shortly after adjourned.

Talk in the Studio.

The Amateur Photographic Field Club.—On Tuesday evening last, a lantern meeting was held by this Society in the large room of the Society of Arts, Mr. J. C. Andrea in the chair. Careful comparisons were made between transparencies made by the wet collodion process, and those by the emulsion methods, and the burden of approval fell upon the results obtained by the wet method, especially in the case of Mr. F. Howard's pictures, which were toned with gold. Next as regards merit came collodion emulsion, while the gelatino-bromide transparencies shown were considered to be by no means satisfactory.

Mechanism of the Eye.—Professor McKendrick, in his sixth lecture at the Royal Institution given on Tuesday, Feb. 21, continued his account of the physiology of vision. He described the structure of the various coats of the eye, and in particular that of the retina. He then contrasted the structure of the complete eye with that of the compound eye, found in many invertebrate animals, showing that there are many points of resemblance between them. He next considered the eye as an optical instrument, and illustrated, both theoretically and experimentally, how the image is formed on the retina, and showed the necessity of accurate focussing on the retina by a demonstration on the screen of the experiment of Scheiner. A description was given of the peculiarities of the normal eye—the near-sighted and the far-sighted—and it was stated that most eyes are more or less liable to certain other defects, such as that due to the curved surfaces of the refractive media being unequal, and thus producing "astigmatism." The Professor described the error in regard to colour termed "chromatic aberration," because the eye is unable to focus equally for the rays of the spectrum, more especially for those at the extreme ends, the violet and the red. After alluding to the entopic phenomena of the eye—the dots, streaks, and curious figures sometimes seen floating in the air—Dr. McKendrick showed how we may be made conscious of phenomena in the retina, and even see the shadows of the retina vessels of our own eyes.

To Correspondents.

*** We cannot undertake to return rejected communications.

H. Howard.—1. The lenses you refer to will gives images of the same size, but differing as regards intensity. 2. Rather smaller. 3. Shorter. 4. Yes.

South Devon.—We believe that it will be obtainable in the course of a few weeks.

Election.—1. and 2. From Messrs. Mawson and Swan, of Newcastle-upon-Tyne.

F. E. P.—You can obtain it to order from any foreign bookseller.

M. W.—The dimensions you propose will answer well, and we should certainly recommend you not to make your studio any smaller. 2. About seven feet. 3. Not quite; say within one foot. 4. Half a dozen should be abundance, and rollers form, perhaps, the most convenient arrangement.

B. S.—Nos. 1 and 4 are so similar in character as to leave but little ground for preferring either. Nos. 2 and 4 will not give quite such perfect definition, but are on the whole better suited for general out-door work.

J. W. Browning.—Write to Mr. J. W. Swan, Newcastle-upon-Tyne.

J. Cowley.—1. It has been sent by post. 2. We think it is eight francs. There is no English translation. 3. About one-third of a candle; but if you put on more battery power, a light of nearly one candle may be obtained. Under these circumstances, the platinum slowly volatilises and obscures the glass. We are told, however, that Mr. Swan intends to manufacture a small carbon lamp which will work with two or three cells. 4. Either.

Nemo.—It is quite possible that your collodion may be at fault; try another sample. If you prepare it yourself, increase the proportion of soluble iodide, leaving the bromide as at present.

Walter F. Cooper.—1. You must be guided by appearances at the time, but in most cases we should say rather under 120° than over. 2. It would somewhat increase sensitiveness in the case of emulsion prepared according to the formula you adopt; but we should expect no mischief to follow. 3. It is probable that you do not take sufficient care to clean your vessels from all traces of previous batches; or perhaps you employ vessels of porous or absorbent earthenware.

Spots.—Defective sizing of the paper.

Nitrate.—1. Your best way will be to line with moderately stout linen, cementing it down and saturating with some bituminous varnish, as Brunswick black. An exposure to the light during several days will serve to make the coating hard and insoluble. 2. It is best to avoid nails or screws altogether, and to put the work together with dowels or tongues of hard wood.

Thomas Timms.—You would not find it by any means easy to obtain a satisfactory picture under the circumstances; but if you attempt it, you had better use a wet plate and old collodion.

In a Fix.—Reduce the proportion of iodizer in the collodion, or increase the strength of your bath solution.

Cadmium.—Reduce to two-thirds of the quantity you are now using.

C. C——n.—Add a trace of nitric acid to the bath, enough to make it slowly redden litmus.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1229.—*March* 24, 1882.

CONTENTS.

PHOTOGRAPHIC LENSES.

We are so frequently asked rudimentary questions as to the points which distinguish different kinds of photographic lenses, that we have determined to write a few words and to give diagrams descriptive of the forms most in use.

We do not intend to give our readers in this anything that is new, but simply something which may be useful for them to refer to, and to us to refer our correspondents to.

In the following description we mention the particular uses for which each lens is best adapted. We give a sketch which will show the general appearance of the lens we mention; in the case of each landscape lens, approximately how much slower it is than the ordinary portrait lens; and we give the maximum aperture at which it will work, and also the largest sized plate which it will cover. It is necessary to say a few words on this latter point. We have supposed in each case that the equivalent focal length of the lens in question is 12 inches, and we state the diameter of the largest circle which it will cover. To find whether the lens will cover a certain sized plate, it is only necessary to draw out on a piece of paper a circle of the diameter mentioned, and to try whether the plate can be laid on this circle without any of its corners being outside the circumference. If the focal length of the lens be greater or less, a circle of proportionately greater or less diameter must be drawn. In the diagram, the line-shaded parts represent glass, the black shaded parts brass.

We shall not take into consideration at all the different methods of achromatization. Our readers all know that the object of achromatizing a lens is to make the chemical and visual focus coincide, and that the want of such achromatizing is the last fault which we should expect to find in a modern lens by any maker of name.

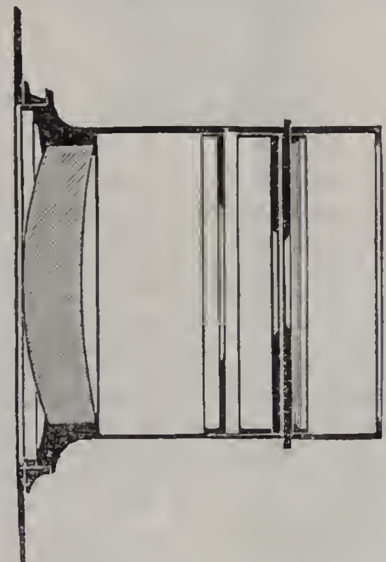
In stating different apertures, we mention them thus:—$\frac{f}{10}$ $\frac{f}{15}$. The lower figure in each case shows how many times the focal length of the lens is longer than the diameter of the largest aperture at which the lens works.

We begin with the

Single Lens.

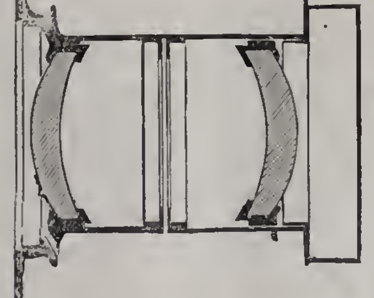
The so-called single lens is an achromatic combination of the meniscus or plano-convex form. The concave or flat side is turned towards the view, and a diaphragm is fixed at some distance in front of it. It is, taken all in all, the most useful of lenses, especially in the modern or "wide-angle" form. It is particularly adapted for general landscape work, as it gives a brilliant and exquisitely-defined image through a considerable angle, and as the illumination is more nearly equal at the centre and at the corners of the plate than with any other form of lens.

It requires to be used with great care for architectural subjects, as if used with a plate subtending any considerable angle, distortion will arise. When used with the largest possible aperture it is fairly rapid. The diameter, if circle



covered with a 12-inch focus lens, is, with the older forms, about 13 inches; with the newer, or "wide angle," about 16 inches. The full aperture is for the older forms about $\frac{f}{20}$, for the newer about $\frac{f}{16}$. The older forms are about 25 times slower than the portrait lens, and the newer about 16 times. Next in order we may take the double combination lens, known as the

Rapid Rectilinear, or Rapid Symmetrical.



This lens consists of the pair of meniscus combinations, each very similar to the "single lens," but of very great focal length compared to its diameter. They are fixed at a considerable distance apart, with the concave sides towards each other. The lens is, as its name indicates, a *rapid* one. It requires an average exposure of about $\frac{1}{4}$ of that required by the last described lens, working full aperture up to about $\frac{f}{9}$. It is thus about five times as slow as a portrait lens. It is admirably adapted for architectural purposes when only a limited angle is required, as it gives no distortion. When used with a large stop or full aperture it is the best form of lens for groups, and is very useful for the so-called instantaneous pictures. It also forms an admirable portrait lens to be used in well-lighted studios with modern dry plates, and especially in the case of large portraits. Its drawback when used with a large aperture is that the illumination of the plate is very unequal.

The diameter of circle covered by a 12-inch focus lens is about 10 inches full aperture, or 15 inches with the smallest stop.

Lenses closely resembling the above are sold under various names, such as "True View," "Euroscope," "Planographic," &c.

The Symmetrical or Wide-Angle Rectilinear.

This lens is somewhat similar in general construction to the last, except that the lenses are placed very close to each other, so that there is only room for the diaphragm between them. They are suitable for architectural work, where it is necessary to include a very wide angle of view. It gives no *actual* distortion, but requires to be used with very great discretion, otherwise a most unpleasant effect is produced, from the fact that the point of view at which the resulting picture is naturally viewed from is further away than the artificial eye of the camera was from the plate in taking the negative. The effect produced is to make the parts of the view which were nearest the camera appear enormously exaggerated; in fact, when stretched to its utmost power, this lens should only be used for very exceptional cases. It makes an excellent lens for general landscape and architectural purposes, when used for plates considerably smaller than the largest size which it will cover.

It is a slow lens working with an aperture, but little over $\frac{f}{15}$, and consequently requiring an exposure even longer than the single lens, or about 20 times as long as the portrait lens. A lens of 12 inches' focus will cover a circle considerably over 20 inches in diameter. The illumination is very equal.

(*To be continued.*)

PHOTOGRAPHIC PAPER WEIGHTS.

During the last six or eight months plain cubes of polished flint glass have been extensively sold as paper weights, and many persons familiar with the difficulty of obtaining a considerable mass of flint glass tolerably free from air-bubbles and from striæ have expressed surprise that such paper weights could be sold at the extremely low prices demanded. Two sizes are in the market, one being about two inches across the face, and the other somewhat more than three inches. The cubes in question are doubtless pressed, or moulded, in the first instance, after which the six faces must be ground and polished. As the sharp edges of the cube are bevelled off, there are no less than eighteen surfaces to be worked true, and polished; and it certainly becomes a matter for wonder that the article in question can be sold for a few pence.

The decoration of the lower surface of a glass paper weight with a photographic picture is by no means new, as we have frequently seen roughly-made and nearly hemispherical glasses ornamented in this way. Such articles have generally a very common and unattractive appearance, owing to the distortion arising from the shape of the glass, and the coarseness of the material. The cubical paper weights now in the market are so well shaped, and made of such excellent glass, that they lend themselves to the production of artistic and highly-satisfactory results. But we consider it better to discard the primitive method of attaching a paper print on the glass, and either to make a collodion or a carbon positive on one face of the cube. As regards the collodion picture, no special precautions are necessary, but, as the ordinary camera and dark-slide are not available, it is best to print on the sensitive collodion film directly from a reversed negative, two thin strips of cardboard being used to prevent actual contact between the wet film and the negative. It will be found convenient to make use of an ordinary gas flame as a source of light, as the approximate parallelism of the rays serves to compensate for the circumstance that the negative and sensitive film were not in thorough contact. Either portraits or views may generally be vignetted with advantage, and an ordinary gold and acetate bath can be used for toning. A mere coating of varnish serves to protect the film, and over the varnish a layer of flake white paint may be applied.

It is, however, easier and more convenient to develop a carbon or autotype print on the cube, and, as the picture is to be viewed through the glass, an ordinary unreversed negative will be required. It is scarcely necessary to say that all the changes of temperature incident to the development of the carbon print must be brought about gradually in order to avoid fracture of the glass. In the case of the carbon picture, the white backing may either consist of flake white paint, or, perhaps, better still, of the phosphorescent paint which has recently been introduced into commerce. The most convenient way of using the paint is to cover the surface of the dry carbon print with the thick portion which settles to the bottom of the bottle of luminous paint, and next to rub down on this a square of glass corresponding with the face of the cube. As soon as the edges are dry, all becomes firmly fixed, and the paper weight is finished. One considerable advantage of the luminous paper weight is the ease with which it can be found in the dark; and as the photographic pictures still remain visible, they may serve as distinctive marks for each particular paper weight. Instead of using the paint, it is sometimes convenient to employ the mixture of phosphorescent sulphide of calcium and paraffin, as used by Mr. Warnerke for making his sensitometer plates; but in this case the cube must be warmed before its application. The sulphide of calcium paint cannot be used over a silver print with advantage, as the metallic image would soon become converted into sulphide.

In order to vary the style of the photographic picture, backings of gold and silver bronze may be adopted, the powders being either mixed with a suitable varnish, or melted with paraffin, as mentioned in the case of the luminous powder.

A REMARKABLE ABNORMAL ACTION OF LIGHT.

A communication singularly interesting to the scientific photographer, as it certainly is to the chemist, was recently made to the Chemical Society of Paris by M. Schützenberger. This chemist has found that certain bodies—to wit, Caucasian petroleum, aniline, and benzole—when they are heated with sodium or copper, and then distilled, possess the singular character, when analyzed, of yielding more than 100 per cent. of constituents; moreover, they maintain the faculty for a long time, if they are kept in the dark.

On the other hand, if a sample of this same petroleum, aniline, or benzole, which has given such a singular result on repeated analysis, is exposed to the action of light for a couple of hours, the normal result on analysis is once more obtained; that is to say, the constituents yielded make up but 100 per cent., as they should. So that it is plain that the action of light has exercised a singular influence upon the bodies in question.

Schützenberger, in explanation of the circumstance, assumes that the composition of water and carbonic acid is not, under all circumstances, that generally supposed. The atomic weights, between certain limits, cannot be fixed, but are oscillatory. If what we term an atom is only the result of an oscillatory motion of the substance, which motion obeys a certain law, then it seems possible that the variation in the atoms of hydro-carbons may be modified by light. Obviously, if light is capable of disturbing our present atomic theory in this way, the disturbance in question will be a most important one for chemists to consider.

At Home.

HERR J. OBERNETTER IN MUNICH.

Whether there is any truth in the proverb that work prospers most upon hallowed ground, we know not; but we can say this much, at any rate, that we did not see better Lichtdruck work during our recent tour in Europe than that met with in Herr Obernetter's establishment. If not situated in the Senefelder Strasse itself, the printing-rooms are within a stone's throw of the thoroughfare named after the discoverer of lithography, and we may surely expect that if photo-lithography, collotype, and arts allied to lithography, are to be found anywhere in perfection, it is near the spot where Senefelder was born.

Be this as it may, Herr Obernetter—who enjoys the reputation of an ardent photo-chemist and experimentalist, not only in Germany, but wherever photography is known—has arrived at a wonderful pitch of excellence in his work. He has no *Schnell-press* on the premises, but only hand-presses; but then his aim is more to do the best work, rather than much of it; that is to say, his principal work lies in the printing of negatives from nature, rather than the printing of negatives of pictures, engravings, &c.; and everybody conversant with mechanical printing knows the former to be the more difficult. Doubtless Herr Obernetter requires a higher price for his work, for, in some cases, it proceeds very slowly indeed.

We need not here recapitulate the processes and formulæ of the Lichtdruck process, which, if not identical, are very similar indeed to those we have already given in our "At Home" at Herr Löwy, in Vienna.* Here, as in that establishment, the main point is the preparation of bichromated gelatine images on the Lichtdruck plates, from which prints are struck off in the press. Herr Obernetter, since he only employs the slower and more careful hand-press, goes to work rather differently in the preparation of his Lichtdruck plates. Instead of the bichromated gelatine being applied to solid plate glass, half an inch thick, only patent plate of ordinary thickness is used. It is more handy of manipulation, and is better adapted to the common printing-frame. Afterwards, when taken to the press, the patent plate is laid upon a bed of plate glass, and in this way receives the necessary support.

Another thing that struck us was that the gelatine images upon the Lichtdruck plates were rather more yellow than those we saw in Vienna. The yellowness, it is true, was a mere tinge, but still those elsewhere were sometimes quite colourless, and this had been pointed out as a sign of perfection. Herr Obernetter's work proves, at any rate, that the yellowish tinge is by no means inseparable from good results.

* See Photographic News for 1881, p. 590.

The laboratory, washing room, drying cupboards, &c., are all on the basement, and here, too, are the reproductions of negatives, made by the graphite process, to the excellence of which Herr Obernetter called attention six or seven years ago, and which then, as now, is one of the most valuable reproducing methods we have. A great many of the clichés Herr Obernetter receives have to be reproduced before they can be transformed into Lichtdruck plates, and he employs either the wet collodion process or the graphite method, according to circumstances. If he desires to make the copy softer than the original, he employs collodion; if he desires to infuse vigour, and make the copy stronger than the original, he uses graphite. The qualities of the gelatino-bromide process, he does not think lend themselves to making reproductions suitable for Lichtdruck.

If a negative is otherwise satisfactory, it usually requires stripping, an operation performed in the simplest manner. The negative is put upon a levelling stand, and fluid gelatine of tolerable consistence poured over it. When dry, a penknife is run round the margin, and the film leaves the glass without any trouble. A stripped film is always preferred for printing the Lichtdruck impression, since, with pressure, there is no difficulty about getting perfect contact; where fine detail exists, this is absolutely necessary. A large series of Lichtdruck plates ready for printing are passed in review, some of them exceedingly delicate. "We are satisfied if we get from 100 to 400 copies from plates like these," says the manager of the laboratory; "as there is no difficulty now in making the plates, we never push the printing too far."

We walk upstairs into the printing room. Here are a dozen presses at work, all of them known by the name of the Star or *Stern-press*. They are small lithographic presses, one man sufficing to work them, who turns a revolving wheel, which reminds one of steering a ship. As we have said, the Lichtdruck plate, gelatine image upwards, is laid upon a sheet of plate glass by way of bed, the film having first been treated with glycerine and water, as we have previously described. The work is very similar to lithography, except that more time and care are spent over it. In the first place, a moist sponge is rubbed over the surface; then comes a soft wash leather roller, whose surface is soft and of the appearance of crêpe, which is rolled over the Lichtdruck plate two or three times to remove surplus moisture. The ink rollers that are now applied are of glue composition, and as the impression requires two inks—it is a Pompeian window—the thick ink is first put on. The roller is not passed once, but half a dozen times at least over the plate, and then another roller charged with thin ink is applied in the same manner. It takes fully five minutes to sponge and roll up the plate, the rolling being done gently, but firmly. A sheet of paper is now laid upon the plate, the tympan lowered, and the scraper adjusted with due pressure; a revolution of the wheel completes the printing, the well-known scraping action of the lithographic press being used in the operation.

A more gentle and time-taking process still is in operation at the next hand-press. Here is a delicate interior (from nature), and the printer, one of the most skilful hands, is paying it great attention. Not only does he spend more time over the sponging and rolling up, but the paper for the print is carefully laid on, tamped with the fingers on the back, and then gently rubbed with the palm of the hand, before the tympan is lowered and pressure applied. Altogether it is a most delicate process, and we question whether a dozen prints per hour are pulled. But they are very fine and perfect pictures that result.

Some of the prints are taken on thick plate paper, and are then ready for binding without further ado; these are usually for book illustrations. Other pictures, that are to pass muster among silver photographs, are, on the other hand, printed upon fine, thin paper, and then varnished and pressed to impart to them a better surface. The varnishing is done by first sizing in a thin solution of gelatine, and then dipping in a solution of shellac in spirit. The "interior" here printing is to be so treated, for it will be critically examined from a photographic point of view. It is an apartment in the *Stadthaus* or town-hall, and the dark oaken wainscoting and furniture necessitated an exposure of eight hours with a gelatine plate; so dark, indeed, was the hall, that it had to be lighted artificially during the operation of focussing.

Another class of work is the printing of little vignetted photographs upon note and letter paper. Everybody is acquainted with the pictorial letter paper, sold at a penny a sheet at all spas and tourist resorts, each sheet having, by way of heading, a coarse engraving of some local spot or building of interest. A German publisher has conceived the idea of printing real photographs, instead of these woodcuts, upon letter paper, and at one of the presses here a collotype printer is printing off such copies at the rate of about sixty an hour. There is likely to be a great demand for letter paper of this kind when once the public learn it is to be purchased, and some of our readers will doubtless do well to give their attention to a branch of photographic industry which is likely to turn out remunerative.

We pass on through the varnishing-room into the photographic studio. As no portraits are taken here, but it serves simply for making reproductions, the only aim has been to make the apartment as light as possible. The photographer attached to the establishment is engaged upon wet-plate work. He does not albumenize before coating with collodion, but prefers well-polished plates, which, he avows, are better produced by rubbing with thin Chinese paper and a little old collodion than in any other way. Chinese paper does not give rise to loose fluff and fibre, like fabric—a point that may well be noted.

Downstairs are the publishing-rooms. "All the works of Albrecht Dürer, and all the known pictures of Rembrandt, are here," says our guide; for one of the first tasks undertaken by Herr Obernetter was the reproduction of these two great masters. Collotype printing has, indeed, made immense strides in Germany, as the vast store-rooms here alone testify. The modern masters are now being attacked by Herr Obernetter, and, in a few years, artists and connoisseurs all the world over will be able to make *fac simile* collections from all the great masters at a most moderate expenditure.

As it is some time since Herr Obernetter's valuable graphite process for the reproduction of negatives was published, we conclude our article with a recapitulation of it as it is published in Germany.

Here are the details. A new, well-polished patent plate is poured over with the undermentioned solution, in the same way exactly as collodion.

Dextrine	62 grains
Ordinary white sugar	77 ,,
Bichromate of ammonia	30·8 ,,
Water...	3·21 ounces
Glycerine	2 to 8 drops

After a complete solution has been made, it is filtered. The preparation will keep good for several days. The plate having been coated, and the superfluous liquid poured off at one corner, it is placed in a horizontal position, and in some place free from dust, to dry, in a temperature of about 40° to 60° Reaumur.

After a period of from five to ten minutes, the solution dries with a mirror-like surface. Whilst still warm, it is put into an ordinary pressure-frame, under the negative, to be reproduced, and exposed to diffused daylight, according to the density of the *cliché*, for a period varying from five to fifteen minutes. If the exposure has been well timed, the picture appears slightly visible upon the film. After the plate has been withdrawn from the printing-frame, it is again put into the drying-oven, where it remains until it has become a little warmer than the atmosphere of the room in which the next operations are carried on. When the plate has reached this temperature, it is carried into an apartment, not too much lighted, upon a sheet of white glazed paper. A fine dusting-brush is dipped in the finest levigated graphite, and this is rubbed carefully over the plate. Breathing upon the plate renders it more capable of attracting the powder. When the desired vigour has been attained, the superfluous powder is dusted off, and the plate is coated with normal collodion. Afterwards the film is cut through at the margins of the plate by means of a sharp knife, and put into water. In a little while—from two to five minutes—the collodion with the image will be detached from the glass; the film is at once turned over in the water, and brought out upon the glass plate. Under a soft jet of water any air-bubbles that may exist between the collodion and the glass are removed, and then the image is poured over with a thin solution of gum-arabic (two grammes of gum dissolved in one hundred grammes of water), and allowed to dry spontaneously in an upright position. After drying, the plate may be varnished in the ordinary way. The addition of glycerine is employed in order to suit the solution to the different conditions of moisture in the atmosphere. Thus in a moist, warm atmosphere in summer, the solution does very well without any glycerine at all; while in winter, on the contrary, in a cold, dry atmosphere, the addition of about 8 drops to 100 grammes of the mixture is necessary.

The "By-the-Bye" next week will be "On Buying and Selling a Business"; the following "At Home" will be "Herr Hof-Photograph Angerer in Vienna."

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Microscopic Photography — Photography and Dust— Photographic Nomenclature — Photography in America.

Microscopic Photography.—The Corporation of London has lately patronised artists—the time may come when it will patronise photographers. There is, however, little hope under the present *regime* of having anything like the Municipal Laboratory of Chemistry in Paris, where microscopic photography is largely made use of in connection with food analysis. M. Tissandier, in a recent number of *La Nature*, has given details of the method of working, which possesses interesting and novel features. The processes are three in number. The first is the ordinary plan of applying directly a small photographic camera to the eye-piece placed vertically as for direct observation, and need not be minutely described. The second method is due to M. Vogel, and consists in seeking the virtual image situated in the microscope by means of a camera with a short-focus object glass. The image is formed vertically in advance of the eye-piece at about 0·12 m. to 0·18 m., according to the magnifying power of the ocular glass. The photographic object-glass is nearly in contact with the eye-piece of the microscope. The third system requires a special arrangement of the dark room, and its advantage is that it allows of taking the photograph of an object in several planes, and is notably applicable to histological sections, trichinæ, crystals, &c. The microscope is placed horizontally in the middle; to the right is a camera, the object glass of which is connected with that of the microscope by means of a long tube; to the left is fixed the oxyhydric or electric light. This apparatus is based on the principle that luminous pencils with very long conjugate foci become nearly parallel, and that the points situated in planes near the focal plane are reproduced by points hardly larger than those of the focal plane. Gelatine plates are used, and some really remarkable results have been obtained with various articles of food, such as chocolate, flour, pepper, coffee, &c. This application of photography to food analysis opens up a wide field for instruction, and, with photographs to guide him, the amateur microscopist might do good service to his household by experimenting on the various "compounds" which are sold as "genuine."

Photography and Dust.—Let not anybody rashly follow Mr. Dunmore's advice and endeavour to put down the dust by stirring it up. If there is dust in the dark-room, by all means let it be there. Even with a damp cloth it is impossible to avoid raising a commotion which will take half a day more to settle down. Mr. B. J. Edwards hit the right nail on the head when he said, "Let sleeping dogs lie." Gerhard Dow, who had a microscopic eye for detail, and whose pictures are the very perfection of what photographers call "cleanliness," had an intense horror of dust. He never had his studio dusted, but he also never allowed anybody save himself to enter. His movements were, as Mr. Dunmore rightly recommends, leisurely, and he never disturbed the dust. Excess of care in some cases is worse than a deficiency—or, to be more correct, an indifference. We remember once seeing an ardent microscopist spending half-an-hour in getting some microscopic sea shells exactly in position. He scarcely dared breathe during the whole time, and just when he had triumphed, his suppressed breath found its way through his nose, and wafted the shells away, never to be recovered.

Photographic Nomenclature.—Not the least important factor in the progress of a new science is the formation of its nomenclature. New terms have to be invented to suit processes and manipulations; and to discover the origin of technical terms in common use would furnish a subject for curious inquiry. "Switch," "shunt," "brake" are familiar enough now, but must have sounded strangely in the early days of the railway system. The advent of the electric light will probably introduce some names which at first will appear odd. "Ohm" is not yet understood of the multitude, but this is only a question of time. It is very natural that the terms in so novel a science as photography must at first have puzzled the general public, and, no doubt, when nobody knew anything about it, the public gratefully accepted as gospel any crumb of information which experts deign to give. Turning over the files of an old newspaper recently, we came across a droll instance of this. A young Daguerreotypist had to give evidence in an action, and was asked the question, "What is the result of dampness on the Daguerreotype plate?" "It produces phledgeum," he gravely answered; and "phledgeum" appears to have been received by court and jury as a scientific term belonging to the art!

Photography in America.—What would people say if the *Dispatch* or the *Observer* commenced a series of articles on "Amateur Photography?" Yet this is what the *Boston Sunday Budget* has been offering to its readers for some time past as a great attraction. The paper now before us contains the seventh article on the subject, and every number for the last seven weeks has had from two to three columns of instructive matter. Verily more interest must be taken in photography in America than in England. Article No. 7 deals with dry plates and carbon tissue, and we gather from the remarks on the first-named subject that the American manufacturers of gelatine plates are not so careful as their English brethen. The *Boston Budget* says: "The writer has used both Carbutt's and Eastman's, and finds advantages and disadvantages in both. Carbutt's are apt to be uneven in their working, and are often very carelessly cut as to size, so as to exasperate the amateur beyond endurance in his efforts to get them into the holder. Varying thicknesses of glass is also a trial, though it is probably unavoidable. But there is not the shadow of an excuse for cutting the plates inaccurately as to size. This fault belongs quite as much to Eastman's as to Carbutt's. With regard to Eastman's, it may be added that they are apt to have gelatine slopped on the wrong side, a slovenly condition of things that is very annoying when it comes to developing, and as unnecessary as it is annoying; and yet both Carbutt and Eastman make excellent plates, as any will find who will try them. Their worst faults may easily be corrected if the manufacturers will but take a little more pains." These faults, in spite of the hard words which Captain Turton has said of English manufacturers, are rarely found this side of the Atlantic.

Reviews.

PHOTOGRAPHY WITH EMULSIONS; A Treatise on the Theory and Practical Working of the Collodion and Gelatine Emulsion Processes. By Captain W. de W. Abney, R.E., F.R.S. (*London: Piper and Carter.*)

ALTHOUGH many have been anxiously awaiting for some time past this promised volume, Captain Abney cannot be blamed for keeping it back until such time as he judged the gelatine process sufficiently ripe to warrant the issue of a standard text-book; for while Captain Abney's new work teaches of collodion emulsion, and consecrates a large portion of his volume to that important process, it is, naturally, to the more generally employed gelatine method that most readers will turn their attention.

Captain Abney brings down our knowledge of emulsion photography to the latest moment, not only in respect to its preparation in the most sensitive form, but he also explains and sets out very clearly the most recent modifications in development. Dr. Eder's system of employing ammonia in emulsion making is fully described, as are all the more successful formulæ of our English workers, to wit: those of Mr. Burton, Mr. Cowan, Mr. England, Mr. Henderson, and others. An important chapter on "gelatinized paper" supplies some useful information which photographers, whether professional or amateur, are likely to appreciate fully.

Perhaps the scope of Captain Abney's work is best described in his preface, which we have set down for the benefit of our readers. Captain Abney says:—

"It will be seen that collodion emulsions still occupy a prominent place in the scheme of the work, and it may appear as if an apology was required for allowing them to occupy the position they do. The writer believes that they have not seen their best days, and that when the mania for extreme rapidity (which, however desirable for certain purposes, yet is not everything) has subsided, they will still claim a certain number of adherents, to whom the quality of a collodion negative, and the possibility of giving local intensity, is a desideratum. It has been the wish of the writer to render the work useful to beginners, and also to experts. At first sight it might be supposed that an acquaintance with chemistry was necessary to enable the former to use these pages; but it will be found that all the processes are described in a practical way, and involve no chemical knowledge beyond that of English weights and measures."

THE CHEMICAL ACTION OF LIGHT.

BY DR. J. M. EDER.*

ACCORDING to Chevreul, gold oxide, when acted on by light, gives off oxygen even *in vacuo*, and from Rumford's and Juch's experiments, it appears that a solution of gold chloride in ether or in water is rapidly reduced on exposure to the light. Chloride of gold mixed with sugar, gum, or starch, and applied to paper, silk, woollen fabric, or the human skin or ivory, is also reduced under similar circumstances; with oxalic acid or oxalate of ammonia, the reaction is more rapid in the light than in the dark (Pelletier, Herschel and Döbereiner). On paper the protochloride is first produced, the colour becoming lighter, and then the reduction proceeds (in the light, or subsequently

* Continued from page 132.

n the dark) until the metal itself only remains; the maximum effect is produced by the rays of the spectrum between G and H.

Gehlen found that a solution of platinum chloride in ether, as also platinum chloride, or the double chloride of iridium and ammonium, with oxalic acid or tartrate of soda, separate the metal on exposure to the light. A solution of platinum chloride mixed with lime water and exposed to the light grows turbid under the action of the more refrangible rays, a double salt being produced (Herschel). Platinum chloride, mixed either with oxalic or with tartaric acid, and applied to paper, turns lighter in colour in the light, but with potassium ferricyanide it turns blue; both the iodide and the bromide of platinum are sensitive to light.

Silver oxide becomes darker in colour, either in white or in violet light, being decomposed into oxygen and the suboxide; in the presence of organic substances, metallic silver is also produced (Hunt, and H. W. Vogel). Silver nitrate is blackened by light, and, according to Artus, this occurs when the salt is enclosed in sealed glass vessels, but only in the case of the crystallized, not of the fused, salt. Hunt, Weiler, H. W. Vogel, and Scanlan all maintain that pure silver nitrate undergoes no change in the light, but only in the presence of organic matter; on the other hand, a solution of the pure salt in water exposed to the light deposits scales of metallic silver. The first observation of the property of nitrate of silver to darken in the light was that made by J. H. Schulze in the year 1727; his experiment was conducted with the salt rubbed up with chalk. In 1737, Hellot found that the same thing took place with paper dipped in a solution of the salt, and Herschel subsequently proved that the reaction was promoted by the blue rays of the spectrum. Fulham (1794) and Rumford (1798) made the same experiment with silk stuff, Davy and Wedgwood (1802) with leather, Link with the animal epidermis, Fischer with albumen, gelatine, gum, &c.

The chloride of silver also discolours in the light, and more especially under the influence of the dark violet rays; this was discovered by Scheele in 1777, and subsequently corroborated by Davy and Wedgwood. The colour produced is not black, but a brownish violet (H. W. Vogel). This change takes place either in the hot or in the cold, in moist or dry air, as well as in the Torricellian vacuum; it may occur when the salt is in the solid state, either crystallised or fused, at as low a temperature as that of 22° C., but in any case it is promoted by moisture. It will also take place under alcohol, ether, walnut-oil, nitric acid, hydrochloric acid, solutions of the alkaline chlorides, acetic acid, or dilute sulphuric acid; but it is entirely prevented by the presence of mercury perchloride, strong chlorine water, ferric sulphate, or fuming sulphuric acid; it is retarded by ordinary sulphuric acid, fuming nitric acid, or solution of ferrous sulphate. The action of light on silver chloride which has been precipitated by hydrochloric acid from a solution of silver nitrate and still remains under the liquid is not so rapid at a temperature of 100° C. as it is at ordinary temperature. Chloride of silver paper in a perfectly dry state is not so sensitive to light as when moist (Spiller), but differences in the hygrometric condition of the atmosphere, as well as in the temperature, have no visible effect (Bunsen and Roscoe). Chloride of silver paper is more rapidly blackened when an excess of silver nitrate is present (Fox Talbot, Hunt, and H. W. Vogel); the blackening is also promoted when the paper is placed in a solution of chloride of zinc, or of certain alkalies which have the power of binding the chlorine set free (Spiller) in the presence of gelatine, tannin, or morphine (Eder and Pizzighelli), after it has been fumed with ammonia. There appears to be no relation between the active intensity of the light and the blackening it produces in equal times; for instance, in the experiments of Bunsen and Roscoe, five times as great an intensity increased the blackening only 2·3 times. The sensitiveness of chloride of silver paper probably depends on the quantity of the salt taken up by the paper, and not on the nature of the metal originally combined with the halogen, but it is certain that the silver chloride precipitated by different chlorides becomes tinged by the action of light with different shades of colours; precipitated by ammonium chloride, and exposed beneath blue glass, it becomes olive brown; by sodium and barium chloride, purple; by sodium chloride alone, light purple; by calcium chloride, a rich violet; by iron chloride, blue, &c. (Hunt). The presence of organic substances, such as albumen, gelatine, and starch, give the colour of the silver chloride a red tinge (Davanne and Girard). Silver chloride in chlorine water exposed to the light remains white so long as free chlorine is present; but when all the gas is converted into hydrochloric acid, the salt begins to blacken. This discolouration disappears if the salt be kept in a dark place, but again appears when it is exposed to the sunlight. If the silver chloride is hermetically sealed in a glass tube, it turns violet in the sunlight, owing to the separation of chlorine; but, when placed in the dark, it will take up again the gas, and become white (Tommasi). Most of the chemists who have studied this subject agree that the decomposition of silver chloride in the light is a dissociation phenomenon. Chlorine separates either in a gaseous state, or to be dissolved by the liquid which is present, and ultimately to form hydrochloric acid. In this reaction the dry salt loses weight; according to Fischer, the loss amounts to ·2 per cent.; according to A. Vogel, to ·12 per cent. After five days, and under water, only 1 per cent. of the chloride is reduced to subchloride (Carey Lea). The violet product of the reaction is by several per cent. poorer in chlorine than the white chloride (Tommasi and Spiller), and only after exposure for a year and a-half does it correspond to the formula Ag_3Cl_2. It cannot be considered as pure subchloride of silver, although it is generally written Ag_2Cl. It contains no uncombined metal, since nitric acid does not dissolve out any silver. Metallic silver is only found to be present after very long exposure of the chloride, and when silver nitrate is present, since the metal is separated from the latter salt by the secondary action of the alkaline chloride on the subchloride in the presence of organic substances. There are other chemists who, like Bibra, do not regard the coloured chloride of silver as subchloride, as they are not able to observe any loss of weight, nor other reactions, when the compound is obtained from subcitrate of silver. According to Hunt, when silver subchloride is exposed to the light, over water, it takes up part of the oxygen of the air, and, according to Sahler, the dry chloride blackens in pure nitrogen more slowly than in oxygen; whence these two observers regard the product as an oxychloride. The subchloride, after being decomposed by the action of light, on being heated with ammonia or cyanide of potassium, is split up into the chloride and metallic silver; this is the reaction which takes place when photographic images are fixed.

(To be continued.)

GLASS-MOUNTED PICTURES AT EXHIBITIONS.

The Committee of the Dundee Photographic Society's Exhibition having framed their prize list in such a manner as to exclude all glass-mounted prints from competition—except in a special class set apart for such, and, by the way, offered in that class a bronze medal only—it may be well to shortly consider the subject.

It seems difficult to comprehend for what reason an exhibition committee should lay down this apparently extraordinary condition, and the further we look into the matter so much less reason does there appear in so doing, taking it, firstly, in principle, and then, for illustration, considering the case in question.

In the first place, it cannot be said that a really good print is not improved by this mode of mounting, for in that case we should not find so many really artistic amateurs and professionals adopting it. This evidence must, therefore, be taken as amply sufficient for proving that an improvement—and, in our judgment, a very substantial one—*is* effected. Such being the case, we maintain that the objection raised by one or two in our hearing (that this method of mounting is "illegitimate") falls to the ground; for in these days of advancement we suppose few would be found so antiquated in ideas as to hold that any means of improving landscape pictures (with the exception of working upon the print) are illegal. It being a process of much simplicity and devoid of all secrecy, it is alike open to all to adopt it; but, on the other hand, should there be any little skill required in so mounting prints, surely, as in all other processes, those who exhibit the larger amount of such skill deserve any extra benefit which as a consequence may accrue to them. We fail utterly to see in this process any other principle to follow than that the most competent operator should obtain the best result, and, in all fairness, an advantage commensurate therewith.

We do not hesitate to say that any exhibition rules tending to discourage this mode of mounting are not made in the true interests of art; nor, certainly, will they help to elevate photography. There is a distinctly different effect produced by a plain-surfaced print—say in platinotype—to that by an albumenised paper print; the latter has a charm peculiarly its own, and most certainly it appears to us that to preserve its permanency, to give it the delicious softness and transparency which mounting on glass produces, and, still more, to rob it when framed of one of its reflecting surfaces, is at once to improve it as an object of beauty, and elevate it as an artistic production.

As to the effect of the regulation at the Dundee Exhibition, its (fortunately) unusual character and peculiarity caused much misapprehension, resulting in excellent work by Mr. Payne Jennings, Mr. E. Brightman, and others, being out of general competition, the former eminent professional being awarded the only medal in the class for such exhibits, viz., a bronze one.

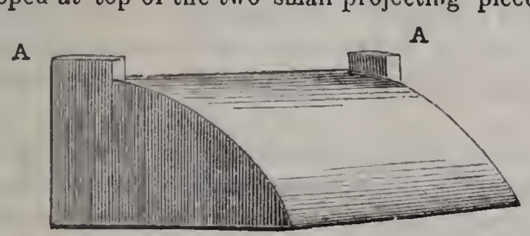
In addition to annoyances such as the above exampled, we fear that many who appreciate the artistic advantages afforded by mounting on glass would refrain from contributing to exhibitions where such restrictions existed, and these alone we would urge as ample reasons for discountenancing any interference of this kind, especially as, so far, we have heard no satisfactory reason for so doing.—*Journal of the Bristol Association.*

COATING PAPER WITH GELATINO-CHLORIDE OR BROMIDE.

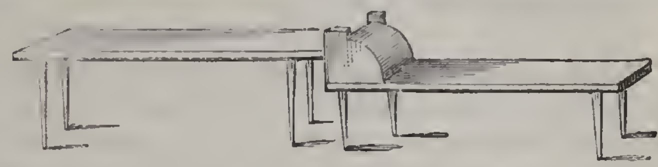
BY T. G. WHAITE.

To successfully cover a large surface of paper with gelatine emulsion in a fluid state will be found by most operators a very difficult proceeding; the irregular expansion and cockling of the paper when the warm emulsion is applied, and the rapid setting in pools and waves, make it almost, if not quite, impossible to obtain a sufficiently level and evenly-coated surface for printing by contact, especially if the smallest piece of the margin should escape coating, which is very likely to be the case, working, as we do, in so dim a light, and with such an obstinate and ill-flowing a medium as gelatine emulsion.

After trying numerous methods with varying success, it occurred to me to try coating the paper with a cold and "set" emulsion; this I find to answer perfectly, leaving nothing to be desired, the apparatus required being exceedingly simple and inexpensive. It consists of a hot water reservoir, as per diagram, made of zinc, It is open at top of the two small projecting pieces A A.



The hot water is poured in at these, and they act as cisterns to ensure the complete filling of reservoir, and, moreover, serve as guides, keeping the paper between them in its passage over the heated surface. The back, ends, and base should be covered with felt. It will then be unnecessary to have any light burning under it, as the once filling with boiling water will be sufficient for three or four hundred feet of paper. At the back and top of this apparatus a levelled bench is placed, say twenty-four inches wide, and the desired length, a little less than half the length of the room, say eight or ten feet, and in front of the reservoir another bench the same length, the upper one for levelling and setting on, the lower one for coating, placed thus—



Suppose the paper used for carbon tissue be selected twenty-two inches wide and cut in eight or ten feet lengths—a convenient size to handle—place one of these on lower bench, and with a stiff hog hair brush about eight inches wide, something like a small whitewash brush, take the cold emulsion either in lumps or after being squeezed through Berlin canvas (I prefer it in lumps), and work it with the brush all over the paper, as a paper-hanger would his paste; it very quickly gives way to a vigorous attack with the brush, and looks very smooth and free from lumps, even at this stage. Now take one end (having previously filled the cistern with boiling water), and steadily drag it from the lower bench to the upper one, between the two uprights A A of hot water cistern: the least contact with the zinc is sufficient to flow it, and it again sets almost as soon as it reaches the levelled bench; it may now be left there until another sheet is covered with the cold emulsion, and then hung up to dry in a cool draught. If it be thought desirable, a second coat can be applied, but this I have not found necessary.

Should a very thick and glossy surface be desired, it may be found necessary to reduce the proportions of gelatine to the chloride or bromide; a much larger proportion of the sensitive salt can then be applied to the paper.

One word of caution: do not let the sheet *remain* still for an instant in contact with the heated surface; a steady drag over is quite sufficient to break down the now well divided up jelly; the least hesitation or prolonged contact will denude it of some portion of the emulsion, and make wavy lines like those we find on ill-prepared albumen paper.

Notes.

Yet another Association of photographers in town. Next Thursday, we see, there is to be a meeting at Ashley's Hotel, when the proposal "by several gentlemen to form a new photographic club" is to be considered. Fortunately, the world is large enough for all.

There is alcohol in all natural waters, is the last sensational announcement in the chemical world. The statement is made by M. Muntz, director of the laboratory of the Institute Agronomique, and he tells us that the proportion of alcohol in the Seine water is exactly one-thousandth, or, in other words, amounts to one pint per thousand pints. The proportion is the same in sea water, and rather more in rain water. M. Muntz concludes from his experiments that alcohol must exist in the atmosphere as well, its presence in air and water being due, he thinks, to the decomposition of organic matter existing on the surface of the globe, in the depth of the sea, &c.

Mr. Muybridge repeated his successful demonstration of animals in motion before the Savage Club on Saturday last, meeting for the first time a full audience of English critics. The clever photographer was loudly applauded, and in the end, the honorary membership of the Club was conferred upon him, an honour all the more gratifying since it comes immediately after the Prince of Wales accepted the same distinction.

Mr. Muybridge took the opportunity to explain that his object in showing his series of photographs of "the attitudes of animals in motion" was to induce further investigations; he offered to place his entire equipment of apparatus and his own experience *gratuitously* at the disposal of any gentleman or Society who might feel disposed to pursue the subject further than he has at present brought it.

Our illustrated journals long ago recognised photography as a material aid to their work, but none of them have gone the length of the *New York Daily Graphic*. The editor of that periodical is "three persons rolled into one," for to the art editor and literary editor has now been added a photographic editor. This is indeed a sign of the times, for while many art establishments have for years past availed themselves of the photographer, there were "none so poor to do him reverence."

An amateur writes, concerning the addition of iodide of silver and chloride of silver to gelatino-bromide emulsion, as follows:—"As a good deal has been said about the difficulty of introducing a small proportion of iodide or chloride of silver into emulsion, I can tell you a very simple way to do it. I only make about eight or twelve ounces of emulsion at a time, and I follow Dr. Eder's excellent plan detailed in the Year-Book; but I find that either a little chloride or iodide—it is immaterial which—certainly does give increased density and clearness to the film."

"It is quite trouble enough, I find, to make one emulsion, and so I get over the difficulty in this way. I coat a couple of 10 by 8 plates with iodised collodion, sensitize in the silver bath, wash the film afterwards in distilled water, and, when well set, scrape off the iodide of silver with a strip of glass. The iodide is put into a small glass vessel, liquefied with as little ether and alcohol as possible, and then gently stirred into the gelatino-bromide emulsion (say 8 ounces). After filtering, for there is a deposit of pyroxyline, the emulsion is fit for coating the plates. When I want to introduce chloride of silver, I chlorise my collodion, first of all, using chloride of sodium for the purpose."

We stated last week that the police, in obedience to a Home Office order to photograph all "bodies found," had secured a picture of the murdered man discovered in Finchley Wood some days ago. This photograph has been the means of identifying the deceased, and also, there is little doubt, of finding the murderer. Serjeant Bridgen, an inspector of common lodging houses, at once named the dead man as soon as copies of the photograph were distributed, and he suggested also the man's companion as the likely murderer. The companion has now been arrested, and it seems more than probable that the police have got hold of the right man.

M. Janssen, the eminent French photo-astronomer, proposes to make use of photography to test the light-giving powers of the heavenly bodies. He says there are three simple duties for the camera to perform in connection with astronomy. Firstly, there is what may be termed descriptive photography, viz., the reproduction of an object or phenomenon, showing its aspect and details. Next, photography of precision, in which the camera is used to obtain images which may serve as the base of particular measurements or calculations. Thirdly, there is photographic photometry, in which we require the sensitive plate to measure the amount of light that strikes it.

This last branch of photography, says M. Janssen, is still to be created. We want photography, in making record of our heavenly bodies, not only to give us an image of a luminous phenomenon, but also to tell us exactly what is the radiating energy of that phenomenon. The importance of the subject is such, that we shall shortly explain to our readers the plan upon which M. Janssen proposes to base his method of photometric photography.

Dr. Heid, of Vienna, who has been engaged in photographing the interior of the Vienna Opera House for illustrating an architectural work, employed electricity as the means of illumination, simply using for his purpose a hundred cells of Bunsen. Albeit the source of light was not strong, and was at a considerable distance from the object, some very satisfactory pictures were secured of auditorium and proscenium with a Steinheil aplanatic lens, and an exposure varying from half-an-hour to an hour.

We generally consider sunlight to be golden, and electric light (not the incandescent lamp) to be of a bluish colour. Dr. Werner Siemens says that the reverse is actually the case. He says it has certainly been proved, by direct comparison of sunlight with electric light, that a white object electrically illuminated appears yellow compared with one illuminated by sunlight, whereas illuminated by gaslight it appears red. Daylight would accordingly appear by night still bluer than the electric light—one proof the more that the eye cannot always be trusted; a photographic film is, indeed, the only impartial observer.

The "reception" of chemists at the Crystal Palace on Wednesday evening was exceedingly successful. The President of the Chemical Society, Professor Roscoe, and the President of the Institute of Chemistry, Professor Abel, discharged conjointly the duty of hosts, and welcomed a gathering that numbered probably fifteen hundred gentlemen or less related to science. The reception was held in the Concert Hall, brilliantly illumined by the Edison lamp, while in the adjoining courts and corridors other glittering systems—the Swan, the Pilsen, the Brush, the Andiè, the Crompton—shone out with all the splendour of rival *débutantes.*

The International Electric Exhibition is indeed beginning to be worthy of its name. The display made by the Post Office is a capital contribution to the history of electricity, and to its usefulness in times of peace, while the adjoining display of torpedoes, electric fuzes, &c., by the War Office, shows the applications made of electricity to warfare. On Wednesday, out of compliment to the Chemical Society, several demonstrations were given by the representatives of various inventors, chiefly with the object of demonstrating the domestic character of electric lighting.

Dr. Robbins, of the Boston Institute of Technology, calls attention to the insufferable pain attendant on contact with the skin of hydrochloric acid. He held the stump of a match which had been saturated with the acid between finger and thumb for half-an-hour, with most dire results. We can quite believe it, for we can remember some years ago visiting a sick photographer who had been making vignette glasses by dissolving off the facing of yellow glass from some plates with hydrochloric acid, and who had burned himself so severely that for some days afterwards he suffered intense pain. A pad at the end of a stick does not afford sufficient protection, for the acid is drawn up by the wood, and thus comes in contact with the fingers. The stick should be jammed into some kind of handle, which facilitates the manipulation of the acid, and effectually protects the hand.

Some discussion took place recently at the Geographical Society as to the existence of a certain snow-clad mountain in Central Africa, known to the natives as the Wamali Peak. Mr. O'Neill, our Consul at Mozambique, who has made a journey of 600 miles through almost unknown country, was reported to have actually sighted the peak, said by the natives to be covered with perpetual snow; but Mr. O'Neill now tells us that, although its position was pointed out to him, he could not distinguish it. The honour of discovering a snow-clad mountain in Mid-Africa is, therefore, left to a future traveller, who would do well to take a camera with him, lest, after so much scepticism has been expressed on the subject, the discovery, when it is made, should fail to find believers.

A little while ago, the directors of prisons insisted on the taking of photographs of the hands as well as the face of the convict; but we did not know that "hand" photographs were becoming fashionable in the drawing-room. Yet *Truth* says:—"The rage for hand albums is increasing. Face photographs are becoming quite uninteresting and old-fashioned as compared with sun-pictures of the hand. There are even enthusiasts who declare that they can discover more numerous indications of character in the shape of the fingers and the lines of the palm, than in the countenance itself. They wax learned over 'musical hands,' sensitive fingers, thieves' thumbs, unemotional joints, and appreciative finger nails."

Our contemporary says, "hand albums" will probably last a season, then be laughed at and soon forgotten. Meanwhile it brings grist to the mills of the photographers, who, thinks *Truth*, of all the business classes, are, next to the butchers and milliners, the most prosperous. We fear both the matter of the hand albums and the prosperity are items of "news" to most of our readers.

We are happy this week in being able to publish Mr. Whaite's excellent plan of coating paper with gelatine emulsion. Some samples he sends us are exceedingly smooth and uniform.

It is likely that a memorial will be erected to the late M. Poitevin at his birthplace. We see that the claim is made on his behalf that he was the inventor of carbon printing and of collotype printing. That he was the originator of all photographic printing processes in fatty ink no one will deny; but in respect to printing with pigments, it ought to content his friends to say that Poitevin had more to do with the creation of the process than anyone else. The reversal of the carbon image prior to development was not discovered until after 1855, when Poitevin published his important paper, and, as everybody knows, the employment of bichromate in photography was suggested by Mungo Ponton as far back as 1839; and these are two important factors in the practical process of carbon printing.

It is not generally known that Lafon de Camarsac, who still enjoys the reputation in Paris of being the best producer of photographic enamels in the French capital, patented, as early as 1855, his method of preparing a film which became more or less hygroscopic after exposure to light. He employed bitumen of Judea for his sensitive surface, which, after exposure to light, permitted a greater or less quantity of particles of pigment to attach themselves. Lafon de Camarsac did not base a carbon printing process on this newly-discovered phonomenon, but employed it in the preparation of photographic enamels.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. 4.—First Lesson on Exposure and Development.

Before giving instructions in the actual manipulation of developing a plate, we must define the terms negative, exposure, and development.

A negative may be said to be a pictorial representation of any object or scene which, on looking through it at a bright light, shows all the shades of nature reversed. Thus, when we look through a negative of a landscape, holding it between us and (say) a gaslight, we see the sky and all objects which are in reality white, represented as black, whilst the darker parts of the landscape are represented by the bare and transparent glass. If the negative be a portrait, we see the face black, looking like a negro's; whilst a black coat looks white, and so on. The negative is produced by the action of light in the camera, the places where the light has acted most strongly being turned black. The time necessary for the light to act on the plate to produce the required effect is called the exposure. Now, we have said that the light acts upon the plate and darkens certain portions of it, but it must be understood that this action is not at first visible. A marvellously short exposure is enough to impress all the details of a landscape on a plate in such a manner that by acting upon the plate with certain chemicals, these details may be made visible. This operation is called development, and consists essentially in the strength of an image so faint as to be invisible to the eye, till it becomes as vigorous as we desire. Anyone, however unconversant with photographic operations, will perceive that when once we have obtained a reversed picture, such as we have described, we have nothing to do but to place this in contact with a sensitive film, and allow light to act through the negative, when we shall have a picture with its shades true to nature. This latter process is performed with sensitive paper, and is termed printing.

Upon correct exposure and development, nine-tenths of the technical success of negative-making depends, and when once the student has thoroughly mastered the relation of the one to the other, half the battle will be over. He cannot do so without practice; but we hope to give him such assistance in explaining the matter as may lead him to the desired end as quickly as possible.

Let the beginner select an object upon which he will make his first attempt. If he can resist the temptation to try a portrait, so much the better. A brightly lighted landscape, with strong contrasts of light and shade, is the best; it need not be picturesque. A suitable view can generally be got out of some window, or a very suitable subject is a bust or statue placed either in a well-lighted room or out of doors. We shall suppose in the present instance that the landscape is selected. The camera should point neither towards nor away from the sun. If the sun shine direct into the lens, the plate will be destroyed; if the sun be directly at the back of the camera, the picture will look "flat." Before beginning operations, we wish to explain what is the meaning of correct exposure. Let the student look attentively at the view which he has selected to make his first attempt upon. He will see that apart from the various colours represented, there is a very great range of light and shade. He knows that this range is brought about by the fact that different objects reflect different amounts of light to his eye. Probably the sky will reflect the most light, and going through the whole range from this he will see that there are a few little bits of the landscape that appear absolutely black. They do reflect some light, but it is so little that by contrast with the brighter objects they appear to reflect none. Now, let our student consider the process which goes on during exposure. He knows that when he has his camera with a dry plate in position, and when he has removed the cap of the lens, a perfect picture of the landscape, with all the shades of light, will be thrown on the sensitive film, and that the light will be acting upon it. Now it is evident the brighter parts of the picture will first take effect, and afterwards the darker, until the exposure has been prolonged to such a period that all the shades of light except those which, as we explained, appear in the landscape absolutely blank, will have impressed themselves. At this point the correct exposure has been given. Had a shorter time been allowed, some of the darker shades, or, as it is technically called, the detail in the shadows, would have failed to impress themselves, and the resulting negative would have been said to be under-exposed. On the other hand, had the exposure been prolonged, the light emanating from the apparently black parts of the landscape would have impressed the plate, which would eventually appear to be darkened all over, and would be said to be fogged from over-exposure. It is said of a correctly-exposed negative, that it has all the detail in the shadows without being fogged.

Now we shall pass on to the practical exposure of a plate, and shall show the student how he can tell, by the behaviour of the plate during development, whether he has hit the much-desired correct exposure, or not.

He will require to light his dark-room lamp, and to get by him the three flat dishes, the two measuring glasses, all the stock solutions which we gave directions for mixing in a former chapter, and his box of dry plates.

Now let him place his camera in position, opposite the view to be photographed; let him remove the cap from the lens, and place his head under the focussing-cloth. Any thick dark cloth or shawl answers the purpose; or a piece of black velvet or macintosh, about two feet square. He should remove the stop from the lens entirely, if it has movable stops, or, if the stops be rotary, should turn them till the largest one is in use. This will make the image on the ground glass very bright, and, by turning the focussing-screw first one way, then the other, he will easily find in what position the image is the sharpest. When he has discovered this, let him place the smallest stop in the lens. We say the smallest stop, not because it is necessarily the best for the picture which he is going to take, but because it will enable him to give a comparatively long exposure.

Having his camera fixed and focused, let him place the cap on the lens once more, and retire to the dark-room with one of his double dark slides for the sensitive plates.

When once here, he must place the dark slide open in front of the lamp. Now, he must lower the light till there s only just enough to enable him to see. He must open his plate box now and take out two plates—two glasses must be placed in the dark slide at once, but one may be a "dummy" if he happen to have but one dry plate; that is, either a clean plate or a spoilt negative. In placing the plates in the slide, let him be very careful that in each case the side of the plate which appears dull, on account of its having the sensitive film on it, is placed towards the outside. Now, having closed his dark slide and wrapped his plates up again, let the photographer return to the camera. He should carry the dark slide under the focusing cloth, for further security against light, and in placing the slide in the camera and during exposure should keep the whole apparatus under the cloth for the same reason. He now removes the focusing screen, and places the dark slide in the position occupied by it, keeping the side marked 1 towards the lens. He now withdraws the sliding door, which is the only thing which intervenes between the lens and the sensitive plate. He takes his watch in his hand, and removes the cap from the lens for (say) five seconds, replaces it, slides in the shutter of the dark slide, and carries the latter off to the dark-room. We have supposed any of the usual view lenses to have been used, the landscape to be brightly lighted, the time of year to be spring or summer, and the time of day morning or noon.

EXPERIENCES WITH COLLODION AND GELATINE OUT OF DOORS.

BY GEORGE BRADFORDE.

While slowly, but surely, drifting away from collodion, and placing our future trust in gelatine, we know that there are many workers who still stand stedfastly by the good old standard, sternly bidding defiance to the intruder; many, again, cast loving eyes upon it, as if loth to leave so old and tried a friend; and very few indeed are the number who have deserted its shelter altogether. There were innumerable difficulties in the studio with collodion, both at its birth and zenith, every worker who has laboured with it these past twenty years can fully testify; but the most annoying disturbances were ever to be found in the field. Here the inconveniences showed their towering heads—first, in the great packing of almost unpackable bottles, funnels, baths, &c.; then the risk of smashing something, and the almost sure certainty of forgetting some little thing of great importance—viz., the tripod screw, a particular flange, or the diaphragms. Why, I have seen a well known landscape photographer in those early days when the more one took to the field with him, he felt the surer of success—I have seen him, I say, dance with fury, and tear his hair out by handfuls with a recklessness that would have delighted the heart of a hair-restorer, all because a dipper had been carefully put in a corner of the dark room, so as to be easily remembered, and as carefully forgotten.

Yes, the nitrate bath, after all, was but a fickle friend, and, like most friends, proved most uncertain when anything particular was required of it. After being at the trouble of doctoring it, making microscopic investigation as to the thorough cleanness of its bath, and coaxing a trial plate from it of great satisfaction; then gently, as if putting a new-born babe to bed, screwing it down, or bottling it up, as the case might be, it was most provoking to find it playing off a number of spiteful and coquettish tricks in the morning. First it might be fogged, when, as most likely, the nitric acid was forgotten; then streaks, which plunging the plate would hardly overcome; then the heat would affect its constitution, and it would refuse to be amiable until cooled down. When this state of affairs was obtained, probably a light breeze might have sprung up, and, bidding defiance to the waving foliage, you try it once more, to find a very decent plate covered with dust, &c.

I need not enumerate the pranks it could play us; everyone knows them pretty well, and knows likewise that to overcome them was, not to lose temper, and tear your clothes, and otherwise behave like a fool, but to patiently discover the cause of the effect, and remove it.

In the field, with collodion, dust and dirty plates and breakages were, in reality, the three principal furies to be battled with. On bright March or April days, the dust was a fearful trouble; whether you pitched your tent among the rocks of an iron-bound coast, or in the depths of a shady wood, the spring wind was certain to send whirls of your torment at precisely the very second you either took the plate from the dark slide or bath, and of a consequence spoil it. The only chance was to extemporize a dark room, but as it often did prove itself to be an out-house for keeping gardener's tools, &c., it was a case of out of the frying-pan into the fire; if a cellar, the humid air affected the plates, if not albumenized, so that it was next to an impossibility to keep the film from slipping off into the bath; a stable is not a bad dark room if well ventilated; if any other outhouse could be obtained, I should prefer it, on account of the ammonia.

Dirty plates, to a certain degree, were the photographer's own fault, the choosing and cleaning of them being generally entrusted to an assistant or a boy. Another great stumbling-block in the path of the out-door worker was false economy—viz., the using of glass that had been used before—glass cleaned by a strong hyposulphite solution, then, to kill the hyposulphite, immersed in nitric acid, finally neutralized by a bath of charcoal; this was a nice plate upon which to secure the "finest results." Was it any wonder that such plates would prove murky, despite the greatest cleanliness in manipulation, or that the bath should get speedily out of order? Then the using of cheap glass. How dear in the end it proves, the thoughtful and calculating may be able to tell! I give it up. As an instance of the existence of this false economic fever, I may mention that, during the past year, in a first-class house, where they pay their operator three guineas per week, and (to express it poetically) situate in the principal street of a certain city that smilingly stands on the sweet-scented banks of the Liffey, cut their glass for out-door as well as studio work from the *waste pieces of common glass* used in picture framing; and with this vile, greasy, putty-smeared, scratched, uneven stuff the operator is expected to turn out first-class work. It is said, "A bad workman ever quarrels with his tools;" but, nevertheless, the best of workmen cannot make a silk purse out of a pig's ear.

By-the-bye, I might have mentioned a very good plan in regard to the possibility of *not* forgetting anything when going on a journey. I mention this simply because collodion has its followers still, and may have young disciples in its ranks who may be amused as well as instructed by my plan—viz., go through the mock operation of taking a negative in the field, and, as you proceed, note down everything you require, then paste a list on the back of your dark-tent. This can apply to gelatine as well; for, in a hurried departure to some outlandish place, "far from the resorts of man," there *might* be a possibility of such an insignificant thing as a wax taper, the dark-lantern, or the still more insignificant matter of a few lucifers, forgotten, and possibly spoil the day's work. At any rate, there is no harm in always having a true—or, should I say, a "correct?—card" before you when going to take the field.

Old King Silver Bath, when he goes in for breakage, strikes his poor servant with awe and horror; if it happens after the day's work is done, and while the porters are dashing the boxes from the van, a profane word or two, and a mental ejaculation of "There goes two pound ten!" may be the philosophic photographer's worst (if you couple a savage desire to witness the owners of certain bags and portmanteaus, which have been liberally drenched by King Silver Bath's blood, as they take out their fresh linen in the morning); but when he slips out of clumsy fingers in a drawing room, while on his way to the lumber room assigned him, or bursts up on the top of a cab, and streams on your head and face, and runs down your back, and calmly settles around the buttons on the new plush-covered seats, it is then—then that you lift up your voice in wild and deep anathema, and feel as if the world was a waste, and that every man's hand was against you, while a certainty settles in your heart that King Silver Bath is neither more or less than Pluto in disguise. One more word upon breakages, and I am done, and a word of caution to the disciples of collodion: never lean your bath against anything during the interim of taking it from its nest in the dark tent and the decanting of it.

By such a little incident a partner and myself were nearly ruined. We had gone to make some 15 by 12 pictures at a Volunteer encampment, and everything went swimmingly until the packing up. In the afternoon there was a grand march round, band playing and everything lively; as a matter of course there were crowds of onlookers, the fair sex, as usual upon such occasions, predominating. *Our* manœuvres were noted as well as those of the gallant Volunteers, and through the whole day we were surrounded by a small group of silent but eager watchers. Thus it happened. We had made our last negative, and Bob had lifted forth the bath with the intention of decanting it, when on the instant up rode an officer to make inquiries respecting our success. Bob leans the bath up against the root of a tree, and goes off to answer; behind the tree stands a lady with white dress, of some expensive stuff, that I forget the name of. Up the little slope rushes a native of the country, grinning like a piece of machinery, and before I could interpose bang! goes his foot on the bath! To my speechless horror the young lady in white was splashed from the waist downwards! On the instant up rushes Bob—collars a cleaning leather, and hurriedly assuring her "that it was merely clean water" proceeded to rub her down, pheezing like an ostler all the time. Then apologising in his best style, he turned to me and abused me for letting the "joskin" escape. To tell the truth, I was so amazed at what Bob termed his presence of mind, that I could think of nothing else. Bob was amazingly pleased with himself all the evening, congratulating himself on his presence of mind: "That dress alone would have taken the profit off the whole job." For my part, I had a presentiment that it might possibly do it yet; and sure as the day of judgment, next morning, a weeping female, accompanied by another bearing a bundle, a fierce-looking sweetheart, and a savage-looking brother, marched into the studio, and threw a bundle of bitter reproaches, abuse, and piebald female attire before us. I say no more. It is the first time I ever went halves in a lady's dress, and judging from experiences undergone since in paying both halves, *that* lady's dress, to use a vulgar but expressive phrase, "must have been a whopper."

Now I will finish up this string of abuse by adding injury to insult; *videlicet*, that of all the thankless, temper-trying, dress-destroying tyrants that humanity ever knew, King Silver Bath and his head minister Collodion, if not the worst, runs a good second. If I had all the wearing apparel they have destroyed for me by occasional splashes, by mysterious dabs and stray sprinklings, by wholesale bursts and leaky dark slides, I faithfully affirm that I could start a big thing in the 'ole clo' line; the only drawback to a speedy sale being a general impression that I must have robbed all the blood-stained victims of the famous and elegant crew that fill Madame Tassaud's Chamber of Horrors.

Now for a sop to Cerberus! As a great panacea I aver that collodion has one great advantage over gelatine in the field—*i.e.*, you know what the results of your labour are on the spot. You develop, fix, and probably varnish your negative on the scene of your work. Your mind is at peace; you can crack your knuckles with satisfaction, and eat your supper with gusto, a degree of excellence not yet attained by gelatine.

In place of the huge unwieldy box, full of smashables, appertaining to collodion, gelatine can walk forth to the field in an easy, upright, gentlemanly sort of manner. In this respect collodion and gelatine resemble the warriors, old and modern: the former went forth to do battle encased in a ton of iron, to wield an axe or level a spear; whilst the latter, trigged out in comfortable—not to say stylish—attire, steps forward with a precise and enjoyable air, and rattles off his so many shots in so many minutes, handling his breech-loader with movements so agile that the eye cannot behold, or reason conceive, how it is done.

With gelatine in the field there is no necessity whatever for an assistant; one can do all the work easily, and with far more satisfactory results. I write from experience, and never, as long as I live, shall I entrust an assistant to change the plates for me, nor shall one go with me, unless it be a boy whose physical and mental calibre will only enable him to fetch and to carry. Last summer, at a very particular engagement where three generations of a family had by arrangement been gathered from all quarters of the globe, I was deputed to make sundry pictures of the different branches, topping off with the living tree, from Alpha to Omega, in one immense group. One day was allowed me, and if I did not meet with success on *that* day, we lost a very remunerative job, inasmuch that certain members of the family had to depart next morning, thus putting it beyond my power to remedy a failure. I had an Irish assistant to attend to the changing of the plates, so as to get the different groups knocked off before the old great grands and the baby great grands should become wearied, and lose patience. I was nervous over the operation, not on account of my own part, but about the Irishman's. He changed them in a Thomas' tent, taking them from the packets, and, after exposure, putting them in rotation in a common negative-box, covered over with folds of yellow cloth. I was drawing a long breath of relief after exposing the last plate (the twenty-fourth, 10 by 8), and went round to the tent where Pat assured me that everything was right. To prove it he threw aside the curtains, and discovered to my startled vision *the box standing open*. The whole were, of course, spoiled, the job lost, and when laying the whole story down in the ear of a sympathetic friend, he, for comfort, coolly asked me, "Why the deuce I did not change them myself?" Experience keeps a dear school, but there is no mistake but that its lessons go home.

Prior to taking an unopened or unusual size of plate to the field with you, it might be as well to fit one into your carrier. An acquaintance lately got an order to execute some 15 by 20, and having great faith in the maker as to the sterling quality of the plates, having used the smaller sizes with great success, he packed them up with confidence. All went well until he drew up the slide, when, flop! the plate fell into the camera. The carrier proved too large, or *vice versa*, and that day's work was lost.

I have seen changing boxes for small sizes of plates, but for large plates, giving ample convenience to the operator, and useful as a receptical for camera, lenses, &c., a Thomas's tent is what I would recommend. This I say to professional photographers intent upon hard work and good results. To the photographer or amateur going upon a pedestrian tour, there are numerous light burden apparatus in the market.

When going out of doors with gelatine, it is as well to be prepared with every requisite should an emergency crop up, as in the case of collodion. Thus I recommend the lantern taper and matches; a piece of ruby glass can easily be fitted over the yellow window of the tent, and the lantern—either inside, or hung outside the window, will greatly facilitate one in changing the plates aright. By no means should a camel-hair brush be forgotten (one as soft as can be obtained), for dust settling on the gelatine film shows as nice a pinhole as a collodion plate. I strongly recommend that two tin boxes, light-tight and padlocked, should be among the necessaries for the field—one containing the plates to be exposed, placed on the right hand; the empty one, to receive the exposed plates, to the left; the operator to lock said boxes whenever done with them, thus putting them beyond the power of accident or some inquisitive bumpkin who may be inspired to take a peep while the operator is busy at the camera. A note-book and pencil are almost indispensable, so as to keep you right with your exposures and developing. The way I do it is quite simple, and proves of singular assistance to me.

When putting a plate in the slide, I take a pin and make a distinct but minute 1 or 5 or 9, as the case may be, in corner. When my exposure is over I enter it in my book thus:—

No. 1. View of house, trees, and distant mountain. Sunshine—flash. Dall., 2nd stop; or

No. 5. Gardener's cottage, hidden in trees. Dull. 4 seconds. Ross, Rec., open A; or

No. 9. Interior of greenhouse. 1 minute ex. Ross wide A.

On proceeding to develop, a reference to the No. and the note-book instantly puts the whole details concerning the picture before me, and gives me confidence how to proceed with development.

Now, having brought everything forward in due order to the scene of operations, the first trouble that gelatine gives the worker is the exposure. Say that he is working with a batch of plates said to be ten times the rapidity of the ordinary collodion. He has a bright, sunny woodland scene, with a gleaming meandering stream in the foreground. For this scene of peace and sunshine he would have given three or four seconds with a wet plate: but how is he going to whip the cap off and on again quick enough? He shakes his head doubtfully, but makes an attempt, returning the cap with such vigour that he nearly brings the camera to the ground. Then a doubt springs up in his mind. Did the camera shake when he removed the cap? This cup is poisoned for the day now; no rest, no peace, no pipe, no supper; his mind is solely and gloomily looking forward to the developing dish in the morning. I merely mention this to show that for miscellaneous work out of doors with gelatine, the good old-fashioned cap will not suffice. It must have its shutter that will give the nearest approach to an instantaneous exposure possible; and for one half second—two or three even—I would advise a Cadett's pneumatic shutter, firmly secured inside the camera. With it there is less risk of shaking the camera while exposing. In long exposures it signifies little what kind of cap may be used.

Apropos! Look well to the firmness of the tripod's legs, and give a sharp look to the thumbscrews before leaving home.

If you have one particular object to take, do not attempt to make a picture of it in a shadow where the sun approaches to within a couple of yards of the object, be it a group, a hearse, or a horse! Such liberties could be taken with collodion, but gelatine will not stand such close quarters. I was forced into trying it on a hunter at a livery stable—that shadow being the only spot at all likely to secure a picture. The sun shone down upon us at right angles, drawing a straight parallel line in front of the wall (against which I placed the beast), leaving a nice diffused light in the shadow of about six feet deep. I expected a failure, but not quite such a kicker as I got. Talk about halation! The half of the plate was halated away. There was the hunter's proud head and his back with the saddle, but his legs, where were they? Tapering away, disappearing gradually until the fetlocks dissolved into a sea of nothingness.

Now, allowing that collodion would have served me the same way, I could have detected it on the spot, and perhaps remedied it. Thus I say, until the worker gains complete confidence in himself—relies entirely on himself, as far as work and changing his plates are concerned—and thoroughly understands the extraordinary power that gelatine plates places in his hands, he will hanker after the slow but sure collodion, and come home from a day's work a miserable, pitiable, wretch.

Gelatine is certain to overthrow collodion in the same fashion as the albumenized paper did the glass picture. I would advise all workers to learn and study as much as they can of it, that is to say, if they do not want to be left far behind the times. To my thinking, for the working photographer, there is far less to overcome in the working of gelatine plates, than there was when collodion first put forth his claim for attention. Thus I say to my brother workers, Esperance and advance! Conquer gelatine as you did old collodion, and then you will return as certain, even more so, of success after a day's labour, as in the "good old days." Remember

> "Ye who toil with a purpose high,
> And fondly the proud result await,
> Murmur not, as the hours go by,
> That the season is long, the harvest late.
> Remember that brotherhood strong and true,
> Builders and Artists and Bards sublime,
> Who lived in the past and worked like you,
> Worked and waited a wearisome time:
> Dark and cheerless, and long their night,
> Yet they patiently toiled at the work begun,
> Till lo! through the clouds, broke that morning light,
> Which shines on the soul when success is won!

PLATINOTYPE.

BY WILLIAM ARMSTRONG.*

I AM not here to-night to compare platinotype with any of the numerous processes at present in vogue, nor to claim for it any special merit, excepting that of extreme simplicity, but merely to give a short sketch of the various stages the process has passed through, since its discovery by Mr. W. Willis, Jun., in 1878, up to the present time, and a practical illustration of its manipulations. I shall leave you to judge for yourselves, from the specimens before you, whether or not it is worthy of your consideration.

The process, as many of you will know, depends, firstly, on the reducing action of light upon persalts of iron. In this case ferric oxalate is employed, which becomes ferrous oxalate; and, secondly, upon the property of a hot solution of this latter salt in potassic oxalate of instantly precipitating platinum, and other of the higher metals, in minute division from their haloid and other salts.

Paper, therefore, coated with ferric oxalate and exposed behind a negative will have produced upon its surface in ferrous oxalate an image corresponding in its gradations to those of the negative. If, then, ferric oxalate be mixed with a salt of platinum, the image will be composed of ferrous oxalate intimately mixed with the platinum salt.

If the paper be now floated, face downwards, on a hot solution of potassic oxalate, the ferrous oxalate is immediately dissolved, and the platinum salt instantly decomposed in its presence—the platinum precipitated in a fine state of division in proportion to the quantity of ferrous oxalate in the image, and consequently, we have platinum black taking the place of the iron salt in the formation of the picture, and embedded in the tissue of the paper. This is the general principle of the reaction; but its details were found to involve serious complications. The image was found to be granular, and only partially adherent to the paper as at first prepared.

To remedy this a primary coating of silver nitrate was given to the paper, which in some way caused the platinum to be deposited in a very minutely-divided state; but this method involved toning with sulpho-cyanide of gold and fixing with hyposulphite, and finally washing—a series of complications as involved as those of ordinary silver printing, and sufficiently serious to condemn its use.

It was next discovered that the admixture of a small quantity of a lead salt with the sensitising solution, and the addition of a platinum salt to the potassic oxalate solution to be used as the developer, greatly enhanced the vigour and half-tone of the image, and left nothing to be done after development except immersion in a dilute solution of oxalic acid to remove the iron salts, and a subsequent washing in two or three changes of water for half-an-hour.

This was a considerable advance in the right direction; but the difficulty in maintaining the developer at a constant strength, the gradual diminution of the platinum salt giving grey and granular images, and the costliness of the platinum solution, precluded its use on anything like a large scale, especially by amateurs. Moreover, the presence of a minute trace of lead salt left in the paper was found in time to destroy the purity of the high-lights, from causes which are obvious.

It was clear, therefore, that unless these objections could be overcome, the process must be abandoned, as presenting disqualifications almost as grave as those imputed to silver printing. Mr. Willis now found that by the addition of more platinum salt to the sensitizing mixture the addition of the platinum solution to the developer could be dispensed with, and that greater variations of tone—ranging from almost a sepia, through a warm engraving black, to a dead cold black—could be produced. The following is a detailed account of the process as we have it at present:—

Paper suitably sized is coated with a solution containing about sixty grains of ferric oxalate, and the same quantity of potassic, chloro-platinite, and exposed under a negative in the ordinary manner, the progress of the printing being determined either by inspection or by an actinometer, after the manner of the autotype process. The latter is the more accurate, but a little experience soon induces the operator to set it aside in favour of the former method, as being less troublesome.

The print is now floated, face downwards, for a few seconds on a solution of oxalate of potass containing 130 grains per ounce, contained in a shallow tray made of iron, enamelled inside, and heated by means of a spirit lamp or gas flame to 170° or 180° F., when the picture at once flashes out in full intensity and detail. It is then immersed, face downwards, in a bath of dilute H Cl, 1 : 80, for ten minutes, removed to another and similar bath, and then washed in two or three changes of water, after which it is ready to be dried and mounted. This last bath of H Cl must show no traces of yellow colour after the removal of the prints; if it do, it must be used as a first bath only, and a freshly-mixed one takes its place.

The developer is returned to the stock bottle, and any waste made up with fresh developer.

* Read before the Newcastle-on-Tyne and Northern Counties' Photographic Association.

The chemical changes during exposure and development are expressed as follows, and for these I am indebted to Mr. H. B. Berkeley, the manager of the Company :—

During exposure :

$$C_6 O_{12} Fe_2 + K_2 PtCl_4 = 2 C_2 O_4 Fe + 2 CO_2 + K_2 PtCl_4$$

On development :

$$6 C_2 O_4 Fe + 3 K_2 PtCl_4 = 2 C_6 O_{12} Fe_2 + Fe_2 Cl_6 + 6 KCl + 3 Pt.$$

The ferric oxalate combines with the potassic oxalate in the developer, and forms a salt which crystallises out of the developing solution on cooling in the form of apple-green crystals, thus :—

$$C_6 O_{12} Fe_2 + 3K_2 CO_2 O_4 = 2 C_6 K_3 Fe'' O_{12}.$$

This has no value.

To ensure success the following simple details must be observed :—The paper, both before and after exposure, must be kept bone dry, or its sensitiveness is impaired, and a grey and granular image is the result. Cylindrical tin cases, having a receptacle at one end for CaCl, are provided by the company for the purpose of storing the paper, which will thus be made to keep almost indefinitely. A sheet of thin india-rubber, known as "insertion," must be interposed between the pad and paper in the printing-frame.

Over-exposure may be corrected by using a cooler developer, and *vice versâ* ; but the use of a too cool developer gives thin, grey images. The best results are obtained from a vigorous, plucky negative, full exposure, and a bath heated to between 170° and 180°.

Printing may be conducted in direct sunlight or in the shade, as is found best suited to the class of negative. The sensitiveness ranges between three and four times that of silver printing. Vignetting, owing to the extreme purity of the white, is a charming study by this process, and, owing to its sensitiveness, enlargements may be done direct by means of the sun or electric light.

The Company claim for their process :—Absolute permanence of the image, as no reagent, excepting boiling *aqua regia* will attack it ; extreme simplicity of the operations, and consequent saving of labour ; great sensitiveness; and beauty and purity of the high-lights of the picture.

ON INSTANTANEOUS SHUTTERS.

BY W. COBB.

It is a well-recognised principle in commercial circles that supply is regulated by demand, and it is curious to note that as soon as a want is created, whether by the surroundings of life or by the exigencies arising out of our advanced state of refinement, human ingenuity taxes itself to its fullest limit in order to meet our requirements. A fair illustration of this may be seen in the neck-and-neck race between rapid dry plates and rapid shutters, rapid exposers, or whatever term we may employ to designate these, at the present time, photographic indispensables. Pneumatics, electricity, and mechanism of the highest order have been brought to bear upon their construction. First in importance for studio work comes that very ingenious instrument known as "Cadett's shutter," which, in my opinion, for portraiture pure and simple, stands unequalled. It has often been urged that it is a mistake to attach this shutter to the lens outside the camera ; with that idea, however, I cannot agree, as I have frequently found, when photographing children, that a preliminary game of peep-bo with the flap has enabled me to arrest the attention, and secure such satisfactory results of the little—well, say darlings—as I could not otherwise have hoped for. It is well to know that it is just as easy to adapt this shutter to the lens inside the camera as it is outside. Effective as this instrument is in its own sphere, something far more rapid in its action is necessary for so-called instantaneous work, such as photographing animals, boating scenes, ships in rapid motion, athletic exercises, &c. For work of this kind I have employed most successfully the shutter known as "Hunter and Sand's."

I will not presume to say that we have reached finality, either in rapid dry plates or rapid exposers ; but I cannot imagine that anything much more effective can be devised for instantaneous work than the shutter just referred to. Its chief point of excellence lies in the fact of its being worked between the lenses, thus giving the additional power of a stop or diaphragm to the lens, opening with the smallest possible aperture, gradually increasing to full aperture, and again closing with the smallest. It may be that the cue for making exposures in this way was taken from a remark made by Mr. Dallmeyer, on the occasion of a discussion upon drop shutters, at a meeting of the Parent Society some two or three years since, when that gentleman remarked that, in his opinion, the proper place for a drop shutter is between the lenses. Be that as it may, I can bear testimony to its value, and that from considerable experience with it, having been able to secure by its aid negatives of objects in rapid motion, possessing all the sharpness and delicacy usually supposed to belong only to those which have received a more lengthened exposure. One other point which should be mentioned is this, that by the adoption of the regulating spring, with which the instrument is now supplied, one is able to vary the exposures from, it is stated, one second to a two-hundredth part of a second. Surely, with such a power in our hands, and the unlimited degree of sensitiveness which is said to be attainable in dry plates, the coming season should show us something even still more wonderful than we have yet beheld!

Correspondence.

PROOFS AND RE-SITTINGS.

Dear Sir,—In reference to the discussion in the News, I may say I send out, and always have done, a finished proof ready for the album or otherwise, and await order. The proof is charged in the dozen ; if it is carte, and no order is given, I charge 6s. ; cabinet, 12s. 6d. If the photograph is not up to standard, I retake without charge ; if good, but expression or dress not liked, a charge of 3s. 6d. for C.D.V., and 5s. for cabinet, is made in addition to the ordinary charge.

I have always found this plan to answer, as, by sending a finished proof, your customers see exactly what they are going to have. You cannot explain to customers who look at a rough proof unmounted, what a finished one will be. You may try to make them understand, but it entails a lot of technical talk, which is best left unsaid. I find all my customers like to see the finished picture. I have often tried rough, unmounted proofs, but it was never satisfactory. So you see, my dear sir, opinions differ. A friend of mine sends out, unmounted, one finished and one unfinished proof, and he says the finished proof is invariably selected ; and he says, too, that his system answers admirably ; but I fail to see his advantage, as he prints two proofs while I print one. But I expect a man's business is just what he likes to make it ; it may be expensive, or the reverse.—I am yours truly, Edinburgh.

Dear Sir,—As it is only advisable to forward reasonably good photographs as proofs, and as the general public are only capable of judging from finished prints, properly retouched and mounted specimens should be sent, the sitters understanding at the time of sitting that all such proofs supplied would be counted as a portion of any amount that they had ordered or would eventually be expected to order. In the case of none of the proofs pleasing (an undesirable state of things), a charge should be made for the proofs supplied, in proportion to the usual terms of the particular photographer.—Faithfully yours, Manchester.

DEVELOPMENT SORES.—LONG EXPOSURES.

Dear Sir,—I see much grumbling about pyrogallic and bromide "sores." Try my "thimble" of gutta-percha, with a quill pen inserted as a finger nail. It is readily put on, it is waterproof, and keeps pyrogallic entirely off the finger when lifting the plate out of developing tray. What more is wanted?

Speaking of rapid exposures with dry plates, I have just exposed one (54-inch plate) with a stop $\frac{3}{8}$ of an inch to large triplet lens; the exposure was four days (and three nights); that is, I left the plate exposing for early and late light. The exposure is just the thing. Each day was a very bright sunny one, not such as you have in London, but really clear fine light for this time of year; the subject required too small a stop to obtain the whole sharp, and this with as rapid an emulsion as I can make. As the Yankees say, "How is this for high?" and where would wet collodion be?—Yours, &c., Thos. G. Whaite.

A WRINKLE.

Sir,—I send a wrinkle that has been of service to me. Any dry plates that have accidentally seen the light, or have been exposed on an object that has moved, &c., &c., can be made into vignetting glasses by the following simple plan:—Take a plate into daylight, and, with a camel's hair brush charged with hyposulphite fixing solution, proceed to work from the centre to any desired form; well wash and develop. Of course, perfect plates can be used, and, in many cases, the vignetting glass can be worked to any special form suitable for a particular negative.—Yours, &c., W. B.

RADIATION OF GELATINE PLATES IN DARKNESS.

Sir,—A curious case came under my notice a few days ago, when, on developing a gelatine negative, I found a distinct image appear of a previously undeveloped plate which had been taken one month before, and which had been in the next groove of one of Hares' changing-boxes to the plate on which its image appeared, showing that gelatine plates have, in some way, the power of radiating their light in perfect darkness. Perhaps some of your other readers have experienced the same thing. I should be glad to hear any remarks on the subject.—Yours faithfully, R. B. White.

[Certain kinds of gelatine are notably phosphorescent, and this circumstance may explain the phenomenon.—Ed. P.N.]

Proceedings of Societies.

Glasgow Photographic Association.

A meeting of this Association was held in the Religious Institution Rooms, on the 16th inst., at 8 o'clock, Mr. Parker in the chair. The minutes of the last meeting were read and approved of. Messrs. E. Beckett and W. Snell Anderson were elected members.

Mr. J. W. Swan gave a lantern demonstration comprising a collection of his most recent micro-photographs; also a series of transparencies, illustrating a town in the Isle of Man, kindly contributed by Mr. Chadwick, of Manchester. Mr. Swan's demonstration gave much gratification to a large gathering of members and friends. The meeting was graced by a goodly member of the fair sex. The Secretary was instructed to convey the thanks of the Association to Mr. Chadwick for his kindness, after which the meeting closed with the usual votes of thanks.

Newcastle-on-Tyne and Northern Counties' Photographic Association.

The ordinary monthly meeting of this Association was held in the College of Physical Science, on Tuesday, the 14th instant, Mr. James Downey in the chair.

The minutes of the last meeting were passed, and the following gentlemen were elected members:—Messrs. J. Pike, M. Auty, A. S. Stevenson, and R. S. Donkin.

The Chairman referred to the loss sustained by the Association through the death of Professor Marreco, who had taken great interest in the proceedings and welfare of the Society. He begged to submit the following resolution:—

"The Council and Members of this Association desire to express to Mrs. Marreco their sincere sympathy with her in the very great loss she has sustained by the death of Professor A. Friere Marreco, late Vice-President of this Association. The valuable assistance which he so willingly rendered to, and the warm interest he took in, the welfare of the Association, contributed to a very great extent to establish the high position it has acquired. It is with the deepest sorrow that we mourn the loss of a gentleman who had won our highest respect and esteem."

(Signed) James Downey, *Chairman.*
March 14th, 1882. J. B. Payne, *Hon. Sec.*.

It was quite unnecessary for him (the Chairman) to speak in its favour. He was sure the loss would be difficult to repair.

Mr. A. L. Stevenson seconded the resolution in feeling terms.

The resolution was carried unanimously, and the Secretary was requested to forward it to Mrs. Marreco.

Mr. E. Sawyer said that the Council recommended that an enlarged photograph of the late Professor Marreco, finished in monochrome, should be obtained and presented to the Institution. He thought it very desirable that this proposition should be carried out.

Mr. P. M. Laws seconded the proposition, and said that Mr. Sawyer had offered to paint the portrait gratuitously.

It was resolved that the portrait should be prepared at the expense of the Association. Also, that Messrs. Sawyer, Laws, and Mendelssohn should be a sub-committee to decide upon the negative, size, and other particulars necessary to the execution of the work.

The Chairman drew attention to the next meeting in April, which, he said, would be an open one. He also mentioned that the Council recommended that a competitive exhibition, confined to the original work of members of the Association only, should be held next November, and that judges should be appointed to select the two most suitable pictures for presentation to the members; each member to receive one copy gratuitously, and to have the right to purchase other copies at cost price. No restriction would be made either as to size, subject, or number to be forwarded. He moved that such an exhibition should be held, and that the Council be empowered to carry out the whole details.

The Hon. Secretary seconded this, and spoke in support of the proposition, requesting that as many members as possible should contribute to the exhibition.

Mr. W. Armstrong then read a paper on "Permanent Printing by the Platinotype Process" (see page 157), and afterwards gave a practical demonstration of the process.

The Platinotype Company very handsomely sent a splendid collection of pictures, which were greatly admired by all present.

The members were greatly interested in the demonstration, and at its close warmly applauded Mr. Armstrong.

The Chairman commended Mr. Armstrong for his clear description and illustrations.

The members gave a very hearty vote of thanks to the lecturer.

The Hon. Secretary next showed and explained a camera, lens, tripod, instantaneous shutter, and dark slides sent down by Mr. G. Smith, of the Sciopticon Company, and also a series of pictures forwarded by the Platinotype Company, all of which were very keenly inspected by the members, and their various points freely discussed. The camera and apparatus were marvellous specimens of ingenuity.

Votes of thanks were passed to the exhibitors and the Chairman, and the meeting was adjourned.

Talk in the Studio.

Photographic Society of Great Britain.—The next Technical Meeting of this Society will take place on Tuesday, March 28th, at 8 o'clock, at the Gallery, 5a, Pall Mall East, when the following questions will be discussed:—"On Protective Coverings for Gelatine Negatives;" "What would be the Influence on the Sensibility of Gelatine Plates on the Addition of Hydrochloric Acid to the extent of Five Minims per Ounce?" "To inquire the Cause of Scum-like Markings on Gelatine Plates, which are Visible before and after Development;" "The Hardening Effect of Time upon Gelatine Plates."

New Studio Accessories.—Messrs R. & H. T. Timperley forward us a catalogue of their "Requisites for the Studio," and a specimen of one of their new balconies.

Mrs. Langtry.—A photograph of Mrs. Langtry is not exactly a novelty; still, the magnificent pictures with which Messrs. Marion and Company have favoured us well deserve a word of comment. They are twelve-inch portraits, the work of Messrs. W. and D. Downey, of Ebury Street, and are mounted tastefully on gold bevelled black cards. Their value in our eyes lies in the fact that it is the woman, rather than the dress, which has received most attention by the artist, who has been successful in securing the lady with an agreeable pose, and under the most pleasing phase of lighting and modelling. Messrs. Marion and Co. tell us these are the only pictures of Mrs. Langtry in "full dress;" but this important fact we are unable to confirm of our own knowledge.

Tracings on Glass for the Lantern.—Several methods of making these have been devised, but, for simplicity and perfection of result, the following method, which was communicated to us by Mr. George Smith, of the Sciopticon Company, appears to be the most satisfactory which we have met with. A piece of very finely-ground glass is rubbed over with a trace of glycerine, in order to make it as transparent as possible. It is now easy to write or draw on the prepared surface with a hard and finely-pointed black-lead pencil, and the glass is so transparent that the finest details of any engraving over which it may be placed can be seen quite distinctly. The drawing having been finished, the plate is washed with water, in order to remove the glycerine, and dried. A thin coating of Canada balsam or of negative varnish now serves to render the slide permanently transparent, and ready for the lantern.

Obituary.—We regret to learn the death of Mr. Wainwright, of the well-known firm of Wratten and Wainwright, at the early age of thirty-three. The funeral took place on Saturday last at Brockley Lane Cemetry.

Influence of the Electric Light on Vegetation.—A plant placed at a distance of 6 feet 6 inches from an electric arc giving a 1,400 candle light, grows about as rapidly as in average daylight, and Dr. Siemens further observes that plants differ from animals by not requiring intervals of rest.

Recent Photographic Spectrum Work.—A series of no less than 22 ultra violet spectra has been issued by the Chemical Society in illustration of Professor Hartley's recent paper on the spectra of the elementary bodies. The prints are by the Woodburytype Company, and are highly satisfactory. Professor Hartley claims to have been the first to apply gelatino-bromide plates to photo-spectral work. Remarkable resemblances may in some cases be traced between the spectra of elements belonging to the same natural group, as in the case of iron, nickel, and cobalt; and no less than 603 lines have been traced in the case of iron, 556 in the case of nickel, and 391 in the case of cobalt. The analogy of magnesium zinc and cadmium is well illustrated, while arsenic, antimony, and bismuth give strikingly corresponding spectra. Those who are not occupied with work of this character can have but a faint notion of the labour involved in satisfactorily purifying the materials, and in other operations. We are pleased to learn that some of Professor Hartley's most important photographic results will shortly be published in a much enlarged form by the Autotype Company.

The Electric Exhibition at the Crystal Palace.—As the Electric Exhibition is now approaching completion, and well worth a visit, we append a list of the principal exhibits, and the localities where they are to be found. Concert Room, Edison; Centre Transept, the Pilsen Lamp and the Crompton Lamp; the Avenue and Opera House, Jablochkoff; Italian, British Electric Light Co.; Renaissance, Andró's; Mediæval and part of Nave adjoining, Electric Light, Power, and Generator Co.; Byzantine, Anglo-American Brush Co.; the North or Tropical End (including lamp of 150,000 candle power) and Alhambra, Anglo-American Brush Co.; Roman, Electric Light, Power, and Generator Co.; Greek, Audré's; Egyptian, British Electric Light Co.; the Entertainment Court (with illustrations of Edison's discoveries, the phonograph, electric pen, electric metre, &c.), Edison; the Avenue next the Chinese Court, Latimer Clarke and Muirhead's Scientific Instruments; Chinese, Crompton; the Avenue between the Chinese Court and Pompeian House, Elmoro's System of Electro-plating, Kelway's Electric Log; the Pompeian House, the Pilsen and Joel Lamps, Rowatt and Fyfe; the Nave and South End, Siemens Brothers and Co., and Siemens Frères; Corridor leading to Brighton Railway and Garden Terrace, Hammond Electric Co. (Limited); Costume, Hammond Electric Co. (Limited); Glass, Gérard; Negretti and Zambra's studio (where portraits are taken by the electric light), Gravier; Furniture, Swan; in the Southern Nave, Strode, Gladstone, and Tribe (chemical and local action, &c.), Swan's Chamber Candles (by Eastern Telegraph Co., Limited), Jablochkoff Candles; the Picture Gallery, Swan; Drawing-room, Boudoir, Smoking-room, Dining-room, and Library, Domestic Lighting Co.; secondary batteries, telephones, bells, &c., &c., &c.; in the Northern Nave, interesting Instruments and Appliances of War Office and Postal Department; West Corridor in rear of Chinese Courts, Ametti's Saw-cutting Machine, Transmission of Energy by Electricity, Rotary Steam Engine, making from 450 to 1,000 revolutions per minute; Gas Engines, Crossley and Co.; Utilization of Water Power for Generating Electricity, Liardet and Donnithorne; Elkington and Co., Electro-plating.

To Correspondents.

*** We cannot undertake to return rejected communications.

C. J. H (Bradford).—Unless some special appliance is employed for agitating the mixture, you will find it inconvenient to work on more than sixty ounces at a time, this being as much as can be thoroughly shaken in a "Winchester" quart bottle, which holds 80 fluid ounces, or 2 quarts.

Lantern.—1. As regards the negatives—old collodion, bright and uniform light, small stop, weak developer, and intensification either with pyrogallic acid and silver, or by the lead method of Eder and Toth. 2. Make your transparencies in the copying camera, and develop with iron. Neither toning nor intensification will be required in the case of letter-press reproductions. It is probable, however, that negatives would be found to suit better than transparencies.

Leo.—Most likely it would cause local fading. 2. In damp weather it is as well to finish the drying before the fire, as a trace of moisture often causes irreparable mischief to the negatives. 3. Trouble may often arise from such a proceeding. 4. Consult our advertisement sheets. 5. Four ounces to each pint of water.

F. K. Barclay.—Nothing is better than a good quality of white paraffin wax. After painting, the prints should be backed up with white enamelled paper.

A Young Printer.—It has been proposed and used for the purpose, but we are inclined to prefer a thorough washing in plain water.

V. L. P.—Water, 1,000 parts; saturated solution of borax, 100 parts; and chloride of gold, 1 part.

George Connor.—From a dealer in lithographic materials you may obtain tolerably thick and uniform sheets of gelatine. Soak one of these in water until it becomes quite flaccid, and lay it on the surface of the negative, this having been previously flooded with water. Next apply a squeegee, so as to force out the superfluous water and bring the gelatinous sheet fairly in contact with the collodion film, after which clamp it round the edges with slips of wood held by American clips. When dry it is easy to detach the whole by raising the edges with a penknife.

E Williams.—The method is an exceedingly useful one, especially in hot weather, and as far as we are aware there is no objection to it except the small additional expense. It is necessary, however, to obtain pure methylated spirit, and not the so called "methylated finish," which contains a small per centage of resinous matter.

A. L. O. E.—It is a collotypic print and you will find abundant directions for this class of work in back volumes of the News. See also the Year-Book for 1881, p. 157.

T. W. Parry.—We will communicate with you by post.

F. H.—Obtain as perfect a transparency as possible, and next soak the plate in water until the film can be removed by a kind of side-shifting action with the fingers; when this has been done you can float it on a fresh plate. The negative will become considerably enlarged during the process, and you will naturally experiment with valueless negatives first.

J. W. W.—It is impossible for us to give you the information, or we should feel much pleasure in doing so.

E. J. B. (Gloucester).—When it appears we will forward you a copy.

D. Newman.—We are informed that a cash equivalent of ten guineas can be had in place of the gold medal; but no arrangement of this kind will be made in respect to the second or third-class awards.

Amperton.—Just like a model chest of drawers constructed of thin sheet metal, each drawer containing some dry chloride of calcium, and the plate is mounted in a frame just over it.

Yorkshire.—As soon as we hear that you are suspected of being the author of the letter in question, we will have great pleasure in giving publicity to your denial.

Thos. Burder.—1. Although the market value is not more than £20 per ton, you could hardly expect to purchase a single ounce for less than twopence. 2. Undoubtedly due to pressure against some hard body.

Nitrate.—Use new glass, and clean it thoroughly with old collodion, and your difficulties will disappear.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1230.—*March* 31, 1882.

CONTENTS.

PROTECTIVE COATINGS FOR GELATINE NEGATIVES.

The due protection of a gelatino-bromide neg .tive against the action of the free nitrate of silver contained in printing paper is by no means an easy matter, those who have had occasion to print long numbers from a gelatine negative having generally found that no varnish proposed up to the present time is so satisfactory as could be desired.

The whole question was discussed at a recent technical meeting of the Photographic Society of Great Britain, and almost each person present had something to say on the subject, while several brought forward specimens illustrative of the defective qualities of existing varnishes.

The experiments of Mr. William Bedford possess considerable interest, and he finds that a thick layer of plain collodion, covered by a film of seed-lac varnish, is more satisfactory than other combinations with which he experimented, and a simple coating of seed-lac varnish proved to be singularly bad, the silver rapidly penetrating and forming round spots. A solution of the so-called xylonite or celluloid in alcohol and ether was tried instead of ordinary collodion; but this proceeding did not prove in any sense advantageous, while attempts to attain a greater degree of impermeability by the addition of a solution of mastic in benzole, or of Canada balsam, to the collodion also proved futile. The sub-film of collodion should be thick, say four times as thick as the usual film of a collodion negative, and it is best to level the plates and allow them to set in a horizontal position. Care should be taken not to apply the varnish until the collodion is thoroughly dry, a prolonged warming of the plate being necessary to ensure this.

The old-fashioned amber and chloroform varnish was favourably spoken of by Mr. Spiller and Mr. Maxwell Lyte: the latter gentleman preferring to saturate chloroform with the soluble matter of amber, and then to dilute the liquid with an equal volume of ether. The importance of thoroughly drying the gelatine film before applying any varnish appeared to be thoroughly appreciated, and Mr. Foxlee's method of removing water by soaking the wet negative in methylated alcohol has proved of considerable value when prints have been required in a hurry.

The plan of placing a very thin sheet of gelatine between the negative and the printing paper met with general approval, and we have ourselves found this method to be of great practical value, as when the first sheet of gelatine has become impregnated with silver, it is easy to exchange it for another, and Mr. England mentioned that he occasionally uses thin sheets of talc in a similar way. We have ourselves frequently thus employed a sheet of talc in printing Woodburytype reliefs, as, if the tissue is not absolutely dry, there is a considerable tendency for the sheet of pigmented gelatine to adhere to the negative, especially when a prolonged exposure becomes necessary.

A simple solution of orange shellac in alcohol was preferred by Mr. Mawdsley and Mr. Ayres, the slight colour being of no practical importance, and the advisability of using cold alcohol in preparing such a varnish was insisted on by several gentlemen; while Mr. Berkeley recommended agitation with precipitated chalk, in order to rapidly clarify the solution from the flocculent matter which, under ordinary circumstances, often takes several weeks to subside.

The ordinary white, hard spirit varnish, diluted with twice its volume of methylated alcohol, was recommended by Mr. Sebastian Davis as being a serviceable and economical varnish for general use; but Mr. England referred to the superior qualities of the brown hard varnish, the shellac being considerably deteriorated in the process of bleaching.

Many other suggestions were made at the meeting, and numerous points were discussed in detail, but it was generally acknowledged that no covering at present known will enable a gelatino-bromide negative to withstand free nitrate of silver in the printing paper so satisfactorily as is the case with a well-varnished collodion negative, and under these circumstances we recommend the following as the most satisfactory proceeding when long numbers are required from a valuable gelatino-bromide negative.

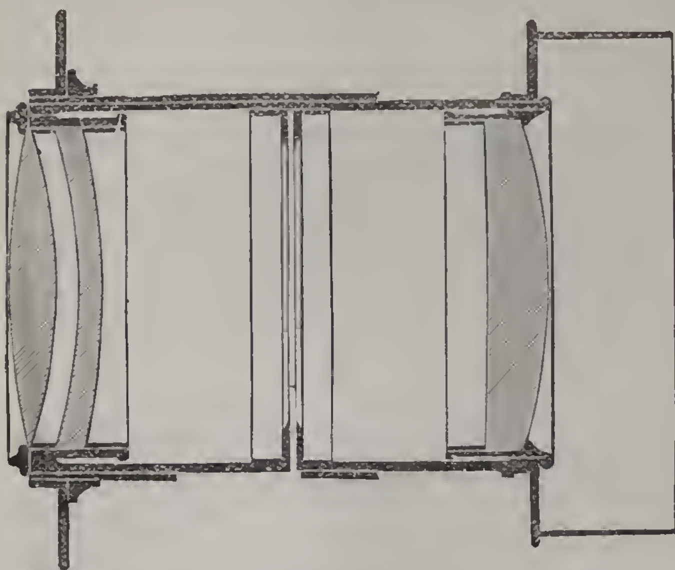
In the first instance, as perfect a transparency as practicable should be made, and before printing a composite film of collodion and insoluble gelatine, made as directed below, should be attached to the negative by strips of gummed paper, this film being changed as often as may be required; but the film we now recommend will last out five or six sheets of the ordinary thin sheet gelatine.

To prepare the composite film, a glass plate is first carefully and rather freely waxed, after which it is collodionised just as if it were about to be used as a support for a carbon picture during development. It is next placed in water at a temperature of about 150° F., and when all traces of alcohol and ether have become removed, it is flooded with a warm solution containing 50 grains of gelatine and half a grain of chrome alum to each ounce. When dry, it is again collodionised, after which it is merely necessary to allow it to dry once more, and to remove the pellicle from the glass by cutting round the edges with a penknife.

PHOTOGRAPHIC LENSES.*

The next lens we come to is more elaborate than any we have yet described;—we mean the

Portrait Lens.



Probably there are few other optical instruments on which so much ingenuity and skill have been spent as upon this lens, and the consequence is that, although it has certain inherent defects, we have in the modern forms a lens which combines extreme rapidity with marvellous definition through a very small angle.

In form it consists of two combinations of lenses, one at a considerable distance from the other. The front combination is very similar to the "single lens," but has the convex side turned towards the view. The back combination is, on the other hand, of peculiar construction, consisting of two lenses having a considerable air space between them. The use of this lens is indicated by its name. It is intended for portraiture pure and simple, and in this it finds its only legitimate use. For landscape work, or even for groups, it is quite unsuitable, as the definition is confined only to a very small circle, whilst the lighting is very unequal, the depth of focus slight, and the field comparatively round. The largest aperture of modern portrait lenses is from $\frac{f}{2\frac{1}{4}}$ to $\frac{f}{4.}$

The largest circle which a 12-inch portrait lens—that is, a lens with a focal length of 12 inches—full aperture will cover is about 8 inches, nor should the attempt be made by excessive stopping down to cover with it a greater size plate than will come within this, as the result will be to produce false perspective, and consequently an unnatural effect in the resulting portrait.

Modifications of the portrait lens are sold under the name of "universal" and "group" lenses. These are simply portrait lenses of very small diameter compared to their focal length, and with the combinations considerably nearer to each other, so that when stopped down with a small stop they can be used for landscape purposes. With large apertures they can be used for groups, and the larger sizes make admirable lenses for portraiture proper with rapid plates. The full aperture is about $\frac{f}{6}$. The largest sized circle covered by a 12-inch focus lens of this type is about 18 inches, full aperture, or with a small stop about 14 inches.

We should have explained that the focal length of a lens is the distance between the point at which the rays forming the image cross, and the plane at which the image is formed; in other words, the distance between the ground glass and the lens when the image is correctly focussed. In the case of a single lens, the measurement is from the lens itself. In the case of a double combination lens it is usually sufficiently exact to measure from the diaphragm. We have frequently given methods whereby it is possible to calculate with great accuracy the point at which the rays cross, if it be thought desirable. It is usual to speak of the "focus of a lens" instead of the "focal length of a lens." This is not strictly accurate, as a *focus* is a point, and has, of course, no length.

Besides the lenses which we have just described, various other forms have been introduced from time to time, but most of them have been superseded by one or other of the former which we have illustrated; we may, however, mention the three following:—"The Doublet" consisted of two combinations of different forms placed at some distance from each other. It has been superseded by the Rapid Symmetrical. The Triplet consisted of three combinations separated from each other, the two outer being of greater diameter than the central one. It has been superseded by the Rapid Rectilinear. The Orthoscope was the first form of landscape lens in which an attempt was made to improve upon the "single lens," so as to reduce distortion, and allow of a larger aperture and a wider angle being used. It consisted of two combinations, the back one much smaller than the front, and of the negative or dispersing form. It has been superseded by the lenses of the rectilinear type.

A lens differing entirely from any of these has been recently introduced by Dr. Steinheil, of Munich. He terms it an "anti-planet." It is composed of two combinations, each having very considerable faults, but in opposite directions, so that the one corrects the other. Two modifications are made, the one suited for landscape, the other for portraiture. We have not yet had an opportunity of practically testing this lens, but our friend Dr. Eder speaks highly of its merits.

* Continued from page 146.

NOTE ON THE CONSTRUCTION OF GLASS ROOFS.

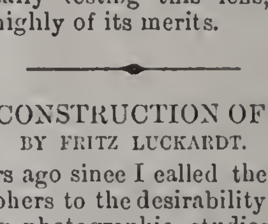
BY FRITZ LUCKARDT.

It is now six years ago since I called the attention of my brother photographers to the desirability of improving the method of glazing photographic studios, and submitted certain points upon which I thought modifications might be made with advantage. Strange to say, most photographers seem perfectly satisfied with things as they are, and new studios are still glazed in the old-fashioned manner. I suppose my friends do not think the construction of the glass roof is a matter that concerns them.

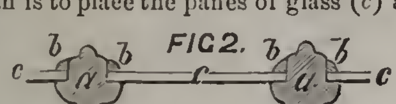
I regret their inaction in the matter very much, as I think things might be changed for the better if a little trouble were taken before the design for the roof is completed. Many studios have been built to my knowledge since I moved in the matter, but all upon the old plan, and they have, to my knowledge, all the old drawbacks. My notions on the subject, which are below, are based upon practical experience.

In the first place, I may mention that it is not only necessary that the glass panes for the roof, Fig. 1, should

FIG. 1.

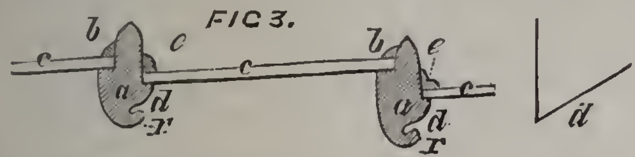


be rhomboid in shape—that is to say, not rectangular—but it is also requisite that they be placed *not horizontally*. Therefore, it is necessary that the iron rods upon which they are made fast should be cast or rolled in such a way that the pane of glass rests a little higher on one side than the other; the drops of moisture or rain will then, as they collect, run down from one edge to the other. At present, the usual plan is to place the panes of glass (c) as in Fig. 2,



in a horizontal position, and the iron rods (a a) also on a level, while the fastenings (b b) are likewise the same one side, as the other.

If, however, as I recommend, the arrangement was that shown in Fig. 3, then the rain drops would be carried off



from one pane to the other by the point d. The rain as it collected would pour from d into the channel r, which might easily be cast upon the iron rods at the time these are made.

I hope that my rough sketches will make my plan understood; it is a little difficult to explain, but simple enough when made clear.

FOG AND LACK OF PRINTING POWER IN GELATINE NEGATIVES.

JUDGING from the flatness and lack of vigour that still obtain in gelatine negatives, and from the fog that frequently mars their printing power, we may safely conclude we have still much to learn and unlearn in their treatment.

The plates in the market are no doubt as diverse in quality as the treatment should be by which these are manipulated. In the main, however, our experience goes to prove that the plates are not so much at fault as the mode in which they are dealt with in exposure and development. The difficulty of timing exposure and of development increases in a ratio corresponding to the increase in sensitiveness of the film. This may be set down as an axiom in photography, and it may be also accepted as a corollary that a delicately sensitive film will not submit to haphazard treatment without showing that the conditions on which success is based have been violated. It is only by most careful and systematic treatment that the finest results can be obtained.

Some operators do not employ weights or measures; they deal in unknown quantities in making up their developers and intensifiers, and wonder why gelatine plates are so much inferior to collodion—why they fog, are feeble, and fail to come up to a high standard. The old wet plates stood dosing and dodging to any extent without much detriment to their quality; not so the dry gelatine. Some approach to scientific accuracy must be observed in its treatment, otherwise nine of the finest plates out of ten will turn out faulty. In fact, they have a dainty appetite, and are easily poisoned. At the same time, success does not invariably crown the efforts of the chemical expert when he has to deal with dry plates. He may overlook some optical phenomena in his studio, lens, or dark-room. Halation, partial or complete fog, may vex his soul at times, and mar his progress. Touching the first of these we have little to say, as it has been treated fully in the pages of this journal.

With a plate properly coated with moderately-opaque emulsion, and exposed under certain conditions, halation would not appear; but if the same plate had been so exposed in a dark interior as to receive the image of a window lit up by direct light, halation might or might not be developed in full force in the negative. It might be brought out in its worse form, so as to cause general fog, by the use of a developer strong in pyrogallic acid and ammonia, and it might, on the other hand, be greatly modified by employing, to start with, a developer weak in pyrogallic and ammonia.

Taking a picture against the light is always apt to cause halation, or halation and fog combined. This may be simply illustrated by attempting to take a landscape and the sun by which it is lighted at the same time. A like result will obtain, in a modified degree, in taking a picture against any bright source of light, unless the lens is protected from the direct rays emanating from the source.

It is thus customary for landscape photographers to employ an artificial shade for the lens, and so to lower it above the lens as to cut off direct rays when the camera is set facing the sun. The shadow of a tree may provide an efficient substitute for the artificial shade.

In studio practice a common cause of fog is to be found, as pointed out in a former article, in reflections from bright surfaces in the lens-settings and tubes. In the best lenses the optician is careful, as far as possible, to remove this cause of failure. The danger of light which has nothing to do with the image-forming rays being transmitted through the lens, is greatly increased when the lens is imperfectly shaded. The lens should be protected on all sides from the excess of extraneous light, so that the actinic image may fall upon the plate in all its purity. Theoretically, every part of the studio, excepting that part occupied by the sitter, should be wrapped in darkness. As for the dark room, it cannot be too dark, in so far as actinic rays of light are concerned.

It is difficult to get a perfectly safe light, and at the same time a light strong enough to work by; still, if we work under something approaching an inert red light, we can always avoid fog from this source. During the early stages of development the tray containing the plate should be kept as much as possible out of the direct red rays, and the plate should never be brought close up to the red glass of lamp of window. It ought also to be remembered that very few gelatine plates can be safely inspected even by the feeblest daylight before fixing. In order to prove this it is only necessary to expose a partially fixed plate to daylight, and return it to the hyposulphite bath. It will be found that the part which contained undissolved silver bromide has contracted a brown stain which completely spoils the negative.

FRENCH CORRESPONDENCE.

CHAMBRE SYNDICALE DE LA PHOTOGRAPHIE—ACTION OF WATER UPON AN AMALGAM OF ZINC COATED WITH BITUMEN—PHOTOGRAPHS OF BIRDS ON THE WING—COLOURED PHOTOGRAPHS ON CHINA.

Banquet of the Chambre Syndicale de la Photographie.—This festive meeting was held on the 14th of March last. The only subject discussed at the meeting to which I need allude was the proposed memorial of Poitevin. M. Lévy, the chairman of the banquet, proposed that a subscription should be raised in favour of the project, and it was decided that the two Societies (the Chambre Syndicale and the Société Francaise) should unite their efforts to make this subscription a success. A considerable sum of money was promised at the dinner itself. It is to be hoped that the list will not be confined to France, but that other countries will also come forward to secure for Poitevin a memorial worthy of his name. No doubt, the original discovery of the action of light on potassium bichromate is due to Mungo Ponton; but to Poitevin belongs the glory of having turned this discovery to practical account. Certainly, the latter never claimed for himself the honour of the discovery itself, for, in his book on "Printing without Silver Salts" (a new edition of which is now in course of publication) he expressly states that Ponton had made use of bichromated paper in 1840, while his own experiments were not made public until 1848. But there is no occasion for any dispute as to the right of priority. Poitevin's share in the working out of the invention is quite large enough to ensure for him a full acknowledgment of his merits.

Action of Water upon an Amalgam of Zinc Coated with Bitumen.—M. Fisch makes a drawing upon a plate of zinc with an ink consisting of finely-divided biniodide of mercury in suspension, thus producing an amalgam, and then coats the plate with a thin layer of bitumen. When this is dry, he lays the plate in water for a couple of hours, and at the end of that time the bitumen can be removed by aid of a brush from all the parts which have been amalgamated. This promises to permit of very interesting applications.

Photographs of Birds on the Wing.—Professor Marey, of the *Collège de France*, writes from Naples to the Academy of Sciences, that he has succeeded in taking the photographs of birds during their flight. He has arranged a kind of gun with a revolving apparatus, something like that which M. Janssen employed for the Transit of Venus. The revolving disc makes one revolution in a second, and in this space of time twelve apertures, each carrying a sensitive plate, pass in front of the lens. By this means a series of twelve successive images is taken, the duration of the exposure for each image being about $\frac{1}{700}$th of a second, or in full sunlight not more than $\frac{1}{1500}$th of an image; in the latter case the motor spring of the disc is at the highest tension. In using the instrument the gun is pointed at the bird just as when shooting it on the wing. Experiments of this kind here indicated, undertaken with a view of analysing the motion of a bird during its flight, are of the highest interest.

Process of Taking Coloured Photographs on China.—Being at present engaged in investigating a means of obtaining coloured photographs on ceramic productions, I have been led to the attempt to get images richer in colouring material. Prints usually obtained by the dusting-on process or by phototypie will not stand a great heat, and can only be produced in the ordinary muffle furnace. The question is whether a means for arriving at a proper density of colouring matter may not be found in the Woodbury process. But, as is well known, gelatine will not burn without contracting; it is, therefore, a substance not adapted to our present purpose. I then thought of making a coloured ink with sugar, which burns up completely in firing; I employed it in solution in water to which potassium bichromate had been added, and found the metallic oxide reduced in the form of an impalpable powder. The thick mucilage is poured on a Woodburytype mould, and compressed with a piece of smooth plate glass; in this state the whole is exposed to the sunlight, which gradually renders the whole of the image insoluble by acting through the thickness of the paper. It is then withdrawn from the mould, and exposed again to the light to increase the insolubility, after which it is soaked in water to remove all the salt of chromium in a free state. This image, taken on a provisional support, and then transferred to the piece of china to be decorated, will resist a great degree of heat. LEON VIDAL.

By-the-Bye.

BUYING AND SELLING BUSINESSES.

ALL things have their palmy days, and photography among the number. Unfortunately, palmy days always carry a discount; they are gone, and never to come. Palminess, like "the good old times," only exist in the past. The palmy days of the drama are gone, and so too are the palmy days of soldiering, sailoring, farming, coaching, hunting, dancing, and the rest. Our modern artists no longer paint like the old masters, and old china is infinitely more valuable than new. The palmy days of chivalry are no more, and to-day, we are assured, is the material common-place age just between the good things that are gone and those yet to come.

Whether all this is true or false, it is very certain that there have been photographic businesses in the past of considerable value. Six thousand pounds is a high price for a "going concern," even in London, and yet this sum was paid not so long ago for a photographic business in the provinces. We know of two gentlemen, at least, who have made upwards of ten thousand pounds out of photography in a single year, in the ordinary way of business, and although it is rather against the theory of "palmy" days, we may adduce our belief to the effect that this sum was exceeded in the case of the lucky man who secured the photographic copyright of "You Dirty Boy," for which he paid one hundred pounds. In the West End there are, of course, businesses to be found at the present day for which six thousand pounds would be refused; but fifteen or twenty years ago, before cartes-de-visite were common, this sum would not have been too much to offer to some of our leading city and provincial firms. Of course, these were less numerous than they are now, and profits fell off rapidly as the ranks of photographers began to fill. A Regent Street firm we wot of, charged a guinea and a-half for six carte portraits in those days, and second-class firms at Notting Hill, Islington, and Clapham would ask three shillings a piece for any extra copies required from a small portrait after the first dozen or half dozen had been paid for.

These prices certainly belonged to the "palmy" days, and are no more likely to return, than we are likely to see salmon again at twopence a pound, or natives at sixpence a dozen. Fortunately, the price of photographs does not depend solely upon quantity; twenty years ago, when photographers, both good and indifferent, were scarce, good and indifferent photographs were alike dear. But good photographers still command good prices, albeit not so high as formerly; and thus it is still possible to sell a photographic business for a tolerable sum. Only, since photography is daily becoming more and more of a fine art, the necessity for a thorough artist as the leading spirit of a firm to keep it going, also becomes imperative. In a word, portrait-photography is a profession, not a business, and you can only sell it in the same way as a doctor or solicitor sells his practice. True, there are certain goods and chattels to be taken into consideration—the photographer's stock of negatives, his deftly-arranged studio, and his apparatus. But the doctor, if he does not purchase glass portraits of his *clientele*, buys the practice books in which their constitutions and ailments are recorded, and he buys, too, as a rule, the surgery to which patients have been wont to come, as well, in all probability, as his predecessor's stock-in-trade of implements and drugs. It behoves him to be as clever as his predecessor, or patients will go elsewhere; and this will happen to the photographer if he does not show himself in every way as skilful as the brother from whom he purchased. People will come to him for prints from negatives that he possesses, and so will patients continue to go to the old surgery for medicines they have formerly been supplied with; but energy and skill are requisite to keep up the business.

In purchasing, then, a photographic business (we are speaking, of course, of a portrait business), we think both buyer and seller should be guided rather by the rules that govern the buying and selling of a doctor's or lawyer's practice, than by the regulations applied to ordinary businesses. A tradesman frequently gets three years' purchase for a well-established business, and, in some businesses, the purchasing value is still higher; but neither doctor nor solicitor can command such high prices. From a year-and-a-half to three years, at the very utmost, is all that a solicitor can ask for his practice, the sum being calculated on nett profits. The purchase money would include "introduction;" that is to say, the selling solicitor would act as partner to the purchaser for a given period.

The doctor does not get quite so much; he never receives a sum equal to three years' purchase; but then, in his case, the amount is calculated on gross takings, and not upon nett profits, as with the solicitor. With an "introduction," a doctor may receive as much as two years' purchase; but more often the sum agreed is only equal to the takings of a year. If a doctor dies before he can sell his practice, the latter is valued at nine months' gross takings, provided, of course, it is a substantial concern, and the purchaser has immediate possession.

In all sales of this kind there are usually exceptional circumstances which influence the bargain one way or another, and, in the case of a photographer, his stock of negatives and his personal qualifications would have to be taken into consideration. Mr. Ackland, of the firm of Messrs. Horne and Thornthwaite (who has, perhaps, had as much experience as any one in such matters), places the value of a photographic business in between the doctor's and solicitor's; but, as in the case of the latter, the purchase is naturally based upon "nett profits." Supposing a photographer's business to be well established (and, of course, the whole basis of the calculation depends upon this), Mr. Ackland thinks that a fair price would be an amount equal to the nett profits during a year-and-a-half to two years. For this sum, the stock of negatives and the books of the concern would be required, and, perhaps, the printing-frames and printing plant, but not lenses, cameras, &c. A separate valuation would be made of these, and also of the fixtures.

We have said that there may be exceptional circumstances, which influence very much the sale of a photographic business. The advent of a photographer of high reputation in the vicinity, or the bestowal of Royal or powerful patronage upon a neighbour, may decrease the value of a business suddenly, just in the same way as that of the more fortunate man is increased. The fortune of war, luckily, has little or no influence in this country; but it is different on the Continent. In the spring of 1870 we visited M. Reutlinger's famed studio on the Boulevard Montmatre. At that time M. Reutlinger was producing a novelty in the form of glazed cabinet portraits with fancy borders, and had, perhaps, the best photographic business in Paris. At the little *comptoir* at the top of the house, a busy clerk sat booking engagements, and all day long a driblet of gold coin fell upon the brass-railed counter. A large number of the callers were English, and loud and pressing were their demands for early sittings. A year later, all was changed. The Franco-German war had come, and M. Reutlinger, as a German settled in France, could expect little quarter. For some years the business at Reutlinger's studio was at a standstill, and it is doubtful whether money enough was taken to pay the rent; but right glad were we to see, when we last year visited the French capital, unmistakable signs of M. Reutlinger's star ascending once more. But the rare combination of skill, energy, and good luck which puts a man before all his fellows is, as everybody knows, scarcely likely to visit an individual twice, and the palmy days of the Reutlinger studio, we fear, are, like all other palmy days, gone for ever.

A business must be well established, we have said, at the time of its sale, or the terms do not hold good. It is not enough that it has existed many years in one spot, and is still doing a respectable business. The takings during the past year may be respectable, but, if they are only half that of the year before, it would not do to make an offer without a searching inquiry into the cause. A fading business is nearly always a bad bargain. In the same way a business that shows steadily-increasing takings is likely to be worth the maximum we have set down for guidance. Again, it should be remembered that no one is in a hurry to get rid of a good thing under ordinary circumstances, and, therefore, unless good and sufficient reasons are forthcoming for the sale, this fact should be taken into consideration in making the valuation. The stock of negatives should always be a valuable item, and if the would-be seller can prove he is making a tolerable income from re-print orders (this is not difficult to show), the fact that the business is well established is pretty well proven.

The "At Home" next week will be "Herr Hof-photograph Angerer in Vienna;" the following "By-the-Bye" will be on "Dark Room Disease."

THE CHEMICAL ACTION OF LIGHT.

BY DR. J. M. EDER.*

Silver bromide behaves in the same way as the chloride under the influence of light—it turns a grey violet colour, and loses bromine. AgCl precipitated from a saturated solution of silver decomposes more quickly in the light than the similarly produced AgBr; on the other hand, AgCl precipitated by a saturated solution of NaCl is decomposed more slowly than AgBr thrown down by a similar solution of NaBr (H. W. Vogel). Silver bromide is more sensitive to colour than the chloride, but does not reproduce the spectrum with its colours. According to Vogel, nitric acid dissolves out no metallic silver from the bromide which has been blackened by the light, but Carey Lea found an appreciable quantity of the metal in the same substance. At all events, the dark colour of the bromide which has been exposed to the light is not removed by nitric acid, whence Eder concludes that sub-bromide is present. Iodide of silver does not present the same re-actions, inasmuch as it is only discoloured (turned a greenish grey colour) by the action of light, when it has been obtained by precipitation from a saturated solution of silver nitrate; but the salt thrown down by a saturated solution of potassium iodide undergoes no alteration at all (Schnauss). The separation of iodine during or after the discolouration of the iodide cannot be detected (H. W. Vogel), not even when the latter is heated (Schultz-Sellack). Acids materially retard the photo-chemical action; nitric acid ($d = 1{\cdot}2$) bleaches the blackened iodide, but without dissolving any metallic silver, while potassium iodide restores the colour. The presence of substances which absorb iodine, nitrate of silver, tannin, arsenite of soda, &c., strongly promotes the decomposition in the light, the sub-iodide being probably formed.

Plates of silver fumed with iodine, bromine, or chlorine will condense the vapour of mercury on those parts of their surface which have been exposed to the light; on this principle the Daguerreotype process is founded. Iodide, bromide, and chloride of silver on paper (Fox Talbot), albumen (Niepce), collodion, &c., on being exposed to the light, become possessed of the property of attracting finely-divided silver in a nascent state, as it is precipitated from nitrate-of-silver solution by means of ferrous sulphate, pyrogallic acid solution, gallic acid, &c., in this way rendering the latent image visible; this is development by attraction, or physical development. Silver bromide, after a short exposure, is rendered capable of being reduced by alkaline pyrogallol, potassium ferrous oxalate, ammoniacal hydrochinone, &c.; this is development by reduction, or chemical development. The development of the latent image is promoted by substances absorbing iodine, bromine, or chlorine, such as tartrate of antimony, sulphite and arsenite of soda, tannin, ferrocyanide of potash, &c., and more especially by silver nitrate—substances which Vogel calls "chemical sensitizers." In the presence of certain dye stuffs, in addition to these chemical sensitizers, the sensitiveness to colour is increased by means of optical absorption. Bromide of silver emulsified in gelatine is particularly sensitive. The chloride also admits of the chemical development; but in this case, weaker reducing agents—such as ammonio-ferrous citrate or neutral pyrogallol—must be employed as

* Continued from page 150.

developers (Eder and Pizzighelli). Both bromide and chloride-of-silver emulsions are rendered more sensitive by half-an-hour's boiling, particularly to the less refrangible rays.

Up to a certain point the capacity of the silver salts to blacken under the developer increases with the length of the exposure, but beyond that point it decreases (the so-called "solarisation"), and this reciprocating process repeats itself several times (Moser and Jansen). This so-called negative action of the luminous rays is more especially manifest towards the red end of the spectrum, owing to the fact that the less refrangible rays interrupt the previous action of the more refrangible rays. According to Abney, solarisation must be considered to be due to oxidation, which, after a long exposure, will make its appearance over the whole spectrum, from the violet to the ultra-red. This phenomenon, as well as the behaviour of the latent image with different chemical agents, point to the presence of infinitesimal quantities of sub-iodide, sub-bromide, or sub-chloride of silver.

Many other of the silver salts, especially those of the organic acids, blacken under the action of light. The carbonate, phosphate, oxalate, tartrate, citrate, and benzoate of silver all behave in this way, and admit of the development of the image with gallic acid and silver nitrate (Hunt), or with alkaline pyrogallol (Carey Lea).

Of the organic substances which undergo decomposition on exposure to the light may be mentioned nitric ether, which turns yellow. The vapour of amyl nitrite forms under the influence of light heavy clouds of amyl nitrate and hyponitric acid, the more refrangible rays being more especially active in producing this effect; according to Tyndall, allyl iodide and isopropyl iodide behave in the same way. Dilute oxalic acid is decomposed with the production of oxygen; its neutral alkaline salts are more permanent, but still not perfectly stable. A solution of oxalic acid will reduce the salts of gold more rapidly after exposure to the light than before.

Graphitic acid turns black in the light, and nitrocumic acid gives a red precipitate; santonin becomes yellow, and the crystals break up with the formation of photo-santonin. Solutions of the quinine salts, as well as dry or moist sulphate of quinine, blacken in the sunlight, particularly under the influence of the radiations which excite fluorescence, sulphate of quinidine being formed. Hœmatoxylin turns red when acted on by light, even in *vacuo*, without alteration of its composition. Paper coated with starch acquires the property of turning a brick-red colour, in a solution of iodide of potassium, after it has been exposed for an hour to the sun. In this reaction the blue and violet rays are most active.

ON ETCHING FLUIDS.

BY MAJOR J. WATERHOUSE, B.S.C.,
Assistant Surveyor General of India.

The following notes on etching fluids for steel, copper, and zinc, gathered from various sources, may be of interest and use now that increased attention is being directed to photographic engraving.

I.—Mordants for Steel.

Nitric acid forms the basis of most fluids for etching steel as well as for other metals. Acetic acid and alcohol are sometimes added, and some formulæ contain nitrate of silver, corrosive sublimate, salts of copper, &c. Iodine is also a most efficient mordant for steel, and Mr. Fox Talbot used the chlorides of iron and platinum for etching his plates through the coating of bichromated gelatine.

Plain Acid Mordant.

1. *Kruger*—First biting—

Muriatic or nitric acid	1 part
Water	8 parts

Stronger.

Acid	1 part
Water	4 parts

Deepest.

Equal parts acid and water.

2. *Fielding.*

Nitric acid	1 drachm
Water	1 pint

3. *Roret*, for delicate work—

Nitrous acid	1 part
Water	4 parts

4. *Kruger.*—Chromic acid diluted according to the effect to be produced. This also serves for zinc, copper, and brass, and bites with great ease and certainty, making a good vertical cut.

5. *Prof. Kick.*—Equal parts muriatic acid and water, with a trace of chloride of antimony. Acetic or pyroligneous acids are sometimes added to the nitric acid, as in following—

6. *Fielding.*

Pyroligneous acid	1 part
Nitric acid	1 ,,
Water	3 to 6 parts

7. *J. Barth.*

Fuming nitric acid	1 part
Acetic acid	5 parts

This bites very vigorously, and for fine work may be diluted with distilled water.

8. *Roret.*

Glacial acetic acid	1 part
Nitric acid	1 ,,
Hot water	6 ,,

9. *Ed. Turrell.*

Glacial acetic acid	4 parts
Absolute alcohol	1 part
Nitric acid, sp. g. 1·28	1 ,,

The acetic acid and alcohol are mixed and allowed to stand for half-an-hour, then the nitric acid is added very gradually. This mordant is applied from 1 to 15 minutes according to the strength desired, and may be strengthened by adding nitric acid.

Etching Solutions with Alcohol.

Alcohol seems to be added with the object of softening the action in the first biting, and of making the mordant bite at once. For etching Niepce de St. Victor's asphaltum plates, M. Lemaitre used for the first biting—

10. Nitric acid at 36°...	1 part
Distilled water	8 parts
Alcohol at 36°	2 ,,

And finished off with nitric acid and water, without alcohol

11. Pure nitric acid	4 parts
Absolute alcohol	1 part

Many formulæ contain nitrate of silver in addition to the alcohol.

12. Nitric acid...	1 part
Alcohol	1 ,,
Water	8 parts

For the first etching, add to this mixture half part of a solution of—

Nitrate of silver	1 part
Water	6 parts

The acid should be changed every ten minutes.

13. (*Kruger*), Glyphogen. (*a*). First etching.

Nitric acid	1 part
Alcohol	5 parts
Water	10 ,,

(*b*). Deep etching.

Nitric acid	4 parts
Alcohol	12 ,,
Nitrate of silver	4 ,,
Water	24 ,,

Or

Nitric acid	6 parts
Spirit at 80°	15 ,,
Nitrate of silver	6 ,,
Water	30 ,,

14.

Alcohol 88° *Tralle*	1,500 ,,
Nitric acid sp. g. 1·22	10 ,,

Mix at 60° F., and, when the mixture is complete, add 1 part of nitrate of silver dissolved in distilled water.

If the varnish be weak, the following is better:—

15.

Alcohol	6 parts
Distilled water	9 ,,
Pure nitric acid	16·6
Nitrate of silver	0·83

The liquid improves by keeping. Before beginning, wash the plate for a few seconds with dilute nitric acid (at 4 per cent.), then apply the above mordaut for about three minutes, and wash off with distilled water containing 6 per cent. of alcohol. Repeat the biting as often as may be necessary, well washing between each operation.

16.

Distilled water	15 parts
Alcohol	2 parts
Nitric acid	1 part
Nitrate of silver	18 grains per litre

Strength may be increased by adding nitric acid or nitrate of silver.

17. *Deleschamps.*—Glyphogen.

Acetate of silver	8 parts
Rectified spirit	500 ,,
Distilled water	500 ,,
Pure nitric acid	260 ,,
Nitric ether	64 ,,
Oxalic acid	4 ,,

This is recommended as being free from the defects of many of the other mordants and giving a clean vertical bite.

Several formulæ contain salts of copper.

18. *Roret.*

Nitric acid	62 parts
Distilled water	125 ,,
Alcohol	187 ,,
Nitrate of copper	8 ,,

19. *Roret.*

Crystallized nitrate of copper	15 grammes
Distilled water	$1\frac{1}{4}$ litre
Nitric acid	a few drops

20. *Roret.*

Bay salt	15 grammes
Alum	60 ,,
Sulphate of copper	60 ,,
Nitrate of copper	16 ,,

Moisten with vinegar.

21. *Roret.*

Oxalic acid	2 grammes
Alum	4 ,,
Sal-ammoniac	4 ,,
Sulphate of copper	60 ,,

Grind up in vinegar mixed with common salt.

22. *Tardieu.*

Distilled vinegar	3 litres
Sal ammonia	184 grammes
Sulphate of copper	125 ,,

Boil up twice.

Corrosive sublimate enters into the composition of the following in Roret's manual.

23.—

Tartaric acid	21 centigrammes
Nitric acid	4 drops
Corrosive sublimate	4 grammes
Water	100 cub. cent.

This is a good mordant for soft steel.

24.—

Corrosive sublimate	8 grammes
Alum	8 to 12 ,,
Distilled water	1 litre

25.—

Spirits of wine	125 grammes
Nitric acid	62 ,,
Water	250 ,,
Corrosive sublimate	0·212 ,,
Hydrochloric acid	8 ,,

26.—

Brandy	150 ,,
Nitric acid	32 ,,
Corrosive sublimate	0·212 ,,

Iodine is recommended as a very efficient mordant for steel, being free from the inconveniences caused by disengagement of gas, as when biting with nitric acid. Messrs. Schwarz and Boehme give the followiug:—

27.

Iodine	2 parts
Iodide of potassium	5 ,,
Water	40 ,,

This may be further diluted up to 40 parts more water for etching the finest lines.

It gives good deep lines, sharp, and with clear edges even, for the finest and closely-ruled lines have no tendency to run one into the other.

28.—(*Cooley.*)

Iodine	1 ounce
Iron filings or wire	½ dram
Water	4 ounces

Keep in a stoppered bottle. Also

29.

Iodine	3 drachms
Iodide of potassium	1 drachm
Spirits of wine	1 ounce
Water	2 ounces

Niepce de St. Victor used for biting his photo-engravings in preference to other mordants, water saturated with iodine at a temperature of 50° to 59° Fahr., so that it has a good yellow colour, but does not reach orange red. It requires renewing after remaining on the plate a quarter of an-hour. This only serves for the first bitings, and the plates must be finished with nitric acid.

Fox Talbot used perchloride of iron and bichloride of potassium for biting his photographic plates through the gelatine. His formulæ for the iron solutions are—

30.

No. 1.—Saturated solution of perchloride

No. 2.—No. 1. solution ... 5 or 6 parts
Water ... 1 part

No. 3.—Equal parts of No. 1 and water.

The perchloride of iron is made by saturating muriatic acid with peroxide of iron as much as it will dissolve with the aid of heat. After straining the solution, to remove impurities, it is evaporated till it is considerably reduced in volume, and is poured off into bottles of convenient capacity. As it cools, it solidifies into a brown semi-crystalline mass. The bottles are then well corked up and kept for use.

The formula for the bichloride of potassium solution was:

31.

Saturated solution of bichloride of platinum	4 parts
Water	1 part

This may be strengthened or weakened as may be found necessary after a few trials.

The following resembles the etching fluid for copper, commonly known as "Dutch Mordant."

32. (*Cooley*).

Hydrochloric acid	5 parts
Water	95 ,,

Mix and add,

Chlorate of potash	1 part
Water	50 parts

33. (*Cooley*).—For electric etching with the battery, a solution of common salt is used.

(*To be continued.*)

Notes.

As many of our readers are anxious to see Mr. Muybridge's "Animals in Motion," we may mention that on Tuesday evening next he will give a demonstration before the Society of Arts, and on Wednesday at South Kensington. To-morrow, he shows the Eton boys what instantaneous photographs are like.

Mr. Muybridge thinks we should hear no more about "dead heats" if a plan he proposed four years ago of recording the winner in a race were adopted. "A thread stretched across the track, connected with an electric shutter in front of a camera, would determine to an absolute certainty which horse was an inch, or less, a-head." Mr. Muybridgs adds tersely: "In an important race, the decision of the camera would be preferred to that of the judges."

The total eclipse of the sun on the 17th of May will form the subject of a Government expedition to Egypt, where the phenomenon can be favourably observed. The camera, as a matter of course, will be made use of on the occasion as the most faithful of all observers, and Captain Abney, with a chosen staff of Sapper-photographers, will in all likelihood take charge of the photographic arrangements. Mr. Norman Lockyer is also to share in the expedition, his duty being confined to observing the eclipse through telescope and spectroscope.

It may be remembered that both Mr. Lockyer and the French photo-astronomer, M. Janssen, received promotion in the ranks of science by their careful observations of an eclipse of the sun some years ago, and more especially of the flaming masses of matter known as protuberances, which are only visible to the naked eye when the black disc of the moon obscures the bright disc of the sun; they are among the most important objects to be noted on the instant of eclipse, and these will be photographed to record measurement, shape, and luminosity. These protruding flames signify that the sun is not simply a heated ball, but is enveloped in ragged tongues of fire, due to the combustion of gaseous matter.

Photography first recorded these tongues of fire rising, so astronomers tell us, from the surface of the sun many hundreds of miles high, in 1860; but it was not until 1870 and 1871 that solar protuberances were depicted with any degree of sharpness and detail. Since then, it has been found possible to photograph the monster flames without waiting for the actual disc of the sun to be shut out from our vision by the moon, Professor Young having secured a picture of a double-headed protuberance in ordinary daylight by employing specially constructed apparatus.

The eclipse pictures taken by Mr. Alfred Brothers, in Sicily, in 1870, are among the best we possess of the phenomenon. His pictures were obtained in the simple fashion of employing an ordinary camera and rectilinear lens of four inches aperture and thirty inch focus. With an instrument of this focal length, his image of the sun was, however, only three-tenths of an inch, and it would be well, therefore, if a photographic lens were employed of still longer focal length, so as to give a much larger picture.

Herr Köhnke, an amateur photographer of Schleswig-Holstein, has prepared a new collodion, which is stated to yield dry plates of considerable sensitiveness. When we have practically tried this preparation, which we hope to do in a few days, we will report the result to our readers.

In a communication recently received from Dr. Eder, that gentleman expresses the great pleasure he feels at the compliment paid him by the Photographic Society in electing him an honorary member. "It is a token that honours me in the highest degree," writes Dr. Eder, "and it will encourage me still further to exert my poor talents towards the advancement of photography."

M. Marcy presented, the other day, to the Royal Academy of Sciences at Paris, some pictures of birds on the wing, secured in a camera with an exposure, it is said, of $\frac{1}{100}$ of a second. Mr. Muybridge's "Animals in Motion" include birds on the wing, and he shows, what we believe has never before been depicted, a bird in the air with its wings below its body.

We have not seen M. Marey's apparatus, but it is cleverly constructed like a rifle, so as to be capable of being raised to the eye to take aim and expose. It is on the principle of M. Janssen's *revolver*, which makes a series of rapid exposures one after the other, and with this Mr. Marey is able to secure the bird in various positions. A chronograph regulates the periods of exposure, which may be as brief as $\frac{1}{1200}$ of a second. M. Marey proposes to combine a series of the photographs thus taken, after the manner of Muybridge, and in this way to analyse a bird's movements and demonstrate it in motion, as the American photographer has done with his galloping horse.

Here is a hint for the Dress Reform Association, who are anxious to introduce "dual garments" for ladies, and other radical changes. The popular prejudice against such novelties is due to a widespread notion that their innovators are all of them the most staid and sedate of their sex; therefore, get some pretty models to wear the new dresses, and then distribute photographs of these broadcast; an outlandish dress combined with a pretty face never appears ugly, but is only piquante and bizarre.

Mr. Swan has not been fortunate in the exhibition of his electric lamp to Royalty. When the Duke of Edinburgh opened the Exhibition at the Crystal Palace, something went wrong with the engine at the very moment when His Royal Highness came to inspect Mr. Swan's invention;

and on Saturday last the lamps, which had been burning brilliantly for many hours, suddenly ceased to glow, and enveloped all in darkness while Mr. Swan was in the act of explaining to the Prince of Wales his new mining lamp. The driving band from the engine had slipped, and as the magneto-electric machine thus ceased to act, the electric current was momentarily cut off. Fortunately, the engineer was at hand, and within the space of a minute the steam gear was in order again, and the Swan lamps were once more aglow. But whether these two little incidents were due to accident or design, is, we believe, still a moot point.

A varnish upon which the finest pencilling is possible is described by M. Crova; it is especially suitable for application to glass, and, therefore, we should think of use to photographers as a retouching medium. It is applied cold, and might be used either on the face or reverse of a negative. This is the formula:—

Ether	500	grammes
Gum sandarac	30	,,
Gum mastic	30	,,

Dissolve, and then add a little benzine, by degrees, until the varnish applied to glass gives the latter the appearance of having a ground surface.

Government has decided upon spending fifteen thousand pounds in observing the next transit of Venus, albeit the results obtained on the last occasion, despite the lavish expenditure, were not so very satisfactory. There will, in all probability, only be one station for British observers (that at Madagascar), of which there is little doubt Mr. E. J. Stone will be nominated chief astronomer.

Photography is not in favour this time, and no photographer is likely to accompany the party. Besides the sum we have mentioned, the Admiralty will be called upon to supply a vessel of war, if not to carry the expedition, to protect it; for Madagascar is reported to be a spot scarcely so quiet as astronomers engaged upon watching an interesting phenomenon would most desire. We have always a squadron in African waters, but this is generally occupied at the Cape and on the West Coast.

A Paris photographer is said to make exposures in his studio of but one-hundredth of a second duration. This, however, would not be quick enough to suit some mercurial temperaments, thinks the *Practical Photographer;* the average boy could change his position three or four times during a sitting.

A recent prosecution of licensed victuallers for adding salt to malt liquors has called attention to the fact that some waters contain naturally a large quantity of sodium chloride. Thus Mr. Bartlett points out that a certain Chelmsford water used for drinking purposes actually contains more than one hundred grains per gallon, while ale and porter, as a rule, have but forty grains, unless brewed from a very salt water. In London, there are few waters containing more than twenty grains. The subject of salt in waters is not uninteresting to the photographer, in certain manipulations especially. In the case of washing prints, for instance, many add further salt to that naturally in the water, Mr. Payne Jennings' advice on the subject being, we remember: "When the prints are taken from the printing frames they should be well washed in three or four changes of water, and lastly in a bath containing a handful of salt."

The use of salt water in this way is a guarantee that no silver nitrate remains upon the prints. But in washing negatives, it behoves one to be careful in the use of water containing much salt. Salt is of a most deliquescent nature, and a film, whether it be collodion or gelatine, washed in water that contains much of it and dried spontaneously, is likely to give trouble. Indeed, it is not so long ago that we saw a series of negatives from Essex hopelessly spoiled, simply because they had been washed in water taken near the seashore, and consequently impregnated with salt. If brackish water is used in photographic manipulations, the negative should in the end be rinsed with, or immersed in, distilled or rain water before drying. As every photographer knows, the way to test water for sodium chloride is to drop into it a little nitrate of silver solution.

Photography, we are glad to hear, is likely to assist in giving some protection against explosions in mines, by recording from time to time the amount of explosive gas there is in a pit, in the same way as it is employed to register meteorological changes. Colliery explosions have been woefully frequent of late, and it is certainly high time better precautions against accidents were taken. The danger arises from coal gas mixing with the air of a mine, making an explosive compound, which ignites with terrible effect.

Two or three per cent. of gas mixed with air gives an explosive mixture, but the most dangerous compound is produced when the proportion reaches about ten per cent. Mr. Liveing has invented a clever little instrument by which the percentage may be read off on a photometric index, and if the working of this instrument were made automatic, there is no reason on earth why photography should not be made use of to take readings, and thus afford a record of the amount of gas in the mine every hour in the twenty-four.

Mr. Liveing's instrument is easily explained. At each end of a little box is a light of equal intensity, so that an index placed in between is equally illuminated. This equal illumination means there is no gas in the mine, but the right hand light grows in intensity as the percentage of gas increases. And for this reason. The lights, right and left, are due to small pieces of platinum wire rendered incandescent by an electric current. The left-hand light never varies, for it is in an air-chamber hermetically sealed; the right-hand incandescent wire, on the other hand, is open to the air, and the more coal gas this contains, the brighter glows the wire. Thus, as we have said, the right-hand light grows in intensity with the percentage of gas, and the light index—the matter having previously been determined by experiment—tells what this percentage is.

It is sometimes useful to know how to clean a plaster cast, for dust and dirt stains are exaggerated rather than decreased in a photographic image. Here, then, is a very simple receipt. Make a thick paste of starch, and apply it with a soft brush over the plaster object; put this in a dry place, and when the starch crust flakes off, it will bring the dirt with it.

In all probability there will be another photographic exhibition in Scotland this year, to be held either in Glasgow or Edinburgh. The expense attendant upon such a gathering is the only serious matter to be considered, for there is not a doubt that a fine collection of works would be forthcoming, whether the gathering took place on the Clyde or in our modern Athens.

The Colour Photographic Company being dissolved, the process of producing photographs in natural colours is spoken of no more in this country. But from Germany and Switzerland we still hear of the method being for sale, the price for a licence being no longer a hundred pounds, but a hundred francs. Some clever examples have recently been forwarded to us, and, if only the process had not been represented under "false colours," applications for it might well have been found. Those who forget the details of the process for the moment, will find them given in our Year-Book; but, briefly put, it consisted in producing a faint photograph upon salted paper, colouring this by hand, then albumenizing the surface, and once more printing it under the negative, this time more vigorously.

Those who are hawking the process abroad just now adopt a very ingenious plan. They produce the photograph after it has been coloured and printed a second time, but before it has been toned and fixed, and in this rough condition they exhort the photographer to do what he will with it. He may put it in his own toning and fixing bath and wash it thoroughly, so as to convince himself that the colouring is inherent to the picture. Finding in his own hands that the pigments do remain "fast," he begins to believe they really have been produced chemically or physically, and not unfrequently becomes a purchaser. Colours superposed by a photographic film in this way may, without doubt, be made to produce some charming effects, but whether it is worth while paying for this well-known fact is another question.

"I see him and her too!" was an excited old lady's remark as she came out of the crowd assembled on Saturday at the Crystal Palace to see the Prince and Princess of Wales pass; "and I'll tell you what is so singular," added the delighted dame, all aglow with enthusiasm, "he is so exactly like his photograph, too!"

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. V.—Second Lesson in Development.

In our last lesson we left the photographer at that stage where he had accomplished the exposure of a plate, and was about to commence the development. We should explain that the developer with which he is going to make his first experiment is that known as ferrous oxalate. When he has somewhat advanced, we should recommend him in all cases to use the exact developer recommended in the printed instructions contained in the plate-boxes. This will generally be that known as "alkaline pyrogallic," but the ferrous oxalate has the advantage of such extreme simplicity that it is most suitable for a beginner, and, mixed as we recommend it, is suitable for any commercial gelatine plates of which we have had experience.

The photographer has now, we shall suppose, returned to his dark room. He may lay his dark slide, still wrapped in the cloth, on a shelf, and, turning up the white light, make the following preparations. He lays his three flat dishes in a row along the front edge of the table, the one to the left opposite the red light, the others to the right of this one. We shall call the dishes Nos. 1, 2, and 3, beginning at the left. Into No. 2 he pours two or three ounces of the alum solution; into No. 3 about the same quantity of the "fixing" or "hyposulphite" solution. Now he takes the four-ounce measure, and pours into it exactly two ounces of the potassium oxalate solution. To this he adds half-an-ounce of the sulphate of iron solution. The whole will immediately assume a beautiful ruby red colour; to it he adds about 20 minims of the one per cent. solution of bromide of ammonium. He will now have about 2½ ounces of developer. This is an extravagant amount to use for a quarter-plate, and, if the photographer continues to use ferrous oxalate, he must reduce it to one-half; but at first it is best to use a good dose. Everything is now ready. The white light must be entirely extinguished, and the red light lowered as much as possible, till there is just enough to see by. The plate which has been exposed must be carefully removed from the dark-slide, and laid—film side upwards—in dish No. 1, which is still empty. Now the dish with the plate in it is taken in the right hand, and the measure with the developer in the left. The developer is poured rapidly, but gently, over the plate, the dish being waved or rocked to make the liquid cover any corner which it may incline to avoid, and the whole is placed again in front of the red light. And now (if everything has been rightly done) will commence one of the most wonderful of the phenomena of science or nature which man has been given the power to control—a phenomenon which is always new and always beautiful—the "development of the latent image." Let the beginner watch it closely. The plate had no indication of having been acted upon at all before the developer was poured over it. After, perhaps, ten or twenty seconds there is a slight darkening of some part. When this becomes distinctly visible the light may be somewhat raised, for the plate has become less easily affected by it. It will now probably be seen that the brighter parts of the landscape have become quite visible. In *negative*, be it remembered. The sky will be represented by blackness. Now is the time when we can tell whether or not the exposure has been correct. If it has been, the development will progress with beautiful regularity. The bright parts (or high-lights) appear first; then slowly, but steadily, more and more of the half tones, or less brightly lighted parts, come out; and at last every object and shade except the deepest shadows have their counterpart in the negative. In other words, the plate should be darkened to a greater or less extent in all parts except those few which represent the part of the landscape which appears to the eye quite black, and this should come about in between one and two minutes. If the plates have been under-exposed it will be longer before the high lights appear, and very soon after they do the action will stop, no more detail coming out, but large patches of the plate remaining white as before. If, on the other hand, it has been over-exposed, the high lights will appear a little sooner, and almost immediately afterwards the whole of the plate will be covered with detail, no part remaining white.

The final result of incorrect exposure is, with under-exposure, a hard picture with contrasts over-marked, and with deep heavy shadows in which none of the detail which is visible to the eye is represented; with over-exposure, a flat, uninteresting looking production, showing all the detail which there is in the original, but lacking the bold contrast of light and shade.

We shall suppose the happy medium to have been hit, if not at the first attempt, after a few more plates have been exposed. The development is not of necessity finished when, looking on the surface of the plate, all action seems to have ceased. We have still to wait till the "density" is sufficient.

A little reflection on the principles involved in the process of printing which we briefly described in a former lesson will show that not only is it necessary for the production of a harmonious picture to have all the details which are in the original represented, but in the negative these must be represented by a certain definite amount of opacity, or, as it is usually called, density. It must be understood, then, that as long as the plate lies in the developer, even after looking down upon it, all action seems to have stopped, the density continues to increase, and we may say at once that the most difficult thing of all to judge of in gelatine dry plate work is when the required density is gained. So difficult is this, that even the most experienced photographers may occasionally fail. The reason of this is that the after processes very much modify the apparent density of the negative, and not only that, but in every different make of plate the apparent density is modified to a different degree. We must make it appear far denser than it is eventually to be. It is only by experience that knowledge approaching to exactness can be gained on this point. When we come to the lesson on printing, we shall explain more fully the characteristics of an over dense, and a "thin" or under dense negative. Just now we will merely indicate the manner in which it is usual to judge of the density. The red light must be turned pretty high. The plate must be lifted from the developer and held, with the film side towards the observer, for a second only, close to the light, and between the light and the photographer. He must rapidly judge whether or not the density is correct. We may say roughly that, as a rule, the densest parts should appear almost, if not quite opaque. If they do not, the plate must be returned to the developer.

We shall suppose the correct density to have been gained. The time taken with the developer we have given will probably be from two to five minutes. The developer is now poured back into the measure. If used within an hour or so, one or two more plates may be developed with it. The plate is now thoroughly rinsed under the tap, either held in the hand or left in the flat dish. After this, as much red light may be admitted as is required. Then the plate is laid for five minutes in the alum solution, to harden the gelatine film. It is again thoroughly rinsed, and placed in the fixing solution. It will have been observed that up till this time the plate, looked at from the back, still appeared white. This is because the sensitive salt of silver which was not acted upon by light still remained in the film. On placing the plate in the hyposulphite, this whiteness will gradually vanish. When there is no farther appearance of it from the back, white light may be freely admitted. The plate must still be left a few minutes in the fixing solution, after which it must be most thoroughly washed. It should remain at least half-an-hour either under running water or in frequent changes of clean water. After that, it is reared up on edge to dry, when the negative is complete. Heat must on no account be used in drying.

DIRECT ENLARGEMENTS FROM SMALL NEGATIVES IN CARBON AND SILVER.

BY JOHN HARMER.

The great desirability of being able to obtain an enlargement direct from a small negative, either upon carbon tissue or albumenized paper, induces me to bring to the notice of my brethren an arrangement by which the chief difficulty arising from defects of light can be overcome in an inexpensive way, so that direct enlargements on the substances in question can be made without the sacrifice of too much time or attention. We all know that, hitherto the class of enlarging has been confined to those only who can afford to employ very expensive apparatus, and these appliances, even, are found in practice to be not always equal to supplying sufficient light for all classes of negatives, in consequence of the comparatively small size of the condenser the instruments are furnished with; and, although advances have been made in methods of enlarging by development, yet any photographer who can appreciate the delicacy and beauty of tone of carbon and albumenized paper will scarcely be satisfied with the bulk of the results by other processes. They may answer very well for the cheap and lowest class of club work, but give no pleasure to a photographer or *clientèle* endowed with a little more of the artistic faculty. When many copies of one subject are required, it is undoubtedly better to proceed in the usual way by transparency and enlarged negative. The production, however, of single copies by this somewhat roundabout method introduces a serious item of cost which places such a superior kind of picture beyond the reach of a large class of purchasers who appreciate and desire the better article, but who are not always prepared to pay the greatly advanced price, and consequently prefer to remain unserved. This represents a large monetary loss to the profession. Apart from these considerations, it is tolerably certain that all photographers who care anything about the future reputation of their art, and are not wholly absorbed in getting cash, are agreed that any effort to supersede the fugitive and unlovely productions too often sent out is not energy thrown away.

Some years ago I was employed by a firm who had received a commission to print a series of enlarged transparencies from small and highly non-actinic negatives by a dry plate process, whose chief features consisted in these qualities; one of the conditions of the contract being that they should be very warm in tone, a few stereoscopic transparencies of very rich colour having been left as a criterion as to what was required. In those days the secret of success in this respect consisted in making the positives on collodio-albumen plates by contact or by the wet process in the camera with a well-iodized collodion and a quick exposure. Warm tones from "paving stones" by either of the above methods appeared to be entirely beyond one's power, unless some superior method of illuminating the negative were resorted to. The condensing lens being found wanting, mirrors were suggested, and afterwards successfully used in such a way that if the sunlight reflected from one proved sufficient, their number might be increased to any extent short of fusing the glass upon which the reflections of the series were received. From six to ten of these sufficed for the purpose, and were arranged and used as follows. In the north side of the studio a couple of square feet or so of finely-ground glass was inserted, to which the front of the copying camera holding the negative was directed, with about a yard intervening; and opposite to this, on some rising ground in the garden, were placed the requisite number of plain mirrors rigged up on stands so that a boy could easily keep the beam of sunlight from each upon the glass in front of him, the efficiency of the arrangement being such that no trouble was experienced on the score of exposure, for that was reduced to seconds with the employment of a very small top.

A series of these plane mirrors, each of about a foot square, and mounted by means of a ball-and-socket joint, at a little distance from a slightly concave frame, to admit of adjustment for direction, would, in fact, represent a large flexible concave mirror, having the great advantage for the purpose in view of being composed of facets, each giving its square beam of sunlight. The illumination from the whole is more equally diffused over the square, and quite under command with its power, capable of modification to suit the requirements for thin or dense negatives, as well as their degree of amplification, a slight alteration of the angle of any reflector being sufficient to throw its reflection out or into the focus of the other, a variation not possible with a mirror of continuous curve.

The open space necessary for its employment need not be large, especially in summer time, provided it were not of very great size and power; and as its uses are many—for, besides the special one of enlarging, its concentrated beam directed upon ground glass in front of very dense negatives, in the course of their printing on lightly-salted paper, would tend to soften the print; while, on the other hand, the most could be made of a thin negative in getting a more vigorous transparency in carbon tissue. Therefore, one would feel more justified in incurring the expense of its construction.

The other details connected with the enlarging are as usual, excepting that the easel or frame for carrying the sensitive surface must be fitted with thin plate glass, and means for applying slight pressure to ensure the tissue being kept flat and in place during exposure.

Nothing need be said respecting the requisite time for albumenized paper—that being judged by inspection during printing; but in the case of tissue it is otherwise. Great help, however, can be obtained in practice by noting how many tints the small negative requires in the sun, and then preserving a similar relationship between the number of times a negative is enlarged superficially and the number for reflectors in the "battery." A few trials will give the ratio of the value of the one to the other, and what allowances are to be made for the loss of light by reflection, and in passage through stopped lens and ground glass, the actinometer, of course, being still made use of in the circle of illumination at the edges of the sensitive surface to indicate and register the tints. Vignetting, stopping back any portion, and a great many of the usual dodges resorted to by the successful printer, can be almost as readily performed as when the printing-frame and large negative are employed. The use of an easily-fitting yellow glass cap with the lens will admit of the substitution of an accessory negative for the other, and its adjustment on the sensitive surface, or to a sketched outline of the first negative—if the printing be in carbon—to be effected with little trouble; softening of the edges of any portion or production of atmospheric effect being equally easy.

THE NEGATIVE NITRATE BATH—ITS PREPARATION AND TREATMENT.

When used with the bromo-iodized collodion of the present day, the preparation of the nitrate of silver bath is one of the simplest in practical chemistry, for it merely consists in dissolving pure nitrate of silver in pure water and imparting to it a slightly acid reaction, when, without any other preparation whatever, pictures of the highest class may be taken.

But while the above constitutes a negative bath, there are certain niceties involved in its preparation, which all tend to facilitate the production of, and decrease the chances of failure to do good work. Again, by the very act of using a silver bath it becomes contaminated with foreign matter by which its working becomes impaired; and to render the present article as complete as possible, we shall treat *seriatim* the several components of the bath, together with the disorganizations by which its working becomes affected after having been for any length of time in use.

The water ought to be distilled. In this way only can we be certain that it is free from inorganic bodies. Concerning the elimination of organic compounds by distillation, we prefer not to speak with so much certainty, for while organic bodies ought to be removed by distillation, we know in practice that much of this form of impurity is to be found in distilled water, which is sometimes contaminated from such an apparently simple cause as the steam coming in contact with a joint of one of the boiler fittings in which the surface may have been slightly greasy. Attention is here directed to this because on one occasion a silver bath composed of a very fine sample of nitrate of silver in distilled water gave foggy pictures, which evil was traced to the water.

There is a simple and effective test for the presence of organic matter in water, whether it be common or distilled. Into a clear glass bottle pour the water to be tested, and to this add one or two drops of a solution of permanganate of potash, which solution need not be strong. Instantly the water assumes a delicate and beautiful pink colour, which remains unchanged if the water be pure; but if it contain organic matter the pink colour disappears, the rapidity with which it does so depending upon the amount of organic matter present. Now, while pure distilled water is always to be preferred for making a silver bath, it is not always easy to be obtained. A good substitute is to be found in melted ice or clean rain water which has not been allowed to trickle down the dirty roof of a house or to remain in a water barrel till it has imbibed innumerable kinds of impurity. There are two kinds of inorganic impurities frequently to be met with in common water—chlorides and carbonates. The latter usually assumes the form of lime, which may to a large extent be got rid of by boiling the water, by which the carbonic acid is liberated and the lime precipitated, a fact realised by every good housewife when she looks inside her tea kettle and notices how it is incrusted. When chlorides are present in water the best way is just to allow them to work their own work on the silver after it is added, and a few grains only of which will be lost in the purifying process.

Now, then, having before us two bottles, one containing distilled water of absolute purity, and the other filled with plain water obtained from any source, such as the rain tank, the river, or the lake, but which has been boiled, we shall proceed to make two baths. Notice the points of difference in their behaviour, and see if that from the impure water can be made to rival the excellences of the other.

In each ounce of water dissolve thirty-five grains of nitrate of silver. If the water be pure, the solution will be quite transparent; if it contain chlorides, it will be slightly milky. Now, as a solution of nitrate of silver possesses the property of dissolving a little iodide of silver, and as iodide of silver is formed in the collodion film when a plate is immersed in the bath, it is plain that the first one or two plates immersed would suffer by the solvent action of the bath, to prevent which it is customary to saturate the bath with iodide of silver at the start. This may be done by one or the other of the two following methods. Coat a plate pretty thickly with collodion, and allow it to remain immersed in the bath for about an hour. The iodide at first formed will be eaten out by the liquid. This may be repeated a second time, although it will scarcely be found necessary in practice to do so. Another way is to form iodide of silver by mixing together solutions of nitrate of silver and iodide of potassium in their combining proportions (170) of the former to 166 of the latter, or, for the present purpose, about equal weights of each, when a deposit takes place which, after being washed, is added to the silver bath and shaken well up. The portion that is not dissolved falls to the bottom. As a strong solution of nitrate of silver dissolves more iodide than a weak one, some prefer iodizing the bath when in a concentrated or strong solution, say sixty to eighty grains per ounce, and then, after saturating it, adding water to reduce it to the proper strength, by which addition all excess of iodide is precipitated. Every one to his taste; it is all the same in the end. The object to be attained is the preventing of the bath dissolving the iodide from the plates after the bath is in working order. It is proper to observe here that it is not necessary to iodize a bath in order to obtain a negative, for if a plate be removed before the solvent action commences, a good negative will be obtained; but one does not care to have to stand by a bath while a plate is immersed, and take it out just at the precise time; hence the convenience of the iodizing process.

The addition of one or two drops of nitric acid may now be made, so as to gently redden litmus paper; and, after filtering, the bath is ready for trial, or, we should say, both baths, for we have supposed two to be made, one from pure and the other from impure water.

Now, it is possible that the impurities in the water may be of such a nature as not to interfere in the slightest degree with its producing good negatives, and if this, upon trial, prove to be the case, nothing must be done to it. But if, as may possibly be the case, the shadows are clouded by a foggy haze arising from the organic matter, the following treatment should be resorted to. Add to the bath either a pinch of oxide of silver, or, by preference, a few drops of a weak solution of bi-carbonate of soda, to neutralize the nitric acid that was previously added, and when by this addition the bath assumes a slightly opaline appearance, let it stand exposed to the sun's rays for a few hours. It will at first darken, but, as the organic matter precipitates, the liquid will clear again, after which it is once more acidified, and will be found in splendid working order.

In order to allow the sun to perform (at any stage in the bath's subsequent history) the part of purifier, it is important that the liquid be brought to a state of neutrality or even to alkalinity. To effect this there is nothing more safe or excellent than a weak solution of bicarbonate of soda.

When, in course of long working, something is found to be wrong by the plates being full of pinholes, uneven, streaky, or deficient in sensitiveness, and this hitch is known not to arise from the collodion, give the bath the following course of treatment. If there be pinholes in the pictures, add about a fourth of its bulk of plain water. The probability is that there will be a slight yellow-coloured opalescence produced, caused by the liberation of iodide of silver. Remove this by filtering, and then, but not till then, add crystals of nitrate of silver, to bring up to the original strength of thirty-five grains per ounce. Pinholes are occasioned by the formation of a double salt of silver in the film (the iodo-nitrate), and this double salt is formed only when the silver bath is very fully charged with iodide; hence the value of the removal of a portion. It is also well recognized by many that by a solution of barytes to a bath that gives pinholes, this tendency is removed. In what way it acts upon the iodo-nitrate is not yet well understood. The strength and quantity of the solution to be added must depend upon the aggravated nature of the evil which it is desired to remedy; but a bath will bear a goodly quantity without showing indications of suffering from a surplus.

For remedying fogging, streaks, or stains, first reduce the bath to a state of neutrality by the bi-carbonate of soda, then place in the sun for one or two days, to get rid of the organic matter arising from the ether and alcohol of the collodionized plates. On one occasion, a bath of about a gallon was behaving in a very bad manner. It was neutralized and divided into two portions, one of which was exposed to sunlight for two days, the other having been placed in an earthenware vessel, and subjected to boiling heat for half-an-hour, followed by sunning for two or three hours. Both portions worked equally well after such treatment.

The addition of a few drops of a solution of cyanide of potassium has been known to restore to perfect working order a bath which was believed to be hopelessly bad. In what way the cyanide acts is not well understood; but too many instances of its beneficial action are on record, to permit the fact of its curative functions, under certain conditions, being doubted.

It should be borne in mind that, with the immersion of every plate in the bath, a portion of silver is abstracted, and that a few crystals of the nitrate should be added from time to time to keep the solution up to a proper degree of strength.

But it is possible to produce negatives of a high degree of excellence even from a bath of the worst possible description. In order to understand how this can be so, it is requisite to observe that the function of the bath is of a two-fold nature: it forms the iodide of silver, which is the sensitive material in the collodion film, and it also supplies the free nitrate of silver which is deposited by the iron developer to form the images; and we have found by many trials that the quality of such image is dependent not upon the quality of the nitrate bath by which the plate was made sensitive, but upon that which remains after such sensitizing has been effected. When a photographer has got a large bath which behaves in a reprehensible manner, and which it is not expedient for him to subject to a proper remedial course of treatment, let him use it for sensitising his plates; but let him have a second bath much weaker than the other, and composed of materials in good condition, into which the plate, after being sensitized, is removed and allowed to remain for about half a minute before being exposed. The result shows that the evils that would be attendant upon the preparation of the plate by the first bath exclusively have quite disappeared. It remains for the photographer to make practical application of this fact.

Sometimes, after a long career of useful work, a bath gets into such a chronically bad state as to defy medicine. One who has plenty of time at his command, and is fond of experimenting, may pour the solution into an evaporating dish, expose to heat to drive off the water, and after that fuse so as to get rid of all those impurities that fly before the action of heat. Bad baths may in this way be converted into good ones; but when it is considered that refiners give the full value, either in currency or new crystals, of the silver contained in old baths, quite irrespective of the working condition in which they happen to be, the reader may conclude that there is a stage in the history of a nitrate bath in which it is economy not to waste time over its restoration to primitive excellence.—*The Photographic Times.*

MR. MUYBRIDGE'S PHOTOGRAPHS OF ANIMALS IN MOTION.

The following, from the pen of Mr. W. B. Tegetmeier, appears in the *Field*:—

It may be in the recollection of some of the readers of the *Field*, that in No. 1383, which was published on June 28, 1879, I reproduced eleven instantaneous photographs of a racehorse, which were taken in rapid succession during a single stride of the animal. The very ingenious apparatus by which these photographs were obtained was designed by Mr. Muybridge, of California. In the interval between that date and the present time, Mr. Muybridge has so far improved the arrangements of his cameras, that he has succeeded in taking more than twenty consecutive photographs of a racehorse, from the commencement to the termination of a single stride. This is done by placing a series of cameras twelve inches apart along one side of the track over which the horse passes. As the animal comes in front of each camera he breaks a thread; this releases an electric arrangement by which a narrow opening is rapidly pulled across the lens, which is exposed for an infinitesimally short period of time, each photograph thus obtained showing the exact action and position of the horse when opposite the camera. This ingenious arrangement has been used to obtain photographs of the horse in every pace, namely, the walk, slow and fast trots, canter, and amble, as well as the gallop, and also when in the act of leaping over hurdles.

When seen single, these photographs of many of the paces, more particularly those which are rapid, are strongly opposed to the usual conventional drawings of horses in motion; but when they are placed in an optical instrument, designed by Mr. Muybridge, and by means of an electric light their shadows are thrown in rapid succession on a large screen, the exact natural movements are reproduced in a manner which is truly marvellous; and as the pace may, so to speak, be "slowed" so as to admit of more easy observation, a high degree of interest attaches to the exhibition, inasmuch as every movement of the gallop, walk, or other paces can be traced.

In a similar manner Mr. Muybridge has reproduced the walk trot, and gallop of the ox, the deer, and other animals. The representations of a greyhound in rapid motion are most interesting, as also are the exact reproductions of a professional walker exerting himself to the utmost, and of athletes running, wrestling, leaping, &c.

Mr. Muybridge has given an exhibition of these moving instantaneous pictures before H.R.H. the Prince of Wales, and also before the members of the Royal Academy; but, unfortunately, no arrangement has hitherto been made by which they are accessible to the public at large. In Paris they were viewed with great interest by Professor Marey, the highest living authority on the movements of animals.

These investigations respecting the paces of animals have a practical and artistic bearing of so important a character, that I hope Mr. Muybridge may be induced to carry them out to a further extent in this country. I should much like to see the arrangements for taking these instantaneous photographs erected in England, and feel convinced that much valuable information respecting the paces and action of our horses could be gained by this means, not to speak of the great interest these correct delineations possess when considered from an artistic point of view.

THE PHOTOGRAPHIC SPECTRUM OF THE GREAT NEBULA IN ORION.*

Last evening (March 7) I succeeded in obtaining a photograph of the spectrum of the great nebula in Orion, extending from a little below F to beyond M in the ultra-violet.

The same spectroscope and special arrangements, attached to the 18-inch Cassegrain telescope with metallic speculum belonging to the Royal Society, were employed which have been described in my paper on "The Photographic Spectra of Stars" (*Phil. Trans.*, 1880, p. 672).

The exposure was limited by the coming up of clouds to forty-five minutes. The opening of the slit was made wider than during my work on the stars.

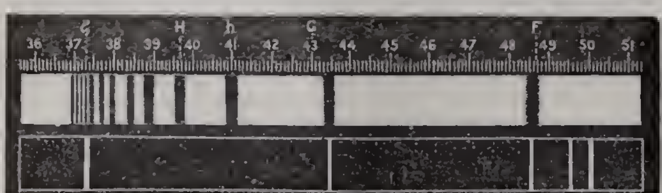
The photographic plate shows a spectrum of bright lines, and also a narrower continuous spectrum which I think must be due to stellar light. The bright stars forming the trapezium in the "fish's mouth" of the nebula were kept close to the side of the slit, so that the light from the adjacent brightest part of the nebula might enter the slit.

Outside this stronger continuous spectrum I suspect an exceedingly faint trace of a continuous spectrum. In the diagram which accompanies this paper the spectrum of bright lines only is shown, which is certainly due to the light of the nebula.

In my papers on the visible spectrum of the nebula in Orion, and other nebulæ (*Phil. Trans.*, 1864, p. 437, and 1868, p. 540; also *Proc.* Roy. Soc., 1865, p. 39, and 1872, p. 380), I found four bright lines. The brightest line, wave-length 5005, is coincident with the less refrangible component of the double line which is strongest in the spectrum of nitrogen. The second line has a wave-length of 4957 on Augstrom's scale. The other two lines are coincident with two lines of hydrogen, $H\beta$ or F, and $H\gamma$ near G.

In the photograph, these lines which had been observed in the visible spectrum are faint, but can be satisfactorily recognised and measured. In addition to these known lines, the photograph shows a relatively strong line in the ultra-violet, which has a wave-length 3730, or nearly so. The wide slit does not permit of quite the same accuracy of determination of position as was possible in the case of the spectra of stars. For the same reason, I cannot be certain whether this new line is really single, or is double or multiple. In the diagram the line is represented broad, to indicate its relative great intensity.

This line appears to correspond to ζ of the typical spectrum of white stars (*Phil. Trans.*, 1880, p. 677). In these stars the line is less strong than the hydrogen line near G; but in the nebula, it is much more intense than $H\gamma$.



In the nebula, the hydrogen lines F and $H\gamma$ are thin and defined, while in the white stars they are broad, and winged at the edges. The typical spectrum has been added, for the sake of comparison, to the diagram.

I cannot say positively that the lines of hydrogen between $H\gamma$ and the line at 3730 are absent. If they exist in the spectrum of the nebula, they must be relatively very feeble. I suspect, indeed, some very faint lines at this part of the spectrum, and possibly beyond λ 3730, but I am not certain of their presence. I hope, by longer exposures and with more sensitive plates, to obtain information on this and other points. It is, perhaps, not too much to hope that the further knowledge of the spectrum of the nebulæ afforded us by photography may lead, by the help of terrestrial experiments, to more definite information as to the state of things existing in those bodies.

Correspondence.

THE PHOTOGRAPHIC CLUB.

Dear Sir,—An advertisement has appeared in the Photographic News calling photographers together to form a new society under the sham name of a club. The reason given for doing so is, that "the existing Photographic Club does not meet the requirements of the art, more especially in not reporting their proceedings." In this elegant diction is the reason expressed. The fact is, that the Photographic Club has refused to adopt any innovation which would be calculated to interfere with the functions of already existing societies, and wishes to retain the true club element. The proceedings of the Photographic Club are of a social and informal character, incubating, so to speak, material that will eventually produce topics for discussion in the existing channels; and I am induced to say this much, as the character of the advertisement alluded to is, to say the least of it, misleading, and may prejudice those who have meditated joining the Photographic Club.—I am, dear sir, yours truly,

C. Dunmore.

PROOFS AND RE-SITTINGS.

Sir,—As this question is a subject of considerable importance to the profession, it may not be altogether waste time if further thought is devoted to it. Naturally, every one must please himself as to the rule to be adopted, and locality and circumstances very materially alter the practicability of any plan.

My object in writing is more particularly to point out that photographers generally, not being good business men, look at this subject photographically, rather than commercially. I presume that the chief aim and desire of all professional photographers is to make money. Proofs, numerous or limited, finished or untoned, are only a means to serve this end.

Then the question of how the proofs shall be issued, what time and expense may be incurred, must always depend upon the price charged, and not upon an uncertain order that may eventually be obtained from the customer. The deficiency of one sitter might be counterbalanced by the profits on a more reasonable client; but even this is unjust, as every sitter ought to pay a fair percentage upon capital and labour.

My opinion is that 70 per cent. of average photographers have no idea as to what their photographs actually cost, and that by many transactions they really lose money, although they think they are gaining it. A rough estimate of cost of materials, with the crudest notions on the actual cost of skilled labour, is the most they arrive at. I remember one studio particularly, in a good business town, where the cost of labour was so out of proportion to the amount of work issued, that it was a financial impossibility for it to succeed, and yet that business should have been a lucrative one.

Finished proofs and re-sittings helped to make sufficient to keep every one employed, although the labour from *bona fide* sitters (I mean without profitless re-sits), might easily have been performed at much less cost.

Notice what "A Bond Street House," writes, about proofs "of no value intrinsically," although to "send them liberally" means time expended by operator, retoucher, printer, and mounter. Although "A doctor or barrister" does not charge for paper, any one of experience knows that the clerk's or dispenser's time is not forgotten in their fees.

Those firms who always demand one guinea as price of "sitting," can afford finished proofs (although I know a firm of this kind, with eight or ten studios, who always send untoned ones); but, with a medium-class establishment, at 10s. 6d. per dozen C.D.V.'s, for two positions, finished proofs are a serious expense.

If good dry-plate negatives, carefully retouched, with finished proofs, are sent out, and no charge made for re-sittings, I consider the proprietor must lose by every re-sitting, if really artistic work is the rule, and skilled labour employed.

Of course the photographer may reduce his cost of production should he do most of the work himself, and place a low rate of value upon his own time.

Our own arrangement is to send out slightly retouched but untoned and unmounted proofs for selection, with printed instructions for their return, and 2s. 6d. extra is charged should another sitting be desired.

I take the question as a purely commercial one, and if these terms are not attainable, I prefer to be without a profitless customer.

With every reasonable endeavour to keep pace with the times, turn out good work, and give universal satisfaction to clients, I always resist any transaction which does not promise to be fairly remunerative.

In estimating expenses, remember always that as a commercial speculation the proprietor is not necessarily the operator, and skilled labour must thus be added to cost of materials. GERMANICUS.

ADDING IODIDE AND CHLORIDE TO GELATINE EMULSION.

SIR,—I have tried the plan given in the NEWS last week, of adding iodide to the emulsion, and it is certainly a very simple one; in fact, I succeeded at the first attempt. Any one who has a dipping-bath still on the premises (and there are few who have not, I suppose, even among amateurs, like myself) will find the process answer. I put the scrapings from my collodion plate, after dissolving them, into the emulsion, before it had well cooled, and then straightway filtered; so that I do not think that the whole process of emulsion making took me much more than an hour. There is not, I think, any other way of making an iodo-bromide emulsion so quickly. Mind, I do not think that an emulsion with iodide or chloride—the latter, I find, gives most brilliancy and density—is always to be recommended. The little I added did accentuate the shadows most decidedly, as you say; but this is not always wanted. If great softness and detail are required, I think pure bromide is better. I send you some prints, which will make more clear what I say.—Yours faithfully,

J. HARTWIG.

INCANDESCENT LAMPS IN THE DARK ROOM.

DEAR SIR,—I have been making some experiments this week with one of the small incandescent lamps of Swan, for the purpose of illuminating the dark-room. So far as the light is concerned, it has been perfectly successful; the only troublesome thing is the battery power required. I use three of Bunsen's quart batteries; these give a very good and steady light for several hours, but I have not had sufficient experience as yet to determine how long they last without renewing the acids. The zinc plates should be kept well amalgamated, then they are tolerably durable. There can be no question of the very great advantages of having such a light in the dark-room where gelatine plates are prepared and developed. Besides its coolness over gas-light, we have the very great advantage of being able to cover or uncover, with a non-actinic shade, in an instant the light, so we can have at will a white or coloured medium with no trouble. This cannot so easily be effected with gas.

I am sorry I cannot give your readers more practical information, but no doubt, now attention is called to this subject, there are many who have had considerable experience in the use of the various batteries, and can make some useful suggestion. What is wanted is a permanent battery that would not often require renewal. There are, I think, such, but perhaps they are not of sufficient power to give a good light; but for the operating room a powerful light is not required.—I remain, dear sir, yours truly,

W. ENGLAND.

THE PHOTOGRAPHERS' ASSOCIATION OF AMERICA.

DEAR SIR,—At the request of the Executive Committee, and Joshua Smith, Esq., of Chicago, President of the Photographers' Association of America, I desire to extend through your columns a cordial and urgent invitation to the photographers of Great Britain to join us in our next Annual Convention, at Indianapolis, Ind., during the second week of next August.

Though we can scarcely hope for a personal presence we will be highly pleased to receive exhibits of photographic work from all who can find it convenient to send.

We would also like to receive stereopticon slides (portrait studies), or papers on topics interesting to the profession. Our Annual Conventions are largely attended. We have exhibits and exhibitors from every state in the Union, from Mexico, and Canada. Many photographers travel thousands of miles to be there. We can assure you that anything that may be sent to us from England will receive much attention, and greatly add to the interest of the occasion.

We are particularly desirous to see work made from the dry plate. The English dry plate has an enviable reputation, and American photographers would like very much an opportunity to compare them with their own.

We would suggest that for the sake of economy and ease in transportation, photographs may be sent in parcel shape.

The Committee appointed for the purpose will arrange them carefully in specially prepared cases.

The name of the maker of the plates, together with the time of exposure and name of lens, should be enclosed.

Exhibits will be returned, every care being taken to preserve them from injury.

Communications should be addressed to Joshua Smith, Esq., 206, North Clark Street, Chicago, President P. A. A.

Exhibits will be addressed, John Cadwalader, Esq., Indianapolis, Ind., Sec.—Yours truly, A. E. DUMBLE.

Rochester, N. Y.

Proceedings of Societies.

THURSDAY EVENINGS FOR PHOTOGRAPHERS.

AT the meeting held on the 23rd inst., Mr. C. G. COLLINS in the chair,

Mr. A. J. BROWN produced some plates prepared with chloride emulsion, which were from two separate emulsions, one prepared with chloride of sodium, and the other chloride ammonium; they were coated at the same time, exposed the same time, and developed side by side. The sodium image appeared first, but the ammonium plate quickly caught it up; and the results of his experiments were in favour of the ammonium, as being better and more sensitive. The plates were developed with Eder's formula, *i.e.*, ammonia and acetic acid in equal proportions, ½ an ounce, and water 1½ ounces.

Mr. BROWN thought that wood blocks for engraving purposes should not be wetted in any way.

The CHAIRMAN thought that the uranium was the best process for the purpose, and that there should not be a film of any kind, as it would be liable to chip under the graver.

Mr. HENDERSON passed round some specimens of etching of porcelain, which were prepared by depositing platinum on the image, then firing, the platinum acting as a glue, and sinking into the plate. They were then treated with fluoric acid, which dissolved out the image, and left a relief print.

Mr. MACKIE said that, having noticed lately in one of the photographic journals a method of increasing the sensitiveness of gelatine plates by treating with an alcoholic solution of potash, he had experimented, and could detect no difference.

Mr. CUTCHEY said he found the best and most reliable method of intensifying was, after well soaking the plate in water, and flooding it with a sherry-coloured solution of iodine, to again well wash, and treat with Wratten's formula.

Mr. OLDHAM (of Grahamstown, Cape Colony) gave an interesting account of the progress of photography in South Africa, and the difficulties encountered with the gelatine emulsion process, owing to the extreme heat of the climate; they were compelled to import plates from England (the cost of which by the time they arrived was about doubled), and their greatest enemy was frilling.

Mr. Cutchey, the chairman of the committee appointed to arrange for the ball, &c., in aid of the funds of the Photographic Benevolent Association, announced that the entertainment would take place at Seyd's Hotel, Finsbury Square, on Thursday, April 27.

Talk in the Studio.

Photographic Society of Great Britain.—The next ordinary meeting of this Society will take place on Tuesday, April 4th, at 8 p.m., in the Gallery, 5a, Pall Mall East, when a paper, "Some Remarks on the Sensitiveness of Gelatiue Plates," will be read by Captain Abney, R.E., F.R.S.

South London Photographic Society.—The next monthly meetiug of this Society will be held on Thursday next, April 6th, at 8 p.m., in the rooms on the Society of Arts, Adelphi. Mr. B. J. Edwards will read a paper upon "Gelatino-Chloride Pictures by Developmeut." Mr. Edwards will also develop some pictures, aud explain the process. Mr. G. F. Williams will show an Electric Instantaneous Shutter with Pocket Battery.

Mr. Muybridge's Instantaneous Pictures.—It is arranged for Mr. Muybridge to deliver a lecture on his now celebrated results, before the Society of Arts, on Tuesday next, the 4th April, at 8 o'clock p.m.

Electric Light in the Developing Room.—The incandesceut electric lamp for dark room use has already been adopted by several photographers. The best lamp for the purpose at present in the market is uudoubtedly Swan's two-candle carbon lamp. This requires three cells of Bunsen's, or the bichromate battery, aud is about the same size and price as the platinum lamp already alluded to. A photographer of our acquaintauce, to light up his outside show frame, proposes a couple of these miniature electric lamps placed inside. Here, then, is an application of the electric light under circumstances which would render gas quite inadmissable. Mr. Paterson, of 76, Little Britain, has just introduced into the market a portable arrangement, consisting of five cells of bichromate battery, and a five-candle Swan lamp; the whole beiug so compact as to be readily carried from place to place. We shall treat of this subject in detail shortly.

Some Chemical and Physical Effects of Light.—Interesting investigatious have been made by Lemoine, who finds that both sulphur and phosphorus are isomerized, while styrolene is rapidly changed into meta-styrolene. Chloral is polymerized and partially decomposed at the same time; and even acetylene undergoes condensation when long exposed to the action of light; while perfectly pure turpentine and cyanogen are unchaugcd. Gaseous hydriodic acid is decomposed, but its aqueous solution resists the action of light; and the same remark applies to a solution of silver-chloride in ammonia. Most of these chauges are effected to some extent by the red rays, although the violet rays are much more active.

Colours on the Retina.—It is related by MM. Macé de Lepinay and Nicati (*Jour. de Phys.*), that, after a mountaiu excursion, and five hours among snow-fields, one of them found all artificial lights in town—candles and oil lamps—to appear distinctly green, the effect lasting from 7·30 to 11 p.m. This case of temporary daltonism for red is attributed to the fatigue of the retina for red persisting much longer than that for other colours. The authors describe a simple experiment by which this persistence may be verified. Three coloured glasses are taken—red, green, and blue—which, with average illumination, all bring the visual acuteness to about the same value. Having nearly shut the shutters, and placed himself a few yards from a white board with printed letters of different sizes on it, the observer finds that, at the first, he can, with the blue glass, make out pretty distinctly the letters of medium size; whereas, with the red glass, the visual acuteness is so much reduced, that he cannot even distinguish the board. But, if the darkness be continued, he observes that, whereas the visual acuteness does not sensibly iucrease with the blue glass, he is presently able, with the red, to make out, first the board, aud then the largest letters. The visual acuteuess in the latter case increases, at first quickly, then more slowly, for half-an-hour, when it becomes nearly stationary. Green glass gives results intermediate between the others. It is important to remark that, in all cases, even after an hour and a-half, the visual acuteness with the red glass remains considerably less than with the blue.—*Nature.*

To Correspondents.

*** We cannot undertake to return rejected communications.

*** Our publishers desire us to call the notice of advertisers to the fact that, next Friday being Good Friday, the News will be published on Thursday moruing.

*** Erratum.—By a silly printer's error we were made to call "hydrofluoric" acid, hydrochloric acid in one of our "Notes" last week.

W. Richardson.—Return to your old system if you wish to produce the best results; the short cut is useful when quality of work may be sacrificed to convenience.

H. D.—1. Add benzole. 2. If you are really anxious to convert it into something photographic, you might, perhaps make it into a drying cupboard, a plate box, or a retouching desk; but you would probably spend more time than if these articles were commenced from the beginning, and it is quite possible they might not prove so convenient as the usual things.

H. Baker.—Such pictures are ordinarily silver prints, and we cannot give you full directions here for carrying out the process; but you will do well to study "Silver Printing," a new work which has been written on the subject by Captain Abney and Mr. H. P. Robinson.

Leo.—1. No arrangement can be better adapted for the purpose than that which you sketch. Use one of your ordinary cameras fastened up as shown in the diagram. 2. In many cases a portrait combination will answer well, and in others you may employ a symmetrical or rectilinear.

A. Read.—If you want the best results possible, it will be advisable to make enlarged negatives and to print from them. Excellent results may be obtained either with a carbon or a gelatino-bromide transparency.

C. A. M. W.—It is not at all likely that auy mischief will arise from the use of the india-rubber sheet if placed as you propose.

G. B.—1. You will find an article on the subject on page 2 of our present volume. 2. The method you suggest is not practicable.

C. Jackson.—1. Yes. 2. Soak a pound of glue in water until it becomes quite soft, then melt by heat and stir in half an ounce of potassium bichromate. 3. It would not prove very satisfactory.

Alpha.—We could not give you useful information in this column, but we will give a detailed description of tho method of working the process before long.

Alfred Newton.—See the "At Home" in onr issue of last week.

F. C. M.—At No. 3, Cheapside, London.

Swan Light.—13, Mosley Street, Newcastle-on-Tyne.

Dr. Ed. Liesegang.—Thank you for the books, which shall be noticed at the first opportunity.

Toner.—1. The addition of glycerine to the albumen is hardly desirable under the circumstances, but if any is used, the proportion should not exceed 2½ to 3 per cent. 2. Increased brilliancy and depth is the result. 3. A consequence of dampness, the presence of glycerine no doubt rendering the paper more difficult to dry. 4. As far as we remember, it was in the early part of 1862, or the latter portion of the previous year. 5. Such expedients, although recommended on the score of economy, are really expensive, as the quality of the work invariably suffers. 6 The solution of oxide of silver in nitrate of ammonia has been used with the greatest success by one well-known printer whom we could mention. It is prepared by dissolving 3 parts of pure nitrate of ammonium in 10 parts of water, and then adding an excess of freshly-washed and moist oxide of silver, the clear liquid being poured off for use as required. The oxide of silver is best prepared by dissolving one ounce of silver nitrate in 10 ounces of water, and adding caustic potash solution (liquor potassæ) until no further precipitation takes place. Several washings by decantation are required to remove all traces of soluble matter, after which the silver oxide should be collected on a filter and preserved in a moist state. About ten drops of nitric acid may be added to each pint of the sensitizing solution, and the paper only requires to be floated on it for a short period. Fuming is desirable. 7. Rest assured that we never feel annoyed when a correspondent asks numerous questions; and pray do not hesitate to send us the remainder.

T. C. H. (Thames Ditton).—Though not a strictly scientific way of putting the case, it is so common that to use exact and circumstantial language would look almost like pedantry.

Albumen.—Dissolve five grains of citric acid in a drachm of water, and mix this with a pint of your old bath; after which ammonia must be added until the solution is slightly alkaline. Next filter, render the liquid feebly acid with nitric acid, and evaporate until the required strength is reached, or make up the strength with fresh nitrate of silver.

Indignant.—There can be no doubt that a gross fraud has been attempted; but if you do as proposed, you will probably have to answer an indictment or a suit for libel.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1231.—*April* 6, 1882.

CONTENTS.

ARRANGEMENTS FOR OUT-DOOR WORK.

The bright spring weather having come upon us rather early this year, very many who intended to have all their landscape apparatus in working trim have doubtless found themselves forstalled by the bright sunshine, and light, rapidly-moving clouds of the spring time. Few will care to work the wet collodion process in the field now-a-days, although it seems but yesterday since we rode out on a tricycle, taking with us a set for whole plates, the tent folding up like a portfolio; and the fixing and intensification being allowed to stand over until our return.

As regards practical convenience, there can be but little doubt that the most convenient method of working is to carry a sufficient number of double dark slides; but the price ordinarily charged for double backs is so high as to frequently prevent the purchase of a sufficient number for a fair day's work. Next in order come changing boxes, complex pieces of cabinet work which appear strikingly easy to use when examined in the shop of the vendor, but he who carries one into the field is fortunate if he escape the combined efforts of damp to swell the wood, grit to prevent the smooth working of the sliding parts, heat to open joints or distort the wood work, and of badly-cut plates to put the whole system out of gear. In addition to these, he is not unlikely to fail unless he guard against the entry of light, by enclosing the box and slide in a dark cloth or bag when he shifts a plate; and this circumstance is calculated to increase the tendency to mistakes as to the order of exposure, especially when the bystanders are keeping up a continual volley of chaff regarding his strange movements.

A simple bag of black cloth provided with a large opening for the slide and plate-box, and two sleeves for the arms, will serve very well, and after a little practice it becomes very easy to change the plates from the slide to the box, and *vice versa*, without any assistance from the sense of seeing. In such a case it is convenient to have a separate box for the exposed plates; and if they are regarded as bearing numbers corresponding to the order in which they are placed, all confusion will be avoided.

When slides are used, it is necessary to take some precaution against double exposures, and we are inclined to consider that the best method is to employ slips of thin gummed paper, about the twentieth of an inch broad at the middle, and spreading out towards each end like the section of an hour glass. One of these is attached to the lower part of each shutter, so as to bond it with the frame of the slide, and when the shutter is withdrawn the narrow strip is ruptured.

An ordinary portable bellows camera is, considering everything, the most convenient. As regards size, little is to be said; this being a matter for the consideration of each individual photographer. We may, however, mention that in the case of a whole-plate camera which we recently had made, it was found of considerable advantage to provide an adapter, by which a set of fourteen quarter-plate double slides could be used with it; and as there were twelve whole-plate slides, a total of fifty-two plates could be carried.

The stand has long been a source of trouble to the out-door photographer, and innumerable devices have been resorted to with a view of concealing the tripod, and make it look like something else. We remember once to have had a very ingeniously-constructed umbrella-stand; but the last occasion when we used it was when a heavy rain-storm broke upon us, and the rustics were surprised to see the owner of a handsome umbrella prefer to carry it in its waterproof case, rather than use it to keep off the drenching rain. The form of tripod which we now prefer is so constructed that the divided legs can be drawn out and clamped at any length, and a good standing can be obtained on a slope or at the edge of a pavement—a position, by-the-bye, which is often best of all for street work.

He who takes only one lens into the field will probably do several times as much successful work as the man who takes the comprehensive series which many consider necessary; and where instantaneous pictures are desired, a portrait lens may do good service. It must not be forgotten that when the front lens of the portrait combination is placed in the position of the back combination, and with the flat or concave side towards the subject, we have an ordinary view lens; the central stops as usually placed being used. It sometimes happens that the camera will not expand sufficiently to admit of this arrangement, and in such a case the best method is to simply remove the back combination, and make use of the front lens and stops as already fixed. In this case, it is well to cover the bright brass screw-thread, left bare by the removal of the back lens, with a strip of black or yellow paper, so as to avoid reflection; and also to take extra care in screening the lens from bright reflections during exposure. Either of the arrangements just proposed will give better results for pure landscape work than can be obtained with the symmetrical or rectilinear, doubtless so much used in the present day; the slight barrel-shaped distortion arising in the first case, and the pincushion distortion which occurs when the single lens is in front of the stop, being of no moment.

The outdoor worker may defy any reasonable amount of wind by suspending a potato-net between the legs of his stand, and loading this with the most weighty stones he can find, especially if he watches for a period of calm. It may be noted that an approaching wind gust may often be detected by noticing the dust cloud which frequently accompanies it, or the bending of the tops of distant trees.

A LANTERN MANUAL.

We have received from Dr. Liesegang, of Dusseldorf, his new hand-book, "Die Projections Kunst," which forms a convenient manual of the magic lantern, and extends to near upon 200 octavo pages, and is, moreover, well illustrated with wood cuts.

The elementary principles of construction are treated of in clear untechnical language, and the various conditions which render special systems of lighting desirable are put forward in such a way as to help a novice in making a suitable selection. A useful comparison of various lights is given, and although a strict and scientific comparison would require minute details as to each light, we reproduce it, as likely to aid our readers in forming a rough estimate.

An ordinary paraffin candle	1
Argand gas-burner	16
Solar lamp	30
Sciopticon lamp...	39
Lime-light—oxygen and alcohol ...	100
do. oxygen and benzole ...	150
do. blow-through jet ...	190
do. mixed gases	427

Most of the usual forms of burner and lantern are figured and described, and detailed directions are given for so managing the lime-light so as to avoid all probability of an accident; and the following particulars regarding the repairing of damaged gas-bags will be read with interest.

One part of fine-cut sheet india-rubber, or of the (so-called) masticated rubber, is soaked in about half its weight of carbon disulphide, until a uniform viscous mass is obtained. For use, this is mixed with a convenient proportion of the following:—One part of similar rubber is heated until it becomes soft and pasty, after which half its weight of powdered resin is incorporated, and about $1\frac{1}{2}$ parts of oil of turpentine are added. The preparation is spread on pieces of india- rubber cloth or leather, and these are used to cover the defective parts; but it is advisable to also smear a little over the corresponding parts of the bag, and the patches should be retained in their places with pressure for some days in order to allow the composition to become thoroughly dry. Bags which are generally leaky, or which allow the gas to slowly diffuse out through the fabric, may be rubbed all over with the above waterproofing composition, and hung up in an inflated condition to dry. In some cases, a coating of glue and glycerine is better, and, to prepare this, the glue is soaked in water and melted in the usual way, after which about one part of glycerine is added for each four parts of glue originally used. The finished bag may be dusted over with powdered French chalk, should it have any tendency to be adhesive on the surface.

The addition of dry common salt to the usual oxygen mixture is recommended, on the authority of Professor Günther, as moderating the violence with which the gas is otherwise given off, and causing the evolution to stop almost as soon as the burner is removed from under the retort.

The following proportions are recommended:—

Chlorate of potassium	10 parts
Dry common salt	5 ,,
Black oxide of manganese	1 part

The photographic methods available for use in making lantern slides are described in tolerable detail, and careful directions are given for painting slides or tinting photographic pictures, while numerous mechanical arrangements for actuating movable slides are described. The latter portion of the book contains directions for performing numerous mechanical, physical, and chemical experiments in such a way that the results may be visible on the screen; and we also notice directions for raising Professor Pepper's once famous ghost.

At Home.

HERR HOF-PHOTOGRAPH VICTOR ANGERER IN VIENNA.

Vienna has long enjoyed a reputation for brightness and gaiety among European capitals. It now bids fair to lead the way by reason of the magnificence of its architecture, the grandeur of its public buildings, and the handsome character of its squares and public gardens. The Ringstrasse, as a thoroughfare, is likely to be unique; the broad belt of fortified wall and glacis, which formerly surrounded the city, has given place to a handsome and airy boulevard, with lofty buildings of white stone, green gardens, and verdant avenues. The fortifications, therefore, if they did not stop the Prussian army twenty years ago, have been useful in peace, if not in war; for, had they not existed, there could have been no open space around the city for the construction of a Ringstrasse, and Vienna would have been the poorer by its finest thoroughfare; while, from a sanitary point of view, it had been bereft of a healthy breathing apparatus. We doubt, indeed, if ever fortifications were put to a better use.

Viennese life has much of the *élan* of Paris life, while being peculiarly its own. The warmer climate permits of more out-door recreation, and consequently café and "Vauxhall life" are found in perfection; music is a part of the existence of a Viennese citizen, and waltzing is not an accomplishment, but a custom. The busy streets have a tinge of Eastern life about them—Turks from Constantinople, Greeks from the Levant, and turbaned Armenian Jews are occasionally met. The Graben, Kohlenmarkt, and Kärntner Strasse are always bustling and lively, the Viennese cab-driver contributing thereto his fair quota (for he usually drives a pair), and, with the loosest of reins, maintains his steeds at a hand gallop through the streets, let them be wide or narrow. The handsome Opera Ring (a bit of the Ringstrasse where the Opera is situated) forms a magnificent promenade, and so does the Volksgarten, which abutts the same circular street a little farther on. Verily, there is but one Kaiserstadt and only one Ringstrasse.

The name of Angerer has long been associated with the Kaiserstadt. It was not Herr Victor Angerer, however, but his brother, who first enjoyed the title of Court-photographer. The present principal is one of the most genial of men—suave, polite, and eminently good-natured. He is a keen sportsman, and a great fisherman, besides being an accomplished photographer. A more unpretending, courteous gentleman, it has not been our lot to meet.

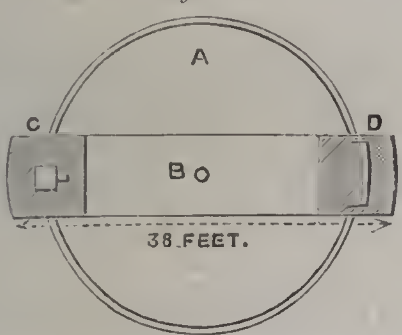
We visited the Angerer studio ten years ago. Then the glass-room was entirely of blue glass—perhaps the only establishment that has ever been glazed throughout in this manner; but, whatever theory may say as to the benefits to be derived from such illumination, in practice, white light has decidedly the advantage; the blue-glass studio of Angerer exists no longer. The present glass-room of the Court-photographer is very spacious and lofty, and, strange to say, it is the only instance we remember of a studio being "downstairs," for thither we are at once invited to meet our host.

But though asked downstairs, we do not leave the waiting room for the moment, and for this reason. A young lady and gentleman have just come from the studio, and are now at the further end of the room in conversation with a clerk who holds a ledger before him in his hands. The gentleman is arrayed in a tie of snowy whiteness, and the young lady, in bridal attire, carries a bouquet. They have been photographed in anticipation of the wedding, and are a little flurried; the lady evidently thinks the man with the book means marrying them out of hand, and perhaps a passing thought that she has been inveigled here for the purpose crosses her mind. In any case, she will have nothing to do with the clerk. The gentleman is equally timid, and objects flatly to give either his name or address, under the impression that he is being taken advantage of. "I have paid, and that's enough," cries the bridegroom. "But, sir, we must have some address to which we can send proofs," urges the book-keeper. The customer begins to see there is some force in this argument; but after a moment's thought he relapses into his fit of obstinacy again. "No, you don't want any address; I will call," and away rush the timid lovers.

The studio where Herr Angerer bids us welcome is said to be the largest in Vienna. It measures fifty-four feet in length, and at its highest is twenty-five feet. A gallery runs along the top of the room, which then slopes gradually down to the glazed side-wall, looking into a cheerful garden. Indian straw-matting is hung about the room, forming alcoves here and there—under the gallery—and altogether the apartment has the appearance of a fine conservatory or palm-house. Blue hangings are to be seen on the glass side, while brown hangings for the most part are on the other. For backgrounds, too, Angerer occasionally employs screens of straw or cane, such as are to be found in drawing-rooms, and in this way he produces portraits that seem to be taken at home. One movable screen we saw was very practicable, as it permitted the lighting up of the lower part of the sitter's garments most effectually. It was simply a stand with two movable surfaces, the top being of light blue, and the bottom of white, as shown in our sketch (fig. 1). Herr Angerer always poses, and indeed is a very hard worker in the studio.

We walk out into the garden. There is here a Swiss châlet or garden-house, with balcony, &c., erected solely for the purpose of taking groups and out-door pictures. It is painted a dark grey, the best colour, Herr Angerer finds, for a photographic background in the open. But what our host desires more particularly to show us is his enlarging apparatus, which is a wonderful structure. Imagine a turn-table, as large as those to be seen on our lines of railway; rails are laid down in a circle, and this big table on wheels then turns on its axis. The diameter of this circular table is no less than 38 feet. At one point, on the circumference, of this table is located the camera, with a recess or alcove built over it, and directly opposite, at the other margin of the table, is another small structure, under which the picture to be copied is placed. Here is a sketch of the whole arrangement (fig. 2). The camera under its alcove can be advanced and retired at will towards the picture. As both the camera and picture are in this way boarded over, no objectionable rays of light can strike either one or the other, while from the fact that the table carrying camera and picture can be turned in any direction, it is possible to choose the very best light for the object. The photographer focuses the picture, and then while still gazing at it on the focusing glass, gives the word to his assistants to revolve the turn-table; when the lighting is at its best, he cries "Halt!" the table is fixed, and the exposure is made. No rays but direct rays fall upon the picture. Certainly the arrangement is very perfect, and it is carried out on a grand scale.

Fig. 1.



A is the turntable, B is the pivot, C is the camera, and D the picture to be copied.

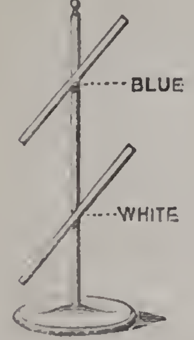


Fig 2.

"I only wish I could print faster," says Herr Angerer, alluding to his large negatives of four and five feet that stand here in their frames in deep shadow. Both silver and carbon printing—the only place in Vienna, where we saw carbon printing—are here in operation; but Herr Angerer cannot get satisfactory results, he says, unless the light is very diffused; and this brings us to the subject of enlargements, which Herr Angerer produces in a different way to that in vogue in this country. Moreover, when we detailed our usual method of making a small transparency in carbon to begin with, he replied that he had tried it repeatedly, but that it did not yield him such perfect results as his own plan. This is, to make from the small negative a large collodion positive, in the first instance, which is done in a dark-room fitted up like a huge camera; from this collodion positive, after careful retouching, is printed in a printing-frame a carbon print, which is developed on a glass plate. This large carbon impression on glass is of course negative, and rarely requires further touching before being employed to produce the finished print. The elaborate retouching is all on the first collodion positive, and not upon the carbon negative, and Herr Angerer believes that when the retouching has been thus translated, the finished effect is better.

Dark rooms and developing rooms open from the studio, which, as we have said, is "downstairs," from the front of the house, although on a level with the back garden. So that the washing rooms and laboratories are half-cellars, exquisitely cool and dark. Herr Angerer employs for his washing, fixing, and toning baths, very large, but very shallow wooden tubs, like low washing tubs, which are, indeed, exceedingly practical.

The "By-the-Bye" next week will be "Disease in the Dark Room;" the following "At Home" will be "The Bruckmann Establishment in Munich."

PHOTOGRAPHING ON COPPER.

BY MAJOR J. WATERHOUSE, B.S.C.,*

Assistant Surveyor-General of India.

It has long been known that copper exposed to the action of bromine, chlorine, and iodine becomes sensitive to light; but, so far as I can ascertain, this fact has never been turned to much practical account, and the only process I know of the kind is the one given in the Photographic News, vol. x, p. 190, as M. Mielcret's, in which a plate of copper is dipped in a bath of sulphate of copper, sea salt, and water, then washed and dried, and exposed to light under a reversed or unreversed negative or positive, as may be desired, for about five or ten minutes, the resulting image being fixed in a solution of hyposulphite of soda containing a little chloride of silver. Very good images may be produced in this way, but I have found the process rather uncertain.

Having lately been asked to produce photographs on copper of some rather intricate drawings of surveying instruments as an aid to the engravers, I tried bitumen with some success, where the drawings were in line alone. The polished copper plate is

* Read before the Photographic Society of Great Britain.

evenly coated with bitumen, and a print of the drawing, or, if suitable, the drawing itself, is laid down upon it and exposed the necessary time to light. On developing with turpentine, a reversed image of the drawing is obtained, showing the lines in bare copper on the bitumen ground. A little solution of platinum may be applied to blacken the lines, and, on removing the bitumen, the drawing shows up in a nice clear black on the bright copper ground.

This method being, however, only suited to line work, the question still remained how half-tones could be got. I then thought of trying the effect of the ordinary dry plate developers on the thin film of bromide of silver, obtained by silvering a copper plate and exposing the silvered surface to the action of bromine. My first trials were made by sensitizing the silvered plate in bromine water, and were tolerably successful. The bromine water was, however, very unpleasant to use, so I tried a five per cent. solution of bromide of copper in water, used in a dipping bath; and this I found answered well, and gave plates of great sensitiveness. Unsilvered copper sensitized in this bath also becomes very sensitive. I have been able to get fairly detailed images in the camera on the silvered plates with about four to six times the exposure of wet collodion; the unsilvered plates require longer. For contact printing under a negative a few seconds' exposure to diffused daylight is ample with either silvered or unsilvered plates, though the former are more sensitive and seem more even in their action. Before exposure to light, the plates are of a dull brownish-grey, darker in the plain plates than in the silvered, which are more yellow. The impressed image is quite invisible with short exposures, and it takes some minutes' exposure in sunshine to bring out a visible image. Both the ordinary alkaline developer, containing pyrogallic acid and ammonia (I used Edwards' formula, with glycerine), and ferrous oxalate, develop the image; but I rather prefer the latter, both for silvered and unsilvered plates. After development, the images developed with ferrous oxalate appear in red on a greenish-yellow ground; those developed with pyrogallic acid are darker and blacker.

For fixing the images on the unsilvered plates, a weak solution of cyanide of potassium seems to be the best. It does not dissolve the yellow ground, but clears it and turns it of a brighter yellow. The resulting images are of a rich brownish-purple, with pale yellowish lights. Hyposulphite of soda also fixes the images; but it dissolves the yellow ground, and unless great care be taken, the image breaks up, especially if developed with pyrogallic. The images fixed with plain hyposulphate or cyanide are powdery, and easily damaged by rubbing. Ammonia also fixes the images, dissolving the yellow ground; but with it also the images have a tendency to break away.

For fixing the images on silvered plates developed with ferrous oxalate, an old hyposulphite solution containing silver seems to answer best; and the resulting pictures, after the powdery deposit has been rubbed off, are very similar to Daguerreotypes, and show a very delicate half tone, particularly in places where a bright blue or purple tarnish comes over the shadows on drying. If the plates could be covered uniformly all over with this tarnish, the images would be very beautiful, and might find application for decorative and ornamental purposes.

I do not consider the process described above at all perfect as a photographic process for general use, and I find it somewhat uncertain and irregular in action; but practically it will answer well for the object I had in view of producing a photographic image in half-tone on copper plates, which can be worked over by an engraver.

The reversed images obtained in the camera would probably be useful for etching from nature, the lights and shadows being also reversed, just as they are on the etched plate.

At any rate, the wet development of these latent images on copper, being, as I believe, new, may be of interest to the Society; and I hope to be able to communicate further improvements.

A silvered plate, exposed under a negative for a few minutes in sunshine, gives a very clear image, either line or half-tone, which may be fixed in the old hyposulphite. If the powdery surface deposit be rubbed off, the resulting images are very much like Daguerreotypes, and are not so strong as those obtained by development, though they are quite clear enough to work upon. For practical purposes this method appears likely to answer better than the developing, being more regular in action.

[In continuation of this subject, we refer our readers to the valuable communication of Major Waterhouse in our columns last week, in which he gives a most complete list of etching fluids suitable for photo-engraving.—Ed. P.N.]

ON THE EFFECT OF THE SPECTRUM ON THE HALOID SALTS OF SILVER, AND ON MIXTURES OF THE SAME.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

There have been many investigations as to the sensitiveness to the spectrum of the haloid salts of silver, from the very earliest days of photography; and when the results obtained by the different investigators are compared one with another, there are often very wide discrepancies apparent. It appeared to me that it was desirable, if possible, to examine the subject afresh, and to endeavour to reconcile or to explain, as far as possible, these discrepancies.

The earlier investigators, such as Herschel, Hunt, Draper, and Becquerel, added much to the knowledge of the subject, but their researches were carried on at a time when the modern modifications and more powerful means of development of an image were unknown. Later investigators, including such eminent names as H. W. Vogel and Eder, have availed themselves of the modern appliances, but their results are not always consistent one with another.

In the following researches points are brought out which are, it is believed, new and deserving of attention, not only on account of their applicability to the practical working of photography, but also because they throw a light on molecular physics.

For solar photography it is essential that a knowledge of the relative effect of the various parts of the spectrum should be known, since, if the photo-heliograph be adjusted for one particular part, and the films employed be more sensitive to another part, it is manifest that no great sharpness of image can be obtained. The following researches, it is believed, show what an enormous effect the mixture of haloid salts has in shifting the position of maximum effect, and it may be possible to either alter the achromatism of the objectives employed, or else solely to use the sensitive compound to which the objective is at present adapted.

Apparatus Employed.—The spectroscope employed in these researches was that already described "On the Effect of the Atomic Grouping of Molecules."† Two prisms of medium dense and colourless flint glass were used to obtain the necessary dispersion. They were set to have the angle of minimum deviation near G. The angle of dispersion between A and H was about $6\frac{1}{2}°$, the length of spectrum between these two lines was about $2\frac{1}{4}$ inches, the spectrum in the ultra-violet extending some $1\frac{1}{4}$ inches beyond H, and the infra-red about $\frac{3}{4}$ of an inch beyond A. The whole spectrum as given by the prisms under consideration thus had a length of $4\frac{1}{4}$ inches, a length in which all phenomena could be fully recognised and measured.

Sources of Light.—The sources of light employed were the sun and the crater of the positive pole of the electric light. Images of these sources were thrown on the slit by means of a condensing lens alone in the second case, and by it and a heliostat in the first case.

Vehicles holding the Sensitive Salts.—The sensitive salts were held *in situ*, in paper, in gelatine, and in collodion, in the last vehicle the salts being prepared either as emulsions in fluid collodion, or by the ordinary silver nitrate bath process. In gelatine the salts were all prepared as emulsions; when in paper they were prepared by soaking it in a soluble haloid salt, and floating on solution of silver nitrate. The question of the production of sensitive silver haloid salts on a metallic silver plate I have left to be considered later, since it has no direct bearing on the points I wish to discuss in this communication.

Exposures.—When it was desired to obtain the expression of the action of the spectrum by its direct effect without the intermediary of a developer, the slit of the spectroscope was opened to a width of $\frac{1}{20}$ of an inch, and the exposure prolonged for five to twenty minutes. When the effects had to be shown by development, the slit was closed to $\frac{1}{300}$ of an inch, and exposure given varying between $\frac{1}{4}$ second and one minute or even two minutes. By having a shutter at the slit of the spectroscope it was easy to give two exposures on the same plate or paper, using half the length of the slit for each exposure. This was excessively convenient, since it allowed the different phenomena arising from different methods of exposure to be accurately compared together. The principle on which the exposures were given was as follows. —1st. An exposure was given to the plate, when a pale solution of chromate of potash so dilute as to cut off the spectrum above E was placed in front of the slit. This exposure was in all cases prolonged in order to see if there was any action produced, how-

* Communicated to the Royal Society at the request of the Committee on Solar Physics. † "Phil. Trans." for 1881; Part 3.

ever feeble, by the spectrum remaining unabsorbed. The next exposure was always taken with the slit unshaded, and on the same plate (or paper) as the first exposure. After a certain interval of time had elapsed, the yellow chromate was again placed in front of the slit, and the exposure continued. The reason for adopting this plan was that the effect of diffused white light (diffused from the prisms during unshaded exposure) would thus be differentiated. Thus, supposing it was found that the first exposure caused no sign of a change in the sensitive salt by the exposure to the spectrum unabsorbed by the chromate, but that the unshaded spectrum caused an action on these parts, it would be evident that the action of diffused light had played a part in causing such an action.

When such phenomena resulted, plates or papers were first exposed to the unshaded spectrum through the chromate solution, then withdrawn from the camera and exposed to the diffused light of the laboratory for a fraction of a second, or for eight or ten seconds, according as the experiment was to be conducted by development or by direct printing action, and again inserted in the slide and exposed to the action of the partially absorbed spectrum. If the experiments were rightly conducted, the results of the last two should be confirmatory of the first two exposures. Other plates or papers were then exposed, giving, unshaded, one half of the slit of a short period, and the other half for a period ten to twenty times as long. By this system all the phenomena met with could be differentiated and traced.

Localities of Maximum Action.—I have followed the usual custom of writers on this subject, and shown the top of my curves as the place of maximum action. Although this correctly shows what appears on the photographic plate, yet in all cases it is apt to give a false notion regarding the effect of the spectrum. If we look at the energy of the spectrum in its different localities, we find that it rapidly decreases as it approaches the violet and ultra-violet. If this diminution of energy be taken into account, it will be found that usually the point of maximum effect nearest the violet indicates the region where the absorption of the rays becomes total, and that the shading off towards the ultra-violet is really only due to the diminished energy of that part of the spectrum. In other cases—as, for instance, where there are two maxima—this will not apply to the second maximum.

(To be continued.)

DEVELOPMENT IN CONNECTION WITH DENSITY AND BRILLIANCY.

BY T. SEBASTIAN DAVIS.*

During some researches made at the conclusion of last season in connection with bromo-gelatine plates prone to give thin and somewhat fogged negatives, I experimented with some differently constituted solutions. It occurred to me that the action of a bromide salt, in its capacity as a fog-restrainer, was connected with its power of forming an insoluble salt with any reduced silver. It seemed, therefore, that if a salt having an alkaline reaction could be substituted, and yet capable of forming an insoluble compound with silver, some advantage might be gained. The two most likely ones to fulfil these requirements are the borates and phosphates of soda, the latter of which, upon trial, offered the greater advantage. Ordinary sodic phosphate ($Na_2H\ PO_4 + 12\ H_2O$) added to the pyrogallic developer produced a marked influence in securing increased density and brilliancy. The most favourable manner in which I have since used the salt is by dissolving about one ounce in twenty ounces of water, and covering the plate therewith for a few seconds, and then pouring it off, afterwards proceeding with the development made of twice its ordinary strength. The sodiac phosphate solution is a powerful restrainer, but its use does not necessarily necessitate longer exposure. The first trace of an image appears very tardily, but the development afterwards progresses with great regularity and rapidity. The film remains clear, notwithstanding the discoloration of the alkaline pyrogallic mixture. The developer I usually employ, without the phosphate treatment, is two grains of pyrogallol dissolved in four drachms of water, two minims of ammonia ·880, and half a grain of potassium bromide dissolved in another half-ounce, and the two mixed immediately before being poured over the plates. Each plate should be fixed in a fresh portion of hyposulphite, to avoid stains.

The above method of development will, I think, be found valuable in cases in which brilliancy and intensity in the finished negative would otherwise be deficient.

* Read before the Photographic Society of Great Britain.

THE RELATION OF THE HUMAN EYE TO THE PHOTOGRAPHIC CAMERA.

BY WILLIAM PEEK.*

It has been a frequently discussed subject by the public and the photographic world, that the human eye and the camera stand in a close relationship. Now to examine the correctness of this generally accepted idea ; at the end of last year, a gentleman, in a communication of his to the "Halifax Photographic Club," endeavoured to prove that the camera and the eye are in close relationship ; and as he but expressed the opinion held by the majority, I have taken the liberty of quoting from his paper. The diagram I have brought with me is similar to the one he used to explain his lecture. He here shows the cornea, the crystalline lens, the diaphragm, and a sort of optic nerve ; but he neglects to point out two refracting media, which I shall have occasion to speak of presently. Firstly, he pointed out the iris as a self-adjusting diaphragm, and explained that, directly the vision becomes centred on a landscape, the iris adjusts itself, and all is directly in correct focus ; the forground being nearest the eye, commands the chief focus of vision ; the middle distance, as it recedes, getting out of the range, becomes of necessity less sharply defined, and the extreme distance still less decided in character. Hence the folly of making the lens into a telescope by using too small a stop, so bringing distant objects into the sharp definition which only correctly belongs to the immediate foreground. After some other observations, the gentleman says,—"The lens should contain the same angle, or field of view, as is contained in the eye ; this ranges from fifty to sixty degrees. It is therefore plain that the eye is a long focus lens, of a limited angle of view. Now, in the old single lens we have that which gives an angle of view the nearest approach to that of the eye ; all other angles must, therefore, be impossible ones." Here the author of the paper states that, immedialety the eye is centred on a landscape, all is directly in correct focus. But, in fact, one point only is focussed ; but there is still a consciousness of the form of the objects surrounding this point, and this consciousness is culled from previous experience. The moment the eye has received the idea of the form of the point mentioned, the eye focusses another point, giving only a blurred image of the first point, which the mind fills up with the aid of remembrance ; thus the eye conveys the impressions of the image by a succession of images respectively focussed on a succession of points, all with such rapidity that the impression on the mind is of a complete-focussed general picture, and, of course, the eye receives a clearer impression of the nearer objects than the more distant ones, because less atmosphere intervenes between them and the eye. Were the eye (incapable of movement) to be fixed on one object, were the observer incapable of moving his head, or of moving on his feet, then might the human eye bear some relation to the camera. But we know this is not the case ; for the eye has a mean vertical angle of 50° above and 50° below its line of axis. The head, with the movement of the eyes, has a vertical angle of 195° : the head, with the eyes, has a horizontal angle of 237°.

The eyes alone have a horizontal angle of 121°. The head alone, with the eyes fixed, has a horizontal movement of 116° ; and a man can easily turn through about 390° with one movement of his body. Let us call the angle of a certain picture 85° ; where, then, is the similarity—the eye moving in a moment through all the angles mentioned, the lens having but an angle of 85° ?

Therefore, in composing a picture, it is necessary, if we wish to give a pleasing effect, that the picture should contain a large and varied sweep of vision ; although the eye, strictly speaking, does not focus this, but compensates for it by its varied movement. It is held among artists, and also among photographers, that all the accessories should point to the principal object, or the idea, suggested by the picture. The way that photographers generally understand this is, that should they be called upon to take, say, a portrait, they sharply define the figure, while a balustrade, a pillar, or the portal of a near mansion (which are too often considered necessary accessories) are all thrown into one blurred mass. Few photographers have the art at their command of introducing interesting accessories without spoiling the principles of the picture. I observe that lately a photographer has broken through this custom, and struck out a bold path for himself, by publishing a photograph of Mr. Ruskin surrounded by a pleasing natural background of trees and ferns. The background is in sharp focus, each plant having its individual interest ; and Mr. Ruskin appears more at his ease than if he had been photographed unnaturally leaning against a pillar, with velvet curtains overhead.

The artist photographer must remember, when struck with the beauty of a subject for a picture, that its capabilities to become a pleasing photograph lie in its character, interest, or form; for although, to the eye, colour or distant surroundings, or to the ear, pleasing sounds, or to the mind, sweet memories, may make the picture before him, yet but three of these will be reproduced by the aid of the camera. Often, when a picture is pleasing upon the focussing-screen, the image on the developed plate will lack interest; it is because colour was the attraction of the original. In these points which I have mentioned, I think the human eye and the camera bear but a very small relationship, and that exists in their both being able to transcribe forms.

And here I may suggest that, in ordinary landscape dry-plate practice, much disappointment might be saved, did the photographer thoroughly analyze to himself what constitutes the charm of the picture he is about to perpetuate.

Mr. Heighway has said that "the ultimatum of a picture lies in a suggestion," and, in this way, by clever and astistic handling, may the camera be made on an equality with the human eye. For that the eye is chiefly an instrument useful as giving suggestion, I think may be proved by the fact that persons seldom read the figures on the face of a clock, but merely judge of the time by the relative position of the hands. That this is so may be demonstrated by the many clocks designed by Sir Edmund Beckett, which have stars in place of the figures. The clock at the Town Hall at Manchester has a similar arrangement, and yet no difficulty is experienced in at once telling the time; in fact, the absence of the figures themselves is seldom noticed. Another and better example of this may be given in the old double-needle instruments used for telegraphy. In this case the dials were at a much greater distance apart than could be focussed at one time by the eye, yet the eye so quickly caught each composition of the deviations of the needles, that the instrument could be read with facility. I lately tried an experiment by putting two single-needle instruments at such a distance that the angle taken to them from the eye would equal 130°, yet I found I was perfectly able to comprehend the deflections on each; hence I think we may conclude that, in each of these cases, a suggestion only is given by the eye, whereas the rest is filled up by collateral knowledge; while in the camera we must, to a very great extent, absolutely define what we wish to depict. And Mr. Heighway also holds "that the object of every composition is to place the matter of the work before the observer, so that, supposing him to be tolerably intelligent and sensitive, he may be able to grasp the intention, motive, and scope of the work, and to sympathize with it."

What I have said may, I think, be illustrated by the photographs which I have brought. In the two by Mrs. Cameron there is a story or impression conveyed to the mind which we so seldom see in modern photographs. I am, of course, aware that Rejlander's "Two Ways of Life" is a composition picture; but in no portion of that is anything willingly placed out of focus. In Mr. H. P. Robinson's great picture, "When the Day's Work is Done"—which, I believe, is also a composition picture—the peasants, the cottage interior, and the landscape seen through the window are all sharply focussed; yet, in the case of the human eye, only one such portion of the picture could be seen distinctly at the same moment, although the eye would rove so rapidly from one subject to the other that it would give the same effect. Hence it is that the greater depth of focus that can be obtained by photographic lenses, the more pleasing and artistic the result will be. In all cases where I have referred to the "camera," it must be understood to comprise both the camera, the lens, and the focussing-screen. We must only regard the camera in the light of a rude mechanical contrivance, which, however, is the best we are as yet acquainted with for chemically producing delineations of light and shade. So far from believing in this supposed relationship, I think the camera is to the photographer, as the palette is to the artist, his means of expressing his ideas by pictorial representation; but, in the hands of the unskilled, they both are useless. Some photographers have lately been telling us that we must not expect every one to be a born artist. This is perfectly true; but if these gentlemen are lacking in artistic culture, how comes it that they are engaged in a profession that ought to be a truly artistic one? It would be just as sensible if a man were to set up as a shoeblack, but profess his ignorance of how to shine boots.

In conclusion, I have to point out that the eye is no single lens at all, but is a triplet, having three compound refracting media: firstly, the cornea and the aqueous humour; secondly, the crystalline lens; thirdly, the vitreous humour. Therefore, if we wish our lenses to be like our eyes (if that is of any advantage), we had better use triplets, rather than the old-fashioned single lens recommended by Mr. Clement Williams.

There is yet one more point to clear up, and this is, "How does the eye focus itself for various distances?" Now, this is the most difficult of all questions to answer, for no one quite knows how this is accomplished; but the most generally-accepted explanation is that which ascribes it to the slight advancement of the lens to the cornea for the focus of near objects; this is caused by muscular contraction. At the same time, the lens is rendered more convex by the same power, acting through the posterior elastic layer, which not only converges the rays more quickly, but also slightly increases the length of the axis of the eye.

PASSING THOUGHTS.

BY J. H. T. ELLERBECK.*

I have been asked, or rather commanded, by our ever-to-be-obeyed Secretary, to supply a paper for this evening. Perhaps if a few stray thoughts were jotted down, which otherwise might be forgotten, it may be useful; whether they are worth recording is for you to judge.

Some years ago I read a paper on "Exposure." I see Mr. L. Warnerke has turned his attention to the subject, proposing to persuade makers of lenses to mark all these and their stops with a number which shall denote the rapidity thereof, and suggests $\frac{f}{a}$ squared and divided by 4 as the quantity. The principle is good, as it saves others from taking the trouble of making the calculation which I then advised; but I would urge rather that the figures thus obtained should not be divided by 4, but left as they are, as they show at once the relative value and are more readily understood for any lens already made, or may be sent out without being so marked. Many makers might see the utility of the one without seeing the force of taking any standard of rapidity other than their own, especially as it is quite unnecessary. In coming to any decision on this point it should be remembered that it will affect more the lenses already made than those to be made. There is no doubt that if a definite quantity were given to each stop, references to exposures, &c., would be more intelligible than now; but that quantity must be made on a basis which would be understood by all, otherwise it would be worse than useless. For that reason I maintain that the first and undivided figures arrived at are the best, because the simplest.

I thought, too, that if makers of dry plates could be induced to mark them with a number indicating their rapidity it would be good. It could easily be done in conjunction with the foregoing, thus:—The bulk of plates I have tried (and their name is legion) require for an ordinary subject as many seconds for exposure with $\frac{f}{20}$ (=400) as it takes minutes to make one tint equal to the Autotype actinometer, or the 3rd of Woodbury's. Could not this be taken as a standard, and call such plates 30 (30 seconds being the time required to form one such tint in the best English light we ever get)? A quicker one might be 20, or the (at present) quickest 10, slower 40 or 50. This, of course, is only a suggestion; but there can be no doubt that some such method would be better than vaguely stating they are 10, 20, or even 30 times quicker than wet plates—themselves always variable. Perhaps when Mr. Warnerke's committee looks after the making of lenses it will look after the marking of plates also.

I have been thinking it is a great pity that stereo. views are so utterly gone out of fashion. I intend this year to devote a portion of opportunity to this branch, using the stereoscope as made by Warner. It is a great pity, too, that panoramic views cannot be utilised for this purpose. I cannot but think it is only due to a mechanical difficulty, which may some day be overcome.

Taking of panoramas: I generally, when it is possible, take two on one plate, one above the other, oblong, so that, if the sky be dense enough, each can be printed on the lower half of a whole piece of paper, and clouds printed in afterwards, thus getting two whole-plate pictures out of one plate. To do this without losing a quarter of an inch in the centre, as is the case with extending dividers, I substitute a metal plate with a hole the size of half the plate cut out. Placing this in a groove before the dark slide, and then reversing it for the second exposure, I find that not a sixteenth of an inch is lost. The same for

* Read before the Liverpool Amateur Photographic Association.

upright, half, or quarter-plates, so that it is equally possible to get four pictures on the same plate, only taking care to give the same exposure to each, or there will be a difficulty in developing. In order to expose the lower half of the plate properly, I have made the front to slide down; and to avoid a long slit—a possible reverse of light in the camera—there are duplicate screw-holes at intervals downwards.

I have been thinking that whether we get our studio or no, many of us would be glad of a practical demonstration in posing. To me and to many others this is a most unsatisfactory task, and one we are often apt to shrink—whether it is the introduction of figures in a landscape or trying to portray a friend.

I have been thinking for a long time that, if those who can afford to do so would mount their pictures on separate mounts and get them bound afterwards, they would in their unbound state be available for exhibition at St. George's Hall and our own private show. It would be thus a great help to our hard-worked Secretary, who has at such times enough to do in arranging without hunting for them. I don't know where we would have been last year if it had not been for Mr. Watling's collection, so few were the contributions.

I have been thinking it should be an understood rule that all members be represented in our portrait album, with their names and date of entry beneath; said album to be always on the table during the meeting. This would be of great assistance in our social relationship. We are very much "at home" here to-night, but I cannot help noting that we form two sections—old and new—which, like the Arve and the Rhône, move side by side silently, only very slowly intermingling. While on this subject I would like to make another remark. I find the bulk of those who attend the Tuesday "at homes" are old friends. Now, without wishing these to stop away, I want to see new faces, that they may become old friends. This was one of the objects in proposing these meetings.

I notice in the News that Mr. Warnerke suggests rolling sensitive paper tightly round a roller to protect it. Having adopted this plan for many months, I can safely recommend it. The outside sheet can be used as a wrapping-paper for successive parcels, acting as a filter to the deleterious effects of the atmosphere.

When Messrs. Morgan and Co. first brought out their argento-bromide paper, they, in reply to a suggestion, promised to turn their attention to making it so that the film could be transferred from the paper when finished. The uses of such paper would be great for negatives, transparencies, &c. Perhaps a reminder may bring some result this time. If so, I hope they will fulfil their promise to send me some of the first batch.*

In anticipation of that good time, and for use with gelatine films, I utilise the present double dark slides, only dispensing with the inner division, making a block of light wood or card-board the requisite thickness—that is, a little more than double the thickness of ordinary glass plates. I place the films on each side. Of course when the slide is closed the films or papers are held tightly in their place by the pressure round the edges. (If blocks like Warnerke's are supplied they will be much flatter and more convenient.) If they show any signs of bulging, a coating of india-rubber solution to each will make them stick securely. Glass can, of course, be used with advantage, but wood is lighter. The arrangement allows all to use their ordinary slides without additional trouble or expense.

I have been thinking I have been taking up much valuable time this evening in what will be uninteresting to many. The demand of our worthy Secretary is my only excuse.

* Since writing the above I see that Messrs. Morgan and Co. have succeeded in this very enterprise, and the Editors speak of it in glowing terms. I immediately wrote to the makers, but unfortunately was not able to obtain any sheets for trial. By our next meeting it is to be hoped they will be ready, as our working time is rapidly approaching, and wise folks are laying in a stock of materials before the warmer weather commences.

ON A NEW DEVELOPER.

Captain Abney, at the last General Meeting of the Photographic Society, made a communication regarding a new developer. He said that, in connection with the subject of phosphates, he might mention a new developer which he had lately used as a scientific novelty. Hypophosphite of soda might be used, instead of ammonia, with pyrogallic acid. About twenty minims of a saturated solution in water took the place of the same quantity of a ten per cent. solution of ammonia. Plates which had been terribly prone to green fog when developed with it gave no trace of such an evil. This he looked upon as important, because it gave a clue to the cause of its production. The hypophosphites reduced silver salts to the metallic state; hence it might be proved that they are more energetic than ammonia.

Mr. Berkeley was surprised to hear Captain Abney's experience with hypophosphite. Some time ago he (Mr. Berkeley) tried using hypophosphite in conjunction with the hydrosulphite developer, but could not say that he had found it an improvement. It did not seem to add to the reducing capacity of the developer. The action was very slow, though, of course, that was also the effect of the hydrosulphite when used alone. He was speaking of collodion, as he had not tried it with gelatine. If ammonia was added to the hydrosulphite, it quickened the action.

Captain Abney: But then you are developing with ammonia. The hydrosulphite developer is very slow, but the hypophosphite is not.

Mr. Berkeley: It is curious the hypophosphite did not make the hydrosulphite more rapid.

Captain Abney: You used it with hydrosulphite, and I used it by itself. If the members try it, I think they will not get any green fog; and for that reason, as throwing a light upon the origin of this fog, I look upon it as interesting.

Mr. Spiller inquired whether Captain Abney had succeeded in developing with hypophosphite alone.

Captain Abney: You must use bromide with it, of course.

Mr. Bird: It replaces ammonia in the developer?

Captain Abney: Yes.

Mr. Maxwell Lyte: With the many new processes consequent upon the use of gelatine, I think that any improvement in developing is of the highest importance. I would add to the list of developers one other deserving of study, and that is glucic acid, obtained by taking grape sugar and saturating it with hydrate of lime or any alkaline earth capable of being subsequently extracted by precipitation. By the addition of oxalic or sulphuric acid, glucic acid is separated, while the lime is separated as an oxalate or a sulphate. As a developer, glucic acid possesses some properties which render it worthy of experiment. It gives a negative when used alone, but with not much intensity. I find intensity can be increased by mixing it with an iron developer, the action of which seems considerably improved by it.

A SUGGESTION FOR IMPROVING THE CLEARNESS AND PRINTING QUALITY OF GELATINE NEGATIVES.

BY W. WILLIS.*

It is generally conceded that no thoroughly satisfactory method is known for the intensification of gelatine negatives. The suggestion now offered is not put forward as a solution, but rather to direct attention to untried or neglected methods.

I believe it is pretty well known that the action of acid ferric oxalate on metallic silver results in the formation of silver oxalate. If, then, a solution of ferric oxalate be applied to a negative, the dark silver image will be rapidly converted into a white image of oxalate of silver. The silver in this image may be reduced by a subsequent application of the ferrous oxalate or alkaline pyrogallic developer, but preferably by the former.

On applying this method to gelatine negatives it will be found, especially with negatives having a yellowish tint, that the shadows are cleared, while the high-lights are increased in density.

In the early days of gelatine, a large number of very yellow, feeble, and sickly-looking negatives were produced. To anyone who is possessed of such, and wishes to improve them, I would suggest the following method, which, in my hands, at least, has been perfectly successful:—

Apply ferric oxalate to the negative until the image has been whitened right through to the back of the plate; then rinse well in water for two or three minutes, and afterwards apply the ferrous oxalate developer. This will, in most cases, give a rich brown coloured negative free from the all-pervading yellowness it previously had, and much improved in printing quality.

It should be noted that the image, after the application of the ferric oxalate, frequently appears rather yellow in colour than white; and that the ferrous oxalate developer usually takes some little time before the full density is produced.

I have been endeavouring to find a simple plan for the inten-

* Read before the Photographic Society of Great Britain.

sification of negatives by means of platinum. The following method has, in some cases, been successful. The negative is first whitened by ferric oxalate ; it is then washed in distilled or rain water, and afterwards treated with a weak solution of potassic chloro-platinite. This salt decomposes the silver oxalate, with the formation of argentic chloro-platinite—

$$C_2Ag_2O_4 + K_2PtCl_4 = Ag_2PtCl_4 + C_2K_2O_4.$$

On now applying the ferrous oxalate developer, all the silver will be reduced, and with it some metallic platinum. The platinum salt has, unfortunately, a great affinity for gelatine, with which it forms an insoluble compound, and this fact may account for some failures which have occurred. I have in some cases used the potassic chloro-iridiate instead of the platinum salt ; but it seems to have no advantage over the latter.

Notes.

Major Waterhouse, the Deputy Surveyor-General of Ordnance in India, promises to send us a further paper on photo-engraving and photo-etching processes next week.

At the annual dinner of the Syndicate of Photography in Paris last week, it was resolved to raise a fund for a monument to the late M. Poitevin ; five hundred francs were subscribed at the outset.

There are at this moment two regal photographers in Europe, the King of Portugal and the King of Servia ; the former is a member of the French Photographic Society, the latter a landscape photographer of considerable ability.

Electricity and photography are just now working hand in hand with a result of which few people appreciate the importance. The electric light in the studio has been made much of recently as an effective means of taking portraits, and electric studios are now to be seen in the principal capitals of Europe. But a far more valuable application of electricity has meanwhile been gaining ground in London and New York. We mean the copying pictures and sketches for publishing purposes.

Some months ago we gave an account in these columns of a visit to a City Photo-type establishment. At that time the camera work was done by daylight, but still so quickly were the different processes carried out, that it was sometimes possible to fulfil them all within twenty-four hours; that is to say, if you brought a sketch on paper into the establishment at noon one day, by noon the following day you would receive a zinc photo-type block ready for the printing press. Our cheap illustrated journals cannot afford woodcuts, so they get printing blocks made in this way from a black and white sketch upon paper.

Instead of four and twenty hours, the work is now done in three or four. The artist finishes his sketch late at night, and in the early morning the photo-type block is already in the machine printing off pictures along with the letter-press. Indeed, in the City, they prefer to do the camera work at night, for there is then no vibration in the studio. The artist's sketch is stretched on a board, a wet collodion plate is put into the camera (for collodion is more easily intensified), and by the aid of the electric light a negative is secured. The film is rapidly dried, and then, on prepared bichromated paper, an impression is secured, also by electric light, which, quickly moistened and treated with greasy ink, is now pressed upon a lithographic stone. The lithographer rolls up his impression, improves it to the utmost of his ability, and then takes off an imprint, which is pressed against a sheet of zinc. The latter is put into an acid bath (very slightly acid to begin with) and gradually the metal is eaten away, except where protected by the greasy lines forming the sketch. In three hours, as we have said, the hollowing out of the zinc plate is complete, and the photo-type is in the hands of the printer.

The big posters one often sees that display an enlarged sketch of a sensational picture, to be found in some newspaper or other, are generally produced by photography. At the photo-type establishment an enlargement of the artist's sketch is made in the camera, and a large greasy imprint then transferred to a zinc plate of giant size, which is etched in the ordinary way. The publisher thus gets rid of the expense of making large and small wood blocks, the cost of zinc photo-types from first to last being but twopence-halfpenny to fivepence per square inch.

We are glad to see that Mr. Woodbury has brought the Stannotype process out of the domain of theory into that of practice. Some pictures we have recently seen printed by this simple method appear quite equal to those furnished by the original Woodbury process, where the engraved plate is produced by powerful hydraulic pressure.

Herr Victor Angerer states that the addition of tannin is advantageous in the development of gelatino-chloride and gelatino-bromide plates. In the case of gelatino-chloride, the tannin is added to the citrate-of-iron developer, bringing about a more vigorous tone. Added to the oxalate solution in gelatino-bromide development, tannin, according to Herr Angerer, brings out more detail, and a greater variety of tone.

No place now-a-days seems too isolated or remote for the establishment of an observatory. The top of Ben Nevis has for some time been a meteorological station, and a few months ago, an observatory on the summit of Mount Etna—the loftiest in the world—was established by the Italian Government. The Russians have a polar observatory at Nova Zembla, and now talk about establishing a second station in that frozen wilderness. Strange to say, there is never any lack of volunteers among our scientific men to take charge of these veritable hermitages, though the inhabitants of convents on the Mount St. Bernhard, the Simplon, and other lofty passes, are in clover compared to these solitary observers.

Tuesday evening at the Photographic Society was rather quiet. Still there was plenty to occupy attention in a paper on "Green Fog," by Captain Abney, and another by Mr. C. R. Wood on the "Production of Coloured Transparencies by Converting the Silver Image into a compound of Lead, Copper, Chromium, &c." The tinted images might possibly be employed in enamel photography, if only they would keep their colour in burning; this, however, is very doubtful in the case of some, at any rate.

Mr. William Bedford, on the subject of coloured transparencies, re erred to the gelatino-chloride pictures of Dr. Eder, which were recently exhibited at the Society of Arts, and which varied from a deep red or ruby, to sepia and black. Mr. Bedford stated that, by following implicitly Dr. Eder's instructions about development, he had experienced no difficulty in reproducing the beautiful tones in question, and he recommended the process, therefore, as a thoroughly practical one. An amusing incident, by the way, occurred through a confusion of Captain Abney's specimens with those of Mr. Wood, one choice example of "green fog" being mistaken for an attempt at colour by Mr. Wood.

But perhaps the most important feature of the evening was Mr. G. L. Addenbrooke's new shutter, which is timed to give regulated exposures varying from one-twenty-fourth of a second, to a period of two seconds and three-quarters. A tiny clock-work arrangement with spring supplies the motion, which the inventor prefers should commence some slight interval before the exposure is made. We hope to publish a description of the new exposer in our next.

We know the peripatetic photographer often does a good day's work, but it is something new to hear of a young fellow, half in joke and half in earnest, taking a camera to Hampstead Heath on Easter Monday and netting between three and four pounds in portrait taking. He assures us that not only did the job pay him handsomely, which we can well believe, but that the incident gave himself and friend a fund of funny reminiscences for a twelvemonth. "If a lady and her swain thought a shilling too high, I took the pair for ninepence. It is usually the lady who wants the photograph, and who finds the money. 'Arry thinks cash invested in a less æsthetic manner more satisfactory. But then it is the lady who keeps the portrait, you see, so of course she doesn't mind paying." In these days, when being photographed together constitutes good evidence in a case of breach of promise, obviously the lady invests her money with considerable discretion.

By-the-way, it is not generally known that in the case of professional peripatetics who frequent places of public resort, they are not unfrequently all of them assistants to the same principal. This is so, we are told, with those to be found on Margate and Ramsgate sands, many being engaged simply from the Saturday to the Monday, and on high-days and holidays. The "standings" of many out-door photographers are of considerable value.

We hear Her Majesty has completed the catalogue of "presents" which have been made to her during her reign. The work, which is not intended to be published, is illustrated throughout with photographs of the objects in question. The illustrations, if not all, are, at any rate, for the most part, the work of Mr. Jabez Hughes, the Queen's photographer at Ryde.

His Royal Highness the Prince of Wales has always shown himself appreciative of photographic art. When at the Pall Mall Exhibition some years ago, he begged permission to carry back with him to Marlborough House an album full of Rejlander's studies, that he might inspect them at his leisure; and a similar request he has now made to Mr. Muybridge, in whose "attitudes of animals in motion" the Prince has taken a lively interest. Mr. Muybridge has, indeed, arrived in London at a fortunate time. Several invitations have been extended to him to assist at fashionable "at homes" and other gatherings of the élite, and to bring his wonderful photographs with him.

A grand international art exhibition, the greatest of the kind for many years, was opened on Saturday at Vienna by the Emperor. While France, Germany, Austria, Hungary, Belgium, Spain, and even Sweden and Norway, are represented by at least a hundred pictures a-piece, Great Britain, it appears, exhibits but six paintings and one piece of sculpture. Altogether there are 7,000 paintings arranged under the direction of the well-known Viennese artist, Makart. Our readers may call to mind that the promenade portrait is in Vienna and Hungary termed the Makart portrait, out of compliment to the great local painter.

We hear that one of the eclipse "staff," which proceeds to Thebes next month, to observe the total eclipse, is a novelist, no other than Mr. William Black, the author of "A Princess of Thule." Mr. Black is a mutual friend of Mr. Lockyer and Captain Abney, and although not officially appointed to the expedition, he will doubtless be its chronicler. Becoming in this way familiarised with the work of the spectroscope and of the camera, we shall not be surprised to find the charming heroine in Mr. Black's next novel chatting in a lively way about hydrogen lines in the ultra-violet, and the peculiar subtleties of gelatino-bromide development.

Professor Civiale is preparing a photographic history of the Alps. For ten years, from 1859 to 1868, the author travelled in the Alps with his camera, constantly taking panoramic and smaller (detailed) views. The latter, according to *Nature*, some 600 in number, principally show the glaciers with their crevasses, moraines, and the rocks forming their banks; the mountains, valleys, glens, natural geological sections; the rocky eminences groved, polished, or ground by former glaciers, and the course of various rivers. The panoramic views (forty-one in number) are taken from the summits, and comprise all the large Alpine chains. Each consists of a number of plates, and twenty include the whole circle of view.

As the making of sketches in Court is becoming a common practice, the following suggestion has interest for many. "I am thinking of making a detective camera, similar to Mr. Bolas', but inside a hat, the lens to peep through an orifice in the crown, where many people have a ventilator. 'Hats off in court,' is the rule, so that there would be nothing unusual in your laying your hat on its side upon the reporter's desk or elsewhere. The prisoner sits quiet enough after he has got used to the court, and then if you watched your opportunity you might get a good long exposure, uncapping your lens by simply placing your hand on the brim of the hat to touch the spring. The only difficulty I see is, that sometimes the light all comes in from a skylight just above his head." Our correspondent gives us liberty to print his letter in case any of our readers aspire to be a "Court-photographer."

Millbank is the only one of our penal establishments that possesses an official professional photographer. At Pentonville, the gentleman occupying the post of dispenser is required to undertake photography with his other duties; but in most other prisons, portraits are taken at so much a head. The negative is carte size, a half-length portrait being secured and for this a sum as low as twopence halfpenny is considered adequate in some establishments.

That our criminal portraiture frequently leaves much to be desired, is scarcely to be wondered at in these circumstances, for even the most careful photographer cannot ensure success with every plate, and if he uses a couple over the job, his narrow margin of profit is at once swallowed up. So a portrait is usually considered a portrait, for negatives at half-a-crown a dozen must not be criticised too severely. Fourpence and sixpence are common prices, and tenpence a negative is, we believe, the highest sum paid, unless it is a question of taking isolated prisoners.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. VI.—Lenses.

Of all the apparatus which the photographer uses, there is none of so great importance as the lens. With a bad camera shift can be made, and excellent work turned out, the only drawback being harder work and inconvenience for the operator; but with a bad or unsuitable lens nothing can be done. This being the case, it behoves us to give a short description of the various different lenses in use, saying for what kind of work each is best suited. Before doing so, however, we will give a few general facts with regard to lenses, and especially we shall lay stress on the manner in which it is possible to compare the rapidity of different lenses. It will be necessary to define a few technical terms continually applied to lenses. By *depth of focus* is meant the power in a lens to represent sharply objects both near and far from the lens. The larger the aperture of the lens, the less the depth of focus. With every lens is supplied a set of *stops* or *diaphragms*. These are simply plates with holes of larger and smaller sizes in them, which are made to slip in front of or between the combinations of a lens. The more depth of focus is required, the smaller a stop must be used, and consequently the slower the lens will be.

By *width of angle* is meant the amount of picture which can be included. For example, with a camera placed in a certain position and pointed to a row of houses, one lens will include perhaps two houses, another four.

Distortion is a fault met with in photographic lenses. It causes straight lines near the sides of the object to be represented by curved lines in the image. *Flatness of field* is the quality in a lens of having the definition at the edge of the plate good, as well as that at the edge.

The *focus*—or, more strictly speaking, the *focal length*—of a lens is the distance between the lens and the ground-glass when the image is sharply focussed. In a single lens the measurement is taken from the centre of the lens. With compound lenses it is near enough to measure from the diaphragm to the ground glass.

The *aperture* in a lens is the diameter of the stop or diaphragm, or, where none is used, of the actual lenses. The rapidity does not require to be defined, but we propose to explain the factors which regulate it. Every lens is different in rapidity from others of another form, and each lens has a number of diaphragms varying its rapidity, so that at first sight it might appear a difficult task to put a value on the rapidity of a lens using any particular diaphragm. The law which governs the rapidity of lenses is, however, so very simple that its application is most easy, and we would try to impress on the beginner that he should thoroughly master it at the commencement of his practice. If he does so he will find the estimation of the necessary exposure a comparatively simple matter. In changing one stop for another, or one lens for another, he will have nothing to guess except the intensity of the light.

The method of comparing lenses—and which applies to all lenses—is as follows. State the ratios between the apertures of the lenses and the focal lengths of the lenses as fractions—the aperture as the numerator, the focal length as the denominator. Square the fractions thus obtained, and the resulting figures will give the ratios of the rapidity. It is usual to state the fractions thus: $\frac{f}{4}$ $\frac{f}{12}$ $\frac{f}{40}$. These fractions refer to lenses the first of which has an aperture one-fourth of the focal length, the second one-twelfth, and the third one-fortieth. We shall take a practical example. We are using a portrait lens 10-inches focus, and aperture $2\frac{1}{2}$ inches; that is, the focal length is 4 times the aperture, or we say the lens is working at $\frac{f}{4}$. The focal length, be it remembered, is the distance between the diaphragm and the ground glass. We now substitute a single lens of 12-inch focus with a stop $\frac{3}{4}$ inch in diameter. The aperture is now $\frac{1}{16}$ of the focal length. The lens is working at $\frac{f}{16}$; square these two fractions, thus:—

$$(\tfrac{1}{4})^2 = \tfrac{1}{16} \quad (\tfrac{1}{16})^2 = \tfrac{1}{256}.$$

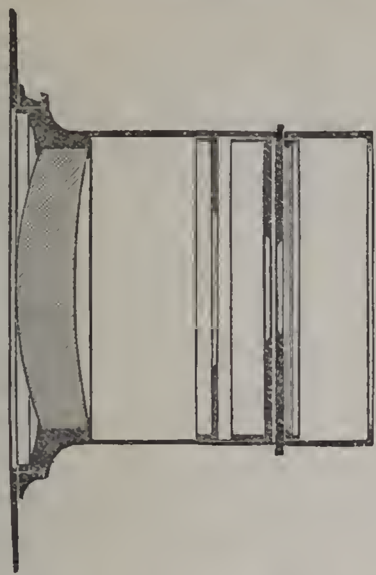
The rapidity of the lenses is as $\frac{1}{16}$ to $\frac{1}{256}$. The exposure required will therefore be as 16 to 256, or as 1 to 16. Thus, if we had been giving two seconds with the portrait lens, we should have to give thirty-two seconds with the single lens. If the beginner will exercise himself in this rule for a little time, he will find that he soon gains wonderful facility in applying it, and he will find that it gives him a very great power in estimating the necessary length of exposure. With the same lens and different stops the rapidity varies as the square of the diameter of the stop, or as the area of the stop.

We shall now go rapidly over the different kinds of lenses most in use, giving the purposes for which each particular form is best adapted.

We have first

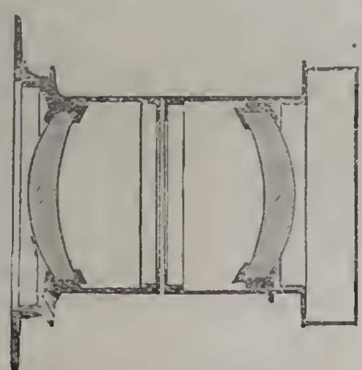
The Single Lens.

It is the one with which we should recommend the beginner to provide himself, as it is the simplest form of lens, and is also the most generally useful. It is fairly rapid, has a fairly large angle, and gives wonderful definition and depth of focus. Its only drawback is that it gives slight distortion. If, for example, it be attempted to pho-



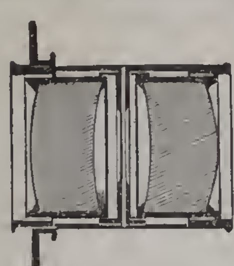
tograph a building of large size with it, the boundary lines will appear slightly curved, and the building will appear barrel-shaped.

The Rapid Rectilinear or Rapid Symmetrical



is one of the very most useful of lenses. It is very rapid, and one should be purchased when the photographer has so far advanced as to wish to attempt instantaneous effects. It gives no distortions, and about the same angle as the single lens.

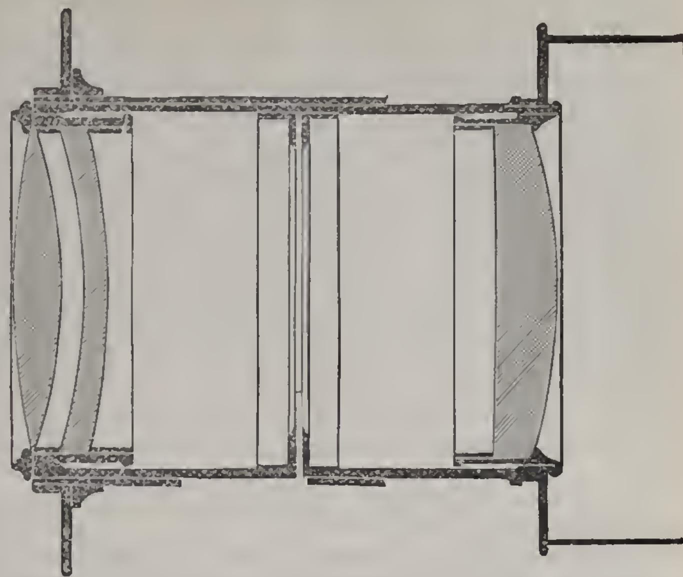
The Symmetrical or Wide Angle Rectilinear



is a very slow lens, but takes in a wonderfully wide angle, so that it is useful for photographing objects when it is impossible to get the camera far enough away from them to use the rapid rectilinear. It is quite free from distortion.

The Portrait Lens

is intended for portraiture pure and simple. The utmost ingenuity has been spent in the case of this lens to get the greatest possible rapidity, but many other good qualities have been sacrificed. Thus the field is round, the marginal definition bad, and there is very little depth of focus. For its own particular purpose it is, however, admirably adapted. With the very rapid plates which can now be had, it is quite possible to take portraits even indoors with the rapid rectilinear or even the single lens, and we would not advise the beginner to purchase a portrait lens, at least, at first.



There are numerous photographic lenses sold under names different from any of the above, but all of them will be found to be very similar to one or other of the kinds described. As we are entirely avoiding in these lessons all historical reference, we shall not say anything of this form of lenses, which have now gone out of use, and are not manufactured.

PRINTING ROOM NOTES.

BY LYDDELL SAWYER.

Does the printing of photographs, as a rule, receive the necessary amount of attention in photographic houses? I should say no—that is, on the average, and when we except our leading studios, for there they are generally fully cognisant of its importance, and reap an immense advantage by their recognition of this fact.

A good operator assisted by a bad printer is like a valuable jewel in a brass setting.

It is a common natural law that "extremes meet," and a negative, brimful of true modelling and delicacy, yet exacts more skill and consideration in printing than a cliché rendered really inferior by greater intensity.

Many an operator's heart has temporarily sought a new berth in the region of his boots on beholding the begrimed-looking assortment of proofs yielded from a negative which in itself he had almost opined was to make him famous; and, however earnest he may be after the shattering of a few of his idols in this fashion, he invariably yields to circumstances, accepts the inevitable, and makes negatives not what he considers best, but rather what he hopes will print, intensified until the more gentle details have succumbed, and merged into high lights.

Printing is not purely a mechanical process, and the early acceptance of this fact will greatly conduce to the further assimilation of art—that is, of course, when monetary considerations will permit of its recognition. I fear, by the way, that this same £ s. d. question has much to answer for with photographers. But I am diverging: I commenced writing, intending only to jot down a few notes of what I find of utility in practice at our own place.

There is never any occasion to have mealy or impoverished silver prints. When they do show signs of these disorders, it is due to either weak or acid silver bath. Keep a small carbonate of silver deposit in the bottom of the bath bottle, and retain the strength of the silver solution at from forty to fifty grains per ounce, and I can confidently assert that the proofs will be healthy, unless the albumenized paper is primarily bad, which, in my experience, I have seldom found is the case. Of course, it i essential to avoid sun printing—at least, in the summer months.

I notice that an article in a contemporary journal alludes to the utility of the argento-meter for indicating the strength of the silver printing bath; but this really useful little instrument for *new* silver solutions is only monopolised as an argento-meter because of its being guaged to the density of nitrate of silver salts in solution; and the writer of the paper in question apparently omits to remember that it is still amenable to other influences (although in a different degree), such as nitrate of soda and organic matters which are sure to accumulate and affect the density of baths when in ordinary use. Of course that renders this guage very untrustworthy for the purpose indicated by its advocate. I do not know any more reliable method of regulating the strength than to ascertain by experience what diminution of strength attends a certain recognized decrease in the bulk of the bath, and to make a reserve solution, proportionately stronger, with which to keep up the original quantity and density of the bath at one and the same time.

In drying sensitized paper, blotting-boards are decidedly preferable to spreading it out in the clothes-drying fashion. A book, consisting of about a quire of blotting-paper, will remain all right in use for an almost indefinite period, long after it has become blackened, if it be kept clean and free from extraneous dust, &c. It economizes space; it protects the paper; it effects a more perfect dispensation of free nitrate; and it dries the sheets flat, making them easier to handle; indeed, it is not often that so many advantages accrue from so small an alteration.

Why is sensitized paper not universally cut and trimmed in the first instance to the required carte or cabinet sizes? A sheet of paper may, with practice, be cut as quickly as it can be torn, doing away with subsequent trimming, and producing a good saving of material.

If it be found necessary to keep on the edges for handling purposes, it is the condition of the fingers, and not the paper, that wants looking to. I am used to see forty-eight carte sizes obtained out of one sheet of paper, and no more difficulty experienced in "filling-in" the printing-frames than if there remained an inch to spare each way in every carte piece. Indeed, it is only carelessness that tolerates this waste; it is derogatory to workmanlike ability that such slovenly methods are accepted, and prolific of good to no one, unless it be the albumenizers and chloride of gold manufacturers.

Let me explain a new method of preserving sensitized paper, one which certainly deserves recording, if only for its simplicity. It was shown to me by our printer some time ago, and has since acted admirably. He cuts all the sensitized paper to whatever sizes are required; say, that it is C.D.V. size—he then piles all the pieces squarely on top of each other, and places them between a couple of 12-sheet boards, cut to precisely the same dimensions; and now they present almost the square and trim appearance of the edges of a book. All that is wanted is to wrap them in brown paper, and put them under a heavy weight, which will so far exclude atmospheric influence, that the paper is little or nothing impaired by a month's keeping, and its perfect flatness is an additional pleasant recommendation. For cabinet or other sizes it is only necessary to have stout boards increased in proportion.

The placing of this ready-trimmed paper in proper position on the negative to be printed is easily managed by the printer having his changing light in front of him, when by slightly raising the top end of the printing-frame it is generally sufficient to show the image perceptibly enough through the sensitized paper to readily square it.

Perhaps the termination of my notes smacks little of that art which I insinuated as requisite in printers at the commencement of them; but what I have written pertains to mechanical skill—a power so beloved by his sister art, that she seldom, in her coyness, woos the world and lives safe beneath his encouraging smile.

Correspondence.

ADDING IODIDE AND CHLORIDE TO GELATINE EMULSION, FOR PHOTO-LITHOGRAPHIC WORK.

Dear Sir,—I quite agree with Mr. Hartwig that the addition of iodide and chloride to the gelatino-bromide emulsion is not always an advantage; but it is so in the case of photo-lithographic work, and where great density and transparency are necessary in the negatives. I have never been able to employ the gelatino-bromide process for photo-lithography, for the simple reason that I could not get sufficient density and transparency in my shadows in the plates I purchased. All the commercial plates I am acquainted with (and I have used those of many makers) gave me plenty of detail; but, intensify as I would, there was never sufficient contrast for black-and-white work. I am told that there is, nevertheless, both iodide and chloride in most of the plates sold.

My own home-made emulsion was just the same, until I added the scrapings of a collodion plate, as recommended in the News. I suppose I have overdone the dose for ordinary work, but for black-and-white subjects my emulsion is now just the thing. Not only is there much more density, but my clear glass is now really clear, a thing seldom seen in gelatino-bromide plates. I followed your advice, and put into six ounces of the gelatino-bromide the scrapings from two 10 by 8 inch collodion plates.

I have tried the scrapings from two iodized plates, from two chlorized plates, and from one iodized and one chlorized. The two former samples (that is, either pure iodide or pure chloride) gave the best photo-lithographic negatives—*i.e.*, negatives with the most violent contrasts.—Faithfully yours, A Photo-Lithographer.

[The recommendation in the News was to add the iodized or chlorized collodion from two 10 by 8 plates to *eight* ounces of emulsion; but, no doubt, for photo-lithographic work, the quantity recommended by "A Photo-Lithographer" would supply the increased contrast necessary for black-and-white pictures.—Ed. P.N.]

THE PRINTING BATH.

Sir,—Although so much has been written on the above subject, the minds of many photographers appear to be still unsettled as to the best method of managing the printing bath to insure good and uniform results. There can be no doubt, as Mr. C. J. Hopkins and others have pointed out, that solutions used for sensitizing albumen paper soon become contaminated with impurities, which, if not removed from time to time, are certain to injuriously affect the character of the resulting prints. The presence of these objectionable matters is indicated by the solution becoming more or less brown, and although there are many ways of removing the discolouration, most of them are open to the objection that, while rendering the bath clear, they quite fail to remove the impurities referred to. This applies to the use, now so much advocated, of a bath kept in a neutral condition by means of carbonate of silver, which, though recommended by some high authorities, has not in my practice yielded entirely satisfactory results. After many experiments, I have arrived at the conclusion that nothing fulfils the required conditions so well as the now almost forgotten permanganate of potash, and I find the following *modus operandi* to be convenient and expeditious. Keep the permanganate in a solution of twenty grains to the ounce, and when about to float your paper, add half a drachm to each pint of the discoloured bath solution. Give it a shake, and after allowing it to stand for a quarter of an hour, run through a funnel loosely plugged with cotton wool. The filtering need only occupy a few minutes, and the waste of silver is almost inappreciable, while the brightness and uniformity of the prints obtained will amply repay the slight extra trouble.—Yours, &c.,

H. C. Parlour.

PHOTOGRAPHIC CLUBS.

Sir,—In last week's News a letter appears from Mr. E. Dunmore, concerning the advertisement calling a meeting to discuss the advisability of forming a new club. Mr. Dunmore should have had the good sense to have waited until the meeting in question took place before he wrote his letter. He would then have found that the proposed club was no "sham society," but a stern reality, and that thirty-three gentlemen, including several officers of the Photographic Club, were enrolled on the spot. Besides, several gave monetary guarantee to make up any deficiency that might arise in consequence of the small annual subscription—viz., five shillings.

It is the intention that the new Club be large, and number its members by hundreds, if not thousands. Take the Edinburgh Society per example.. If Mr. Dunmore will become a member of the new Club, he will, no doubt, get a wrinkle or two that may be useful to him in his position as Hon. Secretary of the old Club.

Apologizing for encroaching on your valuable space—but I am compelled, in self-defence, and as the author of the advertisements, to reply to Mr. Dunmore's courteous letter,—I remain, yours respectfully, A. L. Henderson.

Sir,—I notice a letter from Mr. Dunmore in your issue of the 31st ult., as to the new photographic club. It is a pity that Mr. Dunmore did not re-read his letter before sending it on to you—or, better still, wait until after the meeting, at which I was advertised to take the chair, had been held, and then I think he would not have written of "sham" societies. It is a fact, and Mr. Dunmore knows it, that the Photographic Club does not meet the requirements of the art, and non-publication is one of its failings. The popularity of the "Thursday Evenings" is a proof of this. Its reports are read by all, and by many supposed to be the reports of the Club. Thus, you see, the Club gets a "sham" credit.

It is to be regretted that Mr. Dunmore did not attend these meetings; he would have found them far more "social," and, I think, more interesting than his other meetings.

As to the new Club (for it is *un fait accompli*) being a sham, why that is for new members to say, as thirty-three were enrolled on the first night (many of them members of the present club), and of course if this Club be a source of weakness to the old Club, the managers have themselves to thank for that entirely. As to its being a source of weakness to the old societies, that I think all must deny, as I rather think it would be a source of strength to them; and on South London nights the meetings never begin till past nine, so as not to interfere with the Society.—Yours truly, C. G. Cutchly.

INCANDESCENT LAMPS IN THE DARK-ROOM.

Dear Sir,—I am glad to see that an experienced photographer like Mr. England is taking up your suggestion to employ the incandescent lamp in the dark-room. I have also been making experiments in the matter, and I can bear out all you and he have written on the subject. The subject of the battery has been a stumbling block to me also, but now I see the existence of a two-candle carbon lamp of Swan, mentioned in the News, I do not see why a bichromate battery should not be made to answer the purpose.

Could you refer me to any other information on the subject of these lamps and batteries—I mean for use in the dark-room? I have read your admirable leader in the News of the 10th ult., but I may possibly have overlooked other information. I see Mr. England in his letter refers to the fact of attention having been called to the subject.—Faithfully yours, W. G.

[We think Mr. England was simply referring to our leader. See the description of Mr. Paterson's battery in another column.—Ed. P.N.]

"PHOTOGRAPHY WITH EMULSIONS."

Sir,—May I ask the favour of your inserting the following rather important errata which occur in the second edition just published of my work on "Photography with Emulsions."

At page 139, after the different weighings, it is said:—"Nos. 1 and 2 are rapidly covered with water, &c." It should read:—"Nos. 3, 5, and 6 are rapidly covered with water." And in the fourth line below, instead of "They are then dissolved in 1 dr. and 1½ ounces of water," it should read: "Nos. 1 and 2 are then dissolved in 1 dr. and 1½ ounces of water."

Some of your readers may be in possession of the book, and I would ask them to note these corrections. The publishers have taken steps to make them in all copies which have not left their hands.—Yours faithfully,

W. de W. Abney.

Proceedings of Societies.

Photographic Society of Great Britain.

The eighth technical meeting was held on Tuesday, February 28th, 1882, Captain Abney, R.E., F.R.S., vice-president, in the chair.

Mr. Cowan showed two negatives taken under two sensitometers, and stated that commercial plates usually brought out 18 to 20 under the standard sensitometer.

The Chairman remarked that in making plates he had tried to arrive at 23.

Mr. Cowan said that he developed with ferrous oxalate or pyrogallic. He was satisfied when 20 was arrived at, but under 15 the plates were slow. He also exhibited three bromo-chloride plates developed with ferrous citro-oxalate, and stated that they were from five to ten minutes in the solution.

Mr. Charles Whiting then gave an outline of the matter in reference to collodion films being repellent, after an exposure of about twenty minutes on 24 by 18 plates. Upon examination of a plate after exposure, and previous to development, it was found that the silver had drained down the plate about half way, terminating in an abrupt although very uneven line, and leaving isolated patches or pools of free silver on the upper half. In developing such a plate, it invariably happens that a much more vigorous image is produced upon the parts of the plate that are covered with the free silver, while the portions which are surface-dry remain poor and flat. He thought it was sometimes due to the cotton used in making the collodion giving a horny and repellent film.

Mr. Brownrigg stated that, when in Dublin, he had given two hours' exposure to some collodion plates. He rejected iron, and used pyrogallic acid, with plenty of acetic acid, and the results came out very clean.

Mr. Whiting said that when his exposures were only five or ten minutes he did not get stains.

The Chairman remarked that if a collodion emulsion is boiled with nitric acid the film becomes repellent, and the same might occur with wet collodion, with nitric acid in the bath. He also stated that some years ago he had to give three hours' exposure; but he dipped the plates in distilled water, and there were no stains.

Mr. T. S. Davis alluded to a practice he introduced many years ago in the manipulation of wet collodion, which was to move the plate up and down in the bath, and not allow it to remain still until the solution flowed evenly; also that where there was a large quantity of collodion on a plate there would be greater intensity in the markings, according to the direction of the dip of the plate.

Mr. W. Bedford said that possibly the defect complained of might be due to the use of a super-iodized collodion; in that case the addition of plain collodion, or strengthening the silver bath, might rectify the evil.

The Chairman suggested that a bath should be made with 500 grains of silver nitrate to 16 ounces of water.

The conversation then became general; details of treating the bath, its usage, and other matters relative to the collodion being discussed.

The Chairman put a question asking for any experience of intensification by any method of development of gelatine plates with ammonia and pyrogallic, with the subsequent addition of ammonia.

Mr. Cowan stated that the slow addition of ammonia gave the greatest intensity.

Mr. Davis said it might be interesting to state that he had been experimenting with hydrochloric acid introduced into gelatine emulsion, five minims to one ounce, at a temperature of 140°. The negatives were very clean. When there was an excess of hydrochloric acid, the development could be pushed to a much greater degree than without the same.

The Chairman also had tried hydrochloric acid; it gave wonderful clearness, and seemed to be perfectly incapable of fog.

Mr. Berkeley said that hydrobromic acid had the same effect.

Mr. W. Bedford stated that emulsion prepared with hydrochloric acid and excess of bromide darkened in the light, proving the presence of chloride of silver; there resulted great clearness of shadows.

The Chairman observed that there was one advantage in adding acid to gelatine, it got rid of something, the absence of which also seemed to get rid of fog; that when fresh gelatine was mixed with a gelatine emulsion prepared by ammonia, after washing, wavy markings were sometimes seen; also that rapid plates seemed generally dull looking, and slow plates shiny.

A conversation took place respecting gelatine—its tendency to form pits when it sets too quickly, its conduct when soaking in water, and the quantity taken up.

Mr. Davis added that the purest gelatine contained impurities, but which were left behind if the gelatine was passed through wash-leather.

The monthly meeting of this Society was held on Tuesday, at 5, Pall Mall East, Mr. J. Glaisher, F.R.S., in the chair.

Mr. W. Wainwright, Junr. was elected a member.

Capt. Abney read a paper on Sensitometers, in which he pointed out that the ratio of sensitiveness of different plates, judged by phosphorescence, was not always to be depended upon. Some plates appeared to be more rapid under such circumstances than when tested by gas light. For this reason he preferred to use the latter rather than the phosphorescent surface. Capt. Abney showed, by the experiments he had made, that the sensitometer was not to be uniformly depended upon, but that the instrument should be used with judgment and care.

Capt. Abney also read a paper on the cure of green fog by the use of ferric oxalate and redevelopment with ferrous oxalate, and gave a formula by which the ferro-citrate-oxalate developer might be prepared.

Mr. C. R. Woods read a paper on "Coloured Transparencies from Silver Images," in which he detailed a number of experiments with the double cyanides of iron and platinum, by means of which he had converted the silver image into the salts of other metals, thus obtaining different colours. Mr. Woods also stated that he had succeeded in developing the photographic image with molybdous salts. This developer was energetic in its action, but gave so thin a negative as to be practically useless.

Mr. W. Bedford observed that he had found no difficulty in producing coloured transparencies by Dr. Eder's method.

Capt. Abney said the difference between Mr. Wood's method and Dr. Eder's was, that in the one case the result was certain, while in the other it depended upon the skill of the operator.

Mr. Addenbrooke then described a new apparatus for automatic exposure. This instrument consisted of a clockwork adjustment which opened a double shutter, and which could be regulated to give exposures varying from a minimum of $\frac{1}{24}$ of a second to a maximum of $2\frac{3}{4}$ secs. Mr. Addenbrooke claimed for this shutter an advantage over the shutter of M. Boca, inasmuch as, being detached from the camera, there would not be any vibration.

In reply to Mr. Davis, Mr. Addenbrooke said he meant the instrument to be held in the hand.

Mr. Davis suggested the use of a stand, which might be placed in front of the camera.

Capt. Abney said this plan was already in use in connection with photographing torpedo explosions. He could see, however, no difficulty in exposing with the instrument held in the hand.

Mr. W. K. Burton thought very highly of the apparatus, especially commending it for the adoption of as much as $\frac{1}{24}$ of a second for a minimum. He ridiculed the idea of being able to construct a shutter which would give an exposure of a 5000th part of a second. No apparatus would stand the shock.

Mr. England did not think the plan of holding the instrument in the hand a good one. It was sometimes necessary to wait five minutes for the exposure, and to hold the apparatus would be very tedious.

Mr. Ined concurred. He had used a drop shutter attached to the lens, and found no vibration.

Major Brownrigg was also in favour of the shutter being attached.

Mr. Payne Jennings said that theoretically the separation of the shutter from the camera was right, but practically it was difficult to carry out.

Mr. Maxwell Lyte believed that the best place for the shutter was behind the lens as nearly as possible in the centre of the camera.

Mr. Francis Galton thought it was quite possible to give an exposure of 1-5000th part of a second, and gave some calculations derived from Mr. Muybridge's photographs in support of his statement.

Mr. Burton said that if his (Mr. Burton's) calculations, derived also from Mr. Muybridge's photographs, were correct, he was still of opinion that such an exposure could not be attained without a shock to the instrument.

Mr. Addenbrooke, in reply, said his object was not so much to make an instantaneous shutter, as to construct an apparatus which could be adjusted to instantaneous shutters, and to give photographers the means of estimating correctly an exposure, which they could not do at the present time, and so had to stop down their lenses, and thus injured the picture. With regard to vibration, he might say that the apparatus could be attached to the camera if necessary.

The President said that the great desideratum in an instantaneous shutter was that it should not cause vibration, and in all the shutters hitherto exhibited, except those which opened by means of a pneumatic bulb, this defect was noticeable. The apparatus of Mr. Addenbrooke, he thought, was most ingenious.

A vote of thanks having been passed to Mr. Addenbrooke, the proceedings terminated.

Liverpool Amateur Photographic Association.

The monthly meeting of this Society was held on Thursday, the 30th ult., at the Free Public Library, Mr. E. Roberts (president) in the chair.

The minutes of the February meeting having been read and confirmed,

The Hon. Secretary brought before the meeting a letter which he had received from the Hon. Secretary of the Executive Committee of the Associated Scientific Societies of Liverpool, asking if the Liverpool Amateur Photographic Association would be willing to continue its membership of the Association, and to renew its contribution to the guarantee fund for 1882. It was unanimously agreed that this should be done once more, and the Hon. Secretary was requested to write to that effect to the Hon. Secretary of the Executive Committee.

Mr. W. H. Kirkby then read a paper on "Instantaneous Shutters."

Messrs. Ellerbeck, Forrest, Bean, Bruce, Kirkby, Crowe, Roberts, and others, exhibited instantaneous exposers of different kinds.

Dr. Kenyon objected to the bulky size of most of the shutters, and expressed a decided preference for exposers constructed on the principle of that invented by the late Mr. M. Noton, of Manchester.

Mr J. L. Corkhill complained that many shutters, through faulty structure and design, produced a jerk of the camera at the very moment of exposure.

Mr. W. T. Bruce said that he was about to introduce an important improvement in his shutter by making the aperture of the shape of a heart, so as to give a longer exposure to the foreground.

Mr. J. H. T. Ellerbeck read a paper entitled, "Passing Thoughts" (see page 182). He exhibited an improved form of actinometer by Mr. Crowe.

Mr. J. H. Day passed round some excellent negatives taken on Morgan's paper with an exposure of three seconds in bright sunlight, with stop $\frac{f}{15}$. After development and fixing the paper had been well washed, dried, and waxed. The prints from these negatives were exhibited by Mr. Day, and were of excellent quality.

Mr. J. A. Forrest remarked that the sight of these pictures recalled to his mind the very early days of his own photographic work, when beautiful results were obtainable by the old waxed-paper process. In answer to a question by a member, he (Mr. Forrest) stated that the usual exposure in those days was half-an-hour.

The Chairman then announced that some of the members were desirous of renting a studio in some in some central part of the city. After much trouble and inquiry he had found exactly what was needed in Church Street, at the corner of Whitechapel. He proposed that those members who would be glad of the advantage of a studio for practice in lighting, posing, &c., should pay an annual subscription of a guinea, and so be entitled to a key of admission. He thought that now the Society was in an increasingly-flourishing condition it might contribute from its funds a portion of the rent.

Mr. Forrest warned the Society against the temptation to rely too much upon financial success. Twenty-five years ago, in a similar mood of enthusiasm, the Association had constructed a studio for the use of its members, but had involved itself in considerable financial difficulties in consequence.

Mr. W. H. Wilson re-echoed the warnings of the last speaker, and strongly deprecated the adoption of the proposal on the responsibility of the Association.

The Rev. T. B. Banner remarked that when the Society possessed a studio it was never used. He strongly objected to any scheme which might involve the Association in debt.

Mr. W. H. Kirkby was afraid that the studio proposal might result in the formation of a separate society.

Mr. H. N. Atkins thought that the common use of apparatus and chemicals belonging to the Association would prove a serious difficulty.

Mr. J. Pelham wished to remind the meeting that there were other expenses, in addition to that of rent, to be taken into account. He was sure that when taxes, cleaning, warming, and lighting had been paid, the annual expense would not fall short of £40.

Mr. W. Macindoe proposed as a resolution—"That the Hon. Secretary be requested to issue a circular to ascertain the number of members who would be willing to join in renting a studio at a rental of £1 or of 10s. 6d. per annnum a-piece."

Mr. A. Tyrer seconded the proposal.

The Rev. T. B. Banner proposed as an amendment—"That it is unadvisable for the Society to move at all in the matter at present."

Mr. Forrest seconded the amendment.

The Chairman, in putting the question to the meeting for decision, remarked that the question was not one of building, but of renting a studio, and that he did not intend the Society to incur any risk of debt; because if an insufficient number of members came forward to support his scheme, it would, *ipso facto*, fall to the ground.

The amendment was then put to the meeting, and carried by a majority of votes. The resolution accordingly fell to the ground.

The Rev. H. J. Palmer exhibited Messrs. J. Lancaster and Son's enlarging lantern, and gave a demonstration of its usefulness by enlarging a quarter-plate negative of a waterfall in Switzerland up to the size of a full sheet of Morgan's paper. In answer to questions put by members, he (Mr. Palmer) stated that the condensers were five inches in diameter; that the lens in use was Dallmeyer's lantern combination; and that the requisite exposure for a negative of medium density, and without stopping down the lens, was ninety seconds. He further stated that the best lens he had seen for enlarging purposes was one of Mr. Knott's make, which cost 25s. This lens gave good definition up to the edges of the enlargement. He (Mr. Palmer) then developed the picture, and, in spite of the difficulty in the development of so large a sheet of paper in an ordinary room, the result was entirely satisfactory.

The Hon. Secretary (the Rev. H. J. Palmer) announced that there would be an excursion to the Falls of Dolgarrog, in the Valley of the Conway, on Wednesday, April 19th, and requested all members who desired to join to be good enough to communicate with him. He (the Hon. Secretary) said that he had received from Mr. A. Pumphrey, of Birmingham, a donation of prints made by his mechanical process for the Society's album.

A number of prints taken by Messrs. Kirkby and Bruce, in illustration of their respective shutters, were handed round, and were much admired.

Dr. Kenyon exhibited two prints from a portrait negative—the one weak and unsatisfactory, and the other brilliant and all that could be wished. The latter had been printed from the original negative, strengthened by the superposition in printing of a glass positive.

Mr. Day exhibited one of Lancaster's new *Le Meritoire* cameras.

Votes of thanks were proposed, seconded, and carried unanimously to Messrs. Kirkby and Ellerbeck for their papers; to the Rev H. J. Palmer for his demonstration of the process of the enlargement of views; and to Mr. Pumphrey for his donation to the Society's album.

The meeting, which was very largely attended, then separated.

Glasgow Photographic Society.

A meeting of this Association was held in the Religious Institution Room on Thursday, the 31st ult., at 8 o'clock p.m., Mr. John Parker, president, in the chair.

The minutes of last meeting were read and approved of. Mr. Thompson gave notice that at next meeting he would move—"That arrangements be made for a photographic exhibition to be held in Glasgow."

Mr. John W. McCall, F.R.H.S., London, delivered a lecture before a large attendance of members and friends, his subject being "Holiday Rambles in Texas; how I went, and what I saw." His lecture was most interesting and instructive, and was profusely illustrated by a large number of coloured transparencies thrown upon the screen by the lantern; thereafter he recited the poem "Jane Conquest," which was also illustrated by the same means, by a series of pictures taken from life models.

After a very enjoyable evening, the proceedings were brought to a close by the Chairman proposing a hearty vote of thanks to Mr. McCall for his kindness.

Thursday Evenings for Photographers.

At the meeting (largely attended) on the 30th ult., the question of forming a new club was taken into consideration. In the unavoidable absence of Mr. Cutchey, who was to have taken the chair, Mr. A. Haddon was unanimously elected chairman. Letters were read from Messrs. Brown, Cutchey (the late Hon. Secretary of the Photographic Club), and others, giving their views, &c. It was proposed by Mr. Riemann, and seconded by Mr. Coles, "That, in the opinion of this meeting, it is desirable that a new club be formed, the proceedings at all meetings of which shall be open for publication." This was carried with but one dissentient, who subseqently gave in his name as a member of the new Club.

A long discussion then took place as to the nature of the new Club, in which Messrs. Cobb, Fry, Henderson, Pearsall, and others took part.

Messrs. Debenham and Coles having borne their testimony to the advantage they had derived from attendance at the Thursday evening meetings,—

The following resolution, proposed by Mr. Prestwich, and seconded by Mr. C. G. Cutchey, was put to the meeting and carried unanimously:—"That a photographic club be formed, the annual subscription to be 5s., and that the names of those willing to become members be now taken."

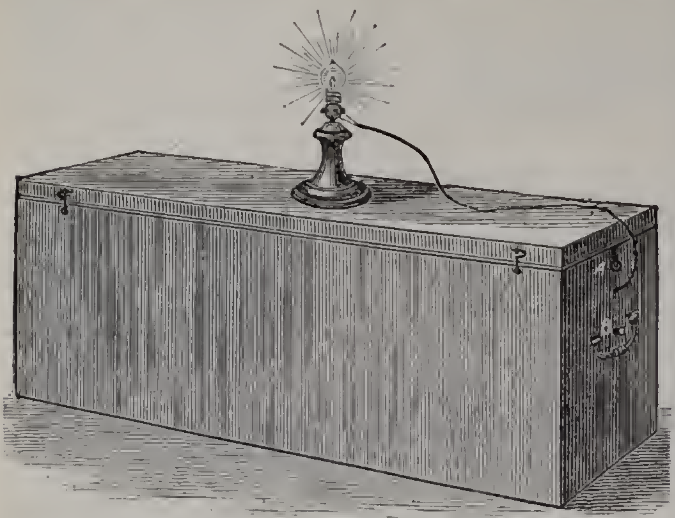
Over thirty names were then handed up to the Chairman as intending members, and a provisional committee was formed to draw up a set of rules to be submitted to the next meeting, to be held that day fortnight.

A cordial vote of thanks to the Chairman terminated the proceedings.

Talk in the Studio.

Royal Institution.—The following are the lecture arrangements after Easter:—Mr. E. B. Tylor, four lectures, on the "History of Customs and Beliefs," on Tuesdays, April 18 to May 9; Professor A. Gamgee, four lectures on "Digestion," on Tuesdays, May 16 to June 6; Professor Dewar, eight lectures on the "Chemical and Physical Properties of the Metals," on Thursdays, April 20 to June 8; Mr. F. Pollock, four lectures, on the "History of the Science of Politics," on Saturdays, April 22 to May 13; and Professor D. Masson, on "Poetry and its Literary Forms," on Saturdays, May 20 to June 10. The Friday evening meetings will be resumed on April 21, when Professor Dewar will give a discourse on the "Experimental Researches of Henri Ste. Claire Deville, Hon. M.R.I."

The Swan Lamp in the Dark Room.—We are now enabled to place before our readers a cut of the portable battery with the Swan lamp attached, as manufactured by Mr. Paterson, of 76, Little Britain, who informs us that he has fitted



some of these with red shades, so as to adapt them for dark room use. The lamp gives a steady light equal to five standard candles, and the five-cell bichromate battery contained in the box is brought into immediate action by lowering the plates into the cells, a pulley-like arrangement for this purpose being shown at A B. Not only is an apparatus of this kind useful for dark room use, but, should it be necessary to work with ether or other inflammable liquid in the evening, a safety light of this character will prove of considerable value. We intend before long to describe some new arrangements which we have made for facilitating the use of the incandescent lamp in the dark room.

How do the Horses Go?—Most horses are four legged: the legs arranged like those of a table—whence we often hear of a horse and his 'table companions (the famous Table Bay is, we may note, neither a bay horse nor a bay table). The difficulty is to know which of the legs are used in certain movements (in the table, by the way, you can always tell, however quickly it is moved, the near legs from the *off* leg). Mr. Muybridge, of San Francisco—or Frisky, as they call it over there; appropriately with respect to horses—has solved this problem, with the aid of the camera. This he has demonstrated to the Royal Institution and the Savage Club, so that all the *savans* are satisfied. In walking, the horse raises two feet on the same side, and in doing so supports himself on two feet on the same side, which of course is the other side. In the amble he is, so to speak, ambledexterous (it doesn't matter how many "hands" he is); in the canter (is it Mr. Muybridge who gives the Canter Lectures at the Society of Arts ?) and gallop he varies at will, apparently, in a sort "of go as you please" style. One result is to show that almost all the horse-painters are at fault, including Frith, who in his "Derby Day" has shown ten horses galloping with all four feet off the ground at once—an impossibility, but perhaps due in his case to the misleading though familiar Derby cry, "Now they're off!" when they are simply going *on*. Mr. Muybridge's wonderfully clever photos. are shown in action by an instrument the name of which we forget, but Aunt Towzer thinks it's the Zoedone's-cup.—*Funny Folks.*

Singular Explosion of Oxygen.—M. Sébère, of St. Brienne, has been in the habit of storing his oxygen in a large gas-holder of galvanized iron, holding a hundred litres, and sunk in water. After being nearly half full for several weeks, he was about to make use of it by carrying a jet of the gas to a flame, with the result of the whole violently exploding. An investigation proved that no carelessness was at the bottom of the matter, the explanation being of a most simple nature, and one that theory would have predicted. A galvanic action had been set up between the iron and the zinc, and hydrogen had been liberated, an explosive mixture of the most powerful character being thus manufactured in the middle of the laboratory. M. Sébère's arm was broken, the place was deluged with water, and considerable further damage resulted. In order to prevent a similar accident, for the future M. Sébère will always keep the interior of his gas-holder well varnished.

Solvent for Gallic Acid.—Mr. Frederick Long says, in the *British Medical Journal*, that he has accidentally discovered a method of dissolving gallic acid. Having a short time since a case of hæmaturea, the result of uric-acid gravel, he chanced to prescribe a mixture containing half a drachm of gallic acid and a drachm and a half of citrate of potassium, and, to his surprise he found he had a perfectly clear liquid, the gallic acid being completely dissolved. He has since made further experiments, and he finds that, with care, 20 grains of citrate will dissolve as much as 15 grains of gallic acid in an ounce of water, and remain quite clear for any length of time. To be able to give gallic acid in perfect solution is a great advantage, as absorption must take place more rapidly when the salt is in solution than when simply suspended in mucilage. The citrate, being a very simple salt, can do no harm in any cases in which gallic acid is required.

A Horse in Church.—On Saturday afternoon, about five o'clock, a horse belonging to Messrs. Marsh Brothers, photographic artists, Henley-on-Thames, which had just been brought out into the street to be attached to a trap, started off at a rapid pace, and the principal entrance of St. Mary's parish church being open, and in a direct line with where the animal was left standing, trotted into the sacred edifice, going as far as the chancel steps, where it reared up on its hind legs facing the altar. When seized by the bridle it was found that the horse could not be turned round in the open space, and so with some difficulty it had to be backed the whole length of the church to the door by which it had entered. No damage whatever was done either to the horse or to the church.—*Globe.*

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News*" *Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed* "*Union Bank, Photographic News Co. Account.*"

*** We cannot undertake to return rejected communications.

W. Rogers.—Thank you for the suggestion, which has already been under consideration; the plan has its advantages, but also its disadvantages, we find.

A Beginner.—There are many advantages resulting from the use of a moderately small stop when the increased time of exposure is allowable; but it is doubtful whether it is ever desirable to reduce the diameter of the stop to less than one-fortieth or one-fiftieth of the equivalent focus of the lens. In all cases, when a small stop is used, care should be taken that the hole is countersunk; so that the light is cut off by a sharp edge, and not by a tube of appreciable length in relation to its diameter.

P. D. R.—No thoroughly satisfactorily instrument of the kind exists.

Easton.—1. You will find the exposures nearly 30 per cent. less than in this country. 2. Hardly. 3. Unless you are prepared to carry a considerable amount of luggage, you had better put off the development of the bulk of the plates until you return.

Thos. J. Bennett.—You might apply to Mr. Paterson, of 76, Little Britain.

Edwin Billing.—We cannot find space for an illustrated notice.

J. Robinson.—1. You should use a much weaker developer, say five grains of iron to the ounce. 2. Add about four drops of water to each ounce of collodion, carefully dust the interior of your dark slide, and place moistened blotting-paper at the back of the plate. 3. For the present, be content with the lenses you possess.

C. M. Hargreaves.—All the samples of the gelatine in question which we have tried have been so uniformly good, that your experience surprises us. It might be well to assure yourself that your thermometer is correct.

Fritz.—One part of cuttle-fish bone in the state of an impalpable powder, and six parts of oil of turpentine, forms an admirable mixture for the purpose, and it may be applied by means of a pledget of cotton-wool or the top of the finger.

James Bloore.—1. Not unless some reducing agent is also present. 2. Although nearly insoluble in alcohol, a very perfect decomposition is attained if the directions are carefully followed.

C. B. Cooper.—1. Not if the washing has been sufficient. 2. Several complaints have reached us, and we are glad to say that the matter will soon be fully discussed.

Robert Laking.—Neither salt will produce the effect which you describe; get your friend to go carefully into the matter again, and you will probably arrive at the truth.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1232.—*April* 14, 1882.

CONTENTS.

A NOVEL METHOD OF CONTROLLING A SHUTTER BY AIR CURRENTS.

Few of the minor appliances incident to photographic manipulation have been received with so much favour as the pneumatic arrangement of Mr. Cadett, by which a shutter can be opened at will, or allowed to close; and the application of Mr. Cadett's idea to the release of a drop or spring-shutter has, perhaps, come more into general use than the original invention. A Brighton photographer, whose name has not yet transpired, has constructed a pneumatic apparatus on a novel principle, which not only allows of the shutter being opened, but also closed, by the impulse of a current of air; and the simplicity of the whole arrangement warrants us in thinking that it is likely to come into very general use for studio and out-door work. As the inventor sent his apparatus for exhibition at a Thursday Evening meeting (see page 207), and we are authorized by the management of the meeting to publish a description, we suppose that the arrangement is not patented. The mechanical principle on which its action depends may be summarized as follows.

A flap (which forms the shutter) is mounted on an axis placed at a point below the centre of gravity, and stops are so placed that the flap can move to a limited and equal extent, either to the right or to the left. Under these circumstances the flap will remain at rest when in contact with either one of the stops, but will be in a state of unstable equilibrium when in any other position; and, as a matter of fact, it is so delicately mounted that a slight puff of air can easily blow it from one position of rest to the other. It is almost needless to say that one of these positions corresponds to open lens, and the other to light shut off.

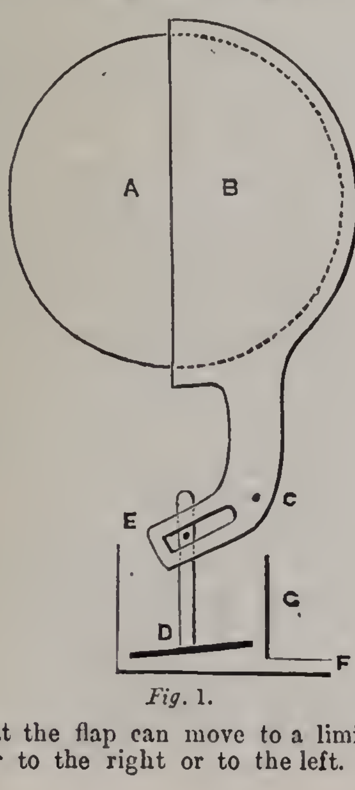


Fig. 1.

It is evident that numerous arrangements could be devised in which the above mechanical principles are carried out; but it is interesting and satisfactory to note that the inventor of the arrangement we are about to describe deserves as much credit for the mechanical details as for the principle of action which he has adopted. The forward air current is obtained by *rapidly* compressing the usual india-rubber pear or injection bottle, and the backward or exhaust current arises when the compressed pear is *suddenly* released, the gradual compression of the pear, or its gradual release, producing no effect on the shutter. In actual practice, two half-round flaps are used, so as to obtain the advantage of more equal lighting than would otherwise result, and fig. 1 is a diagram of the shutter when closed, A being the aperture of the lens, and B one of the half-round flaps. G is a cylinder in which the piston D fits quite loosely. The india-rubber pear or injection bottle is connected by means of any required length of flexible tube with the inlet pipe, F. When the pear is

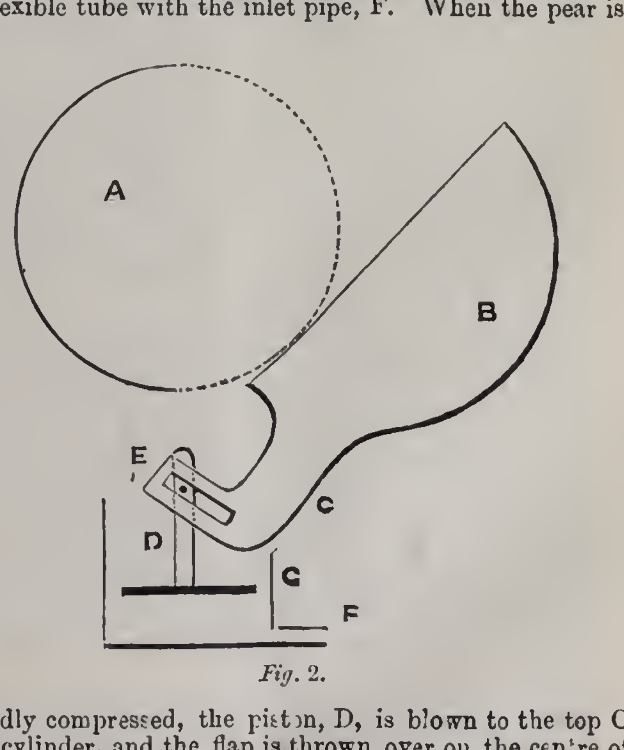

Fig. 2.

rapidly compressed, the piston, D, is blown to the top C the cylinder, and the flap is thrown over on the centre of into the position shown in fig. 2, the compressed air rapidly escaping through the space between the piston D and the cylinder G. If, now, the pressure on the pear is suddenly relaxed, the rush of air against the upper surface of D tilts the flap back into its first position, or closes the lens ; but should it be desired to leave the shutter open for some minutes, it is merely necessary to relax the pressure gradually, so that the returning air shall pass between D and G so slowly as not to move the piston. When it is wished to close the shutter, it is merely necessary to once more compress the ball, and then to allow it to expand suddenly. In our diagrams we have, for the sake of simplicity, represented the apparatus as having only one flap, but there are, as before stated, really two; the parts represented by B C E being duplicated so as to cover the other half of the aperture.

The complete command which one has over the shutter while handling the pneumatic ball is surprising ; but as it is hardly practicable to give a much shorter exposure than one-fifth of a second, it will not serve for the most rapid work unless a spring arrangement is attached.

While speaking of shutters, we may call attention to the extremely ingenious and simple electric release as fitted to a drop shutter by Mr. G. F. Williams, and exhibited by him at the meeting of the South London Society (see page 206). A small electro magnet is bolted against the face-board of the shutter, and angular pole-pieces actuate a small armature, which is included in the thickness of the face-board. When this armature is attracted, the shutter falls. Mr. Williams uses a small Gaiffe's chloride of silver battery contained in an ebonite tube rather over an inch in diameter, and perhaps three inches long, contact being made by a button at the top of the ebonite cell. A connecting cord of two-strand telephone cable completes the arrangement.

MEASURING THE LIGHT OF HEAVENLY BODIES BY PHOTOGRAPHY.

We stated the other day that the eminent French astronomer M. Janssen proposes to employ photography as a precise and ready method of measuring the luminosity of the heavenly bodies. One of the most valuable advantages of this method of photometry, writes M. Janssen, will consist in the permanence of the elements of comparison. While photometric observations by the eye of the intensity of two separate sources of light are necessarily fugitive, and generally require the simultaneous presence of the sources, photography will be able to furnish us with permanent elements of comparison which can be referred to whenever necessary, and which may even be transmitted to posterity. Further, the property which a sensitive plate possesses of allowing an almost infinite accumulation of luminous actions to be impressed on it, will afford the means of studying and comparing the action of radiations of the very lowest degree of power, such as are quite outside our present means of measurement.

The photographic result of the action of the luminous radiations is, so far as our present processes are concerned, to produce a metallic deposit on the support ; and it is this deposit which we can take as our standard of measurement. We cannot weigh the deposit—its quantity is too small—but it is very easy to take its degree of opacity as the base of our measures, since on this opacity depends the image which the light produces. Besides, in adopting this base we take advantage of the natural parallelism which exists between photographic and ocular photometry, for in the latter method we look to the degree of illumination of a surface. This first point being fixed, we have still to fix the method to be adopted for taking the measurements.

For measuring the intensity of the luminous radiations from two different sources of light, two methods present themselves. We can take, as our base, either the ratio of the opacities of the metallic deposits produced in equal times, or that of the times necessary for obtaining the same degree of opacity. The latter of these methods appears to be the most practicable ; it is comparatively easy to judge by the eye which two deposits are equal in opacity, but, since the opacity of a deposit does not vary as to the intensity of the source of light that has produced it, it would be very difficult to measure correctly two different degrees of opacity. On the other hand, it is evident that, if two deposits on the same plate are equal in opacity, the action of the light in the two cases must have been equal in degree. In other words, this action for each source of light must be proportioned to its intensity, and to the time during which it acts. We have, in fact,

$$i \times t = i' \times t'$$

Or

$$\frac{i}{i'} = \frac{t'}{t}$$

That is, the intensity of a source of light varies inversely as the time necessary for producing a constant opacity in the deposit—or, if it is preferred, for performing the same amount of photographic work ; hence we are able to refer the measure of the intensity of two different kinds of light to the measure of the times necessary for producing the same degree of deposit on the plates treated in precisely the same way.

It was, however, found possible to demonstrate the truth of this principle by actual experiment; this experiment was carried out with two dry gelatino-bromide plates, and with a candle as the source of light. The candle was placed at a distance of 0·79 metre from the plate, the latter being in a vertical position. In front of the plate there was a series of screens increasing in height in such a way that by lowering them successively, more and more of the plate was exposed to the light. The first screen was lowered so as to give an exposure of 4 seconds for the upper part of the plate, and each of the other screens was lowered in order, at an interval of half a second. In this way a number of horizontal bands was obtained on the plate corresponding to the exposures of 4, 4½, 5, 5½, and 6 seconds. Then the candle was placed at twice its former distance from the plate—that is to say, at a distance of 1·58 metre ; and the first screen was lowered after 16 seconds, the other screens successively at intervals of 2 seconds, which gave exposures of 16, 18, 20, 22, and 24 seconds—that is to say, four times those in the first series. It was found that the two plates (made of the same emulsion, and developed in the same way) gave a scale of equal tints in the corresponding order. Thus, a source of light at a distance 1 (the intensity of which we may call 1), and acting for the time 1, gave the same degree of opacity as the same light placed at twice the distance (whose intensity would therefore be $\frac{1}{4}$ 1), but acting for the time 4.

In practice, when measuring the ratio of the intensities of the sources, it is best to obtain from each source a series of tints gradually increasing in depth, by exposing in such a way that the two series may have the largest possible number of corresponding terms. Each tint in the one series, which finds its equal in the other, may be compared by making equal the ratio of the times during which the two sources have acted, to the ratio of their intensities ; care must, however, be taken to compare feeble tints only, as they will give more accurate ratios.

It is, moreover, evident that, if from the action of two different sources of light on the same plate may be deduced the ratio of their intensities, then the action of the same source on two different plates will give the ratio of their sensitiveness. For each plate there must be taken a number of exposures, forming a series, of which the terms may be compared with those of the series for the other plate, the source of light remaining the same. The sensitiveness will then be in the inverse ratio of the time of exposure.

M. Janssen, who has pursued these researches for several years, has recourse to graduated bands, obtained either by means of the screen above described, or by that of the flap of a frame which can be opened to any required extent, according to the width of bands desired to be produced. For investigations of a more precise character he has had a special instrument constructed, to which he gives the name of *photographic photometer*. This instrument consists of a frame to hold a sensitive plate, and in front of which a shutter pierced with an aperture is made to pass; the movement is effected by mechanism, so that it is capable of measurement, and the shape of the aperture varies according to the effect which it is required to produce.

When the aperture is rectangular in form, a uniform tint will be produced on the plate; but if it is triangular, the opacity will decrease from the edge of the plate corresponding to the base of the triangle towards the opposite edge: moreover, the rate of decrease in this opacity is the same as that of the decrease in the intensity of the light, which is given by the form of the aperture. One of the results obtained with this instrument is the observation that the opacity of the photographic deposit is not proportional to the luminous intensity when the latter is very great. For if two similar plates, after being exposed under the action of the same triangular aperture, be superposed in opposite directions, it will be seen that they do not present a uniform tint, but that the opacity is increased towards the centre — a proof that the photographic deposit does not increase so rapidly as the luminous intensity.

To measure the relative sensitiveness of two plates made with different emulsions, they must be placed, one after the other, in the frame of the photometer, and exposed under the triangular aperture. The points which possess the same degree of opacity must then be referred to the corresponding points of the aperture, and the relations of the openings at these points will express the ratio of sensitiveness. By making the light from two different sources act successively on two similar plates, we can also use the instrument for finding the ratio of the intensities of the two lights. Finally, by means of the same instrument, the principal laws of photometry may be verified photographically.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Photographic Competition at the Alexandra Palace—Photography in the County Court—Panoramic Lantern Slides.

The Photographic Competition at the Alexandra Palace.—It is long since "Arry and Arriett" have had so much honour paid them as on Easter Monday at the Alexandra Palace. We are afraid that from "Arry's" point of view the photographic competition was rather slow, and that he would infinitely have preferred a "big mix" and "go as you please" match; still he obeyed the directions given him in the advertisements faithfully, and assembled in his thousands on the south slopes, and to this extent evinced an interest in art. It must be confessed that a "chaffing" rather than a reverential spirit prevailed among the huge crowd, but a few there were who showed a proper anxiety to be "taken." Indeed these exceptions carried their anxiety so far as to remain stationary for several minutes, under the impression that if they so much as moved a muscle or stirred an eyelash, the whole picture would be spoilt. Regarded simply as a mass of people, the enormous crowd which gathered in front of the score of cameras ranged on the top of the grand stand no doubt will present points of interest in the photographs; but so far as picturesqueness is concerned, by far the most effective picture was presented when the sitting was over, and the crowd began to sweep back towards the Palace. If the object had not been to get as many faces as possible into the photographs, a far more entertaining competition would have been a contest with "detective" cameras. Innumerable pictures of Phillis and Corydon disporting themselves lovingly might have been secured. The self-satisfied expression of the young gentlemen who give themselves up with so much energy to the concertina would alone have been worth a journey to Muswell Hill to obtain. Family groups picnicing on the grass on sandwiches—by no means of the Vauxhall type—and bread and cheese brought in the family basket, could have been immortalised. What an inexhaustible field for study of character! It is to be hoped that if Messrs. Jones and Barber cannot see their way to give a prize for pictures of this kind, some of the photographic societies or clubs will take up the idea. Seriously speaking, a series of humorous bits of real life of this kind would pay for the trouble.

Photography in the County Court.—Is a photographer bound to send home the photographs of his customers? The point appears at first sight to be a trivial one, but there are occasions on which it may prove very important. At Southwark County Court, recently, Mr. Kirkby, a photographer residing in South London, brought an action to recover the sum of £1, the balance of £2, the price at which he agreed to enlarge a photograph of the defendant's deceased wife, and to colour and frame the same. It seems the defendant brought the plaintiff a carte-de-visite of his wife, and from this carte-de-visite an enlargement in oils had to be made. When the enlargement was made, defendant called to see it, and made certain suggestions which the artist carried out in his presence. The picture was then in crayons, and it was afterwards finished in oils. The defendant, however, did not like it, and applied for the return of £1 he had deposited, which application Mr. Kirkby naturally refused. The picture was still retained by the plaintiff, who said, in reply to the judge, "I was in hopes, or rather considered it was defendant's duty, if he really wanted the portrait, to come and pay the remainder of the money. I have already expended £1 over the work, and then there was the frame and the mounting. I did not send the picture to defendant, because he made no request, and because he said he did not like the portrait. Under these circumstances I thought he would come for it." Defendant, however, does not appear to have had any intention of so doing, and in this he had the law on his side, for the judge held there had certainly been no delivery of the picture. But he put it to the defendant whether it was worth delaying the settlement of the matter by objecting to the non-delivery, seeing that plaintiff could deliver the picture on that very day, and then sue again. To this very obvious and common-sense suggestion defendant would not agree, his counsel relying upon the non-delivery as one point in the defence; so the judge had no alternative but to declare a non-suit, with liberty to bring another action; and Mr. Kirkby has thus been put to an expense for which, if he gains the day in the second action, he can scarcely hope to be recouped. Photographers, therefore, will do well to remember that, if they have a dispute over their work, they must send the latter home, or deliver it in some way to the customer, if they wish to recover. The case, it may be mentioned, is an instructive one, from a remark made by the judge, which went to the very root of the matter. In referring to the difference of opinion between the plaintiff and defendant, he said: "The question is, whether the picture is like the small portrait, and not whether it is like his (defendant's) wife." In this case the photograph was pronounced by his Honour to be "a wretched, faded thing, and he did not know how it could be enlarged at all;" while the plaintiff stated that defendant himself owned that the carte-de-visite was not a fair likeness of his wife. How often is not this kind of thing repeated within the experience of most photographers! People bring photographs of deceased relatives, which photopraphs are, in nine cases out of ten, declared not to do justice to the original; and yet they expect the artist, out of his inner consciousness, to make good all defects. Whatever the defence may be in the present instance, apart from the non-delivery of the enlargement, we cannot, of course, say; but *prima facie*, Mr. Kirkby appears to have had a good chance of winning the day, had he not committed the oversight referred to.

Panoramic Lantern Slides.—The late Mr. Johnson's panoramic camera, in which the lens moved at a regulated speed, made a sensation at the time of its introduction, but has not, for various reasons, been made use of. A correspondent of the *English Mechanic*, who says that when in India he invented and patented a camera about the same time as Mr. Johnson invented his, and on the same principle, suggests that panoramic slides could be easily made for the magic lantern now that gelatine films can be curved, while, owing to their rapidity, the clockwork movement could be done away with. "M. I. C. E.," the correspondent in question, constructs his camera on the principle that a lens can be turned through a considerable angle round its vertical diameter without moving the picture it produces. "In the same way," he says, "it can be shown that there is some vertical line between the two lenses of the ordinary combination used for portraits, round which the combination may be turned through a small angle without interfering with the picture it produces." To decide the radius of the curve of a dark slide, the distance from this vertical line to the image of a distant object produced by the lens must be measured. The camera, he thinks, should be fan-shaped, the lens being fixed between pivots top and bottom, and in a line with the vertical line, at the small end of the camera. To the back combination is attached a flat tube, through which all the light passes, the end of the tube nearest the film being practically a slit about ¼-inch wide. With one sweep of the hand the lens can thus be turned through the whole angle that it can turn, and so the picture is taken. "M. I. C. E." asserts that transparencies printed from negatives so obtained could only be exhibited in the magic lantern bit by bit, but would be much better than "the peepshow views we are accustomed to." This is quite possible.

ON ACTINOMETERS.

BY DR. H. W. VOGEL.*

The actinometer which I have described in former numbers of the News will find its employment mostly as a means of comparing the relative sensitiveness of photographic plates which have been exposed at the same time, and developed in the same solution. In such cases the temperature of the developer plays no part.

It is another thing, however, when two plates are developed in separate solutions of uneven temperature; in this case the result is materially influenced by temperature. Thus, I obtained with two plates of the same emulsion, which were exposed at the same time, and for the same period, with one, the figure 8, on development by means of a warm solution, and with the other the figure 12, by means of a cold developer. The developer was in both cases the same, with the exception that one had a temperature of 10° R, and the other a temperature of 18° R. The figures 8 and 12 might lead one to think that the plates were sensitive in the ratio of 2 to 3.

Results obtained with the same plates in the case of scientific observations on the relative chemical intensity of light made at different times are, therefore, only comparable when the developing solutions are of the same composition and the same temperature, and the development is conducted for the same period.

Such comparison of results of the light at different periods is required less in practical work than in scientific observations. In most cases I would recommend for the developer a temperature of 15° R., which can easily be secured in summer by means of ice, and in winter with warm water. I may call attention here to the extent to which the development is advanced by a moderate increase of temperature, a circumstance which in practical work, where a very cold developer is frequently employed, should command some attention.

One other important point in connection with this photometer is the necessity for absolutely clean plates; a slight stain or inequality, for instance, in the neighbourhood of the spot where the last number appears makes the result quite useless.

Finally, there remains to be considered the unit of light to be adopted in this actinometer. Magnesium wire furnishes us with a convenient standard. One gramme of the wire is weighed and burnt without reflector, exactly at one metre distance, while the actinometer remains open; then development follows, and the number that appears is read off.

All other observations of the chemical intensity of light may then be reduced to that of magnesium, by dividing the number which appears on the burning of the magnesium wire by that of the other observation.

Warnerke's phosphorescent tablet I do not consider a good unit of light, as its intensity is very materially affected by temperature, the amount of light increasing with the amount of heat at the time being.

* Continued from page 80.

PROPOSED INTERNATIONAL ASSOCIATION.

We have much pleasure in complying with the request of the Chairman of the International Society of Photographers at New York, to publish the following intimation, which is addressed to the photographers of the world:—

The resolution adopted in this city by the last convention of the "Photographers' Association of America," and consequent appointment of a committee looking to the establishment of a grand international society of photographers, is the occasion of this appeal to the fraternity at large, both in this and the old world.

The purposes to be effected are of a character so laudable and desirable, that their excellence becomes evident on a mere statement.

It is greatly to be regretted, but, unfortunately, true, that the profession has been impeded in its progress and in the full unravelment of the possibilities of its art by a feeling of jealousy among its members. Whatever tends to eradicate this feeling—to create a spirit of brotherhood—must inevitably result in incalculable benefit, not alone to the photographer as an individual, but also to his art, and, through it, to mankind at large.

The first steps in this praiseworthy direction have been taken; the photographer the world over has begun to recognize that each is not sufficient to himself; that something may be gained to him by a comparison of the methods and results of his neighbours; that which the individual cannot effect, the united efforts of the fraternity will accomplish.

Local organizations of photographers have done, and are doing, much for the advancement and development of our art, but their efforts are, and naturally and necessarily must be, confined in their limits, hampered in their operation.

Photography is a universal art, not confined to one locality or one nationality, but broad as humanity, as undefined as nature, and her votaries should be united in a bond as complete, as grand and liberal, as unrestrained and unlimited. This object we seek to attain, this union of the efforts of our profession, an interchange of benefits, a dedication to the fraternity of what each has gained for himself, an enlargement of the scope and utilization of the art, a truer and more perfect recognition of the position and merit of the photographer by the outside world.

To co-operate with us in this effort we ask of all, wherever located; to those who have seen and know the advantages of local and national associations, we expect that you will heartily and enthusiastically lend your aid and the benefit of the experience you have gained in that direction. But to the photographer remote from such organizations, we say that you, as well, can aid in this great work—you as well will profit by it.

Photographers! ours is an art of which we should be genuinely proud; it is the only, the true, art preservative. Who will refuse his co-operation in placing that art yet higher, in securing for it the recognition it deserves, the estimation to which it is entitled, in developing to the utmost its wonderful resources, in uniting the brotherhood throughout the world, regarding not race or climate?

Very fraternally yours, D. N. Carvalho, New York City,
Chairman of Committee on Formation of an International Society of Photographers, P. A. of America.

By sending their names and addresses to the Chairman of the Committee, as an evidence of their adhesion to these objects, photographers will most practically and effectually aid this movement.

An expression of views as to the best methods of attaining these ends is cordially invited.

SOME EXPERIENCES IN ANIMAL PHOTOGRAPHY.

BY CHARLES REID.*

In consenting to write a paper on animal photography, the first thought that occurs to me is, that I would much prefer to join you in one of your pleasant excursions to some part of the country where animals are rife, and have some practical illustrations; the camera being to me a far more agreeable article to handle than the pen, and even the development of dry plates in the faint light of the dark room is a more congenial employment than the arranging of my ideas in a form in which they will bear the light.

Portrait photography in the studio has its uncertainties, but they are few compared with those met with in the securing of animals outside of it. Yet to me the latter has a charm peculiar to itself, which makes it a positive pleasure compared with the monotony of the former. The photographing of animals has grown so strong with me, that I can see no attractive or unusual subject without feeling the desire to secure it; hence my camera has been pointed at almost every accessible creature, from the ponderous elephant to the tiny half-fledged robin.

Speaking of the elephant, our town was favoured the other day by a visit from Wombwell's Menagerie, which comprises, among other novelties of which portraits would be desirable, two elephants of tremendous height. Excepting the camels which I had taken during a previous visit, these seemed the only accessible portion of the collection. To the question whether he would consent to have them photographed, the keeper replied, "With pleasure, if you let me have a copy, and if it is to my mine, I shall want more." The task of separating the crowd from the huge pair, though difficult, was easy compared to the obtaining of anything promising. If one of them should remain still for a moment, the other was sure to be rocking his body, or solving the problem of perpetual motion with his trunk. Plate after plate was exposed, some of which were evidently wasted, and about all there was some misgiving in my mind as to the result, so long as the two beasts were together. It occurred to me that perhaps with one of them there might be a better chance of success. Mentioning this to the keeper, I asked if they were trained to go through any performance. "Yes; this is the performing one," said he, pointing, with a wave of the whip, to the tallest and best behaved of the two, with a look of satisfaction, if not of pride. "Show what he can do then," said I; "perhaps he may be quieter alone, when he finds he has got something to take up his attention." To which request the keeper shouted, "Come away now, Theodore!" at the same time bending his knee. In response, the unwieldy brute raised his foot, and placed it gently on the outstretched knee of his keeper, who, no doubt, to make the effect as striking as possible, and perhaps recollecting for the moment that he was assuming an attitude in which he was to be scanned by his friends and handed down to posterity, completed the composition by reclining with his elbow on the leg of his friend, and with his hand placed up to his head, while he again shouted, "Up, up, up, Theodore, further up." Matters really assumed a more hopeful aspect as the docile brute flung his trunk in the air and then allowed it to rest on his forehead; but the rest was brief, it seems so impossible for that organ to be still, yet it was long enough to allow of two exposures being made, a copy from the best of which is sent for examination.

The only other opportunity I ever had of taking an elephant was on the occasion of a visit of a menagerie to another town in which I had a studio, but between the late hour of the day, the wind, the crowd, and the unceasing rocking of this particular animal, the result was a poor picture. Expressing a wish to one in charge to have photographs of the lions and other wild beasts, I was met with the frank assurance that I might have every facility for so doing; they would be willing to assist in exposing different occupants of the dens to the gaze of the camera, and a whole day could be devoted to the work. Need it be said the case wore a different aspect, and that the offer was declined with thanks, when it was known that the happy day was to be on Sunday!

Perhaps the most vicious brute I ever took was a huge travelling bear. Hearing of his arrival in the town, no time was lost in finding him out, while performing in the street. After witnessing his performances and watching his slouching gait—a sight in itself—I made up to his owner, a foreigner, and with considerable difficulty got him to understand that I wished to have a picture of his bear. Like the elephant, this subject was very unsteady when left to himself; nothing could be done till he was put through some of his antics. A favourite attitude with him seemed to be standing rampant, clutching a long pole, but the poor fellow was tired with the day's exertions, and always turned away his head, so as to allow it to rest on his fore-paws. As a picture of him in such a position would be worthless, he had to be frequently stirred up, a proceeding he evidently had no relish for, and, judging by his looks and growl, he would have warmly resented it but for the muzzle he wore. After every conceivable expedient to secure his attention had failed, it occurred to me to try and growl as like another bear as possible. Whether he regarded the hideous noise as proceeding from a friend or an enemy, I cannot tell; at all events, he bestowed on me a look of attention, which I would rather witness in the streets of Wishaw with his muzzle on, than behold without it in the forests of Russia. Thanks to the sensitive plate—a wet one—this look was secured, and can be scanned at leisure by such as care to look at the portrait sent.

As no arrangement could be made with the owner to send him a copy for his kindness, he said he would take money instead. This, I may note, is the only time I have paid for liberty to take a picture. People are usually so willing, and even anxious, to have their animals taken, that the photographer is almost unprepared for a blunt demand for coin, such as I had from an Irishman whom I once observed passing through the town with a flock of goats. The sight of such a fine lot induced me to ask if he would allow me to take a photograph of them when they halted, but he could not be got to understand what a photograph was, till an urchin who overheard what had passed shouted out to him that I wanted to "tak' their likeness." It was useless to make him the usual promise of a picture or two. He would give his consent only on condition that he got unreasonable backsheesh. However he ill-naturedly dispelled my hopes of getting a good thing, by rushing among the goats, and ultimately marching them off beyond my reach, to my great disappointment and regret.

It is not my practice to take any sample of an animal that offers, but to select, when possible, the best specimens within reach, and this, as a matter of course, often necessitates a good deal of extra trouble and anxiety; for "the selection of the fittest," in my opinion, not unfrequently means the best health and spirits, and a strong disinclination to have anything to do with photography on the part of my chosen subjects.

In animal as well as in landscape work, a class of people is met with of a stamp altogether different from the goat-herd—people whose readiness to assist amounts to officiousness, whose services could be dispensed with to advantage, and whose absence or non-interference would be cheaply bought by the outlay of some change, should the circumstances admit of such a proposal. If the pleasures of out-door photography are greater than those which pertain to the studio, its disappointments are more galling. Who that has looked forward with anticipation to a day's outing, and has turned the day to good account, but perhaps, through some mishap, allowed the box containing the negatives to fall on the way home, can look with composure on the shattered fragments of what were once considered valuable trophies, got under, it may be, great difficulties?

The misfortune also of losing something of interest or importance which was within our reach is very annoying, more especially if a considerable effort has been made to obtain it. An

* Read before the Edinburgh Photographic Society.

experience of this sort fell to my lot last year. Taking advantage of a holiday, I resolved to visit a farm-steading at a distance, everything about which had a picturesque, tumble-down appearance, hoping to obtain, among other things, a picture of a pair of horses drinking from an old trough beside a delapidated wall which enclosed an orchard. This was to be the picture of the day; but, as it could not be taken till the mid-day rest, there was time to expose some plates on other subjects, and make every possible preparation. The horses were waited for with anxiety, and, when they did arrive (thirsty enough), the man received all the instructions which would be thought necessary as to keeping them from the water till all was ready, and to keep perfectly still while the exposure was being made. The day was clear, but so gusty, that some delay occurred in waiting for a lull. At last a favourable chance occurred, and the signal was given to allow the horses to have the draught they so much needed, and to remind the rider to be steady. The caution was, however, unheeded. Whether his thoughts were all about his horses, or whether he thought he was not sitting erect enough, he knew best himself; but, as soon as the cap was off the lens, he began to draw himself gradually up, and kept so doing during the exposure. It was no use giving way to the feeling with which every photographer is doubtless familiar in such circumstances. The slide was rapidly reversed, in the hope of having another chance before the horses had drank their fill; but it was too late. The fresh grass on the wall beside the trough was the attraction, and kept them in constant motion, thus dispelling all hope of the coveted picture for that day. No doubt they could have been brought back again, but it would only have been to verify the old saying, that "One man can bring a horse to the water, but ten men will not make him drink." It is on occasions such as this, when time is precious, and the photographer feels his helplessness to control the subjects he chooses to depict, that he most perceives the necessity of having himself well trained in the handling of his apparatus, both as regards his method of working, and particularly in being able to go through certain operations with as few movements as possible.

On a previous visit to the same farm I obtained some good pictures of cattle in a stream. The day opened very unfavourably, being dull and showery, and as there was no indication of the clouds clearing off, and being unwilling to lose the day, several plates were exposed, the results being beyond expectation, showing that for some subjects and for the obtaining of certain effects, sunshine is not indispensable. No. 251 is a print from one of these negatives, and is considered among the most successful in my collection.

Being out one day last summer, and after some special studies favoured with a lovely day—a day such as is but seldom seen in a whole season—I found myself with some spare time, after getting through with these subjects (one of which is sent, No. 75). Considering how to turn it to the best account, it occurred to me to try and get a picture of a maid milking a cow. The materials were just at hand. Of cows there were plenty, grazing in a field near by, and no difficulty was experienced in enlisting the services of the dairy-maid, and in the event of the cow being disinclined to perform her part, the services of a son of Erin who was employed on the farm were proffered, he being all alive to see how the thing was done, but little dreaming of the active part he was destined to play before the game was finished. The first thing, of course, was to catch the cow, which turned out to be no easy matter. The one selected was reputed symmetrical and supposed to be quiet, but when the attempt was made to drive her to the spot chosen—a broken piece of ground, covered with daisies, and flanked by an old hedge—she persistently refused to leave her companions. Her obstinacy roused the temper of the young Hibernian, who resolved to corner her at all hazards. After some spirited running this was accomplished, but not before the brute's blood was up to the point at which the prospect of a picture seemed very remote. Pat didn't think so, however. He entered the arena to cope with her single-handed, and his manœuvring to secure a hold was eventually successful. Seizing her by the nose with one hand, and the horn with the other, he managed to pull her up for a moment, thinking no doubt he had got the victory, but this was but the prelude to the combat. The cow resented such treatment, and plunged and struggled for freedom while her captor held on with the tenacity of a bull dog. It was an exciting scene—you might pay a shilling for a poorer entertainment any day—the pair were so well matched that for some time the issue was uncertain; the eye could scarcely follow their movements as they wheeled and dashed here and there, but the possession of an extra pair of legs makes a vast difference in such a tussle. Pat, labouring under a disadvantage in this respect, felt so to his loss as the cow jammed him against the gate, where, something interfering with the free use of his legs, he fell prostrate among her feet, when she instantly shook him off and bounded away, to enjoy her hard-earned freedom, while another of less beauty but greater docility was successfully approached in an open part of the field, she also refusing to oblige us by going near the hedge, where a prettier picture could have been got. Two plates were exposed in haste on account of the uncertainty of her standing any length of time in one position, a copy from one of which is sent.

The most tantalising animals I ever attempted to photograph were deer. Some two dozen of them are kept in a park about two miles off, but there is the greatest difficulty in getting within reach of them. The only party who can do so is the man who feeds them in winter, and if a photographer could manage to visit them every day for weeks with an offering in his hand, there is no doubt he would be rewarded in the end. But as this plan is out of the question, anyone who desires to take them must follow them from place to place with caution. This has been done by me many times without success. On rare occasions the intervening distance has been shortened to an extent which has caused the camera to be set up and hurried preparations to be made, only to find that before the exposure could be effected, the coy creatures were beating a hasty retreat; baffled in this way, the only alternative was to accompany the party who fed them to the field, and though this was done oftener than once, the only passable picture ever got was the one now sent, taken when the ground was covered with snow, which is little better than a silhouette.

To one who is a photographer and nothing more, such failures repeated again and again are very mortifying, and tend to anything but equanimity; but happily the photographer may be a lover of nature, and if so, he can easily afford to forget about his camera and plates in certain circumstances, and enjoy the beauty of the landscape, or be interested in the habits of the animals, though they refuse to disport themselves in the manner he would wish. In the case of the deer, it was positively exhilarating to see them, when it was attempted to corner them, rush past in single file, with startled looks, and to witness their gambols after they had reached a place of safety.

The desire to obtain photographs of animals sometimes leads to strange adventures and into odd company. During a recent fair held here, when quite a host of showmen were about with their horses, it happened that one of them had a fine specimen of a donkey which took my fancy. Finding the owner, and expressing the wish to have a picture of his "neddy," he gladly assented, and agreed to assist as far as he could. It was no use trying to take him in the open field. When approached too closely he had a disagreeable habit of striking out and otherwise showing his displeasure, so it was decided to capture him and tie him up to a waggon. As he absolutely refused to allow anyone to touch him, an extra lot of showmen were called to render assistance. The mode of capture decided on was to surround him at some distance and cautiously approach, a proceeding in which I heartily joined. As the circle narrowed the uneasiness of the donkey increased, and when anyone ventured nearer than the others, he was rewarded with the sight of a pair of heels, no doubt by way of a hint as to what might be expected by anyone who attempted to lay hands on him.

Although thus restricted in his movements, the prospect of a picture seemed no brighter; but while wondering what end could be served by thus encircling a furious donkey, the owner, a lithe little fellow, who had been watching his chance, sprang at him like a cat, and clasping him round the neck held him fast. Thus secured, the animal seemed subdued for a time, but before the bridle could be put on, he made a desperate struggle to get free, and had every appearance of succeeding, when, prompted by excitement and the fear of losing my subject, I also closed on him, and not being able to shake us both off, he was eventually bridled, and secured to the waggon, in which position he may be seen in the picture No. 275, looking round as if he owed me a grudge for the part I took in depriving him of his liberty.

It is very interesting to note the behaviour of different animals while endeavouring to obtain their portraits. The dog and fox are said by naturalists to be nearly related, and indeed their appearance bears out the statement, while in their manner the dissimilarity is very apparent. A good opportunity of observing this occurred in my wanderings last season. A friend had got possession of a fox, and as I had previously lost a chance of photographing one, I resolved, if possible, to secure a picture of this; but when I went to take it, it would not allow me to get near without bolting into its kennel or skulking behind it. There being no chance of getting it after that day, we were at our wits' end, and almost despairing of obtaining a picture unless it was one taken at too great a distance, when it occurred to the keeper to call one of the children with whom it was on good terms, and even playful at times, provided no grown person was in sight. After the girl led it out into an open space, I drew near, keeping behind the camera as much as possible, but as I dared not go so near as was desirable, I effected a compromise by keeping at a sufficient distance to allow the soothing effect of the girl's presence to neutralise the disturbing tendency of mine; with the aid of my boy, who retired to a little distance and diverted the animal's attention, the picture was soon obtained.

The wish to obtain pictures of birds' nests with young, last spring, cost me a deal of trouble. In the first place, the nests were very scarce, owing, probably, to the severe winter. Such a thing as a robin's nest could scarcely be found, even by the most experienced hands—the school-boys, and to obtain a starling's the services of a party with a good steady head had to be obtained. While it was being brought from the top of a high house, a nest was extemporised as like a starling's as the material at our disposal would allow. An old black-bird's nest pushed into a hollow piece of virgin cork, with the addition of a few ivy leaves, formed an appropriate surrounding to our "sitters," although one they did not relish. Being thus disturbed they came to know that they had wings, and were eager to try them; however, they were kept in the nest till a few plates were exposed, the first being the best, as one of them—the fellow in the bottom of the nest—got sick and hung his head all the time he was out in the bright sunshine. In the picture sent the sick one may be noted.

Another picture—geese and goslings—shows what may be accomplished in adverse circumstances by the excercise of patience and perseverance. The silliness of the goose is proverbial, yet sometimes she will behave better during an exposure than other sitters of whom better things might be expected. In the photograph, the geese and goslings appear to be on the best of terms, yet this would be the first time that they would be in such close proximity, as they were mutually averse to each others company, the goslings having been hatched by hens which had at this time to be kept off. To obtain the picture sent, we had to wait on for a considerable time, and actually weary out the goslings till they were glad to squat anywhere. This, and a picture of spangled poultry, No. 89, were taken by the aid of a drop shutter with an aperture about three times the length of the diameter of the lens—a Dallmeyer's Rapid Rectilinear—for which I procured a brass mount exactly corresponding to the original one, being unwilling to disfigure it by cutting a slot for the shutter to work in, which, by the way, works between the lenses in front of the diaphragm slot.

Several of the others shown were taken with a pneumatic shutter, the chief objections to which are its liability to shake the camera in making brief exposures, and the extra amount of exposure given to the foreground.

All those sent were taken on gelatine plates, which I have used exclusively for out-door work for nearly two years. The gain in convenience and sensitiveness is great, while much remains to be desired as to their reliability.

Having used the plates of, perhaps, a dozen makers, I decidedly give my preference to one sold at a low price, of which I once had the good fortune to secure a large supply, giving the order from a sample; but in fairness it must be added that others obtained from the same maker have not been so good. Though I have obtained good results with several high-priced plates, I must join with many others in affirming that there is just cause for complaint in regard to the quality of many of them. It is to be hoped that, by-and-bye, all plates will be more reliable, and as sensitive as they are at present stated to be.

In reference to the latter point, my opinion is, that from three to six times as sensitive a collodion would better represent the comparison, than from ten to twenty-five times, as usually advertised.

In conclusion, I feel as if an apology were due for engaging to write a paper while having so little in the shape of information to convey. Let the apology be that my photographic life, though not brief, has been an almost solitary one, and that circumstances have made me more of a benificiary than a benefactor—more of a copyist than an originator. But, in regard to the subject of this paper, I have learned by experience that, while a happy hit may at times be made by anyone, anything approaching to general success can only be achieved with the aid of skilful assistance, the possession of a love of the work, and fertility of resource; with the exercise of patience, self-reliance, and, above all things, a temper capable of bearing a heavy strain.

Notes.

There was a debate on science teaching in the House last week, when Sir John Lubbock and Mr. Story Maskelyne, late of the British Museum, championed its cause, and urged that more encouragement should be given to it. Unfortunately pure science has few representatives in the Legislature, these two gentlemen, with Dr. Lyon Playfair, being all that are directly interested in the subject.

Germany is bestirring itself to help in the monument to Daguerre, and already the list of subscribers number upwards of fifty. The donations vary from two marks to fifty marks, and the first instalment, amounting to fifteen pounds, has already been sent to the Committee in Paris.

The monster lens for the California Observatory has been attracting attention at Paris. It is of flint glass, and will cost two thousand pounds. The casting of the glass, which, by the way, has been completed without a single bubble, took no less than four days. The weight of the lens is 340 pounds, its diameter is upwards of a yard, and at the thickest part it measures about twenty inches.

The Russian Geographical Society have marked their sense of the value of photography as a means of illustrating travel by presenting to a lady, Madame L. Poltoratzkaya, a silver medal for a collection of photographs of Western Siberia. Another traveller, M. Lakhmaeyer, who has lately visited the Caucasus and Ural ranges, and also put before the Society a series of photographic records of his travels, has been similarly rewarded. Travellers tell less strange stories when they carry a camera, is evidently the notion of the Russian Geographical Society.

A correspondent, touching the subject of photo-type blocks for the printing press, about which we spoke last week, writes: "If pressed for time, why is not the fatty ink impression pressed straight upon the zinc plate, and this put at once into the acid bath. It seems only a waste of time putting the inked transfer down upon the lithographic stone first, and I don't see the good of it." If our correspondent were a practical photo-lighographer he would "see the good of it." Not only is it very desirable to keep from the zinc plate any chance spot of grease (which would prevent the action of the acid), but it is also very requisite that the lines of greasy ink forming the image should be perfect, and without any trace of rottenness, for the same reason. The photograph inked up for transfer is likely to present these defects, and so the transfer to stone takes place first of all, when the skilful lithographer soon remedies all faults. The very reason why so many fail to get clean *photo-type* blocks is because they omit the intermediate process.

Dr. Lagrange recommends, in the *Wochenblatt*, the employment of the ferrous oxalate developer to recover silver from waste solutions, the silver being then precipitated in metallic form. Impure chloride of silver residues, he recommends, should be treated with hyposulphite solution first of all; the hyposulphite dissolves out all the chloride, and then, if ferrous oxalate is added to the solution, all the silver is precipitated in a metallic state. The silver recovered is washed in water and dilute sulphuric acid, and may then be regarded as the pure metal.

To restore the ferrous oxalate developer after it has been employed, Dr. Lagrange recommends powdered iron. To five hundred grammes of the developer are added fifteen grammes of oxalic acid, fifteen grammes of carbonate of potash, and five grammes of iron powder.

The news of the week is certainly M. Garnier's new photographic process, which the inventor terms atmography—printing by vapour. It is a dusting-on process, the deliquescent film being ingeniously produced by the action of hydrofluoric vapour. Our Paris correspondent describes the process, which seems likely to be useful for the production of vitrified photographs.

Siemens' new gas-burner is well worth the attention of photographers, since it affords a ready means of increasing the luminosity of ordinary gas to a most extraordinary degree. The whole secret of the invention may be said to lie in the simple fact of heating the gas to a high temperature—800 to 900° F.—before it is burned. The gas-flame is circular, surrounding a porcelain ring, and becomes pear-shaped by being drawn into the chimney above. From this chimney proceeds a bye-tube, conveying the hot atmosphere downwards, and making it heat the reservoir that contains the gas.

Mr. Wight, an English chemist resident in Berlin, recommends the intensifying of gelatine plates with gallic acid, rather than pyrogallic, since the former, though slower in its action, is more certain and more under control. His formula is :—

a.—Nitrate of silver	... ...	3 grammes
Water ...	... ...	50 ,,
Glacial acetic acid	... ...	1 gramme
b.—Gallic acid	... ...	1 ,,
Alcohol	... ...	10 grammes

The gelatine plate is well washed and alumed, and then one volume of solution *a*, mixed with four volumes of water and with a few drops of *b*, are poured over it.

It is a pity the interesting Submarine Exhibition which opened on Monday at the Agricultural Hall affords no example of a submarine camera. Many attempts to photograph under water have been made—the last, we believe, by Messrs. J. Valentine and Sons, of Dundee, at the time of the Tay Bridge catastrophe—and now there is little difficulty in affording sufficient illumination by means of electricity, there is obviously better chance of success at hand.

Since in developing it is only necessary at intervals to have a light, photographers are in the habit of covering up their developing dishes most of the time, to protect the plate; in these circumstances, the bichromate battery might well be used to start the incandescent lamp into being in the dark room. If the lamp were only luminous just when the photographer desires to see how the development is getting on, there would be no necessity for this covering up of the developing dish at all; while the battery power would be employed most economically. Our idea is to have a treadle to make electrical contact, so that all the photographer need to do is to press his foot down every time he requires to see in his dark-room.

This plan, too, would be far less trying to the eyes than having a red glare always before them. The photographer, developing dish in hand, would be in darkness so long as he does not press the treadle with his foot. In preparing emulsion the plan might not be so convenient, although there are intervals here, when the photographer can dispense with light altogether.

Molybdous acetate, the latest developer in the field, is not likely to trouble photographers much. The metal molybdenum is found in small quantities in lead, and resembles plumbago very closely, the acetate being produced by dissolving the metal in acetic acid. The cost of the acetate, we believe, is about five shillings an ounce; but since Mr. Wood explained that after a long course of experiment he is unable to recommend the compound for practical use, its hard name is likely to disappear from among us as suddenly as it sprang up.

A correspondent thinks we should apologise for bringing before our readers again so soon the sketches of lenses that appeared in our columns last week; this we do, most sincerely, and promise, moreover, that the pictures shall not reappear for some weeks to come.

Mr. W. K. Burton proved pretty conclusively, at the last meeting of the Photographic Society, that it is hardly possible to construct a drop shutter giving an exposure so short as $\frac{1}{5000}$ of a second, or indeed anything like it, the speed of a shutter set in action by a spring moving not in proportion to the strength of that spring, but at a rate only equal to the square-root of its energy. In fact, said Mr. Burton, an object moving at a velocity sufficient to give an exposure of $\frac{1}{5000}$ of a second would have the energy of one of our modern projectiles as it is hurled through space from a rifled cannon. Any structure of the nature of a camera would inevitably be shattered to pieces in arresting a shutter moving at such a high speed.

But what is impossible with a shutter is perfectly possible with a revolving disc; if the latter is employed to open and shut the lens, an exposure of $\frac{1}{5000}$ of a second, or even briefer intervals, might be given. And here it may be well to mention that these brief intervals of time, strange as it appears at first sight, are quite capable of being measured. In fact, it is possible now-a-days to measure the millionth part of a second, which, some clever arithmetician has explained, bears the same relation to a whole second as one minute does to a fortnight.

And since we have referred to modern artillery, it may be pointed out that our scientific gunners actually do measure the flight of a shot to within the millionth of a second. The matter is not so difficult, after all. It is done by revolving a metal disc at a high speed, and leading electric wires from the gun into the vicinity of this disc. The disc is covered with fine soot, and when an electric spark passes from one of the wires on to the revolving disc, the black soot is flicked away, and a tiny bright spot results. The further ends of the wires are fixed inside the gun at certain intervals, and, when the gun is fired, are cut one after another as the shot passes along the bore. As each wire is cut, a spark passes along it to the disc, so that when this is afterwards stopped, the spaces between the little bright spots represent the time the projectile has taken to pass the wires in the gun. As the speed at which the disc is revolving is known, it is easy to translate the distances between the spots into periods of time, and, as we have said, the millionth part of a second may thus be estimated. Captain Noble, C.B., is the inventor of this subtle instrument, which he terms a Chronoscope.

Colours in photography are terribly disappointing. If we are told that an albumenised paper will tone a rich violet, it is not unusual to find the colour a slatey grey, or, instead of being dark purple, to result in a dull sepia. When we are promised ruby red, it generally turns out the appearance of brick-dust. The commutations of Mr. Wood, in which he cleverly changes the colour of the silver image surprising as many of the tints are, embrace very few pleasing results. The pictures produced are no doubt red, brown, yellow, &c., but it is not a nice red, or brown, or yellow.

Perhaps Mr. Wood may be able to improve the colours so as to make them less disappointing, for photographers would be glad enough, no doubt, to get coloured transparencies if the tints were what they wanted. Some years ago we remember paying a shilling at the Dramatic College Fancy Fair to see a fine cherry-coloured cat that was on exhibition at one of the booths. The cat was produced, and a plate full of cherries as well, so that we might compare the two. The cherries and the cat on that occasion turned out both of them to be black, and we were naturally disappointed; but the dis-illusion then, was not greater than it has been subsequently when we have been shown coloured photographic films.

Photography is never more aptly employed than when it records questions of fact. Some experiments have recently been made at Peterhead, to quiet the waves on the bar by pouring oil upon them, so that vessels may pass in stormy weather. Pouring oil upon troubled waters is not a mere figure of speech, as most people know; and at Peterhead they seem to have succeeded, after pumping oil for three-quarters-of-an-hour through an inch tube, to have quieted the waves very considerably, and, in a word, to have changed an unnavigable channel into a navigable one.

Unfortunately, it is a case in which people want to see before they believe. A pair of wood-cuts have been issued, showing the waves raging on the bar before the flow of oil, and the temporary smoothness afterwards. But this is not enough. Woodcuts do not inspire confidence and in any case cannot be taken as evidence of a fact; whereas photography would have carried conviction, with it A pair of "certified" photographs would have established at once the success or otherwise of the experiment, and there would have been no need to bear other witness to the value of the suggestion.

Noted at the Volunteer Review on Monday. During the march past two photographers, one with a smal camera, the other with a large bellows instrument, made their way across the course. At once "spotted" by the eagle eye of the Commander-in-Chief, a couple of aides were immediately despatched with the stern order to capture the trespassers. The small camera man, fleet of foot, was able to make good his retreat; but the other, brought to bay by the gallopers, bravely defended himself with his instrument. To carry out their orders and to bring back the offender, the gallant aides found to be more than they bargained for, as the photographer had simply to flourish his camera in the face of the nearest horse to cause the latter to shie and wheel round spitefully.

Other determined officers came riding up, and the battle between photographer and the mounted military waxed fast and furious. The camera at the end of its stand was a formidable weapon that no horse would face. The photographer dodged and the horses plunged. At last one of the aides caught hold of the bellows with one hand; but his hold was precarious, and with an effort the photographer got loose, and again had the best of it. There was, indeed, nothing for it but a parley; so the victorious photographer was permitted to march off with honours and his camera, and the gallant gallopers rode away to fight again another day.

Monday was a beautiful day at Portsmouth, and many dry-plate workers were hard at it, taking instantaneous pictures of the march past, the staff, and the lookers-on. Both the *Illustrated London News* and the *Graphic* were represented by photographic special correspondents.

FRENCH CORRESPONDENCE.

The French Photographic Society—Postponement of the Gaillard Competition—The Death of Poitevin.—M. Garnier's New Process.

The French Photographic Society.—The French Photographic Society held a most interesting meeting on the 7th inst. The prize commission entrusted with the award of the Gaillard prize gave in its report on the termination of its labours; the report announced the prorogation of the competition until the 31st October, 1883, when the prize of M. Gaillard, of 500 francs, supplemented by a similar sum from the funds of the Society, will be awarded. Five candidates had presented themselves, but as none of them fulfilled the conditions set down by the programme, it was decided to make no award of the prize. But two silver medals were given to those among the candidates who seemed entitled to some encouragement. A new programme was announced, a copy of which I shall have pleasure in forwarding to the Photographic News as soon as it has been revised.

Death of M. Poitevin.—M. Davanne announced the death of Poitevin, and gave an impressive account of the contributions made to the progress of photography by the deceased *savan*. M. Davanne also spoke of the exertions that were being made in combination with the *Chambre Syndicale* to raise subscriptions for a monument to Poitevin. The French Photographic Society officially subscribed two hundred francs for the purpose, and measures were taken to form a society to collect subscriptions.

M. Garnier's New Process.—A most important matter was then brought forward by M. Garnier. That gentleman demonstrated his new process, termed atmography, which is as simple and rapid in operation as its results are surprising. Atmography, as its name implies, is a mode of printing by means of vapour or atmosphere, and, without exaggerating, I may at once say that the demonstration given by M. Garnier was marvellous. In the space of a quarter of an hour or twenty minutes he had produced before the eyes of the assembly as many as thirty or forty atmographic prints. New names are necessary for new processes, and this one of M. Garnier will add another to the long list already known to photographers. M. Garnier's process is, indeed, a curious one. To begin with, we may say, it is based upon the property that certain vapours possess, on being disengaged in contact with a compound capable of producing certain effects, an effect of deliquescence for instance, as is the case here. The deliquescence in this instance is, however, in no way of a spreading character, which would inevitably bring about a diffusion of the fine lines of a print. M. Garnier has found that if you obtain first of all upon a metallic plate a photographic image by a powder process —dry powdered albumen, sensitized of course, being employed for sprinkling in this instance—an atmographic *cliché* may subsequently be produced by the action of vapour. To do this, the plate impressed by photography is exposed for a few seconds to free hydrofluoric acid; the acid vapour condenses upon the lines of the photographic image, and then, on pressing a glass plate against it, the glass plate being covered with a mixture of borate of soda, honey, and dry linseed, the mere contact of the two surfaces is sufficient to bring about a radical change. The hydrofluoric acid vapour retained by the photographic image becomes attached to the prepared glass, and renders its surface more or less deliquescent, exactly in proportion to the vigour of the photographic image. A dusting-on of coloured pigment, reduced to an impalpable powder, follows, and the finished picture is at hand. The same operation may be performed upon paper direct. The process is decidedly ingenious. The same plate submitted from time to time to hydrofluoric acid vapour will serve for the production of a large number of impressions. The printing, too, takes place with a rapidity that is surprising. If the colour pigment employed for dusting-on is a metallic oxide, the image may be forthwith vitrefied, supposing it has been obtained upon glass. No doubt M. Garnier will be able to improve some of the details of his process yet; but already, as he showed it before the members of the French Society the other night, the results obtained were most remarkable, and possessed of a fineness and delicacy one would scarcely anticipate in a chemical reaction produced by the action of vapour. Here, then, is a new byebath of research opened to the experimentalist. My friend Garnier is one of those who have not hitherto benefitted much by photography, albeit he has contributed an important quota to photographic progress. The beautiful process of heliographic engraving employed at present by the firm of Dujardin, and which served to produce the Fox Talbot portrait in last year's News, is the invention of M. Garnier; but while this firm is thriving and prosperous, M. Garnier, I am sorry to say, has derived little satisfaction from his invention, which does not even bear his name. Let us hope that his new process will be more beneficial to him. Leon Vidal.

GELATINO-CHLORIDE OF SILVER PICTURES BY DEVELOPMENT.

BY B. J. EDWARDS.*

From the earliest days of photography chloride of silver has been most largely used in the production of photographs; but hitherto very little has been done in developing the latent image formed by the action of light on chloride of silver films. The idea is not, however, a new one. I have brought for your inspection some fine transparencies developed on collodio-chloride by Mr. H. J. Newton, President of the Photographic Section of the American Institute, New York. These beautiful pictures were presented to me in America in the year 1872—just ten years ago. Since that time others have experimented in the same direction. Mr. Herbert B. Berkeley has from time to time published the result of his researches; and more recently Dr. Eder and Captain Pizzighelli have given details of their method of producing diapositives on emulsion plates containing chloride of silver in combination with gelatine. The same gentlemen have also shown at Vienna, and at the recent technical exhibition in this building, a series of beautiful transparencies which were universally admired. As these pictures seem to have awakened considerable interest in the process by which they were produced, I propose (this evening) to demonstrate the method of producing transparencies on gelatino-chloride plates, and to describe certain modifications in the development which I have found to give the best results.

For the preparation of the emulsion the following simple formula is all that is required:—

Gelatine	... 300 grains
Cold water	... 4 ounces
Nitrate of silver...	... 240 grains
Distilled water	... 2 ounces
Chloride of ammonium... ...	... 100 grains
Water	... 4 ounces

Mix the above in three separate vessels, allow the gelatine to soak for ten minutes, and warm all the solutions to about 120° F. Now add the silver to the gelatine, and immediately afterwards add the chloride. Emulsify at the same temperature for about an hour; then allow the emulsion to set. Pass through canvas, and wash in running water for some hours in the usual way. When washed and dissolved by gentle heat the emulsion will be ready for coating the plates. The glass chosen should be as thin and flat as possible, to ensure contact in printing from the negative. The dried film should appear pure white by reflected light, and of an orange tint by transmitted light. The latter colour is owing to the chloride of silver being held in an extremely fine state of division.

With regard to the sensitiveness of these plates, I have found them at least a hundred times less sensitive than ordinary gelatino-bromide plates. The time of exposure will depend, to a great extent, upon the colour desired in the transparency and the strength of the developer. With a moderately-strong developer an exposure of two or three seconds to diffused light under an ordinary negative will give all the detail.

The developer I use is a modification of Dr. Eder's formula, and that of Captain Abney. A stock solution is made as follows:—

Citric acid	... 5 ounces
Distilled water	... 20 „
Strong ammonia	... 2 „

The heat produced by the addition of the ammonia will cause the crystals of citric acid rapidly to dissolve. As soon as the mixture is sufficiently cooled the solution is ready, and will keep a long time. When required for use, mix three parts of the

* Read before the South London Photographic Society.

above solution with one part of the ordinary ferrous oxalate developer, freshly made, by adding one part of a saturated solution of sulphate of iron to three parts of a saturated solution of neutral oxalate of potash. Now add to each ounce of the mixture two or three drops of a twenty-grain solution of bromide of potassium.

This will form a very powerful developer for the gelatino-chloride plates, and, with a moderately-short exposure, will give a rich purple tone to the transparency. For a pure black tone expose less time, and use equal parts of the ferrous oxalate and citrate of ammonia solutions, with an extra drop or two of restrainer, if required. If much warmer tones are desired, six or eight parts of the citrate solution should be used to one part of the ferrous oxalate. Any shade of colour may be obtained, from jet black to bright ruby red; but, with the weaker developer, it will be necessary to increase the exposure considerably. For instance, to obtain the ruby colour, two or three times the exposure will be required than for the black tones with the stronger developer. In this way, a great variety of beautiful tones may be produced at will; but the great advantage of this method of development consists in the very great latitude allowed in the exposure. When working by daylight, and with negatives of different degrees of density, it is practically impossible to be sure of getting the correct exposure except by repeated trials, unless the developer can be regulated to suit the exposure given. By my method this is easily done. I make three or more portions of developer of different degrees of energy—that is, containing a greater or less proportion of the ferrous oxalate. Should the transparency appear under-exposed, the developer is at once poured off, and the development completed, and all the details brought out with a more energetic solution. In the case of over-exposure the operations are reversed. This power of correcting under or over-exposure in the development of pictures on chloride of silver has not hitherto been obtained by any known method; and I think I may venture to assert that, without the power of compensating for errors in exposure, the process of printing by development on chloride of silver, however beautiful in some of its results, would be practically useless. With regard to the keeping qualities of the developer, I find that after being mixed it gradually but slowly loses its energy, otherwise keeping in perfect condition for several weeks. It can, however, at any time be restored to any desired strength by adding the proper proportion of freshly-made ferrous-oxalate developer, as in the first instance.

With regard to the utility of this really beautiful process, I think few will question its superiority for the production of the most exquisite transparencies for lantern slides, or for making enlarged negatives. There is, however, another application of the process which may eventually prove of far greater importance. I allude to the rapid production of silver prints on paper by development, instead of the present slow process of printing out under the negative. I have already made a few experiments in this direction, and, from the results I have already obtained, I should judge that it is not improbable that the process I have described to you to-night will prove in time the quick-printing process of the future.

ON THE EFFECT OF THE SPECTRUM ON THE HALOID SALTS OF SILVER, AND ON MIXTURES OF THE SAME.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

Silver Iodide.

Visible Effect of the Spectrum on Silver Iodide.—If paper be soaked in a 10 per cent. solution of potassium iodide and dried, and then be floated on a 10 per cent. solution of silver nitrate and exposed whilst moist,† the spectrum will be impressed in five minutes as given in fig. 1, where it will be seen that the whole visible spectrum is impressed. Similar paper, if exposed to the spectrum coming through a weak solution of potassium chromate, exhibits after ten minutes a slight action in the least refrangible region (fig. 3). If, however, the paper be exposed for ten seconds to diffused light, and then be exposed to the same spectrum as the last, the action is more intense than before, though the exposure be for only two minutes (fig. 2). From this we learn that part of the action of the spectrum in fig. 1 is due to the action of diffused light. It next remained to trace the action on the different silver compounds existing in this paper, [which was ordinary sized Saxe paper. Paper was prepared as before, but washed in common water till nearly all excess of silver nitrate was eliminated, and it was then given a wash of potassium nitrite, an absorbent of iodine. Such paper was exposed to the spectrum, first coming through chromate, second unshaded. The print obtained is that shown in fig. 4, by which it will be seen that the same limits were reached as before, but that there is not that abrupt descent of sensitiveness near G; evidently some cause of the extreme sensitiveness near this point had been eliminated, and apparently that could only be the silver nitrate and the presence of the potassium nitrite. To test the matter further, paper was prepared in the same manner, but before applying the potassium nitrite it was soaked in common salt and water, and washed. This would effectually remove all traces of silver nitrate, converting it into silver chloride. Exposure for five minutes to the spectrum gave the result shown in fig. 5, in which it will be seen that whilst the most refrangible portion took a grey colour, the small portion below G became a pink, the line of demarcation between the two being well defined. It now seemed probable that the pink part of the spectrum was due to the chloride, and the grey to the iodide.

To further investigate the matter, the same paper without iodide was floated on silver nitrate and exposed to the spectrum, with the result given in fig. 6, a very faint trace of action being visible where the paper was exposed for a quarter of an hour to the spectrum transmitted by the potassium chromate.

Iodised paper prepared as in the first experiment was well washed, and simply exposed, with the result to be seen in fig. 7. Finally, paper was prepared and washed, then immersed in a weak solution of potassium iodide, washed well, and flooded with potassium nitrite, and the result is given in fig. 8. Now, fig. 1 coincides with the observations made by Sir J. Herschel, on paper similarly prepared, in 1842, and described in the *Phil. Trans.* for 1843, and he classes this spectrum as due to the silver iodide. It will be seen that the printed spectrum due to silver iodide is that given in fig. 8, and that the tail extending to the least refrangible end is really due to the action of that region on the organic salt (and perhaps chloride) of silver present in the paper. Further, it will be seen that the greater part of the darkening in fig. 1 of that tail is due to the action of the different rays after or whilst diffused light has acted or is acting on that organic compound. Confirmatory experiments were made with pure silver iodide in collodion with excess of silver nitrate, and also without such excess, with the result shown in fig. 8.

If further confirmation were required, it was only necessary to add to a film of collodion containing the iodide and excess of silver nitrate a small trace of organic matter, such as resin or albumen, and the result given in fig. 9 was obtained.

Thus, then, we may say that the parts of the spectrum capable of direct action on silver iodide are shown in fig. 8.

The next point to which my attention was turned was to ascertain the true region of the spectrum which was active on silver iodide when developed.

There are several developers for silver haloids:—

Acid Developers.

1.—Ferrous sulphate and silver nitrate.
2.—Pyrogallic acid " "
3.—Gallic acid " "

Neutral Organic Iron Developers.

4.—Ferrous oxalate.
5.—Ferrous citro-oxalate.

Alkaline Developers.

6.—Pyrogallic acid and ammonia.

Now, the first three gave precisely similar results as did the last three. It will, therefore, be unnecessary for me to state for every experiment which developer was used. With collodion or gelatine plates I preferred the 2nd and the 4th developers, and with paper the 3rd and the 5th.

It may be necessary to point to the different materials employed. In the first place, very pure potassium iodide was obtained by Stas's method, and as much as would dissolve was put into collodion; by the free use of water with the alcohol as much as 4 grs. was dissolved. This was employed with a silver bath prepared in the usual way, containing 35 grs. of silver nitrate to each ounce of water.

5 grs. of commercial cadmium iodide was dissolved in an ounce of collodion, and this was also used with a silver nitrate sensitis-

* Continued from page 181.

† The same action was observed where the paper was allowed to dry, but the darkening was less.

ing bath. The pyroxylin forming the collodion was carefully selected. Before taking into use it had been precipitated from solution by water, washed in alcohol, again precipitated, and washed and dried, and then redissolved in equal parts of pure ether and alcohol, at the rate of 7 grs. to each ounce. Such a solution, after prolonged exposure, when impregnated with nitrate of silver, gave no reduction of the salt.

The emulsions of silver iodide were made by dissolving 6 grs. of silver nitrate in alcohol, adding this to collodion, and gently adding the equivalent to 5 grs. of silver nitrate of the soluble iodide (dissolved in alcohol) to it. This formed a perfect emulsion of silver iodide in the presence of a slight excess of silver nitrate, and also, of course, of the soluble nitrates formed by the double decomposition of the above. I may at once say that the

presence or absence of these soluble nitrates had no effect at all on the results, and may at once be dismissed from further consideration.

Gelatine emulsion was prepared in the same manner, keeping in mind, however, that in this case it was prepared with an excess of soluble iodide instead of silver nitrate. It is well to remark that it is impossible to get a fine emulsion of silver iodide in collodion unless the plan indicated above be followed of first dissolving the silver nitrate in the collodion, and then adding the iodide to that, in addition to which it is necessary that the silver nitrate be in excess, or the emulsion becomes granular. With gelatine the emulsification is an easier matter, but in order to prevent spontaneous decomposition of the gelatine it is necessary that the soluble iodide be in excess. Emulsions of both kinds were "washed" by the usual methods known to photographers. In the case of the collodio-iodide of silver great care was taken that nothing but pure distilled water was employed.

It will be well to show here how it was we ascertained that nothing but pure iodide of silver exists in a film. The impurities to be met with are oxides, chlorides, and bromides. Now when an oxide of silver, or silver chloride or bromide, is placed in a solution of potassium or other soluble iodide, the silver compound is at once decomposed, and silver iodide formed in its place. If, then, a film of iodide of silver in collodion (whether prepared from an emulsion or by the bath process) be washed from silver nitrate, and be then immersed in a weak solution of potassium iodide (it must not be strong, or it will dissolve out the silver iodide from the film) or other soluble iodide, it may be seen that there will be nothing but silver iodide in the film, all impurities being decomposed. If the film be washed well with distilled water, and again immersed in the bath, or flowed over with some sensitiser, such as potassium nitrate, sodium sulphite, beer, pyrogallic acid, &c., it may be exposed with the certainty that only pure silver iodide is under examination. It was necessary to make these remarks, since the whole of the utility of the research depends on the use of the pure substance, the collodion being absolutely inert as regards the silver salt. The silver iodide emulsion made from the purified potassium iodide proved to contain nothing but the pure iodide; but that prepared with the cadmium and other iodides, as will be seen, proved untrustworthy as to purity. It was owing to this that I was led into a mistake in a paper which appeared in the "Proceedings of the Royal Society," wherein I stated that owing to the oxygen-absorbing properties of potassium nitrate, I was able to obtain an image lower than ordinary. It seems now that this may have been due to a contamination of bromide or chloride, or to the formation of silver nitrate, any of which would have given me the same results.

One word also as to the neutral or alkaline developer employed. It has been customary to state that silver iodide is unamenable to alkaline development. This is, however, not the case. The ferrous oxalate and the ferrous citro-oxolate bring out a distinct image, as does pyrogallic acid and ammonia, when no restraining iodide is employed. In all dry plates prepared with the iodide and other silver haloids, the iodide is developable (though it gives a weakly image compared with that due to other salts) by the alkaline or organic iron developer.

A plate was coated with cadmium iodised collodion, and placed in the bath for a couple of minutes, and exposed to the spectrum. The top half of the slit was uncovered for one second, the bottom half for ten seconds; the results are seen in figs. 14 and 15. The development took place by the acid developer. Plates similarly prepared and washed, and then similarly exposed, also gave as results figs. 14 and 15. When using ferrous oxalate, the cadmium emulsion also gave the same result. Plates coated with a film of the same collodion, washed, and then immersed in a weak solution of potassium iodide or cadmium iodide, again washed clean with distilled water, and finally treated with silver nitrate, beer, pyrogallic acid, potassium nitrite, when developed by the acid or other methods, gave the results in figs. 10 and 11. The purifications of silver iodide by this treatment cut off the small tail on the least refrangible side of G seen in fig. 14. When the pure silver iodide prepared by the aid of the pure potassium iodide was used, figs. 13 and 12 resulted. A plate was next coated with collodion iodised with the pure potassium iodide, immersed in the bath, washed, and then placed in a solution of common salt (1 gr. to 5 oz.), with the result that figures similar to figs. 16 and 17 were obtained.

A plate similarly treated, except that potassium bromide was substituted for the common salt, gave as a result figs. 16 and 17. There was no marked difference whether the plate was developed by the acid developer or by the ferrous oxalate. It would be useless to describe the many other experiments which were made, all tending to prove that the true action of the spectrum on silver iodide in collodion is that given in figs. 10 and 11. No deviation from it had been obtained, unless impurity in the pyroxyline or in the soluble iodide was proved to exist.

With gelatine emulsions of yellow silver iodide, when rendered sensitive by the use of potassium nitrite or silver nitrate, the same action was found to hold good, and the same may be said for plates prepared with albumen as a vehicle, when all the silver was converted into iodide, and the sensitising was effected by potassium nitrate or some other similar sensitiser.

We next come to the iodide of silver when held *in situ* by paper. The same method of preparation was adopted as that given above for the printing experiments. When paper was exposed with the excess of silver nitrate, on acid development, fig. 18 was obtained. When developed by an organic ferrous developer, fig. 19 was obtained; figs. 14 and 15 were obtained when similar paper was washed and salted with common salt, and washed again, and then sensitised with potassium nitrite.

Figs. 18 and 19 are worthy of attention. It is seen in fig. 18 that the iodide has much greater power of attracting freshly deposited silver than have the impurities present with it in the paper. On the other hand, fig. 19 shows that the ferrous oxalate developer has more power of reducing the impurity (or rather the reduction is better seen) than it has the iodide.

When silver iodide paper is prepared and washed, and treated with a weak solution of potassium iodide and re-sensitised by potassium nitrite, figs. 10 and 11 are obtained.

Fig. 20 shows the action of the spectrum on pure iodide when the exposure is very prolonged. It appears as if the sensitiveness on the more refrangible side of G had diminished. This is not the case, however. The prolonged exposure causes a commencement of what is called a reversal of the image due to oxidation, which I have already investigated in the "Philosophical Magazine," 1880, and the maximum effect has, therefore, apparently shifted to the least refrangible side of G, as shown. This is important, since pheuomena which have been described and figured by other investigators can be shown to be caused by this reversing action. I shall have to allude to it myself again further on.

What has been noted regarding the action of impurities in the silver iodide points to a method of acertaining if an iodide or iodine itself is pure. It is believed that the merest trace of impurity may be recognised by this method of spectrum analysis.

(*To be continued.*)

NEW METHOD OF OIL PRINTING.

Bogaerts, of Herzogenbusch, has inveuted a new method of printing in oil colours, which is said to furnish a very close imitation to oil painting, far surpassing what was possible by means of chromo-lithography. It may be applied to painter's canvas, wood, or metal. The following description of his method is given in *New Discoveries and Inventions.*

The first thing to be done is to make a facsimile of the painting that is to be copied, in which the outline of each simple colour is accurately reproduced. This copy is then transferred to a plate of zinc, which is cut up into as many pieces as the picture contains different colours, in such a way that each piece represents all the parts which in the original are of one colour. Separate electrotypes are made from each piece, and from these the proper colours are printed in corresponding order upon prepared paper. (So far the process is similar to printing chromos.) At the end of this operation, when all the colours have been printed on the paper, the picture resembles an ordinary chromo-lithograph, and like that it is perfectly flat and smooth; the brush marks and roughness of surface noticed in oil paintings are wanting. In order to imitate this part, too, the original painting is covered with a solution of gelatine, in which are impressed with great accuracy the elevations and depressions of the painting. From this plastic copy of the surface another impression is taken in gutta-percha, India-rubber, or other elastic substance, which will stretch so that it can be made larger or smaller, according as the copy is enlarged or reduced. This elastic impression is used for preparing a copper stereotype, with which a negative or depressed copy can be made in a suitable plate. This last plate, of course, will have depressions wherever the painting had elevations or raised spots, and these depressions are filled up with pigment of the same colour as the raised portions of the original. The plate thus prepared is put in a press and the printed chromo laid on it, and then pressure and heat are applied to cause pigments in the depressions to unite with those already on the paper. The picture is now finished all but varnishing. To carry out the resemblance to oil painting it is afterward transferred from the prepared paper to canvas, wood, or metal.

Correspondence.

ECLIPSE EXPEDITION TO EGYPT.

Sir,—I am sorry to say that, owing to medical advice, I shall be unable to take part in the eclipse expedition to Egypt, advice which I need scarcely say has been most unwelcome. I am glad to say, however, that Dr. A

Schuster, F.R.S., is to fill my place, and with Mr. C. R. Wood's assistance I hope will be able to settle what dark rays are in the corona, besides making other photo-spectroscopic investigations during the short minute and twelve seconds for which the eclipse lasts.

I write this note to you as you have mentioned my name in connection with the expedition, and feel that it is due to yourself and the readers of the News to let you know exactly how matters stand.—Yours faithfully,

W. de W. Abney.

ABNEY'S METHOD OF MIXING EMULSION.

Sir,—I have just prepared some emulsion by Captain Abney's process lately mentioned in your paper, in which the silver is mixed with the gelatine, then the bromide is added, and lastly the iodide. The finished emulsion looked exceedingly fine. When, however, I came to expose and develop one of the test plates and look at it by transmitted light, lo and behold, I saw the green-eyed monster —green fog, so often mentioned in your valuable journal. In my experience of over two years in preparing dry plates I have seen nothing like it, and I enclose part of plate. I prepared about twenty-one ounces. Could you or some of your able correspondents say by what means the fog could be eliminated? Could it be judiciously treated by re-washing in bichromate of potash, as recommended by Dr. Kenyon? Peter Collins.

[The texture of the negative picture sent is exceedingly fine, and we found that soaking in a saturated solution of alum for twenty-four hours served to almost entirely remove the discolouration. There appears to be as much brown staining as there is of red fog, and we may mention that our experience indicates that certain qualities of gelatine will not give a good result when the silver nitrate is mixed with the gelatinous solution previously to the addition of the haloid salts.—Ed. P.N.]

THE NEW CLUB.

Sir,—With your permission, I should like to say a few words in reference to the correspondence which has already taken place with regard to the two Photographic Clubs. I must premise that, being myself a member of both these so-called clubs, I may at least be supposed to view the situation in an impartial light—or, at all events, not actuated by feelings of bitter partizanship.

I am by no means an advocate for reports of our meetings being made *in extenso*, but I do consider that country members and others who are unable to attend the meetings regularly, should have the advantage of knowing what is going on amongst us, and to that end I shall work and co-operate with others who are of the same opinion.

Mr. Henderson, in his reply to Mr. Dunmore's letter, is, as usual, too severe and satirical. Mr. Dunmore is made to say "sham society," where it should be "sham club." This is a distinction with a material difference.

One cannot fail to be struck with the funny little echo of Mr. Henderson's letter sent forth by Mr. Cutchey, and I cannot resist the temptation of quoting part of Mr. Henderson's letter, and applying it to that gentleman: "He should have had the good sense to have waited"—well, till doomsday, before referring to the shortcomings of the Club, when he himself was obliged to step aside to allow the chariot of progress and reform to pass, finding that he had not the power to resist effectually its onward march.

It must be admitted that it becomes a serious tax upon one's time and energies—to say nothing of the pocket—to attend the multifarious photographic meetings, and I think it is only fair to assume that the existence of these societies and clubs, whose meetings are so numerous, and, as a rule, so largely attended, furnishes an unmistakable proof that the time has fully arrived when an amalgamation of divided interests should take place, and the attempt be made to establish not a sham, but a veritable club, where we shall not meet simply on sufferance around the tables of a mercenary landlord, and where the desirability of our presence is estimated by the number of glasses with which we are accommodated. Such is the humiliating state of affairs at the present moment. Surely this subject is one which might lead to an interesting discussion, and probably to some practical issue, if introduced at any of the meetings of either society or club. W. Cobb.

Proceedings of Societies.

South London Photographic Society.

The ordinary monthly meeting of this Society was held on Thursday, April 6th, at 8 p.m., in the Large Hall of the house of the Society of Arts, Adelphi, the Rev. F. F. Statham (President) occupying the chair.

The minutes of the previous meeting having been read and confirmed, some formal business was transacted, after which certain new arrangements as regards the prize picture competition were announced; but as minor details were left open, we defer giving particulars until next week.

Mr. B. J. Edwards then proceeded to read his paper on "Gelatino-Chloride Pictures by Development" (see page 202), and after this he demonstrated how, by modifying the exposure and altering the strength of the developer, widely varying tones could be produced.

Some remarks were then made by the President and by a few members who had, like Mr. Edwards, tried Dr. Eder's gelatino-chloride process, when Mr. G. F. Williams was called upon to exhibit his electric shutter. The convenience and excellent design of this apparatus were thoroughly appreciated by the meeting; but, as we describe the shutter in another place see page 193), it is unnecessary to enter into particulars.

Mr. Cowan's automatic dry-plate packer was then shown in action, and block-like packets of plates which had been packed by its aid were handed round.

The meeting adjourned at a late hour, but not so late as to prevent the usual social gathering being held afterwards.

West Riding of Yorkshire Photographic Society.

An ordinary meeting was held on Monday, April 3, at the Market Tavern, Godwin Street, Bradford. There was a fair attendance of members.

After the usual greetings and conversation, the evening was devoted to a lantern exhibition by Mr. Howarth, of Bradford, assisted by Mr. Garratt, of Dewsbury. There were exhibited a number of views of England, France, Italy, China, America, Egypt, Russia, and Japan.

Mr. Forsyth, of Bradford, brought a number of slides made from negatives taken at various times when out "viewing" in Yorkshire.

Mr. Hepworth, of Dewsbury, brought a number of views taken in and around Dewsbury.

Mr. Garratt exhibited several local views, transparencies made in carbon, which were justly admired.

Mr. Howarth exhibited a series of views of tea gardens, and the processes which tea undergoes in its preparation in China, which he had got from a noted firm in London. The said views of life in China could only be termed caricatures, as they were disgraceful daubs, to say the best of them.

At the close, a vote of thanks was given to Mr. Howarth.

A deputation was appointed to wait on the late Secretary and ask him for the books and accounts of the Society.

The last business of the evening was to determine on an excursion, when, after a number of places had been proposed, it was ultimately decided that "Studley Park" should be visited. The next excursion is to be in June, on a date to be settled at next meeting.

Sheffield Photographic Society.

The usual meeting of this Society was held in the Freemasons' Hall, Surrey Street, on Tuesday evening, the 4th inst., Mr. S. Firth in the chair.

After the transaction of the usual business, Mr. Albert Davy was elected a member.

Arrangements were made for an excursion to Haddon on April 27th, and a large number of members and friends are expected to be present. Members of other societies will be cordially welcomed.

Communications from the Photographers' Association of America were placed on the table, the consideration of which was left to a future meeting.

Mr. Ainley exhibited some gelatine negatives made from emulsion of his own preparation, which he had developed with ammonia and pyrogallic in the usual way; but they were useless on account of the green fog which had covered them. He then showed negatives from plates of the same batch of emulsion developed with washing soda and pyrogallic, which, for clearness and delicacy, were all that could be desired.

This peculiarity gave rise to considerable discussion, Mr. Yates expressing an opinion that the fog arose from over-cooking.

A large number of excellent enlargements on Morgan's paper by a Bradford firm were exhibited by Mr. Yates.

Mr. Ainley also brought some of his own enlargements on Morgan's paper, and explained his method of working. They were enlarged by ordinary gas light, without condensers, using a screen of tissue paper to diffuse the light; exposure four minutes.

The results were considered extremely satisfactory, and his simple method of working excited great interest.

Mr. Fixon also showed enlargements by the same process.

After further discussion and votes of thanks to these gentlemen, the meeting adjourned.

Edinburgh Photographic Society.

The sixth ordinary meeting of the current session was held in 5, St. Andrew Square, on the evening of Wednesday, the 5th inst., John Lessels, Esq., the President, in the chair.

The minutes of the March meeting having been approved of, the following gentlemen were unanimously elected honorary members:—Provost James Pringle, David Pringle, James B. Morrison, David Paterson, W. H. Cowan, and D. Chisholm, Jun.

The Secretary read the following communication from Professor C. Piazzi Smyth, Astronomer-Royal for Scotland:—

"15, *Royal Terrace, Edinburgh, 3rd April*, 1882.

"Mr. M. G. Dobbie.

"Dear Sir,—Will you kindly present the two pamphlets I send you by book-post to the Edinburgh Photographic Society, with my respects. Their subject, that of gaseous spectroscopy, does not seem to have much to do at present with photography; but as each science continues to progress and widen its scope year by year, their mutual bearings will doubtless come out by-and-bye to the advantage of both.—I remain, yours very truly,

C. Piazzi Smyth."

The pamphlets were laid on the table, as also a copy of the *Nineteenth Century* for April, 1882, containing an article by Dr. Siemens, F.R.S., on "A New Theory of the Sun," which Professor Smyth requested should also be presented to the Society, suggesting at the same time that the article by Dr. Siemens should be read at one of the ordinary meetings on an early date.

The Secretary was instructed to convey a hearty vote of thanks to Professor Smyth for these papers. His thoughtfulness in sending them was looked on as one of the many evidences of the warm interest he has always manifested in the welfare of the Society, and the progress of photographic art science.

A paper by Mr. Charles Reid, entitled "Some Experiences in Animal Photography" (see page 197), was read, and a vote of thanks for the interesting and racy communication, proposed by Mr. William Dougall, was accorded.

A series of very beautiful landscape photographs by the Hon. A. U. Erskine was examined with much interest. These pictures were subsequently distributed by ballot, under the superintendence of Mr. Jameson, a cordial vote of thanks being awarded for the donation.

The examination of a handsome volume of landscape views by Mr. Robert Murray, C.E., concluded the proceedings.

Photographers' Benevolent Association.

This Association held its usual monthly meeting at 181, Aldersgate Street, on the 5th inst. The minutes of the previous meeting having been read and confirmed, Messrs. G. G. Philips (London), George Wilton (London), and A. R. Hambly (Plymouth) were elected as members of the Association.

The Soirée and Ball in aid of the funds will take place on 27th inst., at Seyd's Hotel, Finsbury Square. Tickets can be obtained of the Secretary. Price: Ladies, 6s., Gentlemen, 9s.

Thursday Evenings for Photographers.

At the meeting held on the 6th inst., Dr. G. D. Thomson in the chair,

Mr. Henderson exhibited some asbestos fibre and cloth, which it had been suggested would be useful for filtering purposes; he also exhibited a shutter (see page 193), the invention of a Brighton photographer. This was constructed to work inside the camera, and consisted of two semi-circular pieces of ebonite, opening from and closing to the centre of the aperture, balanced after the manner of a pair of scissors, and was worked by air acting upon a piston enclosed in a cylinder. The advantage claimed for this arrangement was that, by a slight pressure of the ball, the shutter was opened, and would remain open (giving any required length of exposure) until again pressed, but by a sharp pressure, followed by an immediate relaxation, the shutter was opened and closed instantaneously.

Mr. York showed a very novel and ingenious plate-packing machine, the invention of Mr. Cowan, which will shortly be in the market.

Mr. Haddon asked if anyone present could explain why paper prints change tone when subjected to hot water.

Mr. Henderson could give no explanation, but he promised to exhibit at the next meeting two collodio-chloride prints, hermetically sealed, from which the purple tones had disappeared.

Mr. Henderson suggested that a bromide emulsion might be made without gelatine as follows:—Triturate the bromide and silver together, then add alcohol, and if necessary a few drops of water. This, he thought, would set up a solvent action of the salts, and, as the bromide began to form, the water would pass to the salts still undissolved until all was converted, when the precipitate might be washed, and collodion or any other vehicle added.

Dundee and East of Scotland Photographic Association.

The second annual meeting of the above Society was held in Lamb's Hotel on Thursday evening, April 6th. There was a large attendance of members and office-bearers; Mr. James C. Cox, President, occupied the chair.

The Hon. Secretary read the minutes of the last meeting, which were confirmed.

Mr. W. F. Hill was admitted a member of the Association.

Reports by the Secretary, Treasurer, and Auditors for the Association, and also those of the Hon. Secretary and Treasurer of the Exhibition Committee, were presented.

The President then said—Gentleman, *apropos* of this the last meeting of the Society for the season, it falls to me to draw your attention to the report of our Hon. Secretary, Mr. Johnson, and to the financial statement of our Hon. Treasurer, Mr. Robertson. In the former there is one thing I notice our Hon. Secretary has never had the opportunity of embodying before in his well-compiled and prolific reports, and I feel we must all be pleased to view it as tending to advance the interests of the Society—viz., the reading of papers by its members; and allow me to add that I feel these papers must come more frequently henceforth, to keep life in us. The Exhibition and lantern entertainments are also new undertakings—in a year or two we may have another Exhibition—but the lantern entertainments we must, to the best of our ability, try to secure public interest in. Gentlemen, I beg to move that we approve of and adopt the report, and that we express our thanks to our Hon. Secretary for the clear and full manner in which he has produced it. As regards our money matters, I think they are hardly in the state they should be. Such an item as fifteen subscriptions long past due and still unpaid causes me to make this remark. It is to be regretted that we have so many bashful members. I hope you will accept the balance-sheet, and that we show our appreciation of the services of our Hon. Treasurer by a vote of best thanks. We are also highly indebted to Mr. Baxter and Mr. Roger for their trouble in examining our accounts. Still another report which we must take as read. I have great pleasure in referring to Mr. Rollo (Hon. Secretary) and the Exhibition Committee's report—concise and complete. Like the thorough manner he wrought as our Exhibition Secretary, so has he produced his report. Our Exhibition was in every respect a grand success, and I cannot but congratulate you on the happy result; and I hope that, in two or three years, we, as a society, may be able to bring together another collection worthy of public support and sympathy, which were by no means wanting in the late Exhibition. To the public sympathy and support our success was very much due. You have also heard the clear financial report from Mr. George D. Valentine (Hon. Treasurer to the Exhibition). Few, indeed, know the amount of time and trouble Mr. Valentine has expended on behalf of the Exhibition. The handsome balance he reports, transferring to you to-night, must be very gratifying to him as well as to us, and I cannot but draw your attention also to what the Hon. Exhibition Secretary, in his report, says in flattering terms, anent his assistance. Gentlemen, it affords me great pleasure to propose that we ask our Secretary to embody a special vote of thanks to these two gentlemen, Mr. Rollo and Mr. Valentine. The two auditors for the Exhibition Committee have our acknowledgments for their kind assistance. Before passing from the subject of the Exhibition, I have to ask our Secretary, on behalf of the Society, to embody a vote of thanks to the hanging committee, the judges, and the Free Library Board for the use of their galleries; and last, but not least, to the Exhibition Committee, who have done credit to the undertaking and to the Society. Still one thing more. The term of office held by the various members of the Society terminates at this meeting, and it remains with you to appoint members to re-fill these offices. For myself, gentlemen, allow me to thank you very kindly for the unvarying courtesy and the kindly forbearance I have all along experienced from you.

The election of office-bearers for the ensuing year then took place with the following result:—

President—Mr. James C. Cox.

Vice-Presidents—Mr. W. D. Valentine and Mr. David Ireland.

Treasurer—Mr. John Robertson.

Secretary—Mr. Charles Johnson.

Council—Messrs. G. D. Valentine, S. Rollo, J. Geddes, A. C. Lamb, G. D. Macdougald, and H. G. Fraser.

On the motion of Mr. G. D. Valentine it was resolved that the annual outdoor meeting be held at the Den of Airlie on the first Wednesday in June, and a Committee was appointed to carry out the arrangements.

A communication from Capt. Turton, R.N., Florence, together with letters from New York inviting co-operation in an International Convention, were received, and referred to Council.

A vote of thanks to the Chairman brought the meeting to a close.

Talk in the Studio.

Collodion Afloat.—A Jersey paper says:—"On Thursday last two fishermen, named Mansell and Simon, each picked up a case of collodion which was floating about five miles to the eastward of St. Peter's Port. The cases are about two feet long, and a foot-and-a-half wide and high, and from the marks upon them they seem to have been shipped on board the steamer *Ellora*, of Glasgow, bound to Calcutta. They were brought by the men to the Customs' authorities, who have handed them over to the Queen's Receiver. It appears from the Shipping List that the *Ellora* is a steamer of nearly 2,000 tons, and is owned by the British India Steam Navigation Company, of London.

The Transit of Venus.—The French Government will send out eight different expeditions for the observation of the transit of Venus on the 6th of December next. Four of them are to make observations in the northern and four in the southern hemisphere. They are as follows:—French West Indies, M. Tisserand, membre de l'Institut Astronome de Paris Observatoire; Patagonia, Rio Negro, M. Perrotin, Directeur de l'Observatoire de Paris; Santa Cruz, M. Fleuriais, naval captain; Chubutt, M. Hatt, engineer; Chili, M. de Bernadieres, naval lieutenant; Duba, M. D'Abadie, member of the Institute; Florida, M. Ferrier, lieutenant-colonel, member of tho Institute; Mexico, M. Bouquet de la Grye, engineer. The phenomenon is to be observed in three different ways. 1. By the direct observation of the contact. 2. With the assistance of double refracting prisms and by micrometric distances. 3. By photography. The positions of the stations are placed nearly on the same meridian, so as to observe the whole phenomenon of the entry and issue of the planet, the astronomers hoping thus to determine the exact distance of the earth from the sun. The parties to be sent on the missions have been practising at the observatory, where an apparatus representing the phenomenon has been constructed for the purpose.

The Alexandra Palace.—No less than twenty-five photographers were in readiness to expose on Mr. Barker's balloon "Reliance" as it slowly rose on Easter Monday at the Alexandra Palace; but a very much larger number of cameras were in use for the production of pictures intended to be put in for competition as regards the medals offered for the best pictures of the Easter Monday festivities.—*Globe*

On Thursday last the employées of Mr. A. Bassano were entertained at a dinner given by that gentleman, at Lord's Hotel, Mr. C. Bassano taking the chair, and Mr. E. Lancaster occupying the vice-chair. During the evening some very excellent songs and recitations were given by Messrs. C. Bassano, Lancaster Wyld, Mill, Stephens, Goring, Barrett, Burnill, Butt, Thomas, &c., accompanied on the pianoforte by Messrs. Adkins and Henderson.

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News" Office*, 5, *Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed "Union Bank, Photographic News Co. Account.*"

*** We cannot undertake to return rejected communications.

*** Press of matter compels us to leave over this week Lesson No. 7 on "Dry-Plate Photography," and "By-the-Bye."

J. Maguire.—Thank you.

J. H. O.—1. Black glazed cotton twill. 2. It is a very useful form, but is subject to the disadvantage of not being suitable for use with a pair of lenses, as when one wishes to take stereoscopic pictures. 3. Ordinarily not more than one-sixteenth of an inch. 4. There is not much literature on the subject, as a mere inspection is calculated to teach more than even long articles; but a few papers will be found distributed through back volumes of the News, and in the Year-Books.

A. F.—Such chemicals do not exist; but if you will let us know the purpose for which you require them, we can doubtless suggest to you the names which you have misunderstood.

A Foreign Reader.—There is not one at present; but we hope that this state of things will be altered in the course of a few months.

Assistant.—You should experience no difficulty if you have fairly good recommendations. Probably the simplest and quickest way would be to run over and call on a few of the principal photographers and dealers in materials, these latter usually acting as agents in such matters.

Beeswax.—1. Place the prints, together with the corresponding sheet of glass, in a warm solution of 1 part of gelatine in 10 parts of water, and draw both out together, after which all excess of the gelatinous solution is removed by the application of a squeegee to the back of the print. 2. Approximately as follows: 3½ pints; ½ ounce; 1 ounce.

Nitrogen.—You are mistaken as to the action of nitric acid in this case, as the binoxide is actually liberated during the reaction, and this becomes converted into trioxide or tetroxide on coming in contact with the oxygen of the air.

Bath.—It is quite evident that your solution has become considerably weakened by continued use, and as signs of organic contamination begin to show themselves, you would do well to prepare a fresh stock, and consign that which troubles you to the residue jar.

Enamel.—New glasses often refuse to take the wax evenly, but by long friction on the heated surface you can.

John Bertrand.—The case is certainly one of some difficulty, as by increasing the proportion of gelatine, the tendency of the film to chip off becomes so much greater; but we are inclined to think that the addition of one part of honey for each six parts of gelatine might prove advantageous.

Bradford.—1. Plaster moulds are almost always used. 2. Copper in an extremely fine state of division. 3. No free acid should be present. 4. Not more than thirty grains to the ounce. 5. Those best suited for the purpose are made in Paris, and generally measure about 20 by 16 inches.

Argent.—1. Nothing is better than fusion with the mixed carbonate of potassium and sodium. 2. Numerous articles on the subject have appeared in the News from time to time. 3. See page 46 of Dr. Eder's new book on Dry Plate Photography.

Gelatino-Bromide.—The spots are due to irregularities or pimples on the glass plate.

Charles Grover.—1. It invariably contains a large proportion of mineral matter, sometimes as much as one-sixth of its weight, and nearly half of this is silica. 2. Not at present.

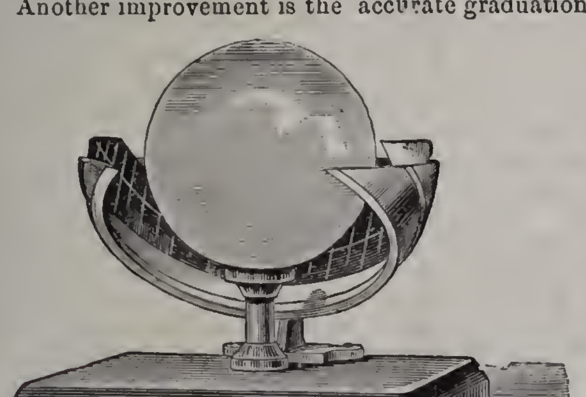
THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1233.—*April* 21, 1882.

CONTENTS.

HOW TO MEASURE THE SUNSHINE.

About thirty years ago, Mr. Campell, of Kensington, fitted a ball of glass into a wooden bowl, the adjustment being so made as to ensure the coincidence of the heat focus of the solar rays with the surface of the wood, so that whenever the instrument is exposed to sunshine of sufficient intensity, the great luminary leaves its trace in the shape of a charred mark on the internal surface of the wooden bowl. This somewhat crude apparatus was found to yield most valuable results, as the depth to which the wood was burned or charred, indicated approximately the intensity of the solar radiations. Professor Stokes has recently pointed out that it is not by any means necessary to sacrifice a whole wooden bowl for each experiment, and that a highly satisfactory result can be obtained by using a strip of card mounted on a kind of half-round gallery placed as shown by the subjoined woodcut. Another improvement is the accurate graduation of



the cards into hours and half-hours; and in order to render the same cards available at all seasons, the frame is so marked off that the position of the printed card can be varied according to the time of year. In this form the apparatus is a sun-dial of no mean value, it being often easy to tell the time by it within ten minutes, and all calculations are rendered unnecessary, owing to the facilities provided for the accurate adjustment of the cards.

Not only does the "sunshine recorder" in its present convenient form register sunshine, but the extent to which the card is charred indicates in a very striking manner the intensity of this sunshine; it being most curious to note how the course of the sun is sometimes marked by a fine line only just visible when the card is carefully placed in relation to the light, and at others by a thorough charring of the card throughout its entire thickness. The photographer knows very well that the thermic energy of the sun's rays does not correspond exactly with their actinic activity; but notwithstanding this, valuable information may be obtained by an inspection of the card when an exposure is about to be made.

The improved form of sunshine recorder as now referred to is in use at most of the meteorological stations throughout the country, and the indications obtained with it seem likely to show that intimate relations exist between sunshine and health on the one hand, and sunshine and fertility of the soil on the other hand. We understand that Mr. R. J. Leeky, of Lorton Terrace, Ladbroke Road W., who is agent for the apparatus, will shortly be in a position to publish important information bearing on these points.

It should be mentioned that an extremely feeble sunshine does not, as might be expected, visibly affect the card; but on a moderately bright day it will record considerably over 90 per cent. of the sunshine; and if the cards were charged with a very small proportion of slightly sensitive chloride of silver, it is probable that even the extremely feeble sunshine might also be recorded.

Any of our readers who adopt the instrument can easily carry out our suggestion for themselves.

THE GRADUAL OXIDATION OF SODIUM HYPOSULPHITE WHEN IN AQUEOUS SOLUTION.

A number of very interesting experiments bearing on this subject have been made by Mr. S. U. Pickering, and he finds that the oxidation of hyposulphite in solution proceeds so slowly, that in ordinary cases the effective strength of fixing solutions is not likely to be seriously diminished by keeping for a moderate time. In the case of a series of solutions which were kept for no less than a year, the proportion of hyposulphite oxidised amounted to 0·14 per cent. as a minimum, and to 2·5 as a maximum. The former solution was, however, preserved in a blue bottle kept in the dark, while the latter was in a white bottle exposed to diffused daylight. A solution which was kept in a white bottle and exposed to daylight and sunlight for four hundred and twenty-one days, lost no less than 7·63 per cent. of its hyposulphite by oxidation.

The practice of keeping a lump of chalk in the hyposulphite is a very common and excellent proceeding, as it neutralizes any trace of acid which may be formed. Mr. Pickering's experiments seem to indicate that a trace of a fixed alkali like potash is much more effectual as a preventive against oxidation than is the volatile alkali ammonia; and other things being equal, the oxidation proceeds more rapidly in a white bottle than in a blue bottle.

THE APPROACHING ECLIPSE OF THE SUN.

The expeditions sent out by Government to observe the Solar Eclipse on the 17th May next, at a spot about one hundred miles north of Thebes, sailed from Gravesend on Wednesday in the *Kaiser-i-Hind*. The principals of the expedition are Mr. Norman Lockyer, F.R.S., and Dr. Schuster, F.R.S., both of whom have had experience in expeditions of the same kind. These are accompanied by Messrs. Lawrence and Woods, and it is hoped that Professor Tacchini will join the party at Cairo.

The nature of the instruments and of the observations to be undertaken are well described in a daily contemporary, which justly says that now-a-days the resources of science place many means of attack in the hands of the astronomer. To get an idea of the physics of the solar atmosphere—what it looks like—to study, so to speak, its circulatory system, to which such special attention has been recently directed by the bold hypothesis of Dr. Siemens; to investigate its extent, and to determine the luminosity of its various regions; we have the astronomical telescope, and, better even than this for some purposes, the photo-heliograph, that is an instrument which enables us to obtain a photograph of all the sun's surroundings visible during the eclipse. To determine the chemical nature of the various regions, a question to which the keenest interest attaches at the present time, we have the spectroscope and the spectroscopic camera. By means of these instruments we can see what we cannot photograph, and photograph what we cannot see.

In former eclipses, when the duration of totality has been longer, it has been possible to have different instruments mounted on different stands—there has been time to go from one to the other. But on this occasion such a course would be impossible. On one stand, therefore, we have four telescopes and two spectroscopes for eye observation. On another stand we have a photo-heliograph and spectroscopic camera for photographic registration. In the observing telescope two spectroscopes are so arranged that a movement of the eye through two inches is all that is required to pass through the whole range of spectroscopic dispersion which can be conveniently employed during an eclipse. In this way it is hoped that the spectrum of the brightest and the spectrum of almost the dimmest part of the sun's atmosphere can be observed, and for the first time in the history of eclipse observation, comparisons will be made with the solar spectrum itself, as a solar photograph taken before totality will be used as a scale. Much is hoped in the way of the photographic record, for since the last eclipse the science of photography, following step by step the new views of molecular grouping suggested by the spectroscope, has provided us with silver salts, identical in chemical composition, but so different physically, that the red part of the solar spectrum can now be recorded as satisfactorily as the blue part of the spectrum has ever been. Nor is this all. The rapidity with which an image can be impressed upon a sensitised plate has been enormously increased, so that if all goes well, seconds now take the place of minutes, and more can be recorded in five seconds now than was possible in five minutes twenty years ago.

Although on the 17th of next month the moon will come between us and the sun here at home in such a way that part of the sun will be covered, at Greenwich, which may be taken as a short title for the British Islands, for this reason our astronomers must go elsewhere to view a *total* eclipse. A thin line can be drawn on the globe from the West Coast of Africa, through Egypt, Persia, Central Asia, and China, along which the moon will entirely cover the sun; and here, instead of a partial eclipse, we shall have a total one.

This is one of the most important phenomena we can observe in the whole domain of physical astronomy, for a reason with which our readers are already familiar—namely, that when the light of the bright interior nucleus of the sun which we usually see is prevented from illuminating our upper air by the interposition of the dark moon, the sun's atmosphere, which we never see except at such times, is revealed in all its majesty, and invites study on the part of those who care for the mechanism of the universe in which their lot is cast. The expedition is going to a point on this thin line—viz., a little north of Thebes, and with camera and spectroscope will no doubt bring home some valuable observations.

By-the-Bye.

DARK ROOM DISEASE.

With the partial, if not general, abandonment of the wet collodion process, we anticipated an improvement in the sanitary condition of the dark room. The fumes of ether and alcohol with which the photographer was troubled, when "cabined, cribbed, confined" in his sombre laboratory, were no more to poison him, and he would be able to breathe air as fresh and good as that in any other room of his establishment. There was no doubt about the noxious influence of these fumes, albeit many were fortunate enough to escape their ill effects. One instance is still fresh in our memory, and to this day we wonder how an assistant we once met during the sultry days of a Paris summer contrived to exist in good health in his close confinement. The dark closet in which he was located was on the roof of one of the big houses on the Boulevards, and here he stayed from morning till afternoon, just under the roof, coating plates with collodion as fast as they were called for in the studio close by. The heat of the studio was already oppressive, and now and then, when the dark room door opened to receive one dark slide and give out another, some idea could be obtained of the hot noxious atmosphere therein. But, like Albert Smith's engineer in a gunboat in the China seas, whose engine-room thermometer stood above a hundred, and who always sat down to enjoy himself, because his confined space prevented him from standing upright, this assistant, we remember, never grumbled at his lot, but took it as a matter of course. He perspired freely in his shirt sleeves, and seemed to exhale in this way anything noxious he might absorb.

That many gentlemen have suffered from inhaling ether and alcohol, and suffered seriously, too, there cannot be a doubt. Ether and alcohol swallowed as vapour is quite as bad, doctors tell us, as ether and alcohol swallowed in the form of liquid. It is for this reason that the use of effervescing and mineral waters has been so strongly advised for such sufferers, together with the cessation of all spirituous liquors; while, of course, fresh air and exercise should be taken as abundantly as is possible.

Unfortunately, it appears that although we may discontinue the use of wet collodion, and thus get rid of ether and alcohol fumes, we cannot get rid of sickness from the dark-room. Several examples have, of late, been cited of disease brought about, it is said, through the practice of alkaline development. One patient recently described an attack as commencing with a small irritating spot on the back of the hand; a number of small pustules next appeared, which spread rapidly up the arms to the shoulders; they next appeared in his legs, especially under the bend of the knee. The disease is very stubborn, and does not, we are told, readily yield to treatment. Its characteristics are sores and lowness of the system.

Now, the difficulty has been to find out really what is the offending agent. In alkaline development we have to deal with ammonia, pyrogallic acid, and bromide of potassium, and it has been sought to fasten upon one of these the insidious action. The ammonia, especially of the strength at which it is used, is almost above suspicion, and no medical man would think of attributing a disease such as we have mentioned to its agency. There only remain, then, pyrogallic acid and bromide of potassium.

Now pyrogallic acid, virulent poison as it is, when taken internally, would not be prone to injure by contact. Its principal feature is, that it is a powerful absorbent of oxygen, but as such is not likely to be harmful to the skin. Again, pyrogallic acid has been so generally used for years past by the photographer *sans peur et sans reproche*, that it is rather late in the day to call out about its noxious influence. Combined with silver it causes some stubborn marks on the skin, but the marks are only skin-deep, and their character, from a hygienic point of view, has never been seriously questioned.

So that there only remains bromide of potassium to be considered, and since the suggestion has been made that there is an eruption already known as "bromide spots," it is to potassium bromide that several photographers have pointed with a warning finger. Now bromide of potassium is of course almost invariably present in an alkaline developer, but it is by no means a dangerous agent. No doubt fingers continually dipped into a liquid containing a solution of bromide might absorb the same into the system, but is it likely that the compound would be taken up in dangerous quantities? Bromide of potassium is a valuable medicine, and it is taken not in small quantities, but in large doses. Twenty grains three times a day—that is, sixty grains per day—is the regular dose prescribed for epileptic patients. Eruptions from the use of the bromide, if they follow, are of exceedingly rare occurrence, so much so that doctors, as a rule, do not take the result into consideration. Bromide has a lowering effect, as most people know, and it is also prescribed as a valuable medicine in connection with bronchial affections. But the effect of such amount as could possibly be absorbed by photographers putting their hands in a weak solution of bromide—like that employed in alkaline development—cannot for a moment be compared to the influence upon a patient who drinks many grains of it a day.

In the interest of our readers we have placed this subject of alkaline development, and its likely influence upon the human system, before two medical men of repute, and have sought their advice. We have detailed the cases of three different photographers which have come to our knowledge, and have placed before them the solutions in general use in the photographic laboratory, so that they might form as sound an opinion as possible on the causes of sickness. Both of these gentlemen agreed there was nothing in the solutions to account for the symptoms complained of. These symptoms were evidence that the sufferers were very much out of health; but that any of the solutions with which they had to do was the cause, there was no evidence at all to show. When further questioned upon the subject of the gelatine process, we mentioned that bichloride of mercury was employed for intensifying. A solution of this, if frequently touched by the hands, might bring about salivation, and attack the gums; but of this there was no complaint. In a word, our medical friends were at a loss to ascribe the disease to any noxious chemicals in the dry-plate laboratory.

But they readily agreed as to the probable cause of the attack, notwithstanding; it was, in their opinion, the dark-room itself that caused the mischief. Cutting off free access of air and light was very likely to produce the symptoms, the absence of light being quite as deleterious as want of ventilation. Many hours a-day in the dark-room—especially in dark-rooms as they are arranged for the gelatino-bromide process—were exceedingly likely, in the opinion of both medical men, to bring about a low state of health, for which they would prescribe steel and plenty of fresh air. We may, indeed, here set down a prescription which one of our friends did not hesitate to advise at once, in the case of a photographer who was in a low state of health from an excess of dark-room work. Here it is, perchloride of iron and strichuine being its principal constituents:—

Liq. ferric perchl. dil....	...	...	$1\frac{1}{2}$ drachms
Liq. strichnæ ...	...	...	...	1 drachm
Aqua chloroform	...	...	...	6 ounces

One-twelfth, three times a-day, after meals.

It would seem from this that it behoves photographers who have much dark-room work to do still to be careful of their health. They may get rid of ether and alcohol fumes by giving up the wet process, but because they do this they must remember that ample ventilation is still necessary, if they wish to enjoy good health. Sensitive gelatine plates necessitate the stopping of every crack and cranny in the most careful manner, and in doing this photographers sometimes stop up at the same time their last chance of ventilation. They breathe a vitiated atmosphere hour after hour, and it would be wonderful indeed if their health did not suffer. Well ventilated dark-rooms are quite as readily constructed now as formerly, although a little more care may be necessary to exclude light.

The matter of darkness, or ruby light, upon which our medical friends laid much stress—for it is a mistake to suppose that only the optic nerves are thereby affected—is a more serious question, especially if the photographer is subject to it for long, and combined with lack of ventilation. Medicine alone will not combat the ill-effects; plenty of fresh air and out-door exercise are the most efficient remedies, the photographer should remember, and these are restoratives, fortunately, within the reach of all. An energetic walk every day after business hours is said to be one of the best antidotes for dark-room sickness.

The "At Home" next week will be "The Bruckmann Establishment at Munich;" the following "By-the-Bye" will be "A Unit of Light."

THE NEW COPYRIGHT BILL.

We have extracted such particulars from the new Bill on Copyright now before the House of Commons as will interest photographers, but we may mention that those who desire to possess a copy of the document can do so on payment of twopence.* It is scarcely likely to pass into law without some amendments, and of these we shall take note at a future time. The title of the Bill is the Copyright (Works of Fine Art and Photographs) Act, 1882.

9. The author of every photograph which shall be or shall have been lawfully made, and which shall not have been published before the commencement of this Act, such author being a British subject, or domiciled in some part of the United Kingdom, the Channel Islands, or the Isle of Man, at the time when such photograph shall be published, shall have the sole right of copying, reproducing, and multiplying the same for the term of *fifty years*, commencing on the first day of the calendar month in which it shall be published: Provided always, that where, in making a photograph, a negative is first made, the said right shall belong to the maker of the negative.

10. Whenever after the commencement of this Act any photographic likeness of any person is executed on commission, it shall be unlawful for the photographer, or for any other person, whether he owns the copyright therein or not, without the consent in writing of the person for whom the work was executed, to sell, offer for sale, or exhibit in public in any shop window or otherwise any copy of such likeness, and if any such photographer or person shall sell, offer for sale, or so exhibit any such copy, it shall be lawful for the person for whom the work was executed to summon the offender before any two justices of the peace, court, sheriff, or other person having jurisdiction in summary proceedings, and such justices of the peace, court, sheriff, or other person, on being satisfied that such photographer or other person has any copies of such likeness in his possession for sale, or that he has exhibited the same in public, shall make an order upon such photographer or other person to deliver up to the person for

* 13, Great Queen Street, W.C.

whom the work was executed all copies thereof in his possession and the negative thereof, and if such photographer or other person shall not forthwith deliver up to such persons all such copies and such negative, or upon proof by the evidence of one credible witness that there is reasonable cause to suspect that such photographer or person has not delivered up all such copies and such negative which are in any house, shop, or other place belonging to him, it shall be lawful for such justices of the peace, court, sheriff, or other person, and they or he are or is hereby required to grant a warrant for some peace officer or officer of the court to search in the day time such house, shop, or other place, and if any such copies or such negative shall be found therein to bring the same or cause the same to be brought before them or him or some other justices of the peace, court, sheriff, or other person as aforesaid, and the same shall be forfeited and delivered up to the person for whom the work was executed as his property.

11. If any person, being a British subject, or domiciled as aforesaid, employs another as his assistant, servant, or workman to work for him for salary, wages, or hire, for the purpose of executing, making, or taking, or assisting in executing, making, or taking, any work of fine art, or any photograph, the copyright in such work or photograph shall belong to the employer.

12. Nothing herein contained shall prejudice the right of any person to copy or use any work of fine art in which there shall be no copyright, or to represent and obtain copyright in his representation of any scene or object, notwithstanding that there may be copyright in a copy or imitation previously made of the original work, or in some previous representation of the same scene or object.

13. If a work of fine art or a photograph in which there is copyright happens to be an object in any scene, the copying of such work or photograph merely as forming part of the scene shall not be deemed to be any infringement of the copyright therein, unless the special purpose for which the scene is copied is the exhibition of the copy of the copyright work.

14. (1.) Copyright under this Act shall be property of the kind called in England personal and in Scotland movable.

(2.) Every assignment thereof other than an assignment by operation of law, and every license respecting the same, shall be in writing signed by the assignor or licensor, or by his agent appointed for that purpose in writing.

15. No person shall repeat, copy, colourably imitate, or otherwise multiply, or cause or procure to be repeated, copied, colourably imitated, or otherwise multiplied for sale, hire, exhibition, or distribution, any work of fine art, or the design of any work of fine art, or any photograph, in which work, design, or photograph, or in the negative of which photograph, there shall be subsisting copyright, or any part of such work, design, or photograph, by any means in any material, or of any size, either in or by the same or any other class or kind of art as or than that in and by which the original work was executed, unless he is the owner of such copyright, or has obtained the written consent of the owner thereof to the making of such copy, repetition, or imitation for the purposes aforesaid, or some or one of them, nor shall any person, knowing or having reasonable cause for believing that any such copy, repetition, or colourable imitation has been made without such consent, import or export any such repetition, copy, or imitation, or exhibit, sell, expose, or offer for sale, or distribute any such repetition, copy, or imitation so made, or so imported or exported, or cause or permit the exhibition, sale, exposure, or offer for sale, or distribution of the same, unless he is the owner of such copyright, or the written consent of such owner has been given so to do. Every person convicted of an offence under this section shall forfeit to the owner of the copyright in the original work, design, photograph, or negative for every copy, repetition, or colourable or other imitation in respect of which an offence is proved, a sum not exceeding *twenty pounds*, and double the full price, if any, at which all such repetitions, copies, or imitations shall have been sold or offered for sale.

16. If after the commencement of this Act any person shall repeat, copy, colourably imitate, or otherwise multiply, or cause or procure to be repeated, copied, colourably imitated, or otherwise multiplied for sale, hire, or distribution any work of fine art, or the design of any work of fine art, or any photograph, in which work, design, or photograph, or in the negative of which photograph, there shall be subsisting copyright, or any part of such work, design, or photograph, by any means in any material or of any size, either in or by the same or any other class or kind of art as or than that in and by which the original work was executed, or shall import or export any such repetition, copy, or imitation, or shall exhibit, sell, expose, or offer for sale, or distribute any such repetition, copy, or imitation so made, or so imported or exported, or cause or permit exhibition, sale, exposure, or offer for sale or distribution of the same, then and in every such case, unless a written consent for so doing shall have been obtained from the owner of the copyright in the original work, design, photograph, or negative, the owner of the copyright may, in addition to any other remedy under this Act or otherwise, recover damages and obtain an injunction in an action or other proceeding allowed by the law of the place where the proceeding shall be taken.

17. In every case of infringement of copyright the owner of the right, instead of bringing an action, may apply in a summary manner to any two justices of the peace, court, sheriff, or other person having jurisdiction in summary proceedings, and such justices of the peace, court, sheriff, or other person may order the person who has been guilty of the infringement to pay a penalty not exceeding *five pounds* and all costs, and the money so paid shall be given by way of compensation to the owner of the copyright.

18. All copies and colourable imitations unlawfully made or imported of any work in which there is copyright, and all plates, blocks, slabs, moulds, dies, negatives, implements, and machinery made or used for the purpose of or in obtaining or making such copies or imitations, shall be the property of the owner of the copyright therein respectively, and they, or damages for their detention, or both, may, after demand for them in writing signed by the owner of the copyright or his agent, be recovered by such owner in addition to his other rights and remedies, and by the same or any other action or proceeding.

22. No person shall do or cause to be done any of the following acts, that is to say:

Sign, place, or affix, or cause to be signed, placed, or affixed upon or to any work of fine art, or photograph, or negative of a photograph, any name, initials, monogram, or mark with intent or in manner calculated to produce belief that the work, photograph, or negative was executed by some person who in fact did not execute it:

Sell, publish, exhibit, or dispose of, or offer for sale, exhibition, or distribution any work of fine art or photograph, or negative of a photograph, with any name, initials, monogram, or mark signed, placed, or affixed thereon or thereto in manner calculated to produce belief that the said work, photograph, or negative was executed by any person whose name, initials, monogram, or mark, or a resemblance or colourable imitation of the same, is or are so signed, placed, or affixed, knowing or having reasonable cause for believing that in fact it was not so executed:

Sell, publish, exhibit, or dispose of, or offer for sale, exhibition, or distribution any work of fine art, photograph, or negative of a photograph as having been executed by, or copied or taken from a work of a particular person, knowing or having reasonable cause for believing that the same, or some material part thereof, was not respectively executed by, or copied or taken from a work of such person.

If the author or maker of any work of fine art, photograph, or negative of a photograph, made either before or after the commencement of this Act, shall have sold or otherwise parted with the possession of it, and any alterations shall afterwards have been made in it by any other person or persons, knowing or having reasonable cause for believing that such alteration has been made, shall sell, publish, or offer for sale such work, photograph, or negative, or any copy thereof, as or for the unaltered work, photograph, or negative of such author or maker.

24 (1). There shall be kept at the Hall of the Stationers' Company, by the officer appointed by the said Company, for the purposes of the Act passed in the sixth year of Her present Majesty, intituled, "An Act to amend the Law of Copyright," a book or books entitled, "The Register of Owners of Copyright in Engravings and Photographs," wherein shall be entered a memorandum of every copyright to which any person shall be entitled under this Act in any engraving, photograph, or negative of a photograph; and such memorandum shall contain a statement of the name and place of abode of the author of the work in which there shall be such copyright, the name and place of abode of the owner of the copyright, the name or firm and place of abode of the publisher of the work, and the calendar month in which it was published, and the date of making the entry, together with a short description of the work; and, in addition thereto, if the person registering shall so desire, a sketch, outline photograph, or other copy of the said work.

(2.) A memorandum of every assignment of any such copyright and of every licence by the owner of any such copyright to copy or multiply copies of any such work, shall also be entered in the register aforesaid, which memorandum shall contain a statement of the date of such assignment or licence, the names of the parties thereto, and the name and place of abode of the person in whom such copyright shall be vested, or to whom such licence shall have been granted by virtue thereof, as the case may be.

FRENCH CORRESPONDENCE.

New Photo-Etching Process—*Zinc and Platinum* Process—Public Lectures on Photography—Resin Sensitized by Potassium Bichromate—Turn-Table—Dialysis through Gelatine.

New Photo-Etching Process.—Captain Biny, who is no less indefatigable than he is successful with his results, has recently brought out two new processes, both of which are, in my opinion, capable of being applied practically. In the first of these processes, a zinc plate is coated with bitumen and exposed beneath a positive; it is then developed, and the image is seen to be formed by the denuded metal. The plate is then coppered either by immersion or by electrolysis (the latter gives greater thickness), and after the remaining bitumen has been dissolved away by benzine, it is etched by a solution of 2½ per cent. of nitric acid in water. The etching must be continued until the fine lines of copper just show signs of disappearing. When this has been completed the plate is brushed with a fine brush under water, and thoroughly washed, and, so soon as it is quite dry, the relief parts in copper are rolled up with transfer ink. A hot solution of pure gelatine containing from 2 to 4 per cent. is then flowed over the plate, and is worked into the depressions with a painting brush, after which it is allowed to dry perfectly. To take a typographic impression in the lithographic press from a plate prepared in this way, it must be slightly wetted; this causes the gelatine in the depressions to swell, and if now the whole plate is sponged over and rolled up with printing ink, the latter will adhere to the parts coated with transfer ink—that is, to the relief in copper—and will be repelled wherever it comes in contact with the moist gelatine. This evidently forms the foundation of a practicable process for typographic printing, when there is reason to fear any stickiness in the lines; filling the depressions with wet gelatine adds to the effect of ordinary printing that of the chemical action which prevents the adherence of the fatty substance. We may therefore hope that this process opens up a new path of progress for typographic printing.

Zinc and Platinum Process.—Captain Biny has published another very interesting process, an improvement of the one in copper and platinic oxide by M. Gronfier. He proposes to treat with dilute platinum bichloride a polished zinc plate on which a negative image, with all the half tones (taken from a positive) has been impressed by means of coal-tar. He finds that a kind of Daguerreotype of great delicacy is produced on the zinc, and with exquisite modelling. These prints will be cheaper than the Daguerreotypes produced by the deposit of mercury on silver plates. So far as I know—and it will be easy to verify the statement by experiment—the black oxide of platinum is deposited to a greater or less degree on all the parts of the zinc plate that are denuded; the half tones of the image formed by the coal-tar will be the resist, and the deposit will be proportional to their intensity. In other words, we shall have an image which, owing to the black colour of the oxide of platinum, will be in harmonious contrast with the bright tint of the metallic zinc, and which will be perfectly modelled.

Public Lectures on Photography.—The month of March has been productive of several photographic demonstrations. I ought properly to leave to others the account of my own performances, but in my position as correspondent of the Photographic News I am bound to give a faithful report of any occurrence which may be of interest to my readers; the more so when, as in this case, the proceedings are a proof of the progress of our art in this country. On the 21st March last I delivered a lecture at the public lecture hall on the *Boulevards des Capucines*, the subject being, "The Chemical, Physical, and Mechanical Effects of Light," and on 31st March a second lecture, at the *Cercle de la Librairie*, "On the Graphic and Industrial Applications of Light," to a numerous audience composed of the principal publishers and printers of Paris. In addition, a lecture has been given every Sunday on all the methods of reproduction for industrial purposes. On the 12th of April M. Davanne was to give a lecture at the *Société pour l'Avancement de Sciences*, on the work of Poitevin, and perhaps in a few days I shall be called on to read a paper to the Congress of the Directors of the Training Schools of the French Departments, which is to meet at Paris, on the "Advantage of giving Special Instruction in the Methods of Copying Manuscripts and Drawings, either by or without the help of Light." It will be enough for me to point out that all these public lectures are so many indications of the interest excited in France by the progress and extension of photography.

Resin Sensitized by Potassium Bichromate.—M. Fisch, whose skill and investigations in our art I have already had occasion to bring under the notice of my readers, writes to me to say that he has discovered a means of incorporating bichromate of potassium with resin. This mixture will give a very sensitive film capable of resisting the action of acids.

Turn-Table.—The same inventor exhibited at the meeting of the Photographic Society of France, a turn-table constructed on the same principle as the pneumatic holder. It is a simple little instrument which will be of great service to those who desire to obtain an even coating on their plates.

Dialysis through Gelatine.—M. Gobert has made a very interesting observation of the dialysis of liquids through gelatine. He made a solution of gelatine, and introduced into it a certain quantity of bromide of ammonium, and when the mass became set, he poured on the top of the cake of gelatine a few cubic centimetres of a solution of nitrate of silver. At the end of four days he found that all the bromide of ammonium had risen to the surface, and had then combined with the silver nitrate to form silver bromide. The salt of ammonium had, in fact, passed through the gelatine to such an extent that in the upper liquid there was no trace left of silver nitrate. Unfortunately, M. Gobert thought that it would be possible to proceed at once to the emulsification of the bromide of silver thus formed, but he tried in vain. M. Fabre, Secretary of the Photographic Society of Toulouse, who attended the meeting, stated that Van Monckhoven had made the same experiment, and that by leaving the bromide of silver long enough in contact with the gelatine he had succeeded in obtaining a modification of the salt, which he was able to emulsify, and which gave a very rapid emulsion.

Leon Vidal.

A RETROSPECT OF PHOTOGRAPHIC EXPERIENCES.

BY T. BIGGS.*

My taking up photography dates back as far as 1852, when I returned to England from India on sick leave; but before entering on the main subject of this paper, I must refer briefly to the circumstances and objects which led to my studying and practising it.

While previously in India I had spent some six years on the Survey, had to pass in three native languages in which the entire work of the Survey was conducted, and, in the course of my duties, visited not only some of the most magnificent scenery in the world, but came across old temples, caves, wells, tanks, idol cars, &c., most elaborately and minutely carved and

* Read before the Bristol and West of England Amateur Photographic Association.

ornamented, and also numerous sculptured and inscribed stones of fields and villages of various dimensions, then used for boundary marks. I was aware that attempts to copy the inscriptions on these stones by hand had failed, and that a more perfect way of copying was most desirable. I brought home with me a large number of copies of sculpture done by hand, and employed myself for upwards of a year in recopying the same in Indian ink into a large folio made on purpose, which is still in the India Office Library. Whilst copying these sculptures into the folio, and having seen somewhat of photography with my brothers, who had lately commenced it, it struck me that it would be a perfect method of copying the sculptures and inscriptions.

When I commenced photography the calotype or paper process was exclusively used for landscapes, and the collodion process, which had just then been introduced, was rapidly superseding the Daguerreotype for portraits. I visited the laboratories of Andrew Ross and Lerebours, and saw the various processes used in grinding, graduating, and preparing the lenses. I also studied the chemistry of the processes, and then set to work to learn by experience what could be attained in no other way. With the collodion process the silver bath presented one of the chief difficulties—if not *the* chief difficulty—and continued to do so for many years.

The paper process was, on the whole, far more easy of manipulation and more satisfactory in its results ; and some negatives taken by it in those days will still bear comparison with many produced on collodion plates even now, particularly those by the late Mr. Samuel Buckle, of Leamington. The formulæ followed by Mr. Buckle were much the same as given in the *Photographic Journal*, page 109, as exercises, and the only lessons I ever had were from Mr. Buckle—two lessons of one hour each. The paper for the calotype needed to be of a fine, hard surface, even texture, and free from metallic particles. No paper I ever saw or heard of equalled Turner's 1874 drawing-paper, though made for quite a different purpose.

In a short time I succeeded with the calotype better than I expected, and before returning to India I represented to the Honourable Court of Directors the advantages of photography for copying the sculptures and inscriptions in India, which were rapidly falling into decay and ruin, and would ere long be entirely lost. I showed the folio of sculptures I had etched, and as they were very desirous to place the folio in the India Office Library, I presented it to them. In return they presented me with a photographic apparatus, by Andrew Ross, for landscapes 16 by 12 and collodion plates 10 by 8.

Shortly after my return to India, orders from the Court came out to Lord Elphinstone, then Governor of Bombay, to employ me on the special duty of copying the sculptures and inscriptions in Western India. His lordship took great interest in the project, and placed every facility in my way. The chief objects laid down were the copying of the inscriptions, and the endeavour, by a careful and studied comparison of the same—with the aid of educated natives who thoroughly understood the Sanscrit, Maharatta, and Canareese languages—to recover the lost language in which the inscriptions of earlier date are written, and thus to regain the hitherto lost and unknown history of India. Also, by a careful comparison of the sculptures on the various temples and caves, portraying the most minute particulars of their religious rites and ceremonies—their wars, their feasts, their sports, their customs, their employments, and manufactures—to trace the rise and decay of art and civilisation in India.

In Bombay itself I found the calotype process much the same as in England in summer, the exposure being three or three and a-half minutes ; but on going to Beejapoor—some 250 miles from Bombay, and 100 miles from the sea, situated in a very dry part—the required exposure averaged fifteen minutes, and the radiation of heat from the ground was so great after ten o'clock in the morning that I could never get a good negative after that time. I used almost always to excite my negative paper overnight for exposing next morning, and as my double frames were quite air-tight they kept perfectly, notwithstanding the heat. Of course I had to carry a still with me wherever I went, in order to secure a supply of distilled water.

At first there was some difficulty in copying the inscriptions perfectly, as the letters were indistinct, filled with dirt, mutilated, and the same colour as the stone ; but I soon found a device which removed all difficulties and answered admirably. I had the stone well washed, then the surface whitewashed, wiping off as much of the whitewash as possible with a cloth while still wet. After a few minutes, when the whitewash was quite dry, the surface of the stove was rubbed over with a rag dipped in indian ink, and wrung nearly dry. This darkened the surface of the stone, leaving the letters and any marks in the stone quite white, and thus the copying became easy and perfect, every letter being discernible.

I had scarcely commenced my second season's operations—after having made minute inquiries through the civil authorities as to the locality of interesting buildings and relics, and gathered all the information I could, having procured a *suite* of tents, carriage, and everything necessary for a long season's work—than the Persian war broke out, and my services were required with my regiment. I had, therefore, to resign the work I was so interested in.

After some months, when it was found that my services were no longer indispensable with the artillery, Lord Elphinstone offered me my former appointment on special duty ; but, as I was holding a good staff appointment with my regiment, and had three times been taken away from civil employment for field service, I preferred remaining with my regiment. The next year the mutiny broke out, and, when the officer who succeeded me as photographer to Government died, the work was altogether stopped.

In 1862 I came home again, and was not a little surprised and disappointed to find the copies of Sanscrit inscriptions, which had been sent to the India Office, had been forwarded to the Sanscrit professor at Oxford, and had never left his portfolio, and that no attempt had been made to decipher one of them, the change of Government seeming to have destroyed all interest in the matter.

The waxed paper process was practised extensively by some, but I never got a really good negative by it, nor did I ever see one produced by it. During my second stay in England I studied more particularly the dry processes, which were then being introduced. Finding the tannin process succeed better than any other, I adopted it in preference, and I put its keeping properties to a severe test on returning to India. I prepared and sensitized a dozen plates at Cheltenham, and exposed them more than three months afterwards at Ahmedabad, in Goozerat, getting good negatives. On my return to Bombay, I was once more employed by Government to photograph the temples, mosques, &c., in Goozerat, chiefly in the city of Ahmedabad, which abounds with numerous elaborately-carved and highly-ornamental buildings, tombs, wells, and tanks.

The climate during the greater part of the year was very dry and hot, the thermometer rising to 115° or 120° during the day for weeks together. The difficulties with either dry or wet collodion were legion, and such as are never experienced at home. Flies and flying insects of all kinds abounded, and seemed to delight in settling on the film of collodion just as it was poured on the plate ; the atmosphere was loaded with dust, which entered every crevice ; rats, squirrels, and cats were constantly careering on the canvas ceiling over the dark room, and shaking down volumes of particles of lime and dust, to say nothing of the intense heat and dazzling radiation from the ground. At one time, after long-continued heat, I could not keep a single negative after I had obtained and finished it. I tried to create a damp atmosphere, and coated the film with albumen, gum, &c., but to no purpose ; for in an hour the whole film had peeled off, and the plate was left quite clean. This continued for a fortnight, when a heavy thunderstorm came, and all went well again. Wet collodion was worked with difficulty in a tent under the above circumstances ; but I got many good negatives—some of animals (bullocks and camels) almost instantaneously.

In 1866 I came to England again at the desire of Sir Bartle Frere to superintend the publication of the three volumes of photographs—namely, Beejapoor, Western India, and Ahmedabad—under the auspices of several native gentlemen in Bombay, whose subsequent collapse and failure put a stop to the publications after some forty copies of each had been issued.

After I left India a distinct department was formed—"The Archæological Society of India"—and I have been furnished with copies of their *Proceedings ;* but I am unable to discover the aim or object of the department. There seems to have been no settled plan or system of research, and no practical results. The old inscriptions are still undeciphered, and, as far as I can gather, no systematic attempt has been made to recover the history of India from the sculptures. Many of the photographs which have been taken are the same as I took in 1854 and 1855, only on a smaller scale. The original grand aim and object appears to have been lost sight of altogether.

In conclusion, I would remark that photography now is very different from what it was. It was formerly a science, and an amateur, to succeed, was obliged to study the chemistry of the science as well as the manipulation. I frequently made my own gun-cotton and collodion, and always my chloride of gold, and albumenized my positive paper. Now, since the introduction of dry plates, photography with many has become a mere mechanical process. No knowledge is necessary beyond the time of exposure and how to develop the negative; nevertheless, many amateurs still study it thoroughly, and I believe it is mainly through their careful researches and experiments that the art has attained the great perfection it has, and will continue to do so.

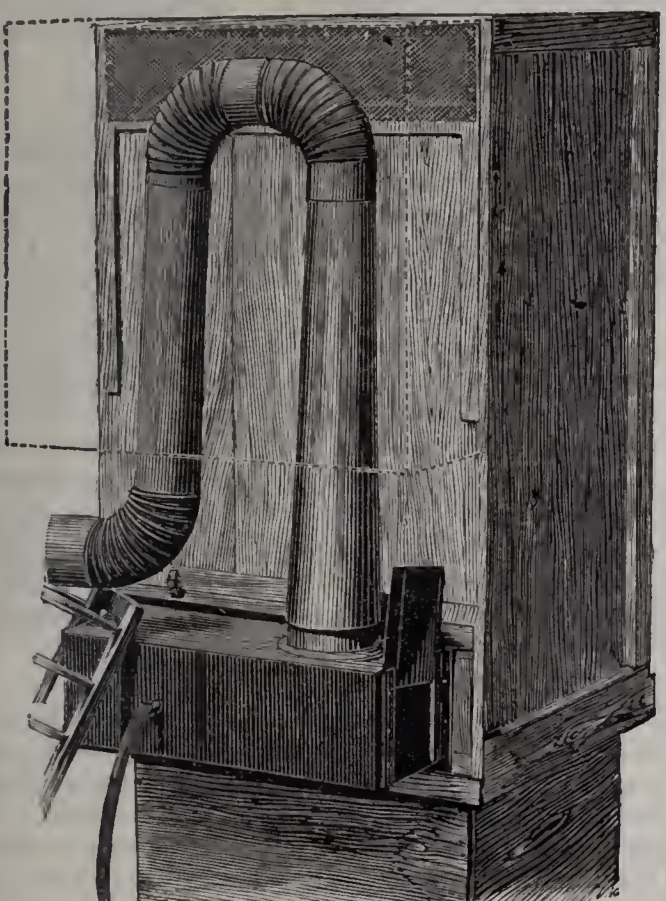
A SIMPLE DRYING-BOX FOR GELATINE PLATES.

BY A. GREINER.

I take the liberty to send you a few photographs of a drying-box made by me for gelatine dry plates. Should you think it to be worthy of a place in the Photographic News, here is a brief sketch of it.

The box is made from a common packing-case, which I lined inside with black paper, to make it light- and air-tight, the door being made also light and air-tight.

Against the inside of the box I nailed some small laths, to put the little frames upon, with pins between. At the back of the box are two openings—one at the top, through which the air enters, and one at the bottom, to let the air out. The openings are about 8 centimetres wide. Across



the upper opening I nailed a piece of brass gauze, to prevent the entrance of dust, &c. Against the lower opening I attached a little box, with a small movable frame with a piece of ruby glass in the centre, to allow at all times to see if the light is burning. On the top of the little box I attached the pipe, which is bent up and down before it enters the chimney. In the inside of the little box I have a Bunsen burner, exactly below the draught-pipe, to increase the current of air; this at the same time gives an agreeable warmth to the outside of the pipe, while warm air constantly enters the drying-box, and circulates among the plates, to leave the box again through the draught-pipes.

The dotted line indicates a cover or outer box outside the pipe, to keep the warmth in the box, and to exclude the light. Inside the box are two boards at the top and at the bottom, to prevent the light entering, and not interfere with the air currents.

The simple construction of the box will enable any person to make a drying-box at very little expense, and I can assure you that the drying-box is one of the best I have been using; and I have tried several.

COPYING DRAWINGS.

Tilhet's method of copying drawings in any desired colour is thus described in the *Polytechnisches Notizblatt:*

The paper on which the copy is to appear is first dipped in a bath consisting of 30 parts of white soap, 30 parts of alum, 40 parts of English glue, 10 parts of albumen, 2 parts of glacial acetic acid, 10 parts of alcohol of 60°, and 500 parts of water. It is afterwards put into a second bath, which contains 50 parts of burnt umber ground in alcohol, 20 parts of lampblack, 10 parts of English glue, and 10 parts of bichromate of potash in 500 parts of water. They are now sensitive to light, and must, therefore, be preserved in the dark. In preparing paper to make the positive print another bath is made just like the first one, except that lampblack is substituted for the burnt umber. To obtain coloured positives the black is replaced by some red, blue, or other pigment.

In making the copy the drawing to be copied is put in a photographic printing-frame, and the negative paper laid on it, and then exposed in the usual manner. In clear weather an illumination of two minutes will suffice. After the exposure the negative is put in water to develop it, and the drawing will appear in white on a dark ground; in other words, it is a negative or reversed picture. The paper is then dried and a positive made from it by placing it on the glass of a printing-frame, and laying the positive paper upon it and exposing as before. After placing the frame in the sun for two minutes the positive is taken out and put in water. The black dissolves off without the necessity of moving back and forth.

A HINT AND A DISCOVERY.

BY REV. J. J. S. BIRD, B.A.*

I.—How to Dry Gelatine Negatives Rapidly.

An inconvenience which has caused no little trouble to workers with gelatine plates, is the length of time they take to dry. A collodion plate can be held to the fire and dried in a very short time, but a gelatine plate under the same conditions would melt and run. Now, a gelatine plate may, under different conditions, be dried quite as rapidly as a collodion plate; and I have frequently taken a negative, dried it, and printed a proof in considerably less time than half-an-hour.

The principle is simply to remove the superfluous moisture before holding the negative to the fire, and this can be done by applying a piece of perfectly clean blotting-paper to the surface of the gelatine, using at first a moderate pressure, and increasing this pressure to any degree required. The blotting-paper will in no way injure the negative, and any stray pieces of fluff will dust off when the plate is dry. Still, it is better to carefully dust the blotting-paper, and to remove any stray pieces of material before it is applied. It will now be found that the negative can be dried at any degree of heat in the space of from thirty seconds to two minutes. This fact led the writer to the following—

II.—Useful Discovery.

If a gelatine negative be dried as above, at only a moderate heat, it will not perceptibly differ from a negative which has been allowed to dry spontaneously; but if a negative from which the superfluous moisture has been extracted by blotting-paper be exposed to a greater heat, the whole complexion of the negative is altered. Not only does the film become horny and tough, but the picture on it appears in relief—so much so, that it seems to me quite possible to produce a cast from the negative capable of being printed from in an ordinary press. This is an extension of the principle referred to in this year's annals, in which hot water is used as a developer; but this does not seem either as simple or efficacious as the method I suggest above. At all events, I think the matter is worthy of the consideration of this Society, and I commend the hints to my fellow-members.

* A communication to the Bristol and West of England Amateur Photographic Association.

Notes.

An International Exhibition of industrial art is open at Lille, which includes a section devoted to photography.

A competition for the "best travelling camera" has been organized by the Photographic Society of Toulouse; all competitors must send in their contributions before the end of the month.

We spoke the other day of two regal photographers—the King of Portugal and the King of Servia—but it seems photographers can count an Emperor among them, one, moreover, who practises the art professionally. According to the *Rèvue Photographique*, the Tycoon of Japan, who has abandoned the empire to the Mikado, has quietly settled at San Francisco, where he has established a photographic studio.

There are still many wet plate workers who have never handled a gelatine dry plate, but we doubt if in this country is to be found the counterpart of a gentleman—Mr. T. M. Easterly—who has just died in the United States. It was his boast that he was never a photographer, but purely a Daguerreotypist. According to our contemporary, the *Practical Photographer*, Mr. Easterly died at the age of seventy-three, and was one of the oldest, as he was the last, to practise regularly the beautiful process of Daguerre in the States. Unfortunately, his principle never to abandon Daguerreotype made him poor in health and pocket, though he appears to have been one of the most competent and worthy followers of Daguerre.

All interested in science and science instruction cannot but feel deeply pained on reading a little pamphlet just issued by an "ex-professor" of twenty-six years' standing, who details the obstacles against which he has had to contend during his teaching at one of the great military educational establishments of the country—the Royal Military Academy. We have merely to point out that the chair of chemistry at this Institution was held by Faraday and by Professor Abel, C.B., before Professor Bloxam commenced his twenty-six years' service, in order to show the dignity that attached to it, while the circumstance that the "ex-professor" is still the popular instructor of chemistry at King's College is proof enough that the Military Academy was well served by its former officer.

Yet, from the pages of this pamphlet, we find that Professor Bloxam has for years past been treated with grave insult and contumely by the military pupils, and that, despite repeated remonstrances to the Governor, the latter systematically omitted to support the civilian Professor, or even to reply to his appeals for help. The most childish and wanton conduct seems to have taken possession of the cadets, as soon as they found that the Professor of Chemistry was at their mercy and unsupported by the Governor's authority. Professor Bloxam, in his own defence, seems to have been compelled to erect an iron barrier in front of his lecture table, and to whitewash the walls of the lecture room, so that the obscene jests thereon might be expunged; but such aggressive measures as an attempt to blow up a wing of the building by the students "maliciously turning on more than a dozen gas taps," as well as the organized disrespect and coming late to lecture, were beyond the power of the Professor to circumvent.

The manner in which the civilian Professor was treated by the military Governor is best shown by quoting one of the latter's curt communications addressed to the Professor, who, broken down in spirit and health, resorted, as a last expedient, to locking his class-room door. This communication, it should be stated, comes from a governor of twelve months standing to one who has occupied the professorial chair for a quarter of a century: "Mr. Bloxam, I must again, for the second time, ask you to obey my orders, and not to lock the door after the second bell.—J. Browne, Major-General." To attempt any longer to impart instruction in the subtleties of chemistry or explain intricate theories in physics, was naturally out of the question after this, and Professor Bloxam very wisely desisted from the unequal combat.

We were at Stratford-on-Avon the other day, and marvelled to find so little that was new to us. Shakespeare's house must have been taken from a photograph, is the somewhat inverted idea that gets into one's mind, so familiar is the little black and white building, thanks to Mr. Francis Bedford and other capable photographers. The grey old church, with its tapering spire rising above the tall elm trees, and at its foot the placid Avon flowing through green meadowland, is also a sweet English scene with which we have grown familiar through the camera. Why should not the photographer go further, and give us scenes from the old manor of Charlecote, where Justice Shallow resided, and Shakespeare "killed the deer," and pictures of the woodland slopes and rich parkland in the neighbourhood where Jacques and Rosalind dallied?

"A painstaking photographer on canvas," is the description of Mr Frith, R.A., by an art-critic in last week's *Truth*. If this means anything, it is, that painters need not go out of their way to be true to nature; and yet our contemporary itself holds so much to the use of the mirror, that it is depicted on the title page with this emblem of veracity in its hand.

By-the-bye, we have thought of a good way of making painters less hostile to photographers and their works. As soon as a painter becomes intimate with the higher efforts of photographers (as he does when he accepts the position of judge at a photographic exhibition, and studies the best work of disciples of the camera), he gains sympathy with his humbler brethren, and is at once charmed with the pictures and poetry they hold fast with the pencil of light. Sir John Gilbert, George Leslie, H. Marks, P. H. Calderon, Walter Ouless, and Henry Moore—to take half-a-dozen well-known names—have all of them thought more kindly of photography since they officiated on the jury at the Pall Mall Exhibition. *Ergo*, ask our great painters to be our judges, and they become at once our friends.

Lest we should appear to be exaggerating in this respect, we would call as witnesses the cordial letters written by painters who have consented to serve on the jury year after year. The close intimacy with the best works of the camera brought about by their duties has led them to express over and over again their appreciation of photographic art. The high opinions of Mr. Marks and Mr. Moore about eighteen months ago we published at the time, and although the communications received by the Photographic Society from Mr. Calderon and Mr. Leslie at the conclusion of their labours last year did not appear in print, it is well known that these artists expressed themselves in high terms over the progress made in fine art by photographers.

They are going to try a strange experiment in Paris. The idea is to combine amusement with scientific instruction, by producing at one of the theatres a series of scientific dramas. The Folies Dramatiques is the theatre chosen for the purpose, and the experiment is to commence during the summer months. Already three plays have been provided for this bold scheme, and their titles indicate plainly in what direction the audience is to be instructed. The first drama is called "Denis Pepin, or the Invention of Steam;" the second is entitled "Kepler, or Astronomy and the Astrologer;" and the third is "Güttenberg, or the Invention of Printing." We would suggest yet another title: "The Triumvirate—Niepce, Daguere, Talbot—or the Invention of Photography."

A new Copyright Bill is before the House of Commons, dealing very definitely with photography, which is classed with engravings. It is to be introduced by Mr. Hastings, Lord Sandon, Mr. Hanbury, Tracy, and others. It is proposed that the duration of the copyright should extend in the case of paintings and sculpture to thirty years after the death of the artist, and in the case of engravings to fifty years from the time of publication. With photographs, the term is also to be fifty years; but photographic portraits taken on commission are not to be sold or exhibited in shop windows without the consent of the person photographed. On another page will be found the more important clauses of the Act.

Most of the staff of the Thebes Eclipse Expedition, including Mr. William Black, the novelist, left England for their destination on Wednesday. Dr. Schuster, F.R.S., is said to command the expedition; but we are incredulous on the subject of his commanding Mr. Norman Lockyer.

Mr. R. A. Proctor, the well-known astronomer, has grown so enthusiastic over Mr. Muybridge's "Attitudes of Animals in Motion," that he offers fifty pounds towards making up the sum necessary to photograph a rowing match, so that we may have an analysis of the various styles of rowing. It is well worth while, thinks Mr. Proctor, to record any pure style of rowing we may witness, and Mr. Muybridge's plan affords a ready means of doing this. Mr. Proctor adds: "Hanlan might, I have no doubt, be persuaded to row past twelve cameras, and so hand down to posterity the perfection of his marvellous style."

At the last meeting of the Physical Society, Mr. C. V. Boys read a paper on a new method of finding the index of refraction of lenses, based on the principle employed by the French physicist, Foucault, of causing the ray of light to return on the same path.

Mr. W. J. A. Grant starts with his camera once more to the Polar Seas next month. This time, the intrepid amateur does not take passage in the *Willem Barents*, but goes in a little vessel built and specially fitted for Arctic voyaging by an adventure-loving friend. The chief object will be to search for Mr. Leigh Smith in the *Eira*, whose crew has been nipped in the ice and imprisoned during the winter. The rescue of this gallant band will be the principal mission of the little craft that carries Mr. Grant due north, but he hopes at the same time to secure and bring back with him some photographic records of the voyage that may be valuable hereafter to Arctic explorers.

A very fine example of the Waterhouse photo-engraving process, in which the grain is produced by sprinkling sand, previously waxed, upon a newly-developed carbon print, was shown us the other day. It was an architectural subject, and if only an ordinary amount of retouching had been performed, the result would have been well-nigh perfection. We congratulate Major Waterhouse on his prospects.

Two charming poses—not nosegays—seen in a show-case at Worcester Station; the first, that of a tiny lad in a man o' war suit hauling away lustily at a coil of monster rope; the other, a girl in nautical costume looking out to sea, her hand deftly poised above her eyes.

Notwithstanding the many shortcomings exhibited b the photographic records of the last Transit of Venus, the French Academy of Sciences has decided to employ the camera once more to make observations. Eight expeditions have been named to take part in the work, but, strange to say, the name of M. Janssen, who has certainly had more experience of photo-astronomy than any one living, is not among those nominated to take charge.

The "caricature-portrait" is the latest squib from the Continent. A huge mirror, sufficiently concave or convex to distort the features considerably, is placed before the sitter, and the reflection in this mirror is then photographed. By slightly altering the way the hair is worn, the cravat or the collar, the most ludicrous effects are secured.

The director of the Jardin des Plantes—the Paris Zoological Gardens—has prepared photographs of all the animals in the collection, forming a series of 500 photo-engravings. These are furnished to the libraries of all the Government schools in France to aid in instructing the classes in natural history. A better means of educating boys and girls in this subject could hardly be devised, for the ordinary coloured drawings of wild animals distributed among our youth are invariably much exaggerated.

These coloured pictures, indeed, do more harm than good, for the child having seen the huge monsters here depicted, gets an altogether false impression of the real size and nature of the animal. Crocodiles and alligators, instead of measuring thirty or forty feet long, he finds in reality to be scarcely half that size; and pythons and bears, far from being able to swallow a buffalo, appear to the youthful visitor at the Zoological Gardens to have some difficulty in managing a rabbit. Thus we feel sure photographs of the animals themselves will be a most valuable aid to the education of young people. The pictures will not be so romantic to look upon as the old coloured prints; but since every child is in the habit of asking "is it true?" we may safely predict that the truth of the photographs will render them quite asattractive.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. VII.—The Management of the Camera in the Field.

If the young photographer have diligently perused the former lessons, and have gone through the various manipulations which are described in them, he will now be ready to sally forth into the field, and, selecting the beauty spots of nature, transcribe them by the aid of his camera and lens. He may, in fact, make pictures.

We have declared our intention of not entering into the question of art in connection with photography, but have referred our readers to more advanced works for guidance in this direction. Yet we may make a few general remarks on the subject, especially in indicating those points wherein the requirements for a photographic picture differ from those for a painting. The chief of these is, of course, the absence of colour. We cannot have transcribed by the camera the broad contrasts which are frequently brought out by colour alone. We must trust to form and to light and shade apart entirely from colour. Very frequently a scene will make a most perfect picture on the camera ground glass, when the experienced photographer knows it will make nothing in the print. Alas! the colour which makes the picture cannot be reproduced. This fact makes it the more necessary in the camera picture to have the form and light well balanced. The picture must not be all on one side, nor must there be running through it in any direction long uninterrupted lines. For the rest, there is wanting to a perfect landscape picture—be it painting, drawing, or photograph—a foreground, a middle distance, and a distance. It is in the latter that photography fails. What to the eye appears a definite distant landscape, the distance, but lending enchantment and softness, comes out in a photograph so dim and faint, that it would seem to be almost hidden by a thick mist. The slight haze which, in this country at least, always stands between us and the distance, is exaggerated so as almost to obscure those things which are quite clear to the eye. A certain amount of haze covering distant objects is necessary to give the idea of distance, but the exaggeration of fog, mist, or haze, which the camera always gives, must be allowed for.

Perhaps the greatest difficulty in photographing, however, is that the sky is not, as a rule, rendered at all. An exposure which will suffice to bring out all the detail in a landscape is such that the sky will be so over-exposed as to show no trace of clouds. It is necessary, to get the sky, to make a special exposure, perhaps about one-tenth of that required for the landscape, and to resort to a "double printing" process, which it is without our province to describe.

The subjects best suited for the camera are of the nature of the following. Any landscape having, apart from colour, broad and well marked contrasts of light and shade, and decided outline of form, are specially suitable. Trees of all kinds are well rendered, both with and without their leaves; in the former case, the difficulty is to get them motionless. A quiet windless day is necessary. Architectural subjects of all kinds are most perfectly reproduced by the camera.

The most charming effects of all are, perhaps, produced in a scene in which there is water—a quiet pool with reflections of trees, for instance.

We will suppose our pupil has determined on some locality where he is sure to find some subjects such as those we have indicated. We shall follow him, indicating how he should act as he proceeds. First, he has to fill his slides. We will suppose he has three of these; they must be packed into a case which should be made to hold them and the camera. Besides these, he must take his lens, his tripod—and let him be most careful not to leave the screw behind him—his focussing cloth, and possibly a "focussing magnifier." This is a small eyepiece to magnify the ground glass image, and enable him to focus with precision. It is useful mostly because it increases the light. When a small stop is used the ground glass image is frequently so dull that it can barely be seen.

Arrived at the scene of action, the photographer must select his point of view most carefully. Let him be in no hurry. Frequently a picture will be made or spoiled by altering by a few yards the position of the camera. When he is quite sure of his point of view, let him unfold his camera, erect it, and place it opposite the scene to be depicted.

A few words on the management of the tripod stand. With the beginner this is apt to prove most wonderful and fearful in its movements. The effect of moving any one leg appears to be the exact opposite of what might have been expected. After long struggles the whole apparatus assumes an appearance of hopeless inebriation, and finally collapses, very possibly pinching severely the tyro's fingers between the tail-board and one leg. Let the stand be, however, once for all placed on the ground with its three legs about equally far, and a good distance, apart, and with one of them pointing towards the middle of the scene to be photographed, and all trouble will cease. There will be room for the photographer to focus comfortably standing between the back legs. To tip the camera up, all that is necessary is to draw the forward leg towards him; to tip it down, he need only push it from him. He may still further tip it up by spreading the back legs apart; and down, by bringing them together.

When the camera is fixed, and the view focussed, it will probably be found that there is too much foreground, and too little sky. Now, one of two things may be done. The camera may be "tipped" up. In this case, if there be any parallel vertical lines in the picture, they will be made to converge at the top, and it will be necessary to bring the swing-back into play, so as to make the ground glass once more vertical. If there be no vertical parallel lines, the camera may be tipped a little without appreciably modifying the result. The camera front and lens may be raised. This is usually the best course to adopt. The use of the swing-back always *strains*, so to speak, the lens, and necessitates the use of a very small stop. Raising the lens also strains it, but to a less degree. Tipping the camera does not at all. Most cameras are made so that either a vertical or horizontal picture can be taken, and judgment must be used to determine in which position it shall be. All the points above indicated having been considered, and the picture being all on the ground glass—proceedings so far having been conducted with open aperture or a large stop—the final focussing must be done. The principal object—generally in the middle distance—must be made absolutely sharp. Now, stops smaller and smaller must be tried till the distance is *just* sharp.

Now all is ready for exposure. Let plate No. 1 be exposed first, and on no account let any plates be exposed other than in their correct order, else the photographer will be likely to expose two views on the same plate. A much more aggravating thing he cannot do. In exposing, procedure is exactly as described in a former chapter. We shall try to give a general idea of the length of a few exposures.

We described fully in the last chapter the means of comparing the rapidity of different lenses and stops. The student ought, therefore, to be able to make the necessary estimation for the particular stop he is using.

With a good spring or summer light and "open landscape" (that is, a view having no objects with very heavy shadows in the foreground), and with the average of rapid commercial plates, the exposure with $\frac{f}{20}$ will be from one to two seconds; with river scenes or seascapes, it may be reduced to one-quarter of a second—about the shortest possible to give by hand. With heavy shadows or dark-coloured trees it may run up to four or five seconds, and, in the shades under trees, even up to minutes. In interiors, such as churches and cathedrals, it is very much longer, even when they appear well lighted. Four or five minutes is a short exposure for an interior with $\frac{f}{20}$, and even when the eye can penetrate to every corner of the building, exposures of several hours may be necessary.

We should say that, for a landscape, the most pleasing lighting is usually a side-lighting. The lighting looking towards the sun is sometimes very pleasing, but care must be taken not to include the sun itself. This must be either to one side or above the picture, or may be kept out of it by the camera being placed in the shadow of a tree or some such object.

(*To be continued.*)

HARDWICH ON THE LIME LIGHT.*

It is now many years since I commenced the use of the optical lantern for educational purposes, and each season I have been in the habit of noting down any little points which struck me as being worthy of record. Some apology is needed for presenting this communication to our Association in so crude a form, but the members will understand that experiments are not so easily conducted in a village school-room as in a well-appointed chemical laboratory with all the appliances suitable for the purpose.

The lime light is often described as radiating from "a point," and the optical parts of the lantern are ground on that supposition. No doubt it is true that the radiant should be a point, and all the aberrations are increased when it is not so. It will be found, however, in practice, that no amount of pressure on the gases will produce a sufficiently-powerful flame unless the heated surface be of a certain size, and that, so far from the distinctness of the picture on the screen being impaired by enlarging the lime spot, it will be increased. Not that the definition of the image is really improved, but that a strong light brings out into view more details than a weaker light.

To give an idea how far we are as yet from the perfection of the theory that the radiant should be a true point, let a clear and bright disc be thrown on the screen, and the front lens of the lantern be removed; then, on placing a sheet of white cardboard in the anterior focus of the condenser, a circle of bright light will be seen of at least half-an-inch in diameter. Such being the case, I fail altogether to perceive how a condenser can be made which will bring the rays from the lime spot to a true focus, so that they will pass through the high powers of a microscope without any loss. Your worthy President, if he should be in the chair during the reading of this paper, will perhaps be able to speak more favourably of the electric light; but as regards the lime light I am satisfied that an incandescent point is not sufficient.

How, then, is this point to be increased in size until it emits enough light for the purpose required? It may be done, partly, by enlarging the aperture through which the gases escape; but to this there is a practical limit, as I shall presently show. It may also be effected by throwing the flame at a small angle of (say) 15°, so as to shoot it along the face of the lime. This produces a very strong light, and I have worked in that way for a whole season; but the objection is, that the lime must of necessity be very near to the jet, or the flame falling at so small an angle will not reach it; consequently, if the cylinder should be badly centred, or should crack during the lecture, it will touch the jet in rotating.

A better plan, and one which I have adopted for the last two years, is to project the burning gases on the lime at a larger angle of (say) 45°, and to remove the cylinder to a greater distance. The flame then spreads, and the heated spot is larger than when the lime is brought quite close. I am aware that jets have been made in this way for many years, and that there is no novelty in the suggestion; but it has not, I think, been generally recognized, otherwise it would be difficult to explain why such directions as the following should be published, namely, "To keep the source of light as nearly as possible to a point, and to bring the nozzle of the jet close up to the lime when the picture is to be of a very large size." I should prefer to read it almost entirely the other way—that is, to heat as large a surface of the lime as you conveniently can, and to remove the jet further off in proportion as the flame strikes the lime at a greater angle.

The small blue flame of the mixed oxy-hydrogen gases is usually spoken of as solid throughout; but I have generally noticed it to be hollow, like the flame of a candle. The hottest part is on the outside, and within is a cone of imperfect combustion. To observe this in perfection, adjust the proportion of the two gases until you obtain the maximum of light on the screen; there will then be a very slight excess of coal-gas tinging the flame red at the edges. Now, if you look closely, you will see a small dark cone projecting from the end of the jet, and, if you push in the lime until it touches the cone, there will be a dark nucleus in the centre of the spot. The hottest part of the flame is immediately beyond the point of the cone, and if you go much further, the force of the blast will be lessened. Now turn on a little more oxygen, and you will find the central dark cone almost entirely to disappear; but the light will not be so good upon the screen. This, therefore, I believe to be the reason why more than the theoretical quantity of coal-gas is needed, namely, to allow for some amount of oxidation by the air as the flame passes through it and carries it mechanically forward.

The coal gas which I use is not pure; it contains free nitrogen and also carbonic acid. One effect of these impurities is to produce a roaring noise in burning, which distracts the attention of the lecturer, and also, to some extent, of the audience. I had often observed that the noise was greater with some burners than with others, which I thought to be due to want of care in polishing the bore of the jet. I now find, however, that, besides this cause, much depends on the size of the "mixing chamber." If you suppress that chamber altogether, the noise becomes intolerable; but if you increase it until it holds (say) a fluid drachm of water, then the flame is quite noiseless. I do not think that the chamber acts by ensuring a better mixture, but rather by *equalising the flow* of the gases— just as the fly-wheel of an engine regulates the speed. With pure coal gas and oxygen free from atmospheric air it may not be necessary to use any mixing chamber, provided the two gases are turned on in exactly the correct proportions.

I shall conclude my communication with a few remarks on the supposed danger of employing the oxyhydrogen lime light. Never on any occasion have I met with the smallest accident, and I can only conjecture that most of the explosions spoken of have been due to carelessness in making wrong connections and putting coal gas into a bag already containing oxygen, or, perhaps, by lifting a weight from one or both of the bags without pre-

* Read before the Newcastle-on-Tyne and Northern Counties' Photographic Association.

viously turning off the taps. This would certainly cause a suction backwards, and would be dangerous even in a case where only one bag was used, and the coal gas supplied direct from the main.

I prefer to keep all the tubes as open as possible, and to dispense entirely with wire gauze, packing of every kind, back pressure valves, &c. These valves are apt to get out of order, and in the long run, by necessitating heavier weights on the bags, to do more harm than good.

The form of jet known as the "safety" jet is more simple than the other, although I do not use it in my own practice; and, perhaps, it may not be generally known that when gas is not laid on, it will answer quite well to store it in a bag, and to weight the bag with a single brick—equal to about seven pounds. The light is not as good as that given by the oxyhydrogen, but it is much better than would be supposed, considering the rough way in which the gases are mixed. The spot is larger, and this compensates in a measure for the lesser intensity. I am sorry that more attention is not paid to the manufacture of these safety jets; no two that one buys are exactly alike, and they are very unequal in heating power. The best form, in my opinion, is where a rather small outside tube carrying the hydrogen projects beyond an inside oxygen tip, having an aperture of about one-twenty-fifth of an inch.

I conclude by a brief description of the mode of working the oxyhydrogen lime light which experience shows me to be easiest for a lecturer employing no assistant:—

1. The mixed gases to issue from an aperture of one-twentieth of an inch, and to strike the lime at an angle of 45°. Ascertain by suction that the burner is gas-tight, and if not, make it so by a small washer of leather or thin sheet lead placed near to the nipple.

2. The lime cylinder, which must be upright, to be fixed at a distance of a quarter of an inch from the burner. It is a great convenience when the lime is made to turn from the outside of the lantern.

3. The soft limes give rather more light than the hard, but I have found them latterly to be unequal in quality, and often badly centred.

4. Three-quarters of a hundred-weight on the oxygen bag is amply sufficient in the general way; but the tap must be "full on" if you are to have a certain measure of the quantity of gas which will be used. The coal gas bag should be weighted a little more heavily than the other, so as to give the required excess of gas, and this may be done with perfect safety, since the flow of the gas can be easily regulated by the tap.

A single set of pressure-boards may be used for both gases if desired, but it has been shown by more than one experimentalist that you do not necessarily obtain equal pressure in that way. I, myself, have found that the pressure varies not only with the leverage, but also with the extent to which the bags are filled. In purifying coal gas, for instance, a half-hundred-weight will force it through a column of liquid seven inches high when the bag is drum-tight, whereas a hundred-weight and a-half will scarcely suffice to do so when the bag is nearly empty.

For lectures such as I am in the habit of delivering, a single lantern answers sufficiently well. The lens and condenser which I use were made for me by Mr. J. H. Dallmeyer; the former being of two inches diameter and six inches combined focus, and the latter a plano-convex of four inches diameter and two and a-half inches focus as it stands in the lantern.

I have latterly tried a biunial lantern, lent to me by Mr. J. H. Steward, to examine whether an aperture of one-twentieth of an inch for the burner could be relied upon. I found that it was not too large, but that if it were much increased the flame passed back into the mixing chamber in dissolving. It is evident that the larger the hole the greater will be the pressure required to keep the flame at the outlet.

In preparing the oxygen gas it is well known that the black powder is apt to rise and choke up the passages, and that explosions have been caused in that way. A simple plan of preventing this is to connect the retort with the purifier by about six feet of stout india-rubber tubing of seven-sixteenths or half an inch in diameter. In passing through this coil of tubing the gas deposits the powder, which can afterwards be sent up the chimney in the form of a dense black cloud of smoke, by blowing through the tube with the breath. Another coil of the same length may be connected with the bag, to collect any water which otherwise might be forced into it if the gas came over with unusual violence.

Correspondence.

TEMPERATURE IN EMULSION MAKING.

Sir,—No doubt your correspondent, Mr. P. Collins, will be interested in the following facts, and will draw his own conclusions from them.

A few weeks ago I prepared a batch of emulsion by Captain Abney's method, in the usual way—nitrate to bromide—with excellent results. These plates being used, I prepared a second batch, green and brown fog resulting; but before they were tested, I prepared a third batch, so confident of results, and these were good in all respects.

In all cases the same sample of gelatine and the same sample of nitrate and bromide were used, and in all respects, so far as possible, the same method of preparation. Now, what made the difference? "There's the rub!" I believe it was in the amount of heat, although, in a water-bath, the bottle may be so near the bottom of the vessel as to become overheated. I have noticed also that a portion of the bromide was deposited, which I consider due to the partial decomposition of the gelatine, and, in future, shall avoid the possibility of overheating, and also reduce the time from thirty minutes to twenty, which I believe to be sufficient. Perhaps, after all, the safer way is in prolonged cooking at the lower temperature.

As to remedy for bad emulsion, I believe the best way is to reduce the silver at once, and make a fresh lot.—I am, yours truly, Frederic Row.

DRYING CUPBOARDS.

Dear Sir,—In your Year-Book appeared a woodcut of George's patent Calorigen; its suitability for drying plates was forcibly inpressed on my mind, and I resolved on a trial, so procured one. It is now fixed under my cupboard, and it will dry perfectly, free from all marking, ten dozen $6\frac{1}{2}$ by $4\frac{3}{4}$ in twelve hours. The principle is this (as most of your readers and yourself will know). Fresh external air is drawn through a pipe, which winds in a coil, through the stove jacket. This coil is heated by gas, the products of which pass off into the open air through another chimney, and nothing but the pure warm air is emitted from the top of the stove. What more is needed by the dry-plate maker? Again, when the stove is alight, it emits not a ray of light, another great advantage. In fact, a better apparatus could not be desired by anyone. I should be glad to send you a detailed description of the drying-racks in the cupboard, which are something novel, and, I may add, thoroughly efficient, only I am afraid drying cupboards have really become dry.—Yours obediently, W. Barry.

STAINED FILMS.

Dear Sir,—I perceive that Mr. Pumphrey has been advising that to avoid stained films, the gelatine plate should be placed direct from the alkaline pyrogallic into the fixing solution. Now, Mr. Pumphrey is one of the scribes, and therefore speaks with authority.

Is this advice "rank heresy," or is it "improved practice?" I should like to hear what the experts say, because I should like to know, being myself only a "bit of a muff." My custom has been to give the plate a good washing before going into the hyposulphate, and I have hitherto thought this the orthodox plan; I must own that my plates always possess the orthodox brown tint.

But, while I am asking, I should also like to enquire whether this yellowish-brown tint is always objectionable? I sometimes think it is advantageous, especially in very thin negatives; for while the shadows are tinted, the deposit on the high lights is by comparison much more strongly coloured, and thus a weak negative is really strengthened.

To illustrate, take a thin yellow tinted negative that produces a fairly passable print, and immerse it in one of the clearing solutions. The yellow colour will now disappear, but the print produced from the negative will be so impoverished as to be useless. And further, if the negative be intensified to compensate for the loss of colour, the negative (if the original thinness be caused by under-exposure) will only yield a hard print much inferior to when it remained in its original tinted condition. Such is my experience, but I should like to hear what others say, as I am only a THICKHEAD.

[We believe M. E. de Zuccato was the first to suggest this plan.—Ed. P.N.]

PHOTOGRAPHIC CLUBS.

Sir,—Had Mr. Cobb have had "the good sense to have waited, &c."—well, doomsday would certainly "have been, and come, and gone" before he had written his funny letter; but Mr. Cobb always is funny.

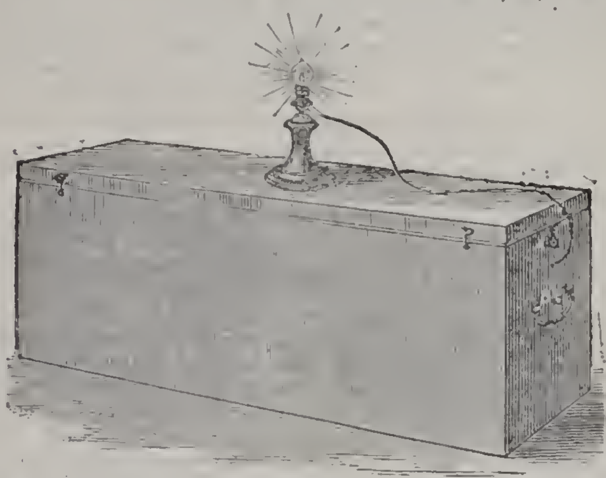
If insults be the reform Mr. Cobb says I stepped aside to allow to pass, why, I certainly did, and will do so again. I am, however, glad to see Mr. Cobb is, at last, a convert to the reform so much pressed by myself and others—viz., the publication of a *resume* of the Club's proceedings.

I must also say I go heart and soul with him in the reform the last part of his letter so forcibly advocates, and shall hail the day with joy when the two Clubs shall be able to throw off the mercenary landlord, and a room or rooms can be found where not only the Clubs, but the Societies can meet and be social, and where such sociability is not to be measured by the number of glasses ordered in addition to the rent of the room, itself a very heavy item (£60 a-year, I think); and if Mr Cobb could find such accommodation that the Clubs, &c., could meet, and, having their own stewards, be sociable, I am sure he would be looked upon as a "friend indeed" to the profession.—Yours truly, C. G. CUTCHEY.

PHOTOTYPES.

Dear Sir,—It may be interesting to the very many readers of your most invaluable journal, to the printing profession in particular, and especially to the correspondent mentioned in last week's issue, relative to the laying down of photo-lithographic transfer direct on zinc, instead of putting to stone, to learn that Messrs. Manning and Son, of Old Street, St. Luke's (the purchasers of the patent, plant, &c., of Messrs. Banks and Co.), have superseded the old and troublesome method of transferring to zinc, and are now photographing direct upon a prepared plate of zinc, thus avoiding the very many intermediate and intricate processes. Any one having had to make the bichromatised gelatine transfer paper in quantities will ever remember the painful sensations occasioned through being closed up, perhaps for some hours, in an ill-ventilated dark-room, and inhaling the fumes from the gas and the warm bichromatised gelatine. It might be as well here to state the several stages through which this material passes before the transfer on zinc is completed. The paper, after receiving the coating of the bichromate gelatine, is taken from dark room to a second dark room, ventilated, &c., so that a constant current of warm air passes through, and hung up to dry, which takes, when in large sheets, a matter of twelve hours; it is then put out to print, and returned to the dark room, in which a lithographic press is kept. A stone being thoroughly cleaned and inked, the paper is passed several times through the press, and receives a fair coating of ink; it is then placed in a dish of cold water to soak, and all surplus ink is washed off with a clean sponge and cold water; it is now hung up to dry, a stone is polished, the transfer laid between damp paper, then laid on stone and passed through the press in the ordinary way. The stone is now prepared for the artist to put in such portions as may be desirable. I need hardly state that all these intermediate manipulations are detrimental; there is a loss of work which, of course, has to be put in by the artist, and it also thickens through the great amount of pressure, which is impossible to remedy. I have only here stated what is actually necessary, to do all of which is superseded by the plan now adopted by the above firm. Of course you will readily understand that it is one of the many trade secrets, else I would freely give formula in detail. My idea in writing is, that yours being the leading journal of this particular art, it is only right, taking an interest in the profession at large, to communicate what is actually being done, and that the art is progressing. I have accordingly produced the accompanying from page 192 of your paper, slightly reduced

The Swan Lamp in the Dark Room.—We are now enabled to place before our readers a cut of the portable battery with the Swan lamp attached, as manufactured by Mr. Paterson, of 76, Little Britain, who informs us that he has fitted



some of these with red shades, so as to adapt them for dark room use. The lamp gives a steady light equal to five standard candles, and the five-cell bichromate battery contained in the box is brought into immediate action by lowering the plates into the cells, a pulley-like arrangement for this purpose being shown at A B. Not only is an apparatus of this kind useful for dark room use, but, should it be necessary to work with ether or other inflammable liquid in the evening, a safety light of this character will prove of considerable value. We intend before long to describe some new arrangements which we have made for facilitating the use of the incandescent lamp in the dark room.

in the first and last stages, so that you may, if desirable, pass any comments on same. I have also sent you a few others, so that you may be able to judge of its merits.—Yours truly, OPERATOR.

[We insert the "copy" sent us, that our readers may see how successful the process is. The process of photo-lithography, &c., as now practised with the velvet roller, is, however, far more simple than that described by our correspondent.—Ed. P.N.]

Proceedings of Societies.

Bristol and West of England Amateur Photographic Association.

The usual monthly meeting was held at the Studio, Portland Street, Kingsdown, on Wednesday evening, 5th inst., the President, Col. T. Biggs, in the chair.

The minutes having been passed,

Mr. H. A. Hood Daniel proposed the first resolution standing against his name on the agenda paper, viz., "That Rule VI. be altered," the words "first Wednesday" giving place to such as may be decided upon by the meeting. This question affecting the days of meeting was fully discussed, and Mr. Daniel proposed, and Mr. E. Brightman seconded, the proposition of the *fourth Wednesday* in the month being fixed upon as the future time of meeting; carried *nem. con.* The meeting being rather a small one, Mr. Daniel begged leave to postpone his second resolution till the next meeting; he, however, brought forward his third resolution, "That there having as yet been no competition, the titles decided upon last year for four competition pictures shall be continued this year." Also, "That two additional simpler titles be decided upon, and bronze medals given for pictures thereof, open to competition by those members who have never previously received any medal or other awards. Such competitions to be conducted upon the same rules as the preceding four." The mover of the resolution remarked that as there had not been sufficient pictures sent in to complete the competitions, he thought it hardly right that those who had taken the trouble to prepare pictures should be in reality worse off than those who made no preparations of any sort, which they would be if the titles did not staud till worked out.

Mr. W. Tribe seconded the resolution, especially as it would have the effect of, in reality, making two classes in the competitions. After some discussion, the resolution was carried *nem. con*.

The Hon. Secretary having brought a second application as to the French Monument to Daguerre, it was decided that it be acknowledged, and allowed to be on the table.

The President then read his most interesting paper entitled, "A Retrospect of Photographic Experiences" (see page 213), which was listened to by the members with evident appreciation.

Mr. Daniel asked if the effect of the radiation of heat from the ground was similar in appearance to the quivering "mirage" noticeable on a hot day in England.

The President replied that it was, only it assumed a much exaggerated form.

Mr. Brightman said he had met with the peeling of the collodion film from the plate in hot weather when the plate was of a lower temperature than the surrounding atmosphere, but not to such an extent as described by the President.

The President said he had never seen anything like it before or since, and found none who could explain it, especially the fact of its not re-appearing after the occurrence of the thunder-storm. He always used a very structureless collodion for hot climates, as being the most suitable. He much regretted that the only inscription ever deciphered was the one he did himself. The sculptures were, in a large number of cases, most beautiful, representing every-day domestic and other employments and events.

The Hon Secretary then read a communication from the Rev. J. J. S. Bird—a member not able to be present—entitled, "A Hint and a Discovery" (see page 215), relative to which,

Mr. Brightman feared that some atoms of fibre from the blotting-paper would adhere to the film obstinately, although Mr. Bird had stated the contrary.

To the President and Rev. J. J. S. Bird hearty votes of thanks were voted, and the meeting was shortly adjourned.

Bolton Photographic Society.

On Wednesday, April 12th, this Society held an "open meeting" in the Baths Assembly Room, Bridgeman Street, and although the weather was unfavourable, there was an assembly of upwards of three hundred and eighty ladies and gentlemen, the latter including most of the members of the organisation.

The President (John Hick, Esq., J.P.) extended a cordial welcome to those present who were not members of the Society. He then stated that about the year 1879 a number of young men, twenty or twenty-four in number, fond of photography, and desirous of making themselves acquainted with and efficient in one of our most delightful arts, banded themselves together for that purpose. It was one of the most unselfish amusements that he knew of, for none could take an interest in it without wishing others to join in their pleasures. Single-handed, it was felt that no great progress could be made, and those young men who originated the movement saw that co-operation in photography, as in other things, was of benefit to all. The attendances had been very good, and the members now, he believed, numbered over forty. Alluding to a large collection of specimen views tastefully arranged on several stalls, Mr. Hick said he had noticed some views which he had never seen equalled. He hoped the Society would go on progressing.

The views displayed for exhibition (between 600 and 700) were for the most part excellent specimens of the photographic art. Picturesque scenery, both local and from a distance, was well depicted, and many spots familiar to visitors were vividly brought to mind, recalling happy reminiscences of past rambles and excursions. Among the principal contributors were Messrs. Harwood, Parkinson, Dalton, Rideout, Taylor, Hawksworth, Foy, Fothergill, Perry, and Sewell. A table in the centre of the room was devoted to a collection of scientific instruments—microscopes, stereoscopes, &c. Mr. Sewell also exhibited a reversing stereoscope containing a number of Breeze's transparencies. The chief attraction of the evening, however, was an exhibition of views by the aid of a powerful lantern, which was excellently manipulated. The members had sent mounted transparencies which showed clearly and most effectively upon canvas, eliciting frequent applause. The views were very numerous and of every possible character, embracing statuary, architecture, and scenery, both local and foreign. Several views of local buildings and of rural landscape were faithfully represented, and some cheering scenes from Lake Killarney district were especially admired, as were also a number of American scenes.

Mr. J. H. Galloway acted in the capacity of cicerone, Mr. George Halliwell gave selections on the piano, and the choir of Claremont Baptist Chapel sang several glees.

The Bolton Photographic Society is to be congratulated on the work it is quietly doing, and no doubt one result of the "open meeting" will be an accession to the members of the Society.

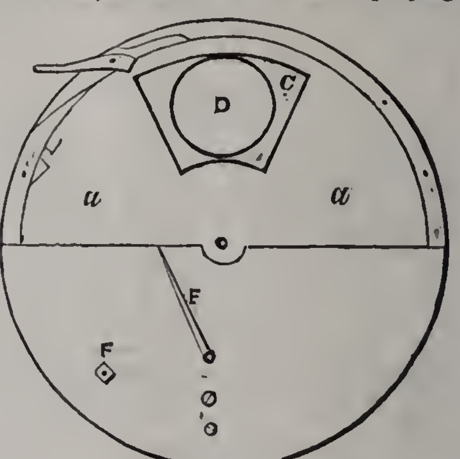
Thursday Evenings for Photographers.

At the meeting held on the 13th inst. the chair was occupied by Mr. R. J. Palmer.

Mr. A. Cowan exhibited an apparatus for filtering emulsion. It consisted of a Doulton-ware jar open at both ends; to the upper part was fitted an air-tight cover, and several thicknesses of wash-leather were strained over the bottom. The emulsion, having been placed in the jar, was rapidly forced through the leather by means of a stream of air admitted through a tube in the cover from another jar, out of which the air was forced by means of a stream of water.

Mr. Prestwich suggested that, instead of the second jar and stream of water, a biscuit-tin inverted, and weighted after the manner of a gasometer, should be used, as the water would force the air out through a hole which might be made in the tin.

Mr. Brown showed a very light and convenient form of shutter for out-door use; it consists of a semi-circular piece of ebonite revolving on a screw, as shown in the accompanying diagram,



and having an opening at C, this passing over the aperture of the lens, D, giving the exposure. To focus, the ebonite is set as in the diagram; it is then pulled round another quarter circle, and is kept in its place by the detent of the trigger, H, falling into a notch in the ebonite; a light touch on the trigger releases the disc, and the exposure is made. There is an india-rubber spring, the tension of which is regulated by the pins as shown in the diagram. The advantages claimed by Mr. Brown are simplicity and lightness (the shutter exhibited was for a 5 by 4 rapid symmetrical, and only weighed ten drs. and one scruple); and last, though not the least, cheapness, as he thought it could be retailed for 2s. 6d.

Mr. G. M. Satchfield showed a chloride plate showing both positive and negative images, and varying in colour from green to purple; this effect, which Mr. Satchfield said he could produce at will, was obtained by giving a short exposure by contact, then developing with a solution of citrate ammonia 4 parts, ferrous oxalate 1 part, a few drops of oxalate, and weak hyposulphate solution being added as an accelerator.

Mr. Henderson showed two pictures taken some years ago by Wharton Simpson's process, and which had been hermetically sealed; all purple tones had completely faded.

Mr. Cobb said he had a picture by the same process in an ordinary frame, and he thought it was as perfect as when first taken.

Mr. Henderson also showed a negative taken by a quarter-plate Voightlander lens, of the 1858 eclipse on plates by Dr. Hill Norris' process.

Mr. Ashman showed a very interesting series of prints from negatives taken at Kimberly.

Glasgow Photographic Association.

A meeting of this Association was held in the Religious Institution Rooms, on Thursday, 13th inst., at 8 o'clock p.m., Mr. John Parker, president, in the chair.

The minutes of the last meeting were read and approved of. Mr. Steven was elected a member.

On the strength of a report given in by the President on behalf of the Exhibition Committee, Mr. Thompson formally moved "That arrangements be made for a Photographic Exhibition to be held in Glasgow," which was seconded by Mr. Gilfillan.

Dr. Fairlie delivered a lecture on "The Phenomena of Colour," which he illustrated with a number of experiments. His object was to prove that the primary colours are not red, yellow, and blue; but red, green (or almond blossom colour, which is greenish pink), and blue. The lecture was most instructive, and was listened to with much attention by the members present.

Thereafter the nomination of office-bearers for the ensuing session took place, after which the meeting closed with the usual votes of thanks.

Manchester Photographic Society.

The usual meeting of this Society took place at the Manchester Mechanics' Institution, on Thursday, April 13, Mr. Alfred Brothers, F.R.A.S. (Vice-president), in the chair.

The minutes of the previous meeting were read and confirmed. Messrs. Daniel Buckley and Obadiah Folds were elected members of the Society.

The Chairman called attention to the chemical composition of hyposulphite of soda, but promised to give further information on the matter at the next meeting.

The subject of out-door meetings was then discussed, and a committee for managing the affair was appointed, consisting of Messrs. Coote, Pollitt, Leigh, and the Hon. Secretary.

Mr. Pearson brought forward the subject before the members in May last respecting prizes to be given for the best pictures produced amongst the members for fixed subjects—such as, for instance, "The best landscape with cattle"—and proposed a committee be again appointed to carry out the arrangements.

Mr. John Warburton said there was a very good feeling existing amongst the members at the present time, and he thought that by offering prizes a jealousy would be brought about, as there were many members of the Society who were young photographers, and he would prefer to run no risk of jeopardizing the harmony which now prevailed. He therefore proposed, as an amendment, that no such committee be formed, and the matter be not entertained with reference to prizes, which amendment was carried by a large majority.

Mr. Holding said he felt quite sure many members like himself would like to see the work done by the Society during the year, and thought that if a special night was set apart as an exhibition night for members' work done during the current year, the case would be met. He had, therefore, great pleasure in proposing that an annual Exhibition of Members' Work be held at the November meeting, which was carried; and after some matters of a private nature had been discussed, the members retired in peace and harmony soon after nine o'clock.

The Photographic Society of Ireland.

The usual monthly meeting was held on Friday, the 14th inst., in the Royal College of Science, Stephen's Green, Dublin, Mr. J. Woodworth in the chair.

The minutes of the former meeting having been read and confirmed, the following gentlemen were duly elected members:—Messrs. Thos. Mason, R. Forbes, Wm. Kewley, and Theo. R. Webb. Mr. Robert Mitchell was proposed for membership.

Mr. Geo. Mansfield read a communication entitled "Notes and Gleanings from a Season's Work," and gave it as his experience, regarding the most suitable plates for out-door work, that the best results were obtained from rapid plates by giving a comparatively long exposure and using a weak developer, than by allowing a short exposure and applying a more normal solution. Some pictures which he exhibited, and which were treated in this manner, certainly were all that could be desired. In the intensification of negatives, he admitted there was considerable difficulty, the silver intensifier causing the plates after a short time to stain, and as with the above method of exposure, &c., great density was obtainable, in a very few instances only was intensification at all necessary.

A lively discussion thereupon arose as to the best kind of intensifier. Some of the members expressed themselves thoroughly satisfied with bleaching the plates with a saturated solution of bichloride of mercury, and afterwards soaking them in a strong solution of ammonia; while others found they could not get good results, as the plates seemed to stain.

Mr. J. V. Robinson explained that this arose from imperfect washing both before putting the plate into the mercurial bath and after fixing, and also after the bleaching before using the ammoniacal bath. He had used Monckhoven's with satisfactory results; but as Mr. Mansfield remarked, intensification of gelatine negatives was always more or less risky, and in his opinion it would be better, if possible, to avoid the necessity for it. The pictures produced were taken on Swan's plates, and in no instance did trouble arise from frilling, the alum bath preventing this evil. He also exhibited a collection of apparatus, including Shew's instantaneous shutter, which evoked a great deal of comment, the majority of those present agreeing that the principle of opening from the centre, and thus allowing most light to pass through the centre of the lens instead of the edge, was bad.

A developing-lamp, burning ordinary candles, was shown, it being constructed so that there was a large current of air passing through, thus avoiding all heating.

There were also an enamelled developing-dish and a new Parisian printing-frame on the table.

Mr. Thomas Mayne exhibited and explained both the single and double-chambered filmograph, as well as a new dark changing-box for either films or plates; his explanation of the above, and also some film negatives, being very interesting.

Mr. J. V. Robinson produced a new japanned tray for inspection, the advantage claimed for it being that there was no possibility of the japan rising and chipping off in the manner that enamel does, thus avoiding the possibility of rust.

Mr. Watson exhibited a "home-manufactured" camera-stand.

Mr. J. L. Robinson exhibited and explained a cheap dry plate camera, which met with much approbation, considering the price, &c.

A cordial vote of thanks was passed to Mr. Mansfield for his communication.

It was then proposed by Mr. Woodworth, and seconded by Mr. Pim, "That the thanks of the Society are due, and hereby given, to Captain Edwards and Mr. Nugent, for kindly placing their negatives at the disposal of the Society," and from which the presentation prints were taken. It was then proposed by Mr. Watson, and seconded by Mr. Mansfield, "That copies of the prints be forwarded to both Captain Edwards and Mr. Nugent." Both the above resolutions were carried unanimously

---

Talk in the Studio.

Photographic Society of Great Britain.—The next Technical Meeting of this Society will be held on Tuesday next, April 25th, at 8 p.m., at the Gallery, 5A Pall Mall East, when the following questions will be discussed:—"What is the Experience respecting the various kinds of Gelatine as Photographic Media?" "What is the Ratio of the Light emitted by Warnerke's Phosphorescent Tables, compared with the Standard Candle?"

A Photometrical Battery Cell.—An ingenious arrangement, by which light is transformed into electricity, has been devised by Laur, and the intensity of the current indicates, to a certain extent, the power of the light. A porous cell containing mercury, and a plate of platinum, are immersed in a solution containing sodium chloride and copper sulphate (this being contained in a glass cell), while a plate of silver sulphide dips into the solution. The plates are connected by a wire through which an electric current passes when light shines on the arrangement, as the silver sulphide is reduced. A galvanometer to measure the current completes the apparatus.

Spectrum Photography.—In a paper on the spectrum of carbon, communicated to the Royal Society by Professors Liveing and Dewar, these gentlemen give a map and table of the wave-lengths of the lines due to carbon in the visible part of the spectrum. The observations were made, for the most part, by means of photography, and the authors thus describe the way in which the photographs and measurements of wave-lengths were secured. A small photographic slide, containing the sensitive plate, fitted the telescope in place of the eye-piece, and so could easily be turned about an axis coincident, or nearly so, with the optic axis of the telescope. In taking a measurement of the position of a line the approximate wave-length was first found by interpolating between the nearest cadmium or other lines of known wave-length in photographs taken with calcite prisms. The telescope was then set to the angle corresponding to this approximate wave-length for the spectrum of the fourth order. The lower half of the slit was closed by a shutter, and the photographic slide having been adjusted for level, the plate was exposed to the light which came through the upper half of the slit, and gave an image of the lines in the lower half of the field. When this exposure was completed, the photographic slide was turned round through 180° about the axis of the telescope, so as to bring to the top that part of the sensitive plate which had been before lowest. It was then exposed a second time, and thus two images of the same line were impressed on the plate, which were necessarily at equal distances on either side of the point where the axis of the telescope met the plate. By a subsequent measurement with a micrometer under a microscope of the distance between the two images, and the conversion of this distance into angular measure, a correction was found, which was added to, or subtracted from, the reading of the circle to get the exact deviation of the ray producing the line under observation. Another photograph of the same line was next taken in the same way as before, except that the telescope was placed at the corresponding angle on the other side of the collimator. From the two angles thus found, the wave-length of the line was calculated. The process was repeated three or four times for each line, and the mean wave-lengths thus found for carbon lines were 2296·5, 2478·3, 2509·0, 2511·9, 2836·3, and 2837·2. The wave-lengths of the remaining lines were obtained by interpolation from measures of photographs on which the iron as well as the carbon lines were shown. The wave-lengths of the iron lines used in the interpolations were deduced from photographs taken with the grating in the same way as that above described for the carbon lines.

A White Enamel for Paper or Pasteboard.—A glaze or coating which is tolerably easy to apply, and can be readily varied as regards hardness, is a desideratum among collotypic printers, and the following formula recently published by Pauer will be found thoroughly reliable. A paste is first made by boiling 10 kilo-grammes of wheat starch with 110 litres of water, and to this is added 150 kilo-grammes of the finest gypsum, 1·5 kilo-grammes of sodium hyposulphite, and 50 grammes of ultramarine. It is generally advisable to thin it down for use with 100 litres of boiling water; and when it is desired to soften it, glycerine should be added, as much as 2 kilo-grammes not being too much in extreme cases. Zinc white may either wholly or partially replace the gypsum, and by stirring about half a kilogramme of stearine into the hot mixture, a much finer surface or polish can be produced. The presence of hyposulphite unfits cards enamelled with this mixture for use as mounts for silver prints.

Phosphorescent Light Emitted by Plants.—Among plants recently observed to show signs of phosphorescence, the following may be mentioned :—Tropæolum majus, agaricus olearius, auricularia phosphorea, polyporus citrinus, and xylaria polymorpha. Crié, who has made these observations, has also studied the light given out by the rhizomorphs of certain fungi, and he will probably publish results of considerable interest before long.

The Solubility of Silver Chloride in Water.—This is known to be much greater than that of the bromide, and Mr. C. P. Cooke has recently shown that one litre of a saturated aqueous solution of silver chloride deposits ·002 gramme of the salt when treated with silver nitrate, but only ·0009 gramme when treated with hydrochloric acid. Photographers who experiment with silver chloride should not forget that it is slightly soluble in pure water, although practically insoluble in many saline or other solutions.

Light and Vegetation.—It appears, from recent researches, that the transpiration of water by plants is directly proportional to the intensity of the light, and Paudion has published an interesting and elaborate series of investigations on the influence which light exerts on the respiration of seeds during germination. As in the case of large plants, less carbon dioxide is exhaled in light than in darkness.

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, *"Photographic News" Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed "Union Bank, Photographic News Co. Account."*

*** We cannot undertake to return rejected communications.

A. Greiner.—You will see we have made use of your communication, for which accept our best thanks.

Centaur.—If you refer to scum on the bath, a careful filtration will prove a remedy; but if the bath is so impure as to produce an appearance of scum on the plates, the best thing will be to render the solution slightly alkaline with carbonate of soda, and to expose it to the prolonged action of sunlight. It must, of course, be acidified before being again used.

West Kent.—1. It is difficult to categorically answer your question, but the simple drop or spring shutter is probably as convenient as any for general use. 2. Only when the most favourable conditions of light exist.

Tiger.—1 and 2. Certainly; and it is often preferable to hyposulphite, especially when subsequent intensification is contemplated. 3. Such a proceeding is very undesirable, and is only admissable when no other course is open. 4. It differs from pyrogallic acid by containing one atom less of oxygen. 5. No.

Otto Pfenninger.—1. It is probable that by using a small proportion of iodide in the emulsion, and developing with more dilute solutions, you will get over the difficulty referred to. 2 We do not think that the coloured shade which you refer to would prove useful; but for the class of out-door work you mention, it is very advantageous to adapt a large funnel-shaped hood to the lens. This may be made of blackened cardboard, and should have a series of square cardboard screens or diaphragms fitted inside, each one being of such a size as just to weaken the image on the extreme edges of the plate. Let us know if these suggestions prove useful.

Bustler.—Probably not so many as in this country; but the highest class work commands a rather better price than is the case in England.

A. N.—Numerous articles on the subject will be found in back numbers and in the Year-Books, but any short directions, such as could be given in this column, would be of no value to you.

T. Cowley.—1. The best material with which we have met is a closely-woven black cotton twill; two thicknesses of this being sufficient if care be taken to shade the bag while working. 2. Simply sewn in, and provided with bracelet of elastic webbing. 3. Ours was about two feet square. 4. Simply drawn together by a tape running in a turned-down edge; but we have seen the jaw-bones of a superannuated carpet bag pressed into service for making a satisfactory and easily closed-opening. 5. It should seldom exceed two seconds, but very often a small fraction of a second would suffice. 6. About one-twenty-fifth of the focus.

H.—We have found nothing to answer better than from 50 to 60 grains of gum-dammar dissolved in one ounce of chloroform.

W. Power.—That which you refer to answers admirably, but there are five or six others which will give as good a result. A simple drop shutter is less likely to get out of order than most of the highly complicated forms.

F. K.—1. We do not think it is an article of commerce, but we recommend you to print in the ordinary way, and to tint by subsequent floating on an aniline dye bath. Judson's blue, diluted with water, and acidified with acetic acid, answers well. 2. A cold saturated solution should be used.

A. N. L.—Apply to the makers of plates, most of whom undertake to demonstrate the process of development.

G. M.—Dissolve one ounce of tungstate of soda in six pints of water, and add from 15 to 20 grains of chloride of gold.

How is it Done.—1. It makes but little difference. 2. The cutting of "cartes" a little smaller than usual is probably a key to the mystery.

R.—They are both of doubtful utility in such a case, and until you can judge the exposure approximately, you will not be a successful photographer.

G. H. P. Jones.—A solution of amber in chloroform would be preferable.

W. Barrington.—There can be no doubt that the continued inhalation of ammoniacal fumes would be injurious to anyone having weak lungs, and it is desirable that you should provide a cover for the dishes you use, and arrange a sink which slopes rapidly down to a trapped outlet.

John G. Noake.—There is no alternative but to slightly warm the plates in such a case.

Palestrine.—There is no need to renew, as it holds good for fourteen years.

E. B.—The general quality of the plates is evidently good, but there are numerous marks arising from particles of dust or dirt, and you have over-exposed.

NEW METHODS IN GELATINO-BROMIDE WORK.

STRIPPING FILMS FROM THE GLASS.
REMOVING DEPOSITS OF REDUCED SILVER.
INTENSIFICATION WITH SILVER.
ISOLATION OF THE SENSITIVE MATERIAL.

The easy separation of the gelatino-bromide picture from its glass support has long been regarded as a desideratum, but has, as a rule, only been uniformly successful when the plates have been prepared beforehand with a view to the subsequent separation of the pellicle. Mr. Joseph Plener has, however, found that by immersing the plate in weak aqueous hydrofluoric acid the film becomes almost immediately loosened from the glass plate, owing to the solvent action of the acid. The etching action of the hydrofluoric acid is so slight as not to injure the glass to any extent, it doing but little more than to thoroughly clean the surface. Mr. Plener's hydrofluoric acid process may be carried out in various ways, as, for example, by building up a wall of cardboard strips round the negative, and, after levelling, pouring on a warm solution of gelatine. When the film is dry, or nearly so, it is immersed in the dilute acid until it can be easily stripped off, after which it is rinsed thoroughly and allowed to dry. If the wet film be carefully squeegeed down on a sheet of waxed glass, it can be easily separated as soon as dry, and under these circumstances the film negative is of course obtained with a beautifully even surface. Another method, which may be occasionally useful, is to immerse the stripped and still wet film into a bath of methylated spirit, a proceeding which causes the swelled film to rapidly shrink to near about its original size; after which drying between sheets of blotting-paper serves to remove almost every trace of spirit, so that the negative may be ready for printing from in a very short time. Wenderoth's method of squeegeeing a sheet of soaked gelatine could be doubtless made available instead of pouring a gelatinous solution on the levelled negative, and if the alcohol method of drying were employed, one would expect to be able to strip a negative and dry the stripped film in the course of fifteen or twenty minutes.

When a positive on paper is wished for, it is very convenient to make the picture on a plate in the first instance, and then to transfer it to paper. In such a case the positive picture on glass may first be coated with a thin layer of gelatine, to which a sheet of smooth-faced paper is next attached, or the paper itself may be brought into contact with the film under a warm gelatinous solution as when prints are mounted in optical contact with glass; remaining operations being so similar to those already mentioned as to require no special description. Mr. Plener showed us many pictures which had been transferred to paper in this way; and the negatives, which had been transferred to a fine or close-grained paper, had evidently lost none of their printing qualities, excepting so far as the paper backing would, unless waxed, considerably retard the process of printing.

Our readers have doubtless often met with negatives which appear to have a fog or deposit of silver between the film and the glass, this deposit being yellowish-brown if viewed by transmitted light, and rather metallic in appearance when looked at by reflected light. A deposit of this kind may, in some instances, be the result of using dirty glasses, but Mr. Plener thinks that in many cases it arises from the fact that the denser grains of the sensitive material (probably a compound of haloid salt and gelatine) settle down to the face of the glass, where those parts of the grains next the plate are so imperfectly protected by surrounding gelatine that the developer induces a general reduction to the state of metallic silver. This view is confirmed by the fact that when such a film is stripped on paper by the method detailed above, so that the deposit originally under the picture is brought to the face, the deposit may be removed by means of metallic mercury, the metal amalgamating and dissolving the coarse granular silver forming the fog or veil, while the true image, which consists of silver intimately united with gelatine, remains untouched, and at the same time comes out clearly and boldly.

Mr. Plener finds that a film which has been stripped by his method, and has thus been washed or cleansed on both sides, is so much more amenable to silver intensification than a film on the glass support, as to render it advisable to strip a film which requires to be intensified; but it is possible that the action of the hydrofluoric acid may have something to do with this circumstance.

Mr. Plener's most important discovery in connection with gelatino-bromide emulsion is, however, his method of separating the sensitive compound of bromide and gelatine. This is rapidly effected by mechanical means, which we shall not be at liberty to describe until the inventor has secured foreign patents bearing on the matter: and, after separation, the material may be washed, and then incorporated with fresh gelatine. Mr. Plener finds, in most cases, that, by separating the sensitive body from an emulsion which gives green fog, with an extremely thin image, and mixing it with fresh gelatine, an unusually vigorous and clean emulsion is obtained; but, in some cases, the desired end may be attained by removing the coarser particles only—an operation which takes but a few minutes.

It is also possible to incorporate the sensitive constituent of gelatine emulsion with collodion; but the result is not so uniformly satisfactory as when gelatine is again used. Mr. Plener, however, showed us a very successful negative made with the collodion mixture. We hope shortly to publish detailed papers by Mr. Plener.

A NEW METHOD OF RECOVERING SILVER FROM OLD FIXING SOLUTIONS.

The recovery of silver from the fixing solutions used in the treatment of gelatino-bromide plates is a matter of considerable importance, much more important than when only wet plates were treated with the hyposulphite solution. And for this reason. In the case of gelatine emulsion plates, from half to three quarters of the silver they contain goes into the fixing solution; whereas in the wet collodion process, a quarter of the silver at most was carried away by the hyposulphite solution. In these circumstances it is obvious that the fixing solution employed for emulsion plates—which, by the way, is usually kept in a dipping bath—is of a valuable character, and it becomes a question of deep interest to the photographer, therefore, how he can best recover the silver contained therein.

As most of our readers know, two methods are in practical use in the photographic laboratory for recovering silver in hyposulphite solutions. The first is that we recently referred to as being in favour with Messrs. Valentine and Sons, at Dundee, viz.: the precipitation of the silver in metallic form by means of sheet zinc; the other method is to add the so-called liver of sulphur to the fixing solution, and recover the silver in the form of sulphide. A third process, apparently equally practicable, has now been put forward by Dr. Lagrange, of Berlin. This chemist recommends the treatment of old fixing baths with the ferrous oxalate developer. In this case the silver is precipitated in a metallic state, and, when it has been washed, may be converted into nitrate of silver by dissolving in nitric acid and evaporating to dryness. The fine division of the metal facilitates its solution, and if the crystals of nitrate are dissolved a second time and recrystallized, or fused, a product is obtained that any photographer may employ with confidence.

We have tried Lagrange's method with success. We dissolved some bromide of silver in hyposulphite solution, and then treated it with a quantity of ferrous oxalate developer. At a low temperature the reduction of the silver was very slow; but on slightly warming, the solution became at once turbid, and silver was precipitated in a fine powder. This finely-divided silver was collected on a filter paper, carefully washed, and examined as to its purity. It dissolved wholly in nitric acid, making a clear solution, and this gave no precipitate either with ammonia or a solution of nitrate of baryta. It was therefore free from sulphur and from iron.

The ferrous oxalate had extracted from the fixing solution the whole of its silver, with the exception of a slight trace; had we treated the hyposulphite solution for a longer period, probably all the silver would have been recovered. After standing twenty-four hours, some iron was precipitated with a trace of silver.

An old fixing bath was now taken in hand which had served for the treatment of a larger number of negatives; as the plates had been developed with pyrogallic acid, and the developer had not been very carefully washed off them, prior to their introduction into the fixing bath (as is the wont in many photographic laboratories), this fixing solution was very brown, and contained decomposed pyrogallic acid and ammonia. On adding to this ferrous oxalate and warming it, a rapid precipitation ensued; but in this case the precipitate was darker than that of the former experiment. A chemical examination showed that the precipitate here contained a small quantity of iron, and traces of an organic substance, clearly observable on heating in a test tube; so that the silver recovered was not quite pure. Still it would be quite possible, we cannot help thinking, to remove such small impurities as present themselves, by treatment with dilute sulphuric acid, as, indeed, Dr. Lagrange suggests.

In order to determine what influence the developer employed has upon the purity of the silver recovered, we next experimented with some old fixing solution in which plates had been treated which had been developed with ferrous oxalate. On adding ferrous oxalate to this fixing bath and warming, we obtained precipitated silver perfectly free from iron, and exhibiting but the very slightest trace of sulphur.

We may, therefore, say of the Lagrange method that it enables one to precipitate a comparatively very pure silver from old fixing baths, and that the method is moreover very rapid and very direct in its action. The finely divided silver may in a short time be converted into silver nitrate, which, when re-crystalized or fused, can be employed in any photographic operation.

There is, however, the question of cost to be considered. Ferrous oxalate, albeit it may be itself reconverted, is a somewhat expensive article. When large quantities of fixing solution have to be treated, or when a fixing bath is poor in silver, the recovery of the precious metal with ferrous oxalate is undoubtedly a more expensive operation than treatment with zinc or liver of sulphur. Precipitation in the form of sulphide of silver—that is, using liver of sulphur—we should still recommend to all who collect their fixing solutions and work them up only at long intervals, and who do not mind the tedious operation afterwards of reducing the silver; or, precipitation with zinc, as practised on a large scale by Messrs. Valentine, when, if not so much silver is obtained, this is in a metallic condition. But in the case of those who desire to secure their silver quickly, and to convert it as soon as possible into nitrate of silver, they cannot do better than resort to the use of ferrous oxalate for recovery of the precious metal from old fixing solutions.

THE LATE CHARLES DARWIN.

There can be no better criterion of the estimate at which a man is held, than the reflection of opinion from all parts of the world that follow so speedily the announcement of his death. On Friday morning last the news was first published to the world that the author of "The Origin of Species" was no more; the following day came back to us from every quarter of the globe heartfelt sympathy and tender regrets at the death of Charles Darwin. The great Englishman's name was a household word at every foreign school and college, for the Darwinian theory is discussed wherever students assemble and men of science gather together.

It is not in our province to pronounce any eulogium upon Charles Darwin; that has already been done by abler pens. But while yet the great man's name is still upon every tongue, we may call here to mind the fact that Mr. Darwin had much to do with photography and photographers. A work published in 1872 on "The Expression of the Emotions in Man and Animals" was very widely read in this country and abroad, and by the aid of photography Mr. Darwin was enabled therein thoroughly to illustrate his words and give full weight to his opinions. We can but ascribe it to Mr. Darwin's deep foresight that he should have chosen as an assistant in his work the man of all others among photographers who was most likely to sympathise with the author's aim, and appreciate and understand his wants: we mean the late Mr. O. G. Rejlander.

To Rejlander, Darwin explained the photographic illustrations of which he stood in need; the philosopher desired to pourtray how definitely in man were the expressions of emotion, and Rejlander threw himself into the work with an energy well worthy of the cause. So enthusiastic was the photographer, that he posed himself again and again as the model, and in the end Mr. Darwin had no cause to regret having placed so important a work in our old friend's hands.

We have extracted a few of the "expressions" to show how worthy was Rejlander of his master. The top figures 1 and 2 are to indicate how the mere fall or separation of the lower lip will indicate care or trouble. Photographers

in their everyday work may make note of this for alterations in the features of their sitters, quite as trivial, are enough to mar their work at any moment. Two other pictures indicate very plainly, joy and grief, or tears and laughter. The lady's face—no other, we believe, than Mrs. Rejlander—indicates scorn or contempt, while the four pictures of Rejlander himself are so graphic, there is no need for any explanation at all. There is anger, astonishment, horror, and indifference very apparent in these photographs, or rather wood-cuts from photographs. In a word, a mere inspection of the pictures will, we feel sure, convince our readers that Darwin could not have selected a more fitting helpmate to illustrate "The Expressions of the Emotions" than the late O. G. Rejlander.

At Home.

HERR FRIEDRICH BRUCKMANN AT MUNICH.

Bruckmann's photographic establishment at Munich is the largest in South Germany, if not in Southern Europe. Herr Bruckmann was one of the first to take up the Woodbury process, and, with the exception of MM. Goupil et Cie., his is the only Continental firm that has worked the method on an extensive scale. In a big oblong building in the Garten Strasse, which has been erected especially for photographic purposes, there are wonders to be seen which no other establishment unites under one roof. The Bruckmann establishment is interesting from another point of view; it is indicative of photographic progress. "Once we used to sensitize 600 sheets of albumenised paper daily," said Mr. Bruckmann junior; "now we only treat 300 sheets." The reason for this is that the mechanical printing processes are rapidly growing in importance, and that the time is not far distant when producers of photographic prints will turn over a new leaf altogether. For some years the Woodbury process was sufficient, in conjunction with silver printing, to keep up with the demands for photographs; now silver printing is declining rapidly in the face of collotype, and it really seems as if for photographic publications the employment of albumenized paper will soon be no longer resorted to.

The Bruckmann establishment, then, is indicative of what we are coming to. Here we find the Schnell-press at work, although it has been installed but a few months; next year, however, will see the addition of another such machine, if not two. "Whenever more than 500 prints are required, we resort to Lichtdruck," says our young host; "if the order were not quite so large, we should probably employ Woodburytype; and very small orders we print in silver." This is the present plan, but any moment may see it again altered.

Here are the Woodbury presses. They are not at work just now, but the circular tables upon which the printing machines stand are in apple-pie order, and fit to begin at any moment. The roomy apartment is paved with flags, and is below the level of the ground, so that it is always cool even in the height of summer, and there is no fear of the gelatinous ink "running." It is only the small Woodbury presses that are on the moveable circular tables; the larger ones, in which ten-inch prints are produced, are placed in a row upon a bench under the window. The place has half the appearance of a cellar, it is so cool and dark.

Some photographs print better by the Woodbury process, and others by the collotype; neither is as perfect as silver printing, as everybody knows, but then the permanence of the latter cannot be guaranteed. Practically, the difference between Woodburytype and collotype may be thus set down. Says Herr Bruckmann: "You cannot always get good white surfaces in a Woodbury print, and you cannot always get good deep blacks in collotype." Collotype printing is cheaper than Woodburytype printing, and that has given a greater impetus to the former.

We pass from the Woodbury room to another similar apartment, a huge place, half cellar, half wash-house. Here the silver prints are washed, toned, fixed, and washed again. The preliminary washing, as also the toning, is done in big oval and very shallow washing tubs; they measure four feet across, and are bound with iron hoops. They look like dairy tubs in which milk is left for the cream to rise. Big receptacles in the apartment receive the first washings, &c., the chloride being thrown down with common salt, and collected with great care, for the silver residues in such a large establishment are worth several hundred pounds a year.

The washing of the prints is effected in a very energetic manner. They are placed upon a tray made of stretched canvas, and put under a water tank at a distance of three feet. In this position the water falls upon the prints with considerable force, in a multitude of little jets, not unlike those that emanate from a watering cart. These jets play unceasingly upon the prints for a period of not less than fifteen minutes, after which they are put for the night in running water. This is deemed sufficient washing, and it is, indeed, a very thorough one.

One of the principal products at the Bruckmann establishment just now, in the way of silver prints, are modern studies, which are coloured and sent to America, in return for the vast quantities of prints that issue from the studios of Mora, Sarony, &c. They are, for the most part, cabinet pictures of beautiful women, the photographs produced at Vienna and Munich. To such an extent are these turned out, that, at the Bruckmann establishment, we counted, in the colouring-room, no less than twenty girls, all of them engaged in painting these pictures for the American market. The painting is not done roughly, although so extensively carried out; the girls are skilled artists, at any rate for the most part, and some of the little paintings are exquisitely finished. The portraits we saw were all upon albumenized paper, proving pretty clearly that, for the best work, the Bruckmann establishment must still have recourse to silver printing.

At the same time, it must be asserted that by the time some of the collotypes have been gelatined and immersed in spirit varnish, they are difficult to tell from albumen prints. By close examination with a sharp eye—or, better still, with a magnifier of low power—the grain is, of course, soon discovered by photographers; but few of the general public, we suspect, would know the difference between prints produced by silver printing and collotype, especially when they have not the means of making comparison between prints from the same negative. In the Bruckmann establishment they produce very good collotypes, and although, as we have said, there is a Schnell-press at work, this is not driven by steam power as yet, but by hand, in the same way as type printing-machines at small offices. Otherwise, the arrangements are the same as we have described in our account of Albert's establishment in Munich, and Löwy's in Vienna. Nearly all the collotypes are printed with black and brown inks, so as to impart some sort of colour, and to make the result appear as much like a silver print as possible. There is also more attention paid to the glazing and varnishing of the prints at the end of the process; of course, with the same object in view. The shellac varnish employed, after the prints have been gelatined and dried, is of the same nature as that referred to in Herr. Löwy's studio. This varnish lightens up a collotype considerably, and gives it the well-known gloss of an albumen print.

The mounting department is also on a large scale, and alone well worth a visit. There is a complete bookbinding establishment, for binding the photographs into albums when mounted. The mounting is invariably done with starch freshly prepared, which is applied by means of very broad sable-hair brushes.

The "By-the-bye" next week will be "About the Royal Academy"; the following "At Home" will be, "Mr. J. E. Mayall's New Electric Studio in Boud Street."

FRENCH CORRESPONDENCE.

Process for taking Positives from Negatives by Contact—The Image with Half-tones on Bitumen—Direct Application of the Method to Woodburytype and Collotype.

Process for taking Positives from Negatives by Contact.—Captain Biny's energy is really inexhaustible; already he has brought out another process, of which the Photographic News will be the first to give an account. In my opinion, this process will not only offer an opportunity for most interesting experiments, but it will also be a point of departure for other discoveries of great value in improving the graphic arts. From Captain Biny's statements it appears that he is able to take images with half-tones by treating them the same as impressions upon gelatine—the carbon process, for example. The action of light renders insoluble a greater or less thickness of bitumen, and, if it be then developed on the side opposite to the impression, a number of depressions, more or less deep, is the result, corresponding to the degree of opacity of the different parts of the negative. Thus very thin pellicles coated with bitumen, and exposed on the reverse side, will give prints with half-tones. This is a most important fact, for it may lead to a very simple and complete process of photo-engraving.

The Image with Half-tones on Bitumen.—Captain Biny thus describes his new process:—He takes any kind of negative on collodion or bromized gelatine, not varnished, and, if possible, not gummed, but in any case perfectly dry. This image he coats with a layer of a 20 per cent. solution of bitumen of Judæ in benzine. The plate is then carefully laid on the turning table, and warmed, until it is quite dry, in a dark room lighted through yellow panes. The bitumenized negative is then exposed to full sunlight with the glass upwards. When the exposure is sufficient (and this may be ascertained by placing a piece of chloride of silver paper underneath the negative, and against the bitumen), the positive in bitumen which adheres to the glass is developed by spirit of turpentine; it is next well washed under the water tap, and it is then very slightly and very rapidly acidulated in order to remove every trace of the turpentine and of the bitumen which has not been exposed. Next, without waiting until the negative is dry, it is placed in a basin containing a saturated solution of bichloride of copper in water; the reduced silver of the negative is at once changed into silver chloride. So soon as the white colour is come out sufficiently, the negative is washed again, and it is dipped into a solution of chloride of potassium, or of hyposulphite of soda. Observing now the process, the silver salts will be seen to disappear completely; the plate becomes transparent, and on removing it from the bath a beautiful positive image in bitumen of Judea, and with all the half tones fully expressed, will make its appearance, since the bitumen has been exposed by the surface in contact with the image itself. This positive will serve for a great number of applications, which any one who is a photographer will be able to discover for himself, so that it is not necessary to mention them. But it is important to lay stress upon the fact that the method above described may be used with bichromatized gelatine, or albumen, or gum, coloured or not, as may be convenient, either for carbon prints, or for printing with fatty ink on glass, or any other transparent support. For example, bichromatised mucilage, coloured with Indian-ink, may be flowed over a glass plate which has been rubbed with French-chalk, and then, having been exposed in contact with a collodion negative, may be detached, afterwards being treated with bichloride of copper (bichloride of mercury will also answer the purpose, but it is much less soluble) and with cyanide of potassium or hyposulphite of soda, the result will be a very fine carbon positive. A bichromatized mucilage, not having any colour in suspension, but, like the bitumen film, taken on a ground-glass plate in contact with a negative, will, after exposure, give a positive, with a fine grain, suitable for printing in fatty ink. Any excess of gum not rendered insoluble by light, or of unreduced silver of the negative image, must, of course, first be removed. Bitumen, either with or without the addition of coal-tar, will, perhaps, render the half-tones on ground-glass better than bichromatized gelatine, because there will be no reason to fear, after the plate has been well wetted, that the relief of the substance not exposed will be too great. In any case, line drawings on bitumen superposed on collodion from which all reduced silver has been removed, and which has afterwards been thoroughly wetted, take the ink beautifully. When the bitumen positives taken from gelatino-bromide negatives by contact are slightly wetted, they show very marked depressions and proportional depth in the half-tones in every part where there is any bitumen; on the contrary, where the gelatine is not enclosed in the film of insolated bitumen, they show relief. Hence, a plaster mould could probably be readily taken from one of these positives, and from this mould a fresh plate by electro deposit.

Direct Application of these Methods to Woodburytype and Collotype.—Having brought these methods to the notice of my readers, I will leave them to reflect on the very interesting facts which I have been able to describe, and will only further mention two most important applications. The first of these refers to the Woodburytype. In the new processes of the Woodbury we all know that a relief is taken in gelatine, which is then developed on glass the same as a carbon print. To produce this relief the paper coated with the mixture requires to have a tolerable thickness of gelatine, and its use is hence often attended with great difficulty. I should prefer to take on a glass plate an image in gelatino-bromide, which, according to circumstances, will be either a positive or a negative, and then to coat this with a film of bichromatized gelatine slightly tinted; after which I should dry the preparation in a box with chloride of calcium, and then develop with hot water, in order to dissolve all the gelatine which has not been acted on by light. By this arrangement, if we began with a negative, we should obtain a positive in relief, and if we began with a positive, the relief would be a negative. As we know, Mr. Woodbury can use either kind of plate and he is able to form a direct mould by forcing a sheet of tinfoil into a negative relief. In the second place, as regards collotype, I would modify the ordinary process, so as to obtain greater solidity in the following way. I would coat a thick glass plate, in the first place, with a substratum of albumen and silicate of soda, according to Obernetter's formula; I would then cover this with a film of gelatino-bromide. I should then print on this sensitive layer a negative by contact with a positive on glass, and when the development is complete, and the plate quite dry, I should plunge it into a bath containing a solution of bichromate of potash; I should then expose, and place it in cold water in the ordinary way. By this means we should be able to get prints of very considerable durability. Of course it would be necessary to take care to remove any salt of silver by means of hyposulphite, so as to have nothing remaining but gelatine rendered more or less insoluble.

Leon Vidal.

EXPERIMENTS WITH A NEW DEVELOPER.

BY C. R. WOODS.*

I have a novelty here in the shape of a new developer, or, more

* Read before the Photographic Society of Great Britain.

strictly speaking, a substance that has not hitherto been put to developing purposes.

Molybdous salts are prepared by taking a saturated solution of ammonic molybdate, adding sufficient hydrochloric acid to re-dissolve the precipitate first produced, and reducing with zinc. The final result is a mixture of zincic and molybdous chlorides. On trying this solution (considerably diluted) on a gelatine plate which had had the usual exposure, an image appeared which could be developed till it was visible at the back of the film, and yet possessed no density. The film was stained a deep yellow, which appeared very marked on fixing.

Molybdous oxide was then prepared in the usual manner by adding a large excess of potassic hydrate to the above solution, and washing well by decantation. The oxide dissolved in hydrochloric acid gave about the same result as the mixture of zincic and molybdic chlorides. The sulphate did not develop the picture so quickly, and gave a yellow stain as before. The nitrate acted a little quicker than the sulphate, but not so quick as the chloride, and the film was not stained so badly. The molybdous oxide, treated with oxalic acid, formed insoluble oxalate, little, if at all, soluble in potassic oxalate. A similar result was obtained with citric acid and potassic citrate. Acetic acid dissolved the oxide readily, developed a gelatine plate with more density than any other molybdous salt; but the image was still very weak, and still accompanied by the yellow stain. The oxide dissolved in ammonic carbonate developed a gelatine plate without this stain; the image was weak, and, owing to the very considerable quantity of carbonate of ammonia required, it furnished a desperate case of frilling.

The solution of zincic and molybdous chlorides also developed a collodion-emulsion plate. Molybdous acetate required the addition of bromide to prevent fog. Both gave no density, and the addition of pyrogallic acid failed to give density.

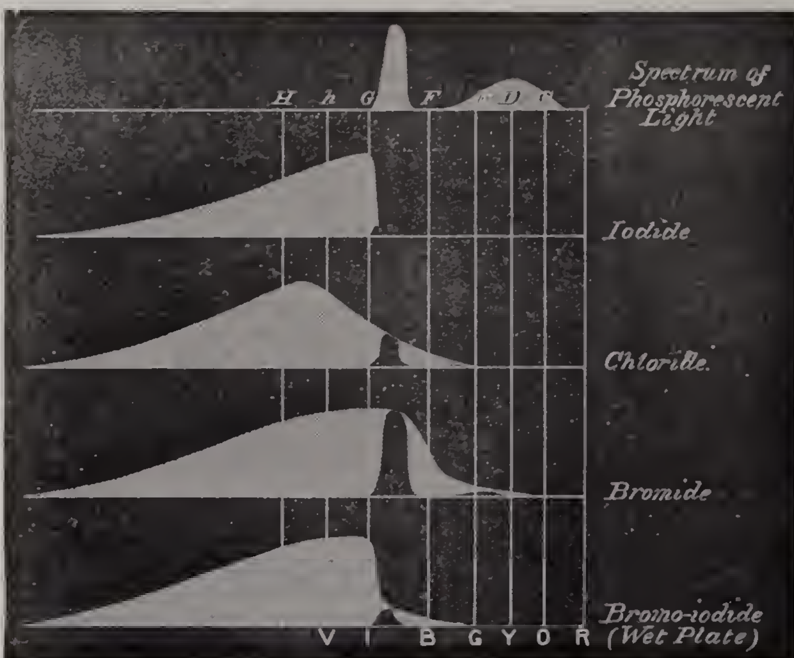
Thus there seems little probability of molybdous salts being practically useful for developing purposes, and their developing power can, therefore, only be regarded as a photographic curiosity. Still, the subject is certainly of theoretical interest, for the developer, in spite of its inability to give density, is a powerful one, acting pretty quickly with ordinary exposures.

ON THE "SENSITOMETRIC" SENSITIVENESS OF GELATINE AND OTHER PLATES.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

In my recent Cantor lectures before the Society of Arts, I touched very briefly on certain failings in sensitometers when illuminated with light from phosphorescent tablets; and I propose to-night, amongst other things, to enter a little more fully into the matter. This subject I undertook to investigate for the Sensitometic Committee. When you examine the light from a phosphorescent plate by means of the spectroscope, it is found that it is composed of a strong band in the indigo below G of the spectrum, and also of faint rays commencing in the green and extending to the limit of the visible red, and no doubt there are some faint rays which lie below the limit of the red. But with those we have not to deal, since ordinary photographic compounds are unaffected by them. The question then arises as to what effect such light would have on such ordinary photographic compounds.

Let us endeavour to trace what would occur. We will commence with the iodide. Silver iodide in its perfectly pure state is sensitive only to a little way below G, and it has very small sensitiveness at all below G. Its real sensitiveness lies in the violet, and also in the ultra-violet, the maximum intensity lying very close to G in the solar spectrum, from which point the sensitiveness makes a rapid descent, as shown in the figure. Now let us see how the light from a phosphorescent plate would affect the iodide. An inspection of the figure will show that it can affect it to a very small extent, only one small portion of



the light, and that nearest to G, being capable of making any impression on it. When we take the case of the chloride, we have the same effect; the light from a phosphorescent plate only indicates a small percentage of the light capable of acting upon it. When we come to the bromide we have a far different result. In the bromide we have the bright band in the spectrum of the phosphorescent light absolutely coincident with the regions of maximum sensitiveness. Perhaps, however, one of the most interesting cases is that of the ordinary bromo-iodide wet plate, in which again we have the position of maximum sensitiveness lying beyond the band in the phosphorescent light spectrum, so that in this case it is only very slightly effective (see fig. 5). I now wish to come to a practical application that must be made of these observations. We are in the habit of saying that a gelatine plate is so many times more rapid than a wet plate, and I believe that this statement is often founded on a measurement of the rapidity of the plates by means of a sensitometer. Let us suppose for an instant that a bromide plate and a wet plate are equally sensitive to white light, and then let us trace what would happen suppose the exposures were gauged by the sensitometer. If the area of the curve of sensitiveness be measured in each case, and called unity (since by hypothesis the sensitiveness is to be equal), and the area of the curve of the phosphorescent light after being drawn be also measured, and the second measurement be divided by the first, we shall have a fraction indicating the sensitiveness to the phosphorescent light. The ratio of these two fractions one to the other will represent the relative exposures that would have to be given, supposing them regulated by a sensitometer illuminated by a phosphorescent plate.

* Read before the Photographic Society of Great Britain.

The respective areas for the iodide, chloride, bromide, and bromo-iodide of silver (wet plate), and the areas of the curve on which the phosphorescent light will act, are as follows :—

	Total area of curve.	Area acted on by phosphorescence.	Proportion acted on.
AgI	189 ...	1 ...	$\frac{1}{189}$
AgCl	266 ...	8·7 ...	$\frac{1}{30}$
AgBr	354 ...	35·8 ...	$\frac{1}{10}$
AgI+AgBr (wet plate)	205 ...	4·9 ...	$\frac{1}{42}$

It will be seen, then, that, judging by the sensitometer, the relative times of exposure between a wet plate and a gelatino-bromide plate would be 42 to 10 ; or, roughly, the wet plate would be given four times too much exposure, or the gelatine plate would be given four times too little, according to which was used as the standard for exposure. With a plain iodide plate compared with a bromide plate the former would be exposed nearly nineteen times too much. Comparing a bromo-iodide plate and an iodide plate together, the exposure of the former would be four and a half times too much.

It is thus seen that the plan of comparing a wet plate with a bromide plate by means of the phosphorescent light is fallacious. The question hence arises, How can you compare these two kinds of plates together ? Without entering into details, I may at once say that a gas-light gives a much nearer approach to truth. In some experiments carried out with a Warnerke standard sensitometer, the following numbers speak for themselves. Bromide (gelatine) plates of the same batch were used in the whole experiments.

Plate used in the sensitometer.	Exposed to	For	No. on sensitometer	Remark.
Gelatino-bromide gelatine	Phosphorescent light	½ minute in the usual way	24	2 separate
Wet plate ...	... ,, ...	1 minute ...	7·8	exposures
Gelatino-bromide plate	Gas light ...	¼ minute ...	24	of ½ minute each were
Wet plate ...	... ...	1 minute ...	15	given

Comparing the wet and gelatine plates excited by phosphorescence and by gaslight, we find, according to Warnerke's table, that with the former light the gelatine plates appear much more rapid than with the latter.*

By gaslight the gelatine plate is only 48 times more rapid than the wet plate, whilst by phosphorescence it is about 200 times. If the first result is divided by the second, it will give the ratio of effective gaslight to phosphorescent light, and this is 4 nearly. The ratio of effective daylight (which is variable, by-the-bye) to phosphorescent light, as obtained by calculation, is 4·2. It is thus evident that gaslight is nearer to white light in its effect on a plate than is phosphorescence. I think it may be safely said that when a comparison is made between a wet plate and a bromide plate by means of phosphorescence, the true superior rapidity of the latter over the former may be very nearly obtained by dividing the result by 5. Thus if a wet plate, according to sensitometer, is 150 times slower than a gelatine plate, the true figure to estimate it at will be somewhere about 30 times.

So far I have only touched upon the sensitiveness of bromide plates in comparison with wet plates. It now remains to remind my hearers that any mixtures with a bromide in gelatine plates also alters the sensitiveness as shown by the sensitometer. In a recent communication to the Royal Society I showed that one salt acted as a sensitizer to another—that is, that silver sub-iodide (Ag_2I) acted as a sensitizer to silver bromide (AgBr), the bromine liberated from it forming a new molecular combination, Ag_2BrI. The result of such sensitizing was to cause a dip in the curve of sensitiveness near G—in fact, at the place of maximum sensitiveness of silver iodide. The same result was shown also to hold good where chloride was mixed with iodide, and where all three were in combination, or rather mixed. It will be seen, therefore, that when using a sensitometer illuminated by phosphorescence, the dip in the curve about G is wholly neglected, and not taken into account. In fact, to reduce the thing to an absurdity, were all rays beyond G towards the red of no effect, the sensitometer would show an equal sensitiveness. Hence, in comparing a bromide plate with any bromo-iodide plate, or chloro-bromo-iodide, or chloro-iodide, the sensitometer-results for the latter would be slightly too high.

* Of course, owing to the double exposure, we have to divide the rapidity of the former by 2, which gives the number shown.

A CURE FOR GREEN FOG.

BY CAPTAIN ABNEY, R.E., F.R.S.*

In an interesting paper read at the last meeting of the Photographic Society an account was given of obtaining intensity by means of converting the image developed by the alkaline method into silver oxalate by means of a solution of ferric oxalate, and then re-converting it into metallic silver by means of ferrous oxalate development. This plan of converting the silver image into oxalate I had described last year in the Photographic News, in an article on a cause of lack of density of the developed image, and had shown that the image could be re-converted into the metallic state by ferrous oxalate development. I had not noticed, however, that it gave any particular density to the image. In repeating these experiments lately it struck me that, if green fog was caused by a silver deposit, it should, on treatment as described above, yield a negative free from any coloured veil, the green veil being replaced by a small deposit of metallic silver. I had by me one or two specimens of plates which had yielded from fog with alkaline development, and on these I operated. The result was, that green fog disappeared entirely, no trace of it remaining ; at the same time there was, undoubtedly, a small trace of veil, due to deposited silver.

I exhibit a couple of plates—one in which the green fog has been abstracted from half the surface, and the other in which the green fog has been totally eliminated ; the first of these plates was treated with ferric oxalate in a cell, and then developed with ferrous oxalate ; the other was differently treated. Potassium bromide, of twenty grains to the ounce, and a solution of ferric chloride of about equal strength, were mixed together, and the plate immersed in it. The image was immersed in ferric bromide, or that and chloride, till it was bleached ; it was then rinsed under the tap, and the ferrous oxalate applied. The result is, that not a trace of green fog is apparent, though it was about as bad a specimen as any I have ever seen ; in fact, the image was absolutely pink, and the shadows pea-green. This negative I had laid aside as useless ; but now it has some value. It appears, however, as if there was a very minute deposit on the shadow—so minute that it can only be seen by placing the negative on white paper. Ferric chloride I also tried by itself ; and this answers the purpose equally well, though it is rather slower in action than the ferric bromide as described above. I should say that any body which has the property of converting the image into a bromide or chloride would be equally effective. Cupric salts with gelatine I am not fond of, as the cuprous salts are insoluble and cannot be washed out of the film, and there is a tendency for muddiness to result when they are used. The ferrous salts are soluble, particularly in potassium oxalate ; hence they may be used with impunity.

At our last meeting I made some remarks on the use of hypophosphites as developing agents, and remarked that plates with which I got green fog when using the alkaline developer did not give this veil when using sodium hypohosphate instead of ammonia. The natural inquiry to make is the reason of the difference. I think we may trace it to the fact that silver bromide is soluble in ammonia, and not in the hypophosphites. The action then seems thus :—In the shadows, ammonia dissolves a certain small quantity of silver bromide, and the gelatine (which in some cases, and only in some, is in a fit condition to act) forms a compound with it which is insoluble in the toning bath. The dissolved silver bromide is very minute, although the compound is strongly coloured. The example of an aniline dye is sufficient to show what a minute quantity of colouring matter is able to give bodies a very definite colour. When the ferric chloride, which gives up chlorine, or ferric bromide, which gives up bromine, is brought in contact with it, the silver is converted into a very delicate layer of silver chloride or bromide ; and in applying ferrous oxalate, this is reduced to the metallic state. I would ask my hearers to recollect that a negative which has to be forced up with ammonia is much more liable to this defect than one which yields to ordinary strength of developing solutions. If any present have negatives which show green fog, let me ask them to try the use of the ferric chloride or bromide, and a subsequent re-conversion of the white image into metallic silver, and I think they will welcome this plan as a boon. It is interesting to watch the parts most covered with the green fog : it will be noticed that they assume a whitish opalescent appearance, which remains until the image is once more reduced to the metallic state. All the operations involved can be carried out, of course, in daylight. A negative should be washed from the fix-

* Read before the Photographic Society of Great Britain.

ing solution previous to treatment with the ferric salt, as otherwise the hyposulphite reduces the ferric salt to the ferrous salt, and the bleaching action is consequently retarded.

Notes.

The present Honorary Secretary of the Photographic Society, Lieutenant Leonard Darwin, Royal Engineers, is a son of the author of "Origin of Species."

The author of "Modern Dry Plates" is becoming a universal favourite in this country; the Photographic Club recently elected him an honorary member.

Mr. Norman May writes us from Malvern, that the two photographs at Worcester to which we referred last week in one of our "Notes," emanate from his studio; we are very glad to it.

Negatives taken on gelatino-bromide paper were shown at the Technical meeting of the Photographic Society on Tuesday, and, as in the case of calotype negatives, the grain of the paper was visible enough, but no trace could be observed on prints made from them.

Our friend, Mr. W. K. Burton, tells us that when he has a batch of plates that exhibit green fog, he stores them awhile in a dry place, when the defect no longer troubles him.

Now that Mr. Plener's simple method of stripping gelatino-bromide films on paper has been published, many will be anxious to make the portfolio take the place of the plate-box.

It must not be forgotten that the paper negatives are very easily shaded at the back, either by washes of transparent colour, or by blacklead in powder applied with a stump; but this work should be done before waxing.

At the same meeting, Mr. Sebastian Davis called attention to the convenience of using a maximum thermometer in regulating the temperature of a water bath in the dark-room. It is merely necessary to take it out occasionally in the light and to observe the temperature; the instrument being re-set during the time taken up in returning it to its place.

The two-candle Swan lamps mounted on a moderator stand is the latest form of our non-actinic electric light. The body of the moderator contains a two-cell Planté battery made on the principles indicated by us in our issue of February 10.

A suggestion of Mr. Plener that hydrofluoric acid might be used with advantage for cleaning glass deserves to be noted. The acid would impart a new and very smooth surface, even to old and worn material. We need scarcely warn our readers of the corrosive action of hydrofluoric acid.

It was a dull day on Wednesday to get a first sight of the Royal Academy. Even that hardy race, the critics, seemed to be affected by the weather, for one or two of the rooms were actually empty, in the afternoon, when we entered. The arrangement of the rooms is a little altered this year; the "lecture room" has been devoted to sculpture, and there is no break of busts and statuary in the rooms devoted to paintings, as there used to be. This is hardly an advantage, we think; for the break was not only a relief, but caused some attention to be given to the sculptor's art, before the visitor was quite wearied out.

The best thing we can advise portraitists to do when they visit the Academy this year, is to study well Mr. Ouless' work. Though the youngest Royal Academician, Mr. Ouless is the most trustworthy of portrait painters. For simplicity of pose and natural grace his studies are unrivalled. He never attempts too much, and, therefore, if he failed, could not fail egregiously. But he never does; a standing portrait (122), and a sitting portrait (446), we consider the best and most unaffected in the gallery. Millais, we are glad to see, has very few portraits this year.

No. 391, Van Beers' "Sirène," is sure to attract the attention of photographers. This, it will be remembered, is the picture about which the Belgian Laws Courts have been so busy of late, in order to decide whether it is a coloured photograph, or a painting pure and simple. The picture is a very taking one. A wooden pier juts sharply out of smooth water, and down the steps comes the Syren, to take boat in a smart little craft manned by smarter sailors. The sky and water are white and clear to a degree, and the Syren, the sailors, the craft, and the landing stage, are vividly sharp against the background. It is this fine, hair-like detail, no doubt, that caused the critic to talk of photography. But whether the camera has aided or not, the painter shows his skill unmistakably.

The costume of the sweet-faced, olive-complexioned Syren is perfection. There is a contrast of angular lines with the most delicate of curves. The waist and arms, enveloped in supple jersey and long silken mittens, impart an exquisite softness and roundness to some portions of the figure, while the diaphanous lace and crushed tulle of the belle's skirt increase the effect still more. Van Beers is not only a consummate artist, but a very ingenious one into the bargain.

"It may be of interest," writes Mr. Whipple, the director of the Kew Observatory, "to know that a magnetic storm of unusual intensity raged about midnight of the 17th." This storm and its duration was observed by photography—for the magnetic needle wrote it down on sensitive paper—and naturally enough Mr. Whipple, on developing his other photographic records, looked to them to see if the abnormal phenomenon could be traced in any other direction. In Mr. Whipple's mind, the magnetic storm coincides with an irruption on the solar disc, for he adds that "a tremendous spot, which appeared on the sun's disc first on the 13th, is now rapidly approaching the meridian, and a group observed on Saturday a little in advance of it appears to have undergone considerable change." It is only since photography has been introduced into our observatories that these subtle comparisons and deductions have become feasible.

The late Sir Henry Cole, who died last week, was one of that small class of men who contrive to do good to the public and themselves at the same time. If Great Britain has benefited by the establishment of the South Kensington Museum—and we do not deny that it is a most important institution—Sir Henry Cole, when at its head, enjoyed rank, emoluments, and patronage without stint. He ruled pretty well as he pleased, and had a voice in most of the appointments. Sir Henry's death was very sudden; he was in his usual health until Monday, when he visited a photographic studio and sat for his portrait. On returning home he complained of feeling unwell, and gradually became worse. Disease of the heart was the cause of death.

Mr. Francis Galton, F.R.S., dating from 42, Rutland Gate, makes an appeal to amateur photographers to help him in adding to his collection of composite portraits. Mr. Galton's method of producing composite pictures—which, by the way, is summarised in the Year-Book, 1882—consists, as our readers know, in superposing, as correctly as possible, portraits of the same family, and making a composite negative. "What I need," says Mr. Galton, "are prints of the portraits of individual members of any family. They may be males or females, and of any ages, but they must not be fewer than of four different persons." Mr. Galton, on application to him, will say how these prints should be taken, and he hopes in return for them to send the photographer a composite portrait, upon which he earnestly entreats the opinions of friends of the family.

Our readers may remember that some time ago M. Forel made some experiments in the Lake of Geneva with a view of ascertaining how far down into the clear blue waters the action of light penetrated. He employed in his trials sensitised albumen paper which was sealed up in glass tubes, and he found that as far down as 40 metres, or 130 feet, there was light enough to impress the paper perceptibly. The subject has now been taken up by another Swiss *savan*, M. Asper, who has experimented in water quite as clear—the lake of Zurich—but who, by employing a more sensitive medium, has been able to secure more valuable results.

M. Asper used gelatino-bromide films in lieu of albumenised paper, and began his experiments where M. Forel left off. Gelatino-bromide plates were sunk to a depth of 40, 50, 60, 70, 80, and 90 metres, and permitted to remain immersed for twenty-four hours, a summer's day being chosen for the purpose, the 3rd August. All the plates were similarly developed with ferrous oxalate, so as to secure comparative results; but in every case, down to 90 metres—that is, at a depth of nearly 300 feet—there was ample light to affect the sensitive films. Unfortunately, all waters are not so clear as those of Lake Leman and the lake of Zurich, otherwise submarine photography would be surrounded by less difficulty.

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. VIII.—Third Lesson in Development.

In our last lesson on development, we considered the ferrous oxalate developer only, this being, as we have said, the best for a beginner. There are some who prefer this developer to any other, even after long experience: but the vast majority of photographers find qualities in the so-called "alkaline pyrogallic" developer which seem to be wanting in the others. The most notable of these is the power to compensate for a certain error in exposure.

In considering the subject of exposure in a former lesson, we assumed that correct exposure is a fixed point, and that any deviation from it would give imperfect results. This is not the case, however, for there is a certain "latitude," which is due to two causes: first, a certain latitude of effect is permissible. Thus, if the plate be a little under-exposed, there will be somewhat less detail in the resulting picture than is visible to the eye, but this need not spoil the effect. Again, if the plate be somewhat over-exposed, the effect will be a slight fog or want of transparency in the shadows of the negative; but the only result of this will be that what is called a "slow printing negative" will be produced. The latitude in effect is not great, however. It may be said that if two seconds be the best exposure, anything between one and a-half and four seconds will give good results. We have, however, a second method of gaining latitude, and this is by means of the treatment with the developing solutions. Thus, simply by leaving the plate for a longer or shorter time in the developer, we can compensate to a certain extent for under or over-exposure. It is, however, by varying the proportions of the ingredients of the alkaline developer that we gain the greatest latitude. We must enumerate the chemicals used in this developer, and try to make clear what are the properties of each one of them.

The essentials are as follows: First, pyrogallic acid, or more properly, pyrogallol; second, liquid ammonia, or occasionally some other alkali; third, a soluble bromide, usually bromide of ammonium or of potassium. The pyro. is the true developer, and acts very energetically when rendered alkaline. The stronger the developer is in pyro., the denser will be the negative; but the effect of increasing the pyro. is to "restrain" development—that is, to make it take a longer time, and to prevent a certain amount of detail from appearing.

The ammonia is used to render the developer alkaline, and the greater the quantity in the solution, the more energetic the action. The effect of increasing the ammonia is to shorten greatly the time of development, to increase to a slight extent the amount of detail, and to increase the density. A point is reached, however, where the action is so energetic as to reduce or blacken even those parts of the plate which have not been acted on by light, and fog is the result. Some plates will stand much more ammonia than others.

The use of the bromide is to retard development—to make it slower, so that it may be more under control. Without it the development is very rapid, and unless the quantity of ammonia be very small, it is difficult to avoid fog. The result of increasing the bromide is to make the developer much slower, to keep back a little of the detail, and to increase ultimate density greatly.

A little consideration of what we have said will show that by varying the proportions of the constituents we have enumerated we have the power of greatly modifying the resulting negative, and have a power of compensating to a great extent for error in exposure. This is especially the case for over-exposure. It is true that in the case of under-exposure we can correct to a certain extent by using an increased quantity of ammonia; but the fog point is soon reached, and thus it is only to a small extent that we can correct in this direction. In the case of over-exposure, however, it is different. Either pyro. or bromide may be increased indefinitely. The latter is the best to increase, as it is the cheaper. By largely increasing the quantity of bromide the development is rendered slow as regards the appearance of detail, but less so as regards the increase of density. It is thus possible to stop the process in the case of an over-exposed plate before the shadows veil over, and yet to have a sufficiently dense negative.

We have said that it is right, in using any particular make of plates, to use the developer given in the "instructions;" but it is by no means necessary to mix the "stock solutions" exactly as directed. On analysing any of the sets of stock solutions given, it will be found that they consist essentially of the three chemicals mentioned before made up in solutions of certain strengths, and generally with some preservative in the case of the pyrogallic solution to prevent its turning brown by oxidation. In almost every case there is a most needless complication introduced which makes considerable calculation necessary to find what quantity of each chemical really is in an ounce of the final developer. There can be no simpler plan than to mix three solutions each containing ten per cent. of one of the three ingredients. The developer can then be made up in any proportion without trouble, and the developer given in any instructions can be used without the intervention of complicated formulæ.

We recommend that the solution be mixed in the following manner:—

Dissolve quarter of an ounce of citric acid in eight ounces of water. Add this to one ounce of pyro. Make the whole up to ten ounces, and label "Pyro solution."

Take one ounce of bromide of ammonia and make up with water to ten ounces. Label "Ten per cent. bromide solution." Take one ounce ammonia, strength ·80, or two ounces of the ammonia diluted with an equal amount of water as recommended before, and make up with water to ten ounces. Label "Ammonia 10 per cent. solution."

There is no developer which is suitable for all subjects. Those given in instructions can only be taken as typical. If the photographer expects to excel, he must vary his developer to suit his subject. Thus, when the contrasts are very strong—say in the case of an interior with white columns and deep shadows—he must reduce the amount of pyro, or he will have a negative giving a "chalky" print.

If the contrasts are naturally weak, as is sometimes the case in open landscape, he must increase the quantity of all the ingredients, but specially of the pyro and bromide. If he knows that he has under-exposed, he must increase the ammonia. If he knows that he has over-exposed, he must increase the bromide.

The following we have found to be a good developer for general purposes:—

Pyro	from 1 to 2 grains
Ammonia	3 minims
Bromide	... $1\frac{1}{2}$ grains

To each ounce of developer.

This is a more restrained developer than is usually recommended. We find, however, that the increase of the bromide beyond that commonly used does not necessitate an appreciable increase in exposure, whilst it gives a better quality of negative, and permits of a considerable latitude in exposure simply by allowing the plate to be a longer or shorter time in the developer.

We shall now tell how the best result can be got from a plate when there is uncertainty as to whether or not it has had the correct exposure.

A developer made as follows should be flowed over the plate:—

Pyro ...	1 to 2 grains according to subject
Ammonia	2 minims
Bromide	$1\frac{1}{2}$ minims

To each ounce of developer.

This is a very slow developer, and even if the plate be much over-exposed, the image will not appear for some time. A little experiment will enable the photographer to know whether the plate has been over-exposed, correctly exposed, or under-exposed by the length of time which elapses between the time of pouring on the developer and the appearance of the image. If the exposure appear to be correct, let one minim of ammonia be added to bring the strength up to that recommended. If it appear to be over-exposed, let development proceed, or even add more bromide. If the image be very long of appearing, showing that there has been under-exposure, ammonia may be added to any amount short of that which will produce fog.

Good plates should stand ten minims of ammonia with one and a-half grains of bromide. The greater the quantity of bromide, the larger the amount of ammonia that may be used; but the quantity of ammonia permissible is not proportionate to the bromide used. Doubling the quantity of bromide will not permit double the quantity of ammonia to be added.

With the ferrous oxalate developer, under-exposure and over-exposure may be corrected to a certain extent, but not so greatly as with the alkaline developer. The developer may be accelerated by the addition of any quantity up to ten minims of a 1 per cent. solution of hyposulphite of soda to each ounce of developer, or retarded by the increase of bromide.

It is commonly said that there is difficulty with gelatine plates in getting a sufficiently dense image. Such a difficulty results from ignorance of the principles of development. The secret of getting "plucky" negatives lies in using an alkaline developer strong in all the constituents, but specially so in bromide, and, if necessary, giving a slightly longer exposure than might otherwise be thought necessary. The real difficulty lies in judging when the density is sufficient.

PHOTOGRAPHY AND THE ECLIPSE.

BY CAPT. W. DE W. ABNEY, R.E., F.R.S.

First Article.

It may be interesting to the readers of the News to have an idea of what will be attempted by photography at the ensuing eclipse, and as all the necessary preparations were carried out in my laboratory, I am in a position to state generally what will be done.

Dr. Schuster will, I have every reason to believe, carry out the work as originally planned, with the aid of Mr. C. R. Woods. The first point to which attention will be paid, is the photograph of the corona itself. The corona, I may perhaps be allowed to explain for the benefit of unscientific readers, is the "glory" which surrounds the eclipsed disc, and which is only visible during the totality of the eclipse, or for a very short time before and after. In the various text-books on astronomy we have various forms of the corona shown, and when the corona as photographed is compared with the corona as sketched by the eye, there are often such remarkable differences as can scarcely be accounted for by want of power of observation of the sketcher. Photography in such matters cannot speak falsely. Whence, then, the discrepancy? Mr. Brothers' famous photographs of the corona have been succeeded by others, but all produced in the same manner, for if we except the eclipse visible in America the year before last, the process used for their production has been the old wet process. The results of the American eclipse have not as yet come to hand, but it is rumoured that gelatine did not behave with one distinguished American astronomer as it should have done. It is whispered that he kept his plates to develop subsequent to the eclipse, and that no image was obtained. Whether this be an accurate statement or not, I cannot vouch. If it is, then gelatine plates did not behave as we are accustomed for them to behave at home. The English eclipse expedition, however, on my recommendation, have mainly pinned their faith on gelatine for this work, though they take with them a complete equipment for wet plate and collodion emulsion work, should it at the last moment seem desirable that they should abandon the new process, though I don't think they will abandon it. The great drawback to the gelatine is the high temperature in the Upper Nile in May. From information received, it may be expected that the shade temperature will be between 100° to 110°, a heat which would be unbearable except in a very dry atmosphere, which, luckily, the contiguity of the desert ensures, there often being a difference between the wet and dry bulb thermometers of 15°. Again, a dry air means cool nights, and a cool night means sleep, and a consequent recuperation of vital energy. When in Egypt in 1874 for the Transit of Venus during October, the thermometer reached 96° to 100° during the day, and at night used to fall as low as 45° when the sky was clear; when cloudy, as was sometimes the case, the night temperature was occasionally as high as 75°. During May we may expect the sky to be cloudless, and it is probable that the night temperature may reach as low as 50°. Of course, if the air were moist, the moisture would prevent the radiation from the earth from proceeding at a rapid rate, and the day and night temperature would, as in some parts of India where I have been stationed, range probably between 96° and 100°. I have been thus precise as to the cooling of the air at night, as it necessarily has a bearing on the process to be used. It would manifestly be a hard task to develop a gelatine plate in a temperature of, say, 100°.

The temperature of the air, however, at night, it seems probable, will be such that a gelatine plate may be developed with the greatest safety. From daily observations made in 1874, it appears that the temperature of the Nile water will be somewhere about a mean between the day and the night temperature, possibly not more than 75°. Care has been taken to send out a freezing mixture which will reduce a large quantity of water 30° below this temperature, so that there will be no danger of the gelatine melting. We may, therefore, hope that gelatine plates may be used and developed on the spot, which is a desideratum.

Now as to the photographs of the corona. The photoheliograph employed consists of one of Dallmeyer's photographically corrected lenses of about 5 feet focus and a diameter of about 4½ inches. This will give an image of the eclipsed disc of a diameter of about half an inch. The plates to be used are quarter-plates, having a sensitiveness of about sixty times that of a wet plate as prepared with a new bath and Mawson's collodion when in its best state. A couple of seconds' exposure on such plates will thus be equal to two minutes' exposure on a wet plate. As the eclipse itself will only last about seventy-two seconds, it is manifest that by the the use of gelatine we are prolonging it to a wet-plate-photographic-equivalent of seventy-two minutes. Experience has shown that with the wet process every extension of exposure gave increased dimensions to the corona; but the size seen, as a rule, by the eye, was never absolutely reached, the brightness of the light rapidly decreasing as its distance from the sun increased. May we not hope, then, that by using these sensitive plates the same area as depicted by eye observations may be registered as photographs? It is expected that one exposure of thirty seconds will be given, besides some shorter ones. A plate sensitive to the dark rays below the red will also be exposed, for comparison with the plates which are not thus spectrally sensitive. In every photograph which I have inspected, the prominences which are seen beyond the eclipsed disc have encroached on the limb of the dark disc, presumably owing to halation. The plates used will have a thick backing of asphaltum, which it is hoped will eradicate—or, at all events, mitigate—this defeet. Thus, then, by photographic means, we may hope that the shape and dimensions of the corona may be recorded for comparison with the photographs and sketches of other and longer eclipses. The phenomena visible during eclipses seem to vary according as the sun is in an active or in a comparatively passive state, the state of activity being shown by the number and areas of sunspots. During the last American eclipse the sun was almost devoid of eruption, and the phenomena noted were few and unsatisfactory as compared with those of the eclipses of a few years earlier, when the sunspots were comparatively abundant. This year we are having frequent outbursts on the sun's disc, and, whilst I write, a spot of enormous size is visible, showing a state of great activity below the solar surface. Such being the state of the sun's disc, we may hope that the phenomena observed during eclipses when we had a maximum of sunspots, and which were absent in the eclipse which took place during a minimum, may again recur.

A NEW AUTOMATIC ADJUSTABLE EXPOSER.

BY G. L. ADDENBROOKE.*

In adding another to the many shutters already brought to your notice, my apology must be the importance of the subject, and the shortcomings of those already in use. While there are innumerable plans more or less ingenious for giving one exposure of indefinite length, and a few shutters attempting regulation to some extent, the matter does not seem generally to have been treated with comprehension; and therefore, before entering into detail, perhaps I may be permitted to say a few words on the need which at present exists for accurately regulating short exposures.

In the days of wet plates, exposures of 5, 10, 15 seconds to a minute, or more, with large stops, were the rule, and could easily be regulated by the seconds-hand of a watch. With the advent of gelatine emulsions, however, conditions were changed; few plates now manufactured are less than ten times, and many twenty or more times, as rapid as wet collodion.

These plates, admitting readily of exposures of a fraction of a second, brought quite a new range of subject within the reach of photographers, of which they were eager to avail themselves, and have led to the invention of innumerable appliances for opening and closing lenses rapidly, with the result of an indiscriminate shooting in all directions. Photographers are, however, now beginning to apply the same criterion to pictures of objects in motion as to others, and, consequently, there has arisen a want for a properly adjustable rapid shutter to meet varying conditions. In confirmation of these remarks, I pass round for inspection two photographs—one of the Khedive of Egypt's yacht passing up the Suez Canal at about seven miles per hour, taken with the third stop of a portable symmetrical; the second is a Sea View off Cape Bon, taken from the deck of a steamer going nine knots an hour, at six o'clock in the evening, with same lens, full aperture. Both were taken on Mr. Bennett's ordinary plates. I do not pass them round as good photographs, which they are not, but merely to confirm this statement, and to show that the plates were altogether ahead of my powers of exposure.

Again, for ordinary landscape work, even the slowest lenses have now to be stopped down as far as possible to obtain a regulatable exposure, and some of my friends apparently think little of two seconds with the smallest stop of a landscape lens. Now I think I may affirm that, supposing two seconds to be a fair average exposure, unaided humanity, acting directly, is unable of itself to make the minute additions or subtraction from this which varying light and the exigencies of occasion demand, and that we may so account for many of the over- and under-exposed gelatine plates of which most photographers must have some

* Read before the Photographic Society of Great Britain.

stock. And, while on this topic, I may say that generally I do not think that photographers take sufficiently into consideration the effect produced by small stops, or shutters opening from the centre, unless placed between the lenses. Since the advent of photography, one of the chief aims of opticians has been to devise lenses to give as equal illumination as possible; and this will be found in their catalogues advanced as one of the chief points in a good lens, as undoubtedly it is. But by using small stops we throw away this advantage; we greatly increase the proportionate difference between the amount of light which falls on the central marginal portions of the picture. There can be no doubt that there is in every lens a normal point at which the superior definition obtained by stopping down is counterbalanced by the increased difference in the amount of light falling on the centre and edges of the plate. To use a lens stopped to this point is to use it to the best advantage. In the symmetricals it is, I think, somewhere about the third stop. Now, to use smaller stops is not only to waste an important power, but it directly produces inartistic results; for if the centre of the picture is properly exposed, the outsides will be under-exposed, and therefore harder and in greater relief, which tends greatly to spoil the balance of the composition.

Lastly, for purposes of comparison and testing plates, the need of some appliance which will always give correctly the same or any other exposure that may be desired is obvious.

Having now glanced at some of the reasons which make it desirable that we should possess an easy means of obtaining, accurately, as short exposures as may be required, I will describe the method I have taken to accomplish this, and which I trust may meet with your favourable criticism and approval.

After much consideration of the various means available for the correct regulation of short intervals of time, there ultimately appeared to be two methods only which promised any chance of success—a clockwork train controlled by a balance wheel, and one controlled by a revolving fan. This deduction has since been fully confirmed by others. Now a movement controlled by a balance wheel would be so complicated and expensive to construct as to put it out of the question altogether. There remains, therefore, only the clock-work train governed by a revolving fan.

I had this theoretical fact in my mind, but could neither see nor devise a shutter to which it might be applied, and which at the same time seemed to fulfil other necessary conditions, until, at a Technical meeting last autumn, Captain Abney stated that tho shutter he found most successful was a drop-action with a long drop, and attached to the camera by a short bag, so as to avoid any chance of shake or vibration. He also added, that with this shutter, accelerated by elastic bands, he had been enabled to obtain exposures of $\frac{1}{70}$th of a second. I perceived at once the excellence of the suggestion; but before using it as a regulatable shutter there were two objections to surmount—the length and practical impossibility of arresting it halfway for purposes of regulation without soon straining the apparatus. The first was obviated by dividing it, so to speak, into two portions, and using two shutters, one to rise and one to fall, by which means the length was reduced to nearly a half, and the foreground obtained a slightly longer exposure than the sky, while effectiveness was in no way sacrificed. The second objection was also removed by the same means, as the opening and closing slides were separate, and could be made to act quite independently of each other.

To any one desiring a simple, compact, and very rapid shutter, correct in principle, but giving one length of exposure only, I can recommend this action.

Both slides are held, when set, by catches; and the opening slide, after traversing its course, releases the closing one automatically.

This is the form of shutter I prefer, and have adapted to my regulating apparatus, though I now see that several of the forms at present in vogue could be made to work with it.

Description.—It will be remembered that the two slides of the shutter are held in their places, when set, by two catches: these catches have each an arm projecting at right angles through the cover of the shutter. Now the problem is to withdraw these catches mechanically at any required interval of time. To do this, I fix a small brass case on the surface of the shutter, and projecting about half an inch; in the centre of this case is a long spring, with stopwork, to prevent its being turned more than once in winding, so as to secure as equal a pull as possible; geared to this spring is a train of two wheels and pinions rotating a small fan (which, first made too large, is snipped down until the apparatus revolves at the proper rate, or an adjustable fan may be used); on the opposite side of the spring-barrel to the fly there is another cog-wheel of rather less diameter than the spring, the arbor of which projects through the brass case; on this arbor, and about one-eighth of an inch above the surface of the case, a brass disc is fixed, which revolves at a steady and uniform rate when the fan is released.

To connect this disc with the catches of the shutter, on the underside of it is fixed a projecting pin, while a moveable arm with a spring carries another pin, which can be placed in any of a series of properly graduated holes round the edge of the disc. When the disc rotates, these two pins come in contact successively with two levers working on central pivots, the other ends of which are directly fastened to the two projecting arms of the catches, holding the shutters, when set, by light metal strips without the intervention of any other mechanism. Whenever, therefore, its pin moves one of these levers, the corresponding shutter is released.

No doubt some of you will be reminded by this description of a shutter lately brought out in France by M. P. Boça, and for which much honour is due to him, as it is a very material advance on anything at present in use. Nevertheless, in justice to myself, I cannot refrain from stating that my apparatus was wholly designed and in part finished before I read any description of this one; nor since have I seen any reason to modify my original plans, though I would gladly have done so if I could thereby have perfected my apparatus in any way. I cannot but think M. Boça's shutter is faulty in being attached to the camera, as such an apparatus can hardly work without some vibration, while it would be cumbersome fixed there, and can only be used with the lens whose flange is screwed to it. These objections, I think, I have avoided by making my apparatus separate from the camera—a method which also has the advantage that, given a shutter of sufficient size for the largest lens to be used, it is also instantly adaptable to any smaller one; and I may here mention that it is intended to make the exposer, as a standard size, sufficiently large for use with a 12 × 10 rapid symmetrical or rectilinear lens.

Again, in mechanical detail, I think M. Boça's clockwork is more complicated than mine, while he only releases by its means the closing shutter, which must vitiate the accuracy of the shorter exposures. I have improved on this by enabling the operator, if he desires to be very exact in the shorter exposures, to start the clockwork, say an eighth or a quarter of a second before it actually releases the shutters, and by which time it attains the proper rate of speed.

As at present made, the longest exposure obtainable is $2\frac{1}{2}$ seconds, and the shortest $\frac{1}{24}$ of a second. If, however, it were desired, the disc might easily be made to rotate in a minute, when all the exposures would be multiplied by twenty. Or, on the other hand, it might be made to move round in one-third of a second, when all the exposures would be divided by nine, and the shortest would be the 216th part of a second, provided the shutter could be made to act in so short a time, which there seems no difficulty in accomplishing, though I have not yet actually tried it.

The graduation of the disc is, of course, quite arbitrary. I will now describe my own proposal, but shall nevertheless be glad to receive suggestions. I have made the disc to revolve in three seconds, because I think longer exposures can be regulated by the watch or by counting with sufficient accuracy, using the clockwork in this case only to open and close the exposer, by stopping it after the first shutter has risen until it is time to end the exposure by letting the second shutter fall.

For a long time I was doubtful whether to graduate the disc decimally or not, but have come to the conclusion that the number twelve being so much more intimately connected with the measurement of time than the number ten, and also as it offered many more convenient fractions, that it was the better. I have therefore graduated as follows:—

The first $\frac{1}{2}$ second to 24ths, giving these convenient fractions besides four others—$\frac{1}{24}$, $\frac{1}{12}$, $\frac{1}{8}$, $\frac{1}{6}$, $\frac{1}{5}$, $\frac{1}{4}$, $\frac{1}{3}$, and $\frac{1}{2}$ of a second.

The second $\frac{1}{2}$ second to 12ths, giving amongst others the following—$\frac{2}{3}$, $\frac{3}{4}$, $\frac{5}{6}$, and one second.

The third $\frac{1}{2}$ second to 6ths.

The fourth $\frac{1}{2}$ second to 6ths.

The fifth $\frac{1}{2}$ second to 4ths.

That is to say, twenty-seven progressive exposures within $2\frac{1}{2}$ seconds.

In order to show at a glance the fraction each graduation represents without unnecessary engraving, I divide the disc by radii into $\frac{1}{2}$ second intervals. In the angle formed by the first two of these is placed the fraction $\frac{12}{24}$, $\frac{1}{24}$ being the interval between the graduations, and twelve being the number of them in the $\frac{1}{2}$-second space. This fraction is repeated below as $\frac{6}{12}$, the denominator representing the space between the graduations in

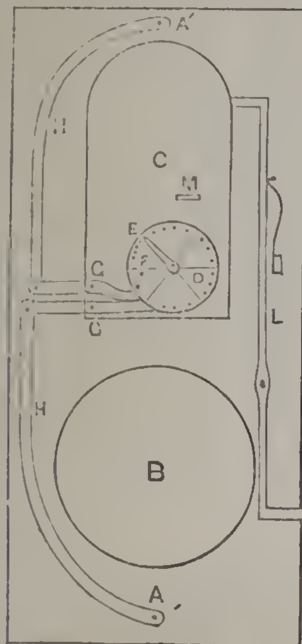


Fig. 1.

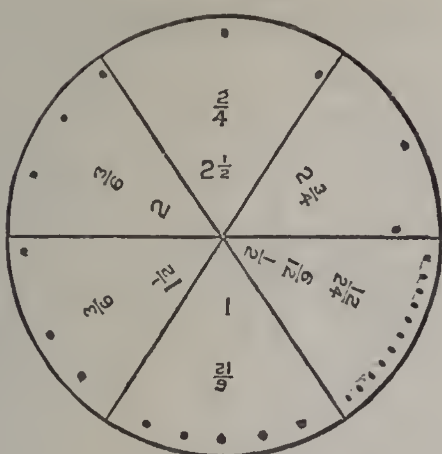

Fig. 2.

The first drawing gives a front view of the exposer, with the outer covering taken off, to show the action of the catches.

The second figure explains the graduation of the dial.

Figure 1. A A. Arms of the two catches holding the sliding shutters when set. B. Aperture. C. Clockwork case. D. Rotatory disc, with fixed projecting pin at E and movable arm, now placed at F. G, G'. Two levers coming in contact with projecting pins on revolving disc. H, H. Metal strips connecting levers with catches. L. Lever and spring which releases the clockwork when set. M. Nut for winding spring.

The dimensions are—Length, $8\frac{1}{2}$ in.; breadth, 4 in.; thickness, $\frac{1}{2}$ in; the clockwork projecting another $\frac{1}{2}$ in.; aperture, $2\frac{3}{4}$ in.

the second $\frac{1}{2}$ second, and the numerator representing the value of the first $\frac{1}{2}$ second in terms of the second $\frac{1}{2}$ second, so as to continue the fraction on, and so on round the disc. Though this may seem a little complicated at first, yet I think a few minutes' study of its principle will enable any one to place the movable arm in the graduation required at a glance. Having now completed my explanation, I trust you will be able to endorse my claim to having designed an automatic exposer which fairly meets the wants already detailed, enabling photographers to readily give any exposure they may deem proper, while at the same time the apparatus is compact, portable, contains no intricate workmanship, and is not likely to get out of order.

I have now only to thank you for your kind and patient attention to this somewhat long and involved paper; but though the apparatus, when once seen, is perfectly simple, it is not easy to accurately describe without going into some detail.

EASY METHOD OF PREPARING FERROUS CITRO-OXALATE DEVELOPER.

BY CAPTAIN ABNEY, R.E., F.R.S.*

I have been asked to give a more ready method of preparing the ferrous citro-oxalate developer than that previously described by me. The matter is very simple. The following formula may be used:—

No. 1.—Potassium citrate ...	... 700	grains
Potassium oxalate ...	... 200	"
Water	... $3\frac{1}{2}$	ounces
No. 2.—Ferrous sulphate ...	... 300	grains
Water	... $3\frac{1}{2}$	ounces

If these two solutions be mixed in equal volumes, we have a solution of ferrous citro-oxalate of strength equal to that I previously recommended. It can be mixed cold, and (of course) as required.

Correspondence.

INSTANTANEOUS SHUTTERS.

Sir,—I had intended to have written a letter further explaining my shutter on some points; but, as it is being brought out commercially, and the explanation might savour of a gratuitous advertisement, I will leave it to its merits alone, as set forth in my paper before the Photographic Society.

I should, however, like to say a few words on shutters fixed to and separate from the camera. I have not committed myself to either form. I adapted the regulating apparatus to a shutter separate from the camera, because I wished to make one as perfect in theory as possible. In the discussion which followed the reading of the paper, the only question which seemed to exercise the speakers was whether this method would be as successful in practice as it was right in theory.

Since then I have practically tested the shutter with some care, and was really myself surprised at the ease with which it could be used when attached by a flexible material to the lens. I found no difficulty in holding it, nor, after getting the thing once straight, was there any necessity to look at it again, and one's whole attention could be given to the view without fear of compromising results. It is also a great point that the shutter is instantly adaptable to different sizes of lenses.

On the other hand, I have also tried the shutter fixed to the camera—that is, to the front of the lens—and so far as my experiments yet show, there is no evidence in the negatives so taken of loss of sharpness from vibration. It must be remembered that the opening slide—the only thing that can cause shaking—though it rises with very considerable velocity, does not weigh more than half-an-ounce, and ends its course against a rubber pad.

Still, I must say I prefer it separate, and I think the prejudice against the use of a shutter in this manner can only be the result of an apparently reasonable but foregone conclusion. Though several speakers formulated this objection, I did not understand that anyone had tried the method and found it wanting, while the only gentleman who apparently had used it—Captain Abney—spoke most conclusively in its favour. It seems to be one of those things which look awkward and difficult until really tried, and then the objections vanish.

With regard to very short exposures, Mr. Muybridge's in

* *Journal and Transactions of the Photographic Society.*

particular, I have somewhat carefully gone into the question with a friend, and while I am by no means prepared to doubt the possibility of making an exposure as short as $\frac{1}{5000}$ of a second, yet it can easily be shown mathematicaly that Mr. Muybridge's results with a trotting horse could be obtained with an exposure of $\frac{1}{1500}$ of a second, a very different thing; even $\frac{1}{500}$ would be sufficient to produce an intelligible picture, though it would not be quite sharp.—I am, sir, G. L. Addenbrooke.

GELATINE NEGATIVES.

Sir,—I have met with an experience in the use of gelatine plates which I have not seen noticed, viz., that negatives produced upon them become in time less intense. For the last twelve months I have entirely discontinued the use of collodion, and have been much pleased with the many facilities and advantages the newer process possesses; but this has been much discounted upon finding that my earlier negatives have lost their printing power, and that, in fact, it is only with considerable care that passable prints can be produced from them, bearing but a poor comparison with the first prints from the same plates. The change does not take place very rapidly, and is not noticeable during the execution of the first order. Can you or any of your readers suggest a cause for this very undesirable experience? Had the plates been intensified in any way, I might have suspected their instability to have arisen from that cause, but these have been simply developed with alkaline pyrogallic, and, I may add, have been produced upon plates by one of the best makers.

I have naturally suspected the evil to arise either from insufficient washing, or from the varnish used upon them. With regard to the former, although I have not an unlimited supply of water, I have washed with great care, always leaving the plates to soak for several hours, giving them repeated changes, and finishing with a good rinse under the tap. As to the varnish, I have used a commercial sample prepared expressly for gelatine work, simply discarding, in carrying out the instructions for its use, the immersion of the plates in spirit, thinking that this was only advised to facilitate the flow of the varnish over the somewhat repellent gelatine film.—Yours truly,

Provincial.

DARK-ROOM DISEASE.

Sir,—In your "By-the-Bye" upon "Dark Room Disease" the writer says:—"Now pyrogallic acid, virulent poison as it is when taken internally, would not be prone to injure by contact." Let him try it. It is easily done. Rub, say, a quarter grain moistened with a drop of water into the skin of the soft part of the arm (his own, of course), three or four times in the course of a day or two; and if he continues this for two or three days on the same spot, he will find that it will afford him endless amusement, now and again, by way of rubbing it—he will not care to scratch, however he may long to do so. Of course this is an extreme case, as pyrogallic solution of this strength is not used in practice. I have done this, also with ammonium bromide, and a strong mixture of the developing constituents, to settle the point as to which was the enemy. The bromide had no effect; the pyrogallic appeared first, but the mixed developer—after its use was discontinued—overtook it and was quite as bad, in fact, it looked very ugly indeed. I applied linseed-meal poultice, which gave ease directly, and soon cured it, but the marks still show. The writer also appears to have forgotten, among other cases published, the one where the photographer, having one hand bad, used the other for lifting the plates, which in a day or two was likewise attacked.

I showed my arm at a Thursday meeting, and those who had suffered said it bore the same appearance as their marks—red ringworm-like patches, with external ridge, which subsequently formed into pustulous sores. Dr. Mahomet, of Guy's, saw it—though not in full bloom—and could not liken it exactly to anything he knew. I understand he would be glad to see a true case; should any of your readers be suffering, perhaps they will make an appointment with him.

It does not follow that because pyrogallic has never been accused before, that it did not deserve to be. We are ever pushing on—have much to learn in every way. It may be that the greater watchfulness required in developing a gelatine plate, the frequent lifting from the solution, the greater number of plates an operator or developer has to get through in a day, may aggravate the evil. All are not attacked; probably idiosyncracy has much to do with it. Mine did not spread in the least; I measured them carefully; nor did any other patches appear. May it not be that it is also necessary to take it (pyrogallic) internally? It was long thought that lead could work its well-known effects by absorption through the skin; it is now known that there must be either an abrasion, or it must find its way into the system through the stomach.

Some photographers, perhaps, do not wash before they take their meals—have to snatch them when and where they can. It would be interesting, too, to know if those attacked measured out their pyrogallic *d ry*. There would certainly then be more chance of inhaling some of the light crystals.—Yours truly, Alf. J. Brown.

[Pyrogallic acid has long been used as a hair dye, and we have not heard that it has ever done mischief to the skin of the head.—Ed. P.N.]

Proceedings of Societies.

Photographic Society of Great Britain.

The ninth technical meeting was held on Tuesday, March 28th, John Spiller, F.C.S., Vice-President, in the chair.

The Chairman read the questions proposed for discussion, the first being "On Protective Coverings for Gelatine Negatives."

Mr. W. Bedford, in introducing the subject of protective coatings for gelatine negatives, said that it had been found that gelatine films when varnished in the usual way, and even when treated with a thin preliminary coating of collodion previous to varnishing, after constant printing in contact with sensitive paper, are liable to become covered, sooner or later, with small specks of a non-actinic brown colour, which increased in size until the negative is ultimately ruined. He enumerated several gums and resins, amongst which were mastic, Canada balsam, india-rubber, and amber, which he had tried either as additions to or substitute for collodion applied previous to varnishing. In order to test the efficacy of these varnishes, two negatives, coated with the substances under trial, were placed face to face with a piece of blotting-paper moistened with a 20-grain solution of silver nitrate between them, and were so left for forty-eight hours. None of the substances submitted to this test seemed to have any advantage over plain collodion and seed-lac, and a plate was passed round to illustrate the effect of these experiments. The treatment he had found best, and now recommended, was to coat the negative with at least three times the usual quantity of a tough plain collodion, and having allowed it to set in a horizontal position (when thoroughly dry) to varnish with seed-lac. Negatives so treated would withstand the test he had mentioned, and would, he believed, be proof against any chemical action during the process of printing.

Mr. Maxwell Lyte said that whilst working in the Pyrenees he found the varnish of seed-lac, in the hot sun, stick to the paper: probably, however, the seed-lac was liable to be adulterated.

The Chairman said that for collodion there was nothing better than the old varnish of amber dissolved in chloroform. Had any of the members used this varnish for gelatine negatives?

Mr. Maxwell Lyte then described a method of making amber varnish, which he did not give as being new, but which consisted in dissolving the resinous part out of amber chips, such as can be had of the pipe-makers and other amber-workers, in chloroform, and then adding a volume of ether equal to that of the chloroform used. The amber breaks up into a sponge, from which the varnish may be expressed through a bit of muslin, and finally filtered. This varnish does not act on gelatine; and no solar heat will affect it. No other gum, in his opinion, could rival amber.

Mr. T. S. Davis said, one great matter was to get rid of all moisture. To facilitate this, it would be found desirable to place the plate in alcohol and water; and he found that the best white spirit varnish, when diluted with two volumes of alcohol, gave a very hard surface.

Mr. England thought the brown hard varnish was better, as shellac during bleaching became altered. Since he had used enamel collodion first and then varnished, none of his negatives had shown spots.

Mr. Mawdsley said his experience had not arisen from printing large numbers. He had used the ordinary solution of shellac; it was never tacky, and the colour was of no object.

Mr. Ayres had used orange shellac, coating the plate first with collodion half diluted with spirit.

Mr. F. Ince stated that, having used enamel collodion only, a negative came out in spots similar to that shown by Mr. Bedford. He then flowed some bichloride of mercury over the plate, which changed the colour of the spots, and the negative then printed well.

Mr. Maxwell Lyte suggested the washing of the plate with weak cyanide of potassium, with a crystal or two of iodine mixed with it.

Mr. Bolas said that spots of this character have not so great a tendency to spread in the collodion plate, as in the case of a gelatine film.

The Chairman remarked that amateurs seldom came across these difficulties. He had coated first with thick collodion, and then used white lac varnish, and he never found any penetration of the silver to the film.

Mr. T. S. Davis then introduced the question, "What would be the influence on the sensibility of gelatine plates of the addition of hydrochloric acid to the extent of five minims to the ounce?" He had prepared plates with hydrochloric in preference to nitric acid; it seemed to prevent the reduction of the silver in the film. Although five minims of hydrochloric acid, sp. gr. 1·160, may be added to an emulsion made with hard gelatine, a like quantity of "acidum hydrochloricum dilutum, sp. gr. 1·052," may be preferable with softer kinds. An addition of either strength, followed by the digestion of the emulsion at 140° for one hour, with subsequent washings, will yield films possessing about one-fourth the sensibility of "instantaneous" commercial dry plates, when developed with solutions of similar strengths. When, however, the emulsion has been prepared with the acid, a more powerful developer may be used, and the sensibility estimated as greater than the above mentioned; the silver nitrate being, in the first instance, added to the full molecular weight, in proportion to the bromide salt used.

Mr. Cowan exhibited two plates—one prepared with the formula he generally used—ammonia-nitrate and no heat; the other with addition of 5 minims of hydrochloric acid to 1 ounce of emulsion, digested at 100°. The first registered thirty-two times quicker than the other.

Mr. Davis had not found any difficulty in using the strong acid on hard gelatine, and even with some moderately softer kinds.

Captain Abney said a moderate proportion of acid, when introduced and boiled with an emulsion, would result in an orange-coloured emulsion.

Mr. Cowan stated that when the emulsion, which he had found to be thirty-two times slower, was mixed with the other one, no alteration in the rapidity was observed.

Mr. W. Bedford had tried Mr. Davis's formula with the strong acid. This emulsion, digested for three hours at 150°, gave 12 with the sensitometer, the ammonia plates giving 23.

Captain Abney said if the emulsion had been boiled three hours, better results would have been attained; and that when the acid was mixed with ammonia, it altered the quality of the gelatine. He reduced the hydrochloric to one-tenth of a drop per ounce, and boiled for three-quarters of an hour. This gave ruby emulsion, which was more rapid than the blue.

Mr. Bolas said that within certain wide limits it did not matter what acid was used.

Captain Abney replied that hydrobromic acid gave very slow plates; hydrochloric acid gave quick, and did not become slow by heat.

Mr. Davis stated that hydrobromic acid destroyed the image; in other words, it destroyed the effect of light.

Mr. England said that he had used half a drop of hydrochloric acid to each ounce of emulsion after washing; this prevented any tendency to green fog.

Mr. Ince inquired whether the introduction of hydrochloric acid or chloride in emulsion had assisted in the reproduction of colour; for instance, in photographing the spectrum.

Captain Abney said that the effect on the spectrum of chloride in emulsion was to lower the maximum of the red.

Mr. Golding then introduced the question, "To inquire the cause of scum-like markings on gelatine plates, which are visible before and after development?" He had not had much experience in making emulsions, but lately these marks appeared. He then showed two plates made from the same emulsion—one with, and the other without, the marks alluded to.

Captain Abney said that in the ammonia process scum was produced more so than with the boiling process; but he got rid of it by letting the emulsion set, and then cutting off the top.

Mr. Davis remarked that the plates exhibited seemed to have an excess of silver bromide in proportion to the gelatine.

Mr. Golding said that the proportions were 120 grs. to 5 oz. of emulsion, with very little alcohol: 1 dram to 5 ounces.

Various reasons were then advanced to account for these markings, but nothing definite was arrived it.

The Chairman said the next question to be discussed was "The hardening effect of time upon gelatine plates."

Captain Abney said that some time ago he had taken unsensitised carbon tissue to India, and left it there unopened for ten years; when it came back it was useless, totally insoluble.

Mr. Berkeley stated, with regard to gelatine plates, he had observed several years ago, that with plates after keeping twelve months or more, it was found necessary to use hot water to get the film off. He would be glad to know whether anyone present had observed a similar hardening of plain gelatine of the softer kind. In reference to protective coverings for gelatine negatives, he said that a good method for clearing solution of orange shellac was to shake it up with precipited chalk, afterwards allowing the latter to settle.

Mr. Bolas, as illustrating the subject, said, that some new plates frilled and would not yield to any cure; but such a plate being left for some time often became harder, and then did not frill at all.

The Chairman asked what effect would time have, when glycerine was mixed with the emulsion?

Captain Abney said that he had batches of plates made with glycerine which developed very well when fresh, but when kept in an alternate dry and damp atmosphere were useless.

Thursday Evenings for Photographers.

At the meeting held on the 20th inst. the chair was occupied by M. A. W. Hosmer.

Mr. Reimann showed a negative developed with the new formula, *i.e.*, common washing soda being used instead of ammonia; he found that with it the image took a much longer time to make its first appearance; but it then developed as quickly as with ammonia, and that it did not produce frilling or fog.

Mr. Brown had also experimented successfully with this developer; the formula he used was :—

Saturated solution of soda	½ ounce
Pyrogallic	1 grain
60-grain solution bromide	8 minims
Water	½ ounce

In his experience the image appeared very rapidly, and was much more dense than by any other development he had used; the film was of an olive colour; he found it caused frilling with some makes of plates; he had also experimented with caustic potash.

Mr. E. F. Goodwin exhibited an ingenious arrangement for drying paper in the dark room; it consisted of a number of wooden rods fastened to a bracket to a wall, and so arranged that when not in use they could be folded flat to the wall.

Mr. Brown passed round some negatives which had been intensified with mercury and ammonia, and had completely faded. He also produced a new shutter; it consisted of two pieces of ebonite with semi-circular openings crossing each other; they were so arranged that when pulled, by two pieces of cord attached to a hinged flap which was raised by the expansion of a small bladder by an ordinary pear-shaped ball, they opened from the centre of the lens, closing again directly the pressure was released.

Mr. Henderson showed an enamel print of a photograph of the moon taken by Grubb's great Melbourne telescope.

It was announced that there would be no meeting this week, in consequence of the Ball in aid of the P. B. A. Fund.

Talk in the Studio.

Muybridge's Photographs.—Messrs. Trübner have just issued a work entitled, "The Horse in Motion, as shown by Instantaneous Photography, with a Study in Animal Mechanics, founded on Anatomy and the Revelations of the Camera, in which is demonstrated the Theory of Quadrupedal Motion," by J. B. D. Stillman, A.M., M.D. The investigations were executed and published under the auspices of Mr. Leland Stanford, of Palo Alto Farm, California. He says, in the preface, "I have for a long time entertained the opinion that the accepted theory of the relative positions of the feet of horses in rapid motion was erroneous. I also believed that the camera could be utilized to demonstrate that fact, and, by instantaneous pictures, show the actual position of the limbs at each instant of the stride. Under this conviction I employed Mr. Muybridge, a very skilful photographer, to institute a series of experiments to that end. . . . When these experiments were made, it was not contemplated to publish the results; but the facts revealed seemed so important that I determined to have a careful analysis made of them. For this purpose it was necessary to review the whole subject of the locomotive machinery of the horse. I employed Dr. J. B. D. Stillman, whom I believed to be capable of the undertaking. The result has been that much instructive information on the mechanism of the horse has been revealed, which is believed to be new, and of sufficient importance to be preserved and published."

Drewton Tunnel.—Mr. W. Barry, of Hull, sends us a capital illustration of tunnel working, such as would create a sensation in any illustrated paper of the day, were it possible to publish widely an actual photograph. The photograph measures twelve inches, and shows us workmen with picks and boring instruments, steadily hewing their way through solid earth 220 feet below the surface. It is perhaps the best, because the most truthful, picture of work in a tunnel that has ever been presented to the public. The exposure, we are told, was ten seconds, the lighting up of the tunnel being effected by "Moule's Composition."

Mr. W. Cobb as a Poet.—Her Majesty the Queen has purchased a photographic copy (transparency) of Mr. Cobb's poem on the subject of the recent attempt on the Queen's life.

Lime Light Explosion at the Court Theatre.—On Friday evening last a sharp explosion took place at the Court Theatre, during the performance of the "Parvenu," and no little alarm was caused for an instant. Almost the whole of the audience, including the Prince of Wales, rose to their feet; but after Prince and people had mutually exhorted each other to "sit still," quiet was restored, and it was found that no mischief worth mentioning had been done.

Royal Institution.—The arrangements for the Friday evening meetings are as follows:—April 28: Prof. Abel, "Some Dangerous Properties of Dusts"; May 5: Prof. R. Grant, "The Proper Motions of the Stars"; May 12: A. G. Vernon Harcourt, "The Relative Value of Different Modes of Lighting;" May 19: Sir Frederick Bramwell; May 26: Sir Henry S. Maine, "Sacred Laws of the Hindus"; June 2: H. H. Statham, "The Intellectual Basis of Music"; June 9: Prof. Burdon Sanderson, "The Excitability of Plants."

Mr. J. D. Linton, Member of the Institute of Painters in Water-Colours, has received a commission from Her Majesty to paint a picture of yesterday's Royal Wedding.

Old London.—The present year's issue of the publications of the Society for Photographing Relics of Old London will contain six fine interior and exterior views of Ashburnham House, including the garden by the Westminster School and the old refectory of the Abbey. Besides these there will be views of that pleasant retirement—Little Dean's Yard, together with the Banqueting House, Whitehall, the old water-gate of York House, and three views of the fine old mansions on the west side of Lincoln's Inn Fields.

The Alexandra Palace Easter Monday Competition.—The Silver Medal was awarded to Mr. R. W. Whitehead, and the Bronze Medal to Mr. J. G. Horsey, but the Gold Medal has not been awarded. Mr. J. McWhirter, A.R.A., Mr. Arthur Lucas, and Mr. W. B. Bolton acted as Judges. Only six sets of pictures were sent in, and it is intended to organise another competition for Whit Monday.

Iridium and the Electric Light.—Mr. W. L. Dudley thus writes in the *Chemical News*:—"A short time ago, Mr. W. M. Thomas, of this city, called on Mr. Holland, requesting a piece of iridium to be used in connection with the arc light. Mr. Holland had a small piece prepared, which was substituted for the negative carbon of the lamp, the first experiment was tried for one-half hour, without any apparent effect on the metal. Since then more complete arrangements have been made, and the lamp containing the same piece of iridium has been in operation for over seventy hours without any appreciable loss of metal. The amount of electricity required to maintain it seems to be much less than for the ordinary lamp. The point of light is always in the same position, and, consequently, can be used in a reflector without the additional clock-work, which is employed to accomplish this result with the ordinary arc light. The light can be made very steady, since the lower carbon, which burns and crumbles away, is dispensed with. When the metal is used where it is subject to intense heat, the phosphorus is removed; but where hardness and non-corrosibility are required, the phosphorus does not offer any inconvenience."

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. Piper & Carter, "*Photographic News*" *Office, 5, Castle Street, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. Piper & Carter, *and crossed* "*Union Bank, Photographic News Co. Account.*"

*** We cannot undertake to return rejected communications.

*** Newcastle-on-Tyne and Northern Counties Photographic Association.—We have to apologise to the members of the Newcastle Association for the non-appearance last week of any of their proceedings; the omission was due to no fault on our part, but to the circumstance that the account was not delivered at our office until Friday morning, several hours after the News was published.

E. E. W.—That is merely the opinion of the inventor; but we imagine a dealer or manufacturer would hardly take the same view. 2. No doubt a letter addressed to the place of meeting would reach the gentleman referred to.

J. Sanford.—The spots doubtless arise from splashings of hyposulphite solution, and if you exercise more care in manipulation, you will no longer be troubled.

Doctor.—After having placed it on a hard unyielding surface, rub the back with a smooth ivory paper knife.

E. E. P.—Energy, judgment, and ability are the principal factors in building up success, and it is probable that with these you will have a fair chance of success in a London suburb or in such a town as Brighton.

Hampshire.—It is a peculiarity possessed by some kinds of gelatine, and notably by certain qualities manufactured near Paris. A prolonged churning of the warm solution proves a partial remedy in some instances.

Nitrate.—You are wrong with respect to the action of light in this case, as organic or other reducing matter must be present.

Cambridge.—1. The parts in question of the spectrum of the electric arc are crowded with a large number of lines, many of which have been mapped. 2. If there is a moderate excess of free acid present, the precipitate will not be formed. 3. The apparatus in question is not manufactured at present, but second-hand ones can often be obtained.

Bichromate.—1. When absolutely dry, gelatine is extremely brittle, and flies to pieces at the slightest touch, like unannealed glass; but you may prevent your difficulty by adding a small proportion of glycerine. From one-thirtieth to one-fifteenth of its weight will suffice in ordinary cases. 2. Absolutely pure zinc is scarcely soluble in dilute sulphuric acid, but minute particles of carbon or of extraneous metals set up a galvanic action, and cause the commercial metal to dissolve readily, and the partial film of gold acts in a similar manner. 3. Quite a mistake, as the salt in question is insoluble in alcohol.

John T. Barnett.—The alcohol of the varnish is sufficiently strong to dissolve the collodion film, and it is probable that the addition of a small proportion of water to the varnish will prevent the mischief; if not, you should flood the negatives with weak gum-water, and dry them before varnishing.

THE PHOTOGRAPHIC NEWS.

CONTENTS.

PHOTOGRAPHS IN VITRIFIED ENAMEL.

Last week we called attention to a manual of the magic lantern, issued by Dr. Liesegang, of Dusseldorf; and we have now to call the attention of our readers to an excellently-arranged and clearly-written hand-book which treats of the production of vitrified photographic pictures in enamel colours.*

The numerous methods which have been proposed for the production of the class of pictures under consideration are brought into review, and described in detail. From a practical point of view, however, the interest centres on two only, these being the dusting-on method, in which a film of deliquescent organic matter, charged with an alkaline bichromate, is used; and the substitution method, in which a silver image is so treated as to lead to the replacement of the silver by such metals as platinum, gold, or iridium. Of these two, the former is referred to as being of the most general applicability, as it will yield excellent results in ordinarily careful hands, while the substitution method, although capable of yielding results superior to the dusting method, requires so much care and experience as to keep the practical working of the process in very few hands. We therefore propose to abstract some details regarding the former method, and refer our readers to the book itself for particulars of the substitution process.

The six stages of the dusting method are as follows: 1. A glass plate is coated with the sensitive mixture of organic matter and bichromate. 2. The plate is, after drying, exposed under a positive. 3. After the shaded parts of the plate have absorbed sufficient moisture, it is dusted with a vitrifiable pigment in fine powder. The united action of the bichromate and light so modify the deliquescent organic matter that it loses its property of absorbing moisture from the air, and the exposed parts of the plate consequently refuse to hold the vitrifiable pigment. 4. The powder picture is coated with collodion, and then soaked in a slightly alkaline solution, in order to remove all traces of soluble materials. 5. The collodion film, bearing the image, is next floated off and laid on a tile or other suitable surface. 6. The image is vitrified or burned in.

The composition of the sensitive mixture may be varied considerably without any very material influence on the result, but the following composition gives very excellent results in ordinary cases:—

Water	100 parts
Moist sugar	10 "
Gum-arabic	10 "
Bichromate of ammonium... ...	4 "

This solution should be used within one or two days of its preparation, and ought to be filtered with the most scrupulous care, as any particle of dust or fibre is likely to cause a white spot on the finished work. The solution is poured on the glass plate after the manner of collodion, and after the plate has been held in a tolerably horizontal position for a few seconds, the excess of solution is quickly poured off, and the plate is set to dry on a kind of desk formed of a piece of sheet iron mounted at an angle of about 15° with the horizon, and kept warm by a spirit lamp placed underneath; but it is advisable to distribute the heat by means of a few layers of blotting-paper placed under the glass, and the heat should not rise above a temperature which the hand can easily bear. It is best to use patent plate glass, and the greatest care must be exercised in cleaning it thoroughly. It is necessary that the positive under which the exposure is made should be quite dry, or even slightly warm; and in ordinary cases an exposure of one minute in sunshine, or ten minutes in diffused daylight, will suffice; but an actinometer should be used as in carbon printing. As soon as the exposure is finished, the plate is taken into the dark room, placed on a white surface, and some of the enamel colour is sprinkled on and worked round and about with a long-haired camel's-hair pencil, both the powder and the brush being perfectly dry. The image now gradually develops, and it is often necessary to shake the powder from off the plate and allow the moisture of the air to act on the film for a short period, after which the treatment with the enamel pigment is resumed. Should the picture appear hard, only the extreme dark shades appearing, the exposure has been too long; but if the image is flat, and all the high-lights are veiled, under-exposure is indicated. Just as in ordinary silver printing, the image should appear a few shades over dark at this stage, as the enamel colours lose a little intensity when fired; but if there should be any difficulty experienced in attaining the required vigour, it is advisable to very gently breathe on the plate—previously freed from all loosely-adhering powder, and then to proceed with the development. When the development is finished, all non-adherent powder should be removed by means of the brush, and any required retouching can be performed either by breathing on the plate and cautiously applying the pigment on the part requiring it, or by removing the pigment by friction with a tuft of cotton wool or a stump. The plate is next coated with a collodion containing from $1\frac{1}{2}$ to 2 per cent. of pyroxyline and about $\frac{1}{3}$ per cent. of castor oil, and after the film has set, it is cleared away from the edges of the plate so as to leave a clear border of about $\frac{1}{8}$ of an inch. The collodionized plate is next soaked in a two per cent. solution of caustic potash until all traces of soluble chromium salts are removed from the film, and after a thorough rinsing in clean water, the plate is immersed in water containing enough nitric acid to make

* "Photographische Schmelzfarbenbilder auf Email Porzellan und Glas. Ed. Liesegang's Verlag. Dusseldorf, 1882.

it taste about as sour as weak vinegar, where it should remain for some hours. By now placing the glass bearing the film in a large vessel containing clean water, and gently manipulating the pellicle with the fingers, it becomes easy to detach the collodion film; which is then caught, collodion side downwards, on the enamel tablet or tile. Should it be necessary to vitrify the picture with the collodion side upwards, the final transfer must be made in a solution of sugar containing one-fifth of its weight of this material, as otherwise the collodion film would be liable to scale off. In this latter case, the collodion must be dissolved away before firing, but when the collodion film is mounted downwards on the enamel plate or tile, this proceeding is not necessary. The most convenient method of dissolving away the collodion film is by soaking the dried plate for a whole day in the following mixture:—

Alcohol	50	volumes
Ether	50	,,
Oil of lavender	100	,,
Oil of turpentine	3	,,

The plate having been again retouched, if necessary, all is ready for the final operation or the burning-in of the image.

For this purpose, some kind of a muffle furnace is required, and, in many cases, the portable muffle furnaces for coke, such as we figure in the subjoined diagram (fig. 1)

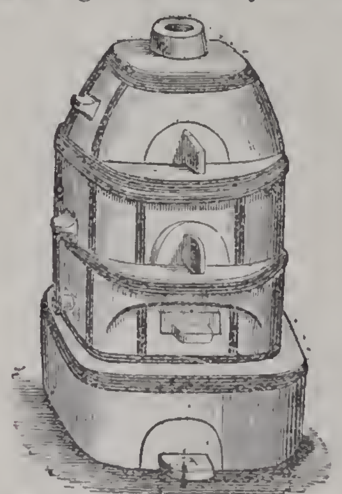

Fig. 1.

will be found convenient. These furnaces can be obtained without difficulty in London, most dealers in jewellers' materials keeping them in stock. It will often happen,

Fig. 2.

however, that the photographic enameller will prefer to avail himself of the superior advantages and convenience of gas as a fuel for heating the muffle, and, in this case the excellent furnaces manufactured by Mr. Fletcher, of Warrington, may be adopted. We subjoin drawings of two forms which we have in use at our own laboratory; the small one (fig. 2) taking a plate about two inches wide, and is well adapted for experimental work; while the larger furnace (fig. 3) will enable us to vitrify a tile

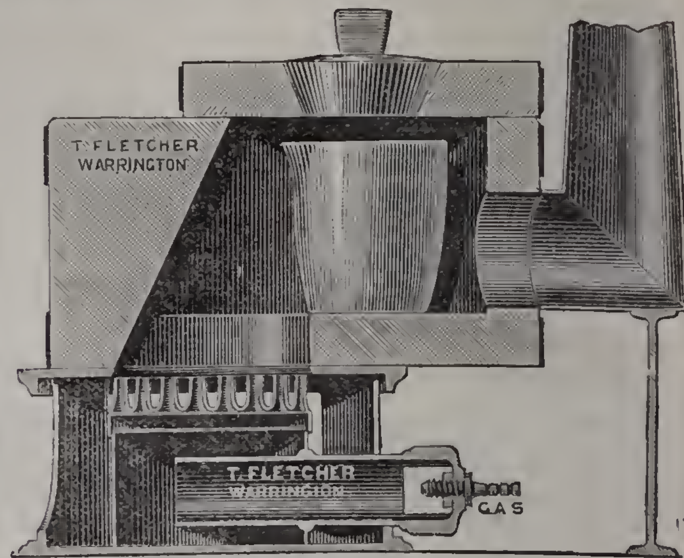

Fig 3.

four-and-a-half inches in width and nearly twice as long. The plates should be heated slowly, and occasionally turned round, so as to ensure equal action of the heat, and it is easy, after a little experience, to perceive the exact point when the enamel melts and unites with the surface of the tile. Although most will prefer to purchase the enamel colour already made, we subjoin a formula for the preparation of a black pigment:—

Oxide of copper	2	parts
Oxide of cobalt	1½	,,
Oxide of manganese...	2	,,
Flint-glass	12	,,

When fairly melted, add—

Oxide of copper	1½	parts
Oxide of manganese	1	part

The melted mixture must be poured into water, and then finely pulverised.

Numerous details and expedients necessary for overcoming difficulties will be learned by a perusal of Dr. Liesegang's excellent manual.

TWO MORE VISITS TO THE ELECTRICAL EXHIBITION.

(FROM OUR SPECIAL CORRESPONDENT.)

Hearing that since my last visit to the Palace* very considerable changes have been effected and notable additions have been made, it appeared to me desirable to make a second journey in search of information. An official programme bearing the date of this visit being obtained, the old announcement, "No extra charge to the exhibition," was found to be prominently printed on the first page. During the long walk through the covered way leading from the station to the Palace, I was gratified by seeing a very respectable installation of plant for producing lights by the Jablochkoff system and by the aid of the Brush machines. On entering the Palace, as nothing of electrical interest appeared to be close at hand, I concluded to go and examine Mr. Woodbury's exhibit illustrative of his method of balloon photography, but, long before reaching it, was stopped by a temporary barrier constructed of

* Photographic News, p. 16.

chairs, the one narrow opening being guarded by a servant of the Company, who held up his arm and said, "Oh, no; you ain't going in here without a concert ticket." A few words of explanation followed, and I found that, at certain times, all those parts of the Gallery which are even within remote earshot of the outside of the Concert Room are closed to all who do not pay the extra charge demanded. During the few seconds which were occupied in obtaining the information given above, no less than twenty-one persons applied at the barrier for admission, and six out of this number had, like myself, come with the view of examining special exhibits. It was, however, gratifying to note that no one out of these persons paid the extra charge, and one irascible old gentleman denounced the whole affair in by no means measured terms, expressing his determination to go at once, and never to visit the Palace again.

As the Gallery near the Concert Room appeared to contain a very large proportion of those exhibits calculated to be of special interest to the photographic fraternity, and it was impossible to view these without encouraging a most undesirable system of extra payment, I determined to reserve this portion of the exhibition for another visit.

In the West Corridor is a half horse-power Otto gas engine driving a small Siemen's dynamo machine, and a current of sufficient energy to keep no less than ten of the full-sized Swan lamps is developed. The arrangement is compact, and appears well suited to the requirements of the photographer, whether for portrait work or for copying. A tolerably heavy iron disc is mounted on the spindle of the dynamo machine, this serving to give that extreme equality of current which is so desirable when an incandescent lamp is worked.

A good show of electric lighting appliances is made by the Brush Company, a large dynamo-machine, for producing a single light of 150,000 candles, forming a prominent object, while several smaller machines as adapted for small arc lights, incandescent lamps, and electrotyping, are shown in action. A compact arrangement consisting of a portable engine on wheels, with a Siemen's machine bolted down on the same bed-plate, is shown by the Electric Light Engineering Company, of Queen Victoria Street, and such a combined engine and machine might in many cases serve well as a portable lighting arrangement for photographic work away from home, as there are few situations in which no standing place can be made available for working the machine within a sufficiently near distance. In the basement of the buildings no less than twelve of Edison's dynamo machines are in action, and in the machine department of the west corridor we noticed another Edison machine, which was being used for charging the modification of Planté's secondary battery which is being introduced into the market by the Faure Company. The Edison machine has very long and comparatively slender field magnets arranged so as not to give consequent poles, and an armature, which is somewhat between that of Siemens and that of Gramme as regards construction and proportion. The west corridor machine department also contains a considerable variety of dynamo machines and motor engines. Among the most promising of the more recently introduced dynamos may be mentioned the Bürgin and the Schuckert, while Elmore's present machine appears to be particularly well adapted for effecting the electrotypic deposition of metals. In very many cases steam engines are made use of as motors, several of the portable and semi-portable forms in which engine and boiler are mounted on wheels being admirably designed so as to ensure portability and efficiency, while direct action steam engines of the Brotherhood type are used in only a few cases. Hodson's rotary engine, driving a Gramme machine direct at a speed of 1,500 revolutions per minute, appeared to work satisfactorily, and was the subject of many comments from well known engineers. To stand continual working at such a speed is certainly a severe test of excellence of material and workmanship.

My subsequent visit was made in order to inspect those parts of the Electrical Exhibition which could not be seen on the former occasion without extra payment, and many objects of notable interest were found to be on view. Mr. Woodbury's electric camera is mounted over a table on the top of which an ordnance survey map of the district around the Palace is fastened; and on the table top is a model of the balloon transport car, carefully fitted up according to the designs recently elaborated by Mr. Woodbury. The actual camera with which Mr. Woodbury proposes shortly to actually carry his ideas into practice is of very considerable interest, and the modes of bringing the four plates successively into position, and making the exposure by the electric impulse, are extremely ingenious. Near to the model apparatus is a small framed picture, representing the apparatus as it might be in actual use for surveying purposes. Nearly opposite Mr. Woodbury's exhibit there are large coloured diagrams illustrative of Shippey's electric light balloon signalling system, which may prove of great practical value in military operations, as by arranging a cypher code on the principle of the Morse alhpabet, a correspondence could well be carried on at night between distant stations, even if no ordinary telegraphic communication existed.

Close by may be found the modified and self-charging Holtz electro-static induction machine as improved by Dr. Voss; this apparatus may be regarded as a continuously acting electrophorus; and as there is practically no friction to overcome, a considerable proportion of the small amount of force required to actuate it is transformed directly into electricity of an enormously high potential. These machines are not so susceptible to the influence of a trace of moisture as is the case with the old form of the Holtz machine, and on turning the handle of one as it stood, sparks of over four inches in length were almost immediately obtained. We see here a large stand of cabinet work for telegraphic instruments, and it is curious to observe how this, like photographic cabinet work, has become a distinct branch of trade. An enormous business has sprung up in telegraphic papers to suit recording instruments, such as Morse and printing telegraphs; and in this branch of manufacture the same kind of care is necessary as in preparing photographic papers. To study the numerous kinds of telegraphic paper shown by Max Sabel and Co. cannot fail to interest the readers of the Photographic News.

Close by the pyramid of telegraphic papers is an exhibit of low resistance galvanised iron telegraph wire, and as this is sold at a remarkably low price, it can often be used with advantage in connecting bells or telephones in houses, and in many cases may serve as battery conducting wires instead of copper, especially when the wires are fixed so that no inconvenience is occasioned by the extra thickness. Mr. Henry Wiggins, of Birmingham, shows a remarkable collection, illustrating the uses of nickel and cobalt, cast and rolled plates of the former over two feet square being exhibited. Nickel plating is far preferable to lacquering for lens mounts and most metal articles used by the photographer, while, when carried out on a moderately large scale, it is no more expensive than careful lacquering. Ebonite articles, as manufactured for electrical purposes, are shown by the Britannia Rubber and Kamptulicon Co., together with sheets ranging from the thickness of paper to one inch, and rod or tube of all ordinary sizes. No material is equal to ebonite for dark-slides or cameras, and it seems strange that no maker of cameras should have taken up the matter, and fairly put such articles in the market. Ebonite syringes, vessels, and other articles likely to be of service to the emulsion-maker, are also shown. A large collection of stoneware and porous vessels is exhibited by Messrs. Stiff and Sons, of Lambeth, and some large flat porous vessels, suited for the single-cell electrotype method, as recommended by Major Waterhouse, were noticeable.

Those readers of the Photographic News who did not visit the Electrical Exhibition in Paris would do well to see the show at the Crystal Palace before it closes; but, before finally fixing a time for the visit, it would be well to write to the Secretary of the Palace Company, to ascertain if, at the time proposed, there will be any extra charge for visiting the Gallery near the outside of the Concert Room, where objects of special interest to them are collected. Widely different accounts were given me by the servants of the Company as to the times at which the extra charge is demanded; but it is only fair to say that most of these persons appeared to be heartily ashamed of such a system of extra charges.

By-the-Bye.

ABOUT THE ROYAL ACADEMY.

We do not profess in these columns to pass criticism upon the annual gathering of new pictures and works of art exhibited at the Royal Academy; to do so, even cursorily, would require more space than we have at our disposal, while the circumstance that so many journals occupy themselves with the task, renders the same by us quite superfluous. As many as seventeen hundred pictures and statues are before the critic when he enters upon his labours, and, did he do his work well and conscientiously, the period for which the gathering remains open to the public would be none too long for his responsible duty.

Our task, fortunately, is a more manageable one. It is to examine the pictures from a photographic point of view, and to make note of such points as may interest our readers. The photographer, as a photographer, may learn in two ways from these annual gatherings—viz., what to adopt, and what to avoid; and we are not sure that the bad pictures he sees do not teach the more salutary lesson. There is always some very big and very bad picture to strike the visitor and set him wondering what could have possessed the hanging committee to receive it, and this year we should award the palm either to Mr. May, for "The Children's Hour" (231), or to Mr. Wells, R.A., for "Friends at Yewden (261). In the first of these ambitious pictures it is the figures that offend; in the second the landscape. "The Children's Hour" shows us a large lady on a large couch, engaged intently in looking at nothing, a child sitting beside her, also with a vacant eye, and a second girl crouching down near the sofa, endowed likewise with a staring, uncomfortable look. The effect is not even sad or lugubrious, it is simply meaningless; yet, if we remember Longfellow's lines aright, he speaks of bonnie girls, full of spirits, making "a sudden raid" upon him.

> "They climb up into my turret,
> O'er the arms and back of my chair.
> If I try to escape, they surround me;
> They seem to be everywhere.
>
> They almost devour me with kisses,
> Their arms about me entwine,
> Till I think of the Bishop of Bingen,
> In his Mouse Tower on the Rhine."

The Royal Academician's picture, which includes portraits of George Leslie, Calderon, and altogether half-a-dozen of the Academy magnates, is probably the worst landscape in the exhibition. The river and foliage is of the true "tea-tray" order, the verdure of a livid pea-green, contrasted with brick dust red, and covered over all with vulgar glaze. Let any photographer paint over one of his camera pictures in this greengrocer's style, and he would be denounced as a dauber of sign-boards.

Among the portraits, there is, as usual, much stiff and inelegant posing to be witnessed. The old conventional pose of a man busily writing, and suddenly startled in his work to find his portrait being painted, we meet in a picture by Mr. Lorimer (262), and elsewhere. Dr. W. Siemens (283), the well-known physicist and electrician, is shown with a pair of compasses in his hand, for some reason; it is a faithful portrait enough by Mr. Lehmann, for it shows Dr. Siemens' set smile, always the most unpleasant part of the doctor's presence, as any one who had seen him twice would know. Mr. Wollen, in a portrait of Mr. Eve (7), and Miss Brooks in one of Mrs. Sedgwick (14), show us again how pictures should not be painted; we should not wonder if these had been taken from bad photographs, they are so stiff and constrained. Mr. Alma Tadema (181) paints a face full of force and vigour, but the pose is best described as being "all of a heap." Another piece of portrait work that leaves much to be desired is Mr. Wells' painting of the Mayor of Newcastle (213), in which we have that dignitary not only sitting on his throne in solitary state, but apparently "left sitting," as the parliamentary reporter has it. The Mayor and his robes occupy the spacious chair in the centre, while right and left are more seats, which, for want of occupants, serve to rest mace and sword upon. Not only the Mayor, but a large portion of the empty Guildhall, is shown, giving the idea that the painter was paid by the square feet he covered.

Turning to the more pleasant features of the Exhibition, we may point to Mr. Norman's portrait (122) by Ouless, and that of Mr. Ralli (446) by the same painter. The first is a standing portrait, the latter sitting, and, in both, a chair-back is the only accessory, the portraits being little more than half-length. In the standing portrait it is a high-backed chair, and the model leans sideways against it, the chair giving a support under the arm-pit, the elbow dropped, and the hand resting on the top of the chair; the other arm is shown at full-length. The pose is simplicity and unaffectedness itself; nor is the other inferior. Here one arm is also thrown over the back of the chair, while the hand grasps the top, the other hand holding a book, which, for the moment, is lowered. "For Papa's Birthday" (64), by M. Munkacsy, we have a lady and children grouped in a manner very different to the "Children's Hour." The lady stands at a table, picking up blossoms and arranging them in a vase, as a surprise for papa, and two little girls, who have evidently been doing some of the picking, are looking on intently at mamma's important work. A third child—a mere baby—is on the floor, plucking a stray blossom to pieces. This is a charming group, and such a one as photographers might attempt with good chance of success. "Marriage Bells (221), by Mr. Hallyar, a group of men of all ages, from the village youth to the shrunken "oldest inhabitant," pulling away at ropes that move the sonorous bells overhead, is another study to be noted. Close to it is a lady's portrait (218), by Frith, which embodies a most easy and graceful pose; the lady stands sideways, her head turned towards the spectator, and her hands dropped at full length one over the other. Another delightful female pose is Mr G. Smith's "Gage d'Amour (424), a lady bending over a table, and examining a bracelet she has taken in her hand, her other toying with the necklet on her bosom. "Sally in our Alley" (316), by Miss Bowkett, is also worth studying. Sally stands on the doorstep, leaning negligently against the threshold; her trim feet peep from beneath her gown, one rounded arm is akimbo, and her expression leads one to think she is awaiting her swain. England is the country for quaint doorways and rustic porches, and photographers may here study how to make use of them to produce a camera picture.

"The Day of Rest" (469), by Lance Calkin, is another subject capable of photographic treatment. Upon a bench on the public highway is seated, at one end, an old lady in a state of somnolescence, having with her a little girl, who stands beside her, and is not only wide awake, but half terrified at the appearance of the occupant of the other end of the bench, who is a rough and morose navvy, but who, notwithstanding his ill-look, is perfectly harmless, since he, too, is fast asleep. "Nearly Bedtime" (481), by Miss Jenkins, reminds one of Mr. H. P. Robinson's Little Sunshine, except that in this case the light flooding the little girl's face and figure is due to a lamp, and not the sun. A little miss sits up in an arm-chair in the dining room, before a table upon which stands a shaded lamp; twilight still lights up the room partially, but illumination from under the lamp shade throws the little face and dress into strong light. "A Tempting Offer" (164), by Mr. J. Clark, is a cottage scene; a woman is sewing, and a little girl stands at her knee, while at a short distance in the doorway stands an old orange-man with straw hat and flowing white beard. He holds out an orange to the lassie, but she is too shy to advance towards it. It is altogether a quiet and successful composition. But the best *genre* picture to our mind is "The Letter-writer" (294), by Mr. Burgess, A.R.A., a bevy of olive-complexioned Spanish girls gathered round the table of a public letter writer, who is following the dictation of one of the maidens. It is a love-letter, of course, that is being penned, and while one girl earnestly advises one course, another, who has evidently suggested some levity, lays her merry face upon the table, and is fairly dying with laughter. A third, more matronly than the rest, quietly watches how matters are going, while a young man, a spectator of the scene at some distance, shows such annoyance at the behaviour of the laughing girl, that one cannot look into his face without laughing too.

There are many charming landscapes this year, Mr. Vicat Cole, R.A., showing one of the best; it is called, "Sylvan Solitude" (92). A placid river is the main feature, the foreground on the right being made up of yellow rushes, while to the left, across the limpid water, is a bushy willow, past which the river flows into the distance. There is very little colour, strange to say, in the picture, scarcely more than there would be in a photograph; yet the effect is delightful. Mr. Vicat Cole is well known as a skilled photographer, and we have little doubt that the picture is both true to art and true to nature. Another picture deserves yet more attention; we mean, "Sweetness and Light" (384), by Mr. F. B. Barwell. This, too, is a sylvan scene, a broad stretch of placid water in the foreground, and beyond, magnificent foliage towering to the sky. A boat and pollard willow break up the foreground, and in the middle distance is again a wealth of clustering foliage. But the point of the picture is that it is filled with soft haze; from the very front to the back it is clouded with blue vapour, and relief is given by slanting rays of golden sunlight—still subdued, be it understood—that struggle here and there through the boughs of the giant trees in the background. The picture is altogether of a low tone and without contrast, but the rays of sunlight seen through the veil of mist exert a most soft and sweet effect upon the sylvan scenery.

Autumn (250), by Mr. J. E. Grace, is another good picture, in composition not unlike some of the bits of nature that Mr. H. B. Berkeley has lately made us familiar with on a small scale. A group of three silver birch stems rise up beside a swamp, and these, together with some ragged tufts of rushes, constitute the foreground; water and picturesque marsh land occupy the middle distance, and beyond are clumps of trees and a range of blue hills. "When Evening's Twilight" (723) is also a delightful landscape that will well repay study. Mr. E. A. Waterlow's "Sheep-Washing" (738) should remind photographers of a picturesque scene within their powers, and the same may be said of "A Shady Lane" (785), by Miss M. Hickson, one of those deeply hollowed ways in red clay, with gnarled roots of beech on either side, and above the beechen leaves of bronze and gold, so dense that the sun's rays which dapple the ground at intervals have hard work to penetrate.

It is not a matter of much importance, but it is well, perhaps, to note how a little snobbishness sometimes mars a very good picture. In Mr. Horsley's "There is no God but God" (522), we have the deck of an Indian mail steamer, the time being sunset, and the "true believers," kneeling on mats spread upon deck, are engaged in devotion. Around them are various nationalities. The Levantine stares with indifference, two Turks are examining jewelry and estimating its value, a Frenchman is asleep and evidently snoring, but an Englishman who is by, stands bareheaded and with reverent demeanour. It is like the story of the three schoolboys who received cakes, one greedily eating it all himself, the second avariciously hoarding it up, and the third dividing it generously among his fellows. Which of these three boys do you like best? was wont to be the teacher's tag to the story; and Mr. Horsley's picture would ask us, of all men on earth, whose character is the most amiable and charitable? Well might the poet sing in H.M.S. *Pinafore*—

> For he himself has said it,
> And 'tis greatly to his credit,
> That he is an Englishman.

The "At Home" next week will be "Mr. J. E. Mayall's Electric Studio in Bond Street"; the following "By-the-Bye" will be "Paris and the Salon."

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

Photography and Protoplasm—Photographic Popularity—Photography and the Royal College of Surgeons—Nervous Photographers.

Photography and Protoplasm.—It is curious to note how photography is constantly being brought in to elucidate scientific questions, and how unexpectedly it frequently throws light upon points at issue. A curious example of this occurred at the last meeting of the Royal Microscopical Society, when a member read a note received from Dr. Loew on the chemical difference between living and dead protoplasm, and exhibited a photograph illustrating Loew and Bokormy's statement as to the different reaction of dead and living protoplasm on silver salts. Messrs. Loew and Bokormy's theory appears to be that while living protoplasm reduces a silver reagent and becomes a blackened mass, dead protoplasm does not. If this theory could be substantiated by experiments, undoubtedly an important fact would be established; but the discussion showed that this was by no means the case, the photographic experience of some of the members furnishing the most powerful argument against its truth. The photograph exhibited represenced two filaments of *spirogyra nitida.* One of these had been subjected in a living condition to the silver reagent, with the effect that all the cell contents had been converted into a black opaque mass. The other filament had been killed by a 1 per cent. solution of citric acid before treatment with the silver solution, and in this case no reduction and consequent blackening was exhibited, the spiral arrangement of the chlorophyl bands being perfectly distinct. Now as the statement stands it would seem fairly conclusive; but, as several members pointed out, the use of citric acid would have an important influence on the result unless it were made clear that the acid had been perfectly eliminated, which had not been done. Every photographer knows that citric acid is one of the most energetic restraining agents which can be used, and unless Messrs. Loew and Bokormy can produce the same effect without the use of an acid of any kind, considerable doubt must be thrown on their theory. But without the experience gained in photography it is questionable whether this point would have been demonstrated.

Photographic Popularity.—Human nature, whether in England or on the Continent, is pretty much about the same. Some time ago we gave a few statistics showing the comparative popularity of notable persons by means of the number of photographs sold. These figures showed that in London and Paris the demand for any particular photograph was by no means in accordance with the merits of the person photographed. A Berlin philosopher has lately been engaged in a similar task, and the result of his labours is not more satisfactory. For instance, the picture of a female acrobat obtained last year 2,000 more purchasers than the latest photograph of Field-Marshal Moltke; Pauline Lucca and Patti have been eclipsed by Lurline, "the water queen;" while the greatest benefactor to photographic publishers who has ever appeared in Europe turns out to be the Shah of Persia, no less than 17,000 copies of his portrait having been sold during his stay in Berlin. Perhaps her Majesty will be gratified in knowing that, since the attempt upon her life at Windsor, her photograph "has become a leading article in the trade" in Berlin.

Photography and the Royal College of Surgeons.—In a recent visit we paid to the Royal College of Surgeons we were struck by the limited use which is made of the astonishing collection, compared with what might be done with it if photography were employed. Of course certain subjects, such as injected preparations, could scarcely be studied through the medium of photographs; but there are hosts of other specimens which could be as well seen in a photograph as in the glass case through which the student has to strain his eyes, and compare with his text-book as best he may. The specimens of bad surgery, for instance, in which the bone has been joined together unevenly, might well be photographed, and the photographs would give about as much information as the specimens themselves. Why should not Sir Erasmus Wilson's invaluable drawings of the various skin diseases be reproduced, instead of being kept shut up, to be looked at, perhaps, a dozen times in the year? It is more than likely that members of the medical profession only visit the Royal College of Surgeons when they are students, and are in process of "cramming." Once established in a practice, they think no more of the valuable hints to be gathered from the museum, and perhaps, if they did, could not avail themselves of its assistance. But a collection of photographs would be always at hand, and would be more accurate than many of the elaborate drawings which illustrate standard works on anatomy. Yet photography is not made use of in any possible way at Lincoln's Inn Fields. Is not the College somewhat behind the times?

Nervous Photographers.—There is more truth in Mr. Brownrigg's objection to Mr. Addenbrooke's ingenious "automatic adjustable exposer" exhibited at the last meeting of the Photographic Society, than some photographers would be willing to admit. Said Mr. Brownrigg: "There is always excitement when you come to the critical point," and this is so true that to have the thoughts fixed upon anything but the instantaneous picture you intend to secure must militate against success. In taking a street scene, or in photographing animals, there is always one moment which is the best for the picture, and the fear lest you should expose too soon or too late is always present in the mind until the shot is fired, and you know you have got your negative for better or for worse. Captain Abney observed that "we are not all such nervous subjects as Mr. Brownrigg," and this may be true, though it is highly probable that in the question of nerves there are more photographers like Mr. Brownrigg than are like Capt Abney. Nine photographers out of ten have the reverse of phlegmatic temperaments. Enthusiasm and concentration belong essentially to the nervous (in the physiological sense of the word) man, and without these two qualities the photographer would not endure the ills which attend the practice of the art either as a professional or as an amateur. In taking instantaneous pictures the photographer must be a philosopher, indeed, who is not anxious about the result, and therefore the less he has to worry him while waiting for the instant to expose, the better. Hence, in spite of the risk of vibration, preference, we fancy, will always be given to a shutter attached to the camera to be opened by means of the pneumatic tube. By the way, it was remarked at the meeting, of Mr. England's apparatus, that it was not everyone who had the advantage of possessing a camera and stand like his. Some curiosity has been expressed since as to what this stand is like, and what produces its extreme rigidity. Mr. England some time ago exhibited his camera and the shutter he uses, at one of the Society's meetings; has he ever shown or described the stand? If not, a few remarks would be opportune now that the season for out-door photography has commenced.

ON ETCHING FLUIDS.

BY MAJOR J. WATERHOUSE, B.S.C.
Assistant Surveyor-General of India.

II.—Mordants for Copper.

The most usual mordants for copper are nitric and nitrous acids, more or less diluted with water. Latterly, however, a mixture of chlorate of potash and hydrochloric acid, known as the "Dutch mordant," has come more into use. For some purposes, perchloride of iron in solution is a useful mordant, particularly in photographic work with gelatine films. These two latter mordants bite more quietly than the acids, so that the lines are not so much enlarged, and there is not the same risk of close lines running together and other inconviences caused by the evolution of bubbles of gas.

Acid Mordants.

1. *Lalanne.*
   Nitric acid at 40 ... ... 1 part
   Water ... ... 1 ,,

With a little old etching solution added, or pieces of scrap copper.

2. *Roret.*—Three strengths of nitric acid at 15°, 20°, and 25° of the *pèse acide*, commercial acid being 36° to 40°.

3. *Cooley.*
   Nitric acid ... ... 5 ounces
   Water ... ... 10 ,,

For fine work add—
   Verdigris ... ... 2 ounces
   Water ... ... 5 ,,

4. *Fielding.*
   Nitrous acid ... ... 1 part
   Water ... ... 5 parts

Add to the pint of mixed acids a piece of sal ammoniac, about the size of a hazel nut. The object of this addition is to give a more vertical bite.

5. *H. Gobin.*
   Nitric acid ... ... 30 parts
   Nitrate of copper ... ... 6 ,,
   Water ... ... 100 ,,

Or, weaker,

6.—Nitric acid ... ... 1 part
   Water ... ... 4 parts

Dilute acid of this strength was used by Dr. Donné, for etching Daguerreotypes.

7.—According to *Kruger*, chromic acid is an excellent mordant. It may be dissolved in water, according to the strength required. The following is similar:—

8. *Malaret.*
   Nitric or sulphuric acid ... ... 1 part
   Saturated solution of bichromate of potash ... ... 2 parts
   Water ... ... 5 ,,

Fizeau used for Daguerreotype etching, a mordant composed of nitric, nitrous, and hydrochloric acids.

Dutch Mordant.

Several formulæ are given for the preparation of this useful mordant. According to Roret's Manual it seems to have been proposed by Messrs. Schwarz and Boehme, whose formula is:—

9. Fuming muriatic acid (sp. g. 1·190) ... 10 parts
Water ... ... 70 ,,
To this is added a boiling solution of
Chlorate of potash... ... ... 2 parts
Water ... ... 20 ,,
This may be diluted with from 100 to 400 parts of water as required.

10. *Hammerton.*
Pure hydrochloric acid ... ... 100 parts
Chlorate of potash ... ... 20 ,,
Water ... ... 880 ,,
Dissolve the chlorate of potash in the water with heat, then add the acid.

11. *Smillie.*
Muriatic acid ... ... 5 ounces
Chlorate of potash ... ... 1 ounce
Water ... ... 25 ounces
made as last.

12. The following is used at the Berlin State Printing Office :—
Pure muriatic acid ... ... 8 parts
Ordinary do. ... ... 2 ,,
Chlorate of potash ... ... 1 part
Cold water ... ... 40 parts
Hot water ... ... 8 ,,
Dilute the pure acid with the cold water, then add the ordinary acid, and finally the chlorate of potash, dissolved in hot water.

13. *Kruger.*
Chlorate of potash ... ... 10 grammes
Water ... ... 100 ,,
Dissolve with heat, and, when cold, add—
Muriatic acid ... ... 75 grammes
Water ... ...200 ,,

14. Perchloride of iron, more or less diluted in water, is, according to Hamerton, an excellent mordant. It bites deep and clear, without enlarging the line much, and there is no ebullition, as with nitric acid. It is particularly useful in photographic etching through gelatine, as the latter is insoluble in it.

In most cases the mordant is flowed over the plate, or kept moving on it in the same way as a photographic developer. Such mordants are generally used for finishing off and deepening the light tints, and are called *eau fortis à couleur* or *à passer*. The following formulæ are given :—

15. *Roret.*—Abraham Rosse's
Strong white or distilled vinegar... 3 litres
Sal ammonia ... ... 180 grammes
Common salt ... ... 180 ,,
Pure verdigris ... ... 120 ,,
A little oxalic acid is sometimes added. The solids are ground up, and boiled in the vinegar. Acetic acid at 3°, or pyroligneous acid, may be used in place of vinegar, and, if too strong, more vinegar should be added.

16.—The following, used by Callot and Piranesi, is similar, and prepared in the same way :—
Strong vinegar ... ... 8 parts
Verdigris ... ... 4 ,,
Sal ammoniac ... ... 4 ,,
Salt ... ... 4 ,,
Alum... ... ... 1 part
Water ... ... 16 parts

17. *Roret.*—Dissolve in nitric acid as much copper as it will take up; also prepare a saturated solution of sal ammoniac in good vinegar; then mix three parts of the copper solution with one part of the sal ammoniac. The mixture may be strengthened by adding nitric acid drop by drop, till it bites well.

Relief Etching.

For etching copper in relief, the following glyphogen is recommended by Deleschamps :—

18.—Nitrous acid at 30° ... ... 2 ounces
Acetate of silver ... ... 6 drachms
Hydrated nitric ether ... ... 16 ounces

The nitric ether is prepared by mixing two ounces each of nitric acid and alcohol, and when the reaction commences, stopping it by adding eight ounces of distilled water.

19. *Roret.*
Silver ... ... 1 part
Dissolved in—
Nitric acid ... ... 1 part
Water... ... ... 2 parts

20. I have found a solution of nitrate of silver, about 20 grains to the ounce, bite very well, giving a good, clean bite quickly, and without any destructive evolution of gas. It does also for ordinary etching.

The formula No. 16 is said to be also good for relief etching; but it is then used stronger, only ten parts of water being added to the other ingredients. No. 12 is also a good mixture for the same purpose.

Tint Etching.

21. Flowers of sulphur mixed with oil forms a good composition for etching tints. It can be applied with a brush. For a flat tint, Hamerton says, "Oil the plate liberally with olive oil, and blow flour of sulphur upon this. The sulphur, if allowed to remain on the plate, will produce a flat tint, more or less deep, in proportion to the time it remains.

22. Roret gives the following formula for tint etching:—
Bay salt ... ... 2 parts
Sal ammonia... ... ... 2 ,,
Verdigris ... ... 1 ,,
These are pounded together, and the mixture kept in a bottle.

When required for use grind up a little in a glass with some syrup of old honey, so as to make a mixture which flows readily, and may be used with a brush like a colour. It is used after the first bitings of aquatint plates with acid, to give finish and vary the tints.

23. *Fielding* (for aquatint).
Nitrous acid ... ... 1 part
Water... ... ... 5 parts
For the strongest touches, nitrous acid and water equal parts, applied with a feather or brush. No. 19 may also be for this purpose, either with or without a little gum.

24. *Hamman.*—Dilute nitric acid at 12° (sp. g. 1·09), mixed with—
Distilled water ... ... 12 parts
Alcohol ... ... 3 ,,
This is said to give a grain in biting, so that the ordinary grained ground may be dispensed with.

Electric Etching.

It has frequently been proposed to etch by means of electricity, and in some cases it may be an advantage to do so.

The copper plate to be engraved is attached to the positive pole of a suitable battery and placed as anode in a solution of sulphate of copper or in water, acidulated with sulphuric acid.

If suitable cases different degrees of depth may be given, putting parts of the anode and cathode nearer together or farther apart.

Grove etched Daguerreotype plates with a single pair Grove or Bunsen cells, by inserting the plate to be etched, and a platinum plate of the same size, in a wooden frame having two grooves a quarter of an inch apart. The Daguerreotype having been attached to the battery as anode, and the platinum plates as cathode, the frame is immersed in a suitable vessel filled with
Hydrochloric acid ... ... 2 parts
Distilled water ... ... 1 part
Contact is made for about half a minute, after which the plate is removed from the acid, washed thoroughly with distilled water, then placed in a solution of hyposulphite of soda or ammonia, and the deposit removed from the surface with gentle rubbing with cotton. It is then again rinsed with distilled water, and dried.

(To be continued.)

Notes.

We are glad to see that a photographic society has been formed at Cambridge University. Members must belong to the Uuiversity, and their number is limited to thirty-five. Candidates, however, are eligible to be elected honorary members.

Professor Thorpe, F.R.S., one of the few chemists who make a study of photography, has been examining the action of zinc, magnesium, and iron as reducing agents with acidulated solutions of ferric salts. Zinc reduces most when the ferric salt is concentrated, and there is a small amount of free acid present, and the temperature is a high one. With iron, a rise of temperature seems to decrease the reducing action.

M. Marcy's gun-camera, with which he photographs the flight of birds, fires off ten shots a second, or, in other words, se cures ten pictures of a flying bird within a second; each exposure is reckoned at $\frac{1}{750}$ of a second.

The Swan lamp as fitted for dark room use was shown at the meeting of the Society of Arts last Wednesday; and we were rather surprised that a small Gramme machine, which stood on the table and was turned by one hand, served to keep no less than three of the medium size Swan lamps in action.

Our huge Indian troopships, each of which is capable of transportiug a couple of battalions at a time, are forthwith to be illuminated by electricity, so to minimise as much as possible the risk of fire.

Although many of our war-ships are capable of showing an electric light from the bridge or masthead, only one, the *Inflexible*, the so-called premier battle-ship of the British navy, by reason of its being the most heavily armed and armoured craft in commission, is illumined by electricity between decks. The *Inflexible* has Swan lamps fitted in her cabins, for the first time lighting up these dark recesses in a comfortable manner, and our Indian troopers are now, in similar fashion, to be lighted below by incandescent lamps.

The electric light was employed for siege purposes during the investment of Paris, when the garrisons occupying the outlying forts employed its vivid rays for sweeping the glacis around, so that no attacking party might approach unobserved in the darkness. M. Mangin now proposes to go further, and to do what Chevalier long ago held to be feasible—viz., to illuminate an enemy's works at night by electricity, so that the bombardment may go on uninterruptedly. Those who possess but little military knowledge know very well that at night-time it is customary to make good as much as possible any harm done by an enemy's fire during the day, and it is to prevent this that M. Mangin brings forward his siege electric apparatus.

One of the difficulties connected with the subject is to reflect the light, and direct the guns at the proper angle, and this, it may be remembered, M. Chevalier sought to solve by the aid of the camera—or rather, his photographic plane-table. In 1868, Chevalier carried out a series of experiments at Vincennes, and these proved so satisfactory, that, by direction of Napoleon III., he was ordered to make trial of his scheme under campaigning conditions. Unfortuuately, M. Chevalier's death put an end to the experiments, but not before he had shown that, by means of his photo-surveying instrument, he could fix and record the angles at which guns should be laid in order to carry on a bombardment against any part of an enemy's works when these are hidden in the darkness.

A silver laurel wreath has been presented to Frederick von Voigtländer, the present head of the firm of opticians in Brunswick. The occasion was to celebrate the making of the 250,000th photographic lens.

Dr. Huggins has written to our friend Dr. H. W. Vogel, of Berlin, that it was by means of a plate prepared with the latter's emulsion that the recent photograph of the spectrum of Orion was obtained; this is certainly the best testimony we have had as to the sensitiveness of the Vogel emulsion.

By the use of dilute sulphuric acid before and after the treatment with hydrofluoric acid, Mr. Plener has much improved his stripping process, the sulphuric acid hardening the film, and it becomes possible to make the film draw together, and thus somewhat reduce the scale of the negative. A final rinse with very weak ammonia is desirable.

Mr. W. D. Valentine, of Dundee, whose experience of out-door photography is naturally somewhat extensive, tells us that a "basket lined with tin" he prefers to any other package for transporting photographic paraphernalia.

The circumstance that the town of Lille possesses a comprehensive collection of early photographic specimens, so complete, in fact, as to form an epitome of photographic progress almost up to the present time, should encourage the South Kensington authorities to renew their efforts to form a national collection illustrative of the photographic art.

Silk-plating, or covering coarse fabrics with a film of silk, is the subject of a German patent. A solution of silk is made, and then the fabric dipped into it, and further treated with sulphuric acid. Persoz fils, our readers may remember, years ago suggested dissolving silk in chloride of zinc, and employing it as a substitute for collodion; and Spiller has shown that silk readily dissolves in hydrochloric acid. Unfortunately, the dissolved silk is very deliquescent, and not easy, therefore, of application as a photographic film either to glass or paper. In a word, it is still open to the experimentalist to produce a silk-plated material as a substitute for albumenized paper.

It is not all work and no play, apparently, with the Royal Commissioners on Technical Education. Mr. Woodall, M.P., Professor Roscoe, and Mr. P. Magnus have just left England for a tour of several weeks in Switzerland and Germany, beginning with Alsace. It is a fortunate coincidence that the time of the year is likely to render the tour a pleasant one.

Mr. Wight, of Berlin, has made some experiments upon the keeping qualities of gelatine plates after exposure. A film exposed in April, 1879, was developed last month, three years, therefore, elapsing between its withdrawal from the camera and the application of a developer. The result was an image, but a faulty negative. Another film, of Mr. Wight's own preparation, developed after an interval of two years and a-half from exposure, was more satisfactory, showing only a few white spots on its surface.

Our Belgian contemporary, the *Bulletin de l'Association Belge*, makes merry over a misprint in our columns, where the word *panache* has been substituted for *patache.* We have all the more pleasure in bearing testimony to the keen perspicacity of our friend, since Belgians, as a rule, are not credited with an acquaintance with classic French. We remember once meeting a youth who had just completed his education in Belgium, and who was assuring a Parisian acquaintance that he could now speak French perfectly. "*Pardon*," was the suave reply, "*M'sieur parle belgique.*"

Photography played an important part in a trial last week. Miss Genevieve Ward's representatives sued for an injunction to restrain a theatrical manager in Leicester from performing a play belonging to her. Taking advantage, seemingly, of Mr. Black's absence from this country, the manager in question had taken the title of his story, "That Beautiful Wretch," and adapted it to the play of "Forget-me-not," the owner of which also happened to be abroad. Miss Genevieve Ward was, in fact, in America, and, worse still, had with her the document in which the authors assigned to her the play. The absence of this latter was an important feature in the trial, as proof of ownership could not be made out; but in the end a photograph of the document was brought forward on behalf of the plaintiff, and the judge, having carefully examined the copy, gave judgment upon it.

This, we believe, is the first instance of a photographic copy of an attested document being admitted in a court of law to be of the same value as the original when the latter is not forthcoming. It will mark a precedent the importance of which cannot be rated too highly, for lawyers are likely, after this decision, to have all their more valuable instruments reproduced by the camera. In fact, the matter will, in all probability, lead to the establishment of a photographic studio specially constructed for copying, in the precincts and under the direction of the law courts.

We have received a circular from the Leipsic Retouching School, in which photographers from all parts are invited to attend classes for instruction in retouching in particular, and art in general. There is not the least doubt that retouching has now become a recognised art, and must be regarded in the same light as wood-engraving and other high-class skilled work. In several respects, in fact, retouching is very much like wood-engraving; the retoucher must possess considerable knowledge as a draughtsman, and must be able to make good deficiencies, as well as remedy defects. The work is of the same fine microscopic character, and the pay is similar, averaging from £2 to £5 a week, although it is rare to find either a retoucher or engraver receiving the maximum sum.

The Leipsic School has been established to give some sort of systematic instruction in retouching. A month's instruction is given for 100 marks, or shillings, two months for 150 marks, and three months for 250 marks. If the lessons are confined to one or two months, only negative and positive retouching and drawing are taught; if students tarry longer, they receive instruction in oil and water colouring. Board and lodging for the students can be obtained in Leipsic for from 60 to 90 marks per month. We have no personal knowledge of the *Leipziger Retoucheur Schule*, but we think many young photographers in this country might do worse than go abroad for a few months to view matters from the other side.

How to make leather in twenty-four hours is the subject of a German patent, which, since it is based upon the employment of bichromate of potash and gelatine, no doubt would scarcely hold good in this country. Mixtures of this kind have been proposed ere now for a hundred and one purposes, from the making of sausage skins to the production of waterproof walls. In the present case, the raw hides or skins are placed in a warm or cold solution of—

Water	1,500 parts
Gelatine...	50 „
Bichromate of potash	30 „

The skins are immersed for the space of a day, and then exposed to daylight to permit the bichromated gelatine, of which the hide is now composed, to become insoluble.

First aid to the wounded is a subject that has attracted much attention throughout Great Britain of late, the classes of instruction being, we believe, under the auspices of the Knights of St. John. Our volunteers, police, and public schools, are taught in a series of lectures the valuable lesson of attending on people suffering from accident, when no medical man is near. In France, M. Fournier has been working with the same laudable object, and has conceived the happy idea of illustrating by means of photography how wounds should be attended to in the battlefield or elsewhere, when no medical aid is at hand. M. Fournier has submitted his photographs, with simple instructions appended, to the Academy of Sciences.

Review.

Cours de Reproductions Industrielles, Exposé des principaux procédés de reproductions graphiques, héliographiques, plastiques, hélioplastiques, et galvanoplastiques. *(Par M. le Professeur Léon Vidal, Paris, Librarie Ch. Delagrave, 15, Rue Soufflot.)*

This manual from the pen of our talented Paris correspondent demands, both from the interesting matters of which it treats, and from its having no counterpart in this country, a somewhat extended notice. It is the text-book for the students in the National School of Decorative Arts, and, forming a supplement to what may be termed purely fine art teaching, is designed to give full instruction in the means of copying and multiplying commercially original works of art or their interpretations, indicating also the manner in which it is desirable that such works should be treated with a view to their reproduction.

Pointing out the immense advantage which its fidelity of copying gives to photography over manual processes like those of the engraver or lithographer, which furnish interpretations, more or less artistic, rather than facsimiles, M. Vidal takes *seriatim* examples of different kinds of works of art, and describes the most suitable means of reproducing them in large or small quantities, in many cases accompanying the description with an illustration produced by the process under consideration.

Much as has hitherto been accomplished by the Woodbury process, by heliogravure, collotype printing, &c., there can be no doubt that photography will play a yet more important part as an adjunct in the pictorial reproduction of works of art; and such a work as this, by attracting the attention of fresh minds, can scarcely fail to add to the perfecting of existing processes, or to the discovery of new methods. Invention, however, is not now idle, for M. Vidal has found himself obliged to take note of many fresh applications and inventions while compiling the present work.

Given a subject to be reproduced, the question arises what process will be best for the purpose. M. Vidal supplies the answer. If a limited number of copies only is required, it is evident that the production of a special plate, to be afterwards printed from by mechanical means, is not applicable, cost being usually an important factor in the matter, and one of the processes of printing direct from the negative by the agency of the light will here be more suitable. Ordinary silver printing finds scant favour with our author, but may be used if permanency need not be considered. He, however, advises recourse to the platinum or carbon processes, which yield proofs of assured durability. The cyanotype processes, too, yielding proofs either white on blue ground, or the reverse, will occasionally be found applicable.

If, however, a large number of impressions is required, then one of the mechanical processes becomes a necessity, and the choice must be determined by a consideration of which will best render the character of the subject; also, in the case of book illustrations, whether the copies are to be inserted in the text, or form separate plates. Enamels, oil paintings, portraits, and metallic objects will be best rendered by photoglypty, known generally here as the Woodbury process, which gives more solidity combined with transparency in the shades than other processes. Unfortunately, proofs cannot in this way be obtained with a clean margin, and consequently, where the separate mounting is objected to, recourse must be had to phototypic printing or to photo-engraving, though with some little loss in result. A comparison of the Woodburytype copy of Hugrel's beautiful painting at page 190, with Rousselon's photogravure rendering of the same at page 152, excellent as the latter is, will be instructive, and show the value of Prof. Vidal's dictum.

The Woodburytype process is not well adapted for subjects with large surfaces of white, which will be better treated by photography or by one of the photo-engraving processes. For drawings in general with charcoal, black lead, conté crayon, and body colour, the preference should be given to phototype, as the impressions can be pulled with or without margin, and veritable facsimiles produced by the use of suitably toned paper and ink; while with a polychrome, original chromo-lithography can be joined with the phototype printing. Similar results can be obtained by heliogravure, though at increased cost both for plate and printing, and the result, while having high artistic qualities, would not in most cases so closely resemble the original.

Where figures have to be inserted in the text and printed with the type, it becomes necessary to resort to typographic engraving—that is, to an engraved plate on which the lines receiving the ink from the roller are in relief, while in an ordinary copper plate they are sunk. The metal usually employed is zinc, and zincography can be applied to the reproduction of all line or stipple drawings with pen or pencil, provided that they are executed on a white or very clear ground. Its incapability of rendering half tone, which has hitherto restricted its use to this class of subjects alone, seems now likely to be removed, as will be found by reference to M. Vidal's article in the News of April 28.

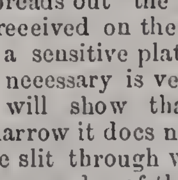
The comprehensive character of the treatise may be judged from the fact that, in addition to a full account of the photo-mechanical, the silver, carbon, platinum, and other printing processes, it embraces a condensed description of manual engraving and lithography, and of such auxiliaries to reproduction as the chromograph, papyrograph, &c., while chapters are devoted to enamels and vitrifactions, to mouldings and electro-metallurgy. The chief interest of the book will, to most, probably lie in the various methods of heliogravure; in the Woodbury process, and its modifications, by which the use of expensive plant is obviated; in the phototype process, which, under its various names of Albert-type, heliotype, collotype, &c., is the most universally employed of the photo-mechanical processes, and is suited to nearly every class of subject. But to some readers the most attractive chapters will be those devoted to the consideration of reproduction in colour, and we purpose returning shortly to this portion of M. Vidal's interesting work.

PHOTOGRAPHY AND THE ECLIPSE.

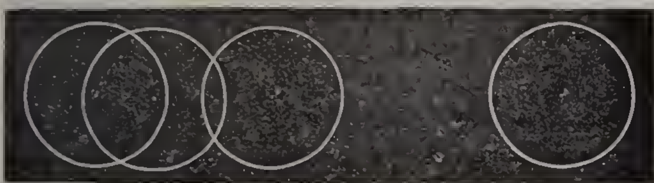
BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.

Second Article.

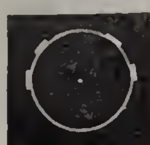
We next come to the spectroscopic photography which will be attempted at the eclipse on May 17th next. The ordinary idea of a spectroscope is that a beam of light passes through a narrow straight slit, impinges on a prism, and that a lens on the other side of the prism catches the rays dispersed, and spreads out the image of its slit into a spectrum, which is received on the eye by means of an eye-piece, or else on a sensitive plate. Now, the notion that a straight slit is necessary is very prevalent; but a little consideration will show that it is not so. As long as the slit is narrow it does not matter what form it takes. Suppose the slit through which the light is admitted to the spectroscope be of the form given below,



the Frauhoffer lines will range themselves side by side in that form, instead of being vertical, as we are accustomed to see them. Again, if we take a circle, the solar spectrum formed will be ring-shaped, and the only inconvenience that would arise would be that the various circles corresponding to the Fraunhoffer lines would over-lap. If, instead of using the sun as a source of illumination, we use incandescent hydrogen, this annoyance would not occur, for, in the first place, there would be no light background of coloured light, and the rings of the spectrum of hydrogen would come out as bright circles. There are four lines alone that are visible to the eye, though we now know, thanks to the researches of Dr. Vogel, that in the ultra-violet there are other lines. The spectrum of hydrogen seen when the ring is used would be thus—



This diagram shows that there will be no difficulty of recognizing circles so separated as these are. When the sun is eclipsed we have a natural ring of light formed round the moon's disc. This ring of light is made up of a narrow layer of hydrogen with some other matter, and beyond this is the corona; the narrow ring, however, is much more intense than the outer light. If a prism be placed in front of a telescope lens, and the image of this ring be caused to traverse it and fall on a sensitive plate, the hydrogen would give an effect as shown in above fig. Instead of being thin lines, however, they will have an appreciable thickness, and each one will present somewhat the following appearance,



the little protuberances being monochromatic images of the prominences. Such an instrument has been taken out to the eclipse. A prism of 60° of three-inch side is fixed in front of a Lerebour's photographic lens of four inches diameter and twenty-two inch focus, and it is mounted side by side with the camera for taking ordinary photographs of the corona (described in my last article), both of which are attached to an equatorial stand to which an accurate clockwork is attached for following the sun's motion. The camera for this was made by Meagher with his usual ability, and is so arranged that a plate can be placed at an angle of 45° with the axis of the lens. By this arrangement the spectrum will be approximately in focus throughout its whole length. The question arises, what advantage will this have over eye observations? The answer to this is, that it might not have much if usual photographic material were employed, but we hope to secure, or prove the absence of, another ring which lies far in the infra red region of the spectrum. Some recent researches have shown Colonel Festing and myself that certain dark and thick lines in the solar spectrum are in all probability due to a hydro-carbon of the benzene type, while others are probably due to a hydro-carbon of the alcohol type. Matter such as these cannot exist close into the sun, as it would be dissociated. They therefore probably exist beyond the hydrogen ring round the sun already alluded to. A plate which is sensitive to this region of the spectrum will therefore be exposed to this ring spectrum, and to give it any chance of success the exposure will last a minute. The first use of this method for photographic purposes was made by Dr. Schuster, in 1875, in Siam, but the dispersion used was small, a prism of 8° alone being used. With the above arrangement the total length of the spectrum will be 4½ inches before being enlarged. This, then, is a new departure in eclipse work, and if everything goes right it ought to tell us something about the outer layers of the sun's atmosphere. When totality is over, I believe photographs of the cusps of re-appearing sun will be taken with the same object in view; thus more chance than one will be available.

Another piece of apparatus adapted for photographic spectroscopic work is also taken out. It consists of a spectroscope having a slit which can be closed to less than the $\frac{1}{500}$ of an inch; there is a prism of 60° behind the collimator, and then a camera also by Meagher with a lens of eight inches focus. The apertures of the lenses of the collimator and the camera are as large as possible consistent with definition. A heliostat has been taken out which will throw the beam of light from the eclipsed sun on to a lens of three inches diameter, and form an image of the black disc and the

corona on the slit as in the figure, S being the slit. By this means the spectrum of the whole width of the corona will be attempted to be photographed, and if its light be anything at all approaching the former accounts of it, the gelatine plates (which contain iodide to lower the maximum position of sensitiveness) ought to receive a very developable image Some parts of the corona are too feeble to give the eye much information; it is hoped that the photographic plate will supply what is deficient. Experiment has shown that the spectrum of a dark cloud on a dull day is impressed on the plate with the same apparatus in less than a minute with vigour. Such being the case, the corona, at all events in its brighter parts, should offer no difficulty. With the same apparatus it is hoped by a few instantaneous exposures to secure traces of the bright lines which flash out for an instant just before totality. Such is a brief outline of what will probably be attempted. "Cui bono?" will most likely be asked. The direct good may not be apparent, but assuredly, as we advance in knowledge in regard to our life-sustaining orb, so do we get nearer to knowledge which will have a direct bearing on the welfare of the human race. If the 17th inst. may be propitious to the travellers in Egypt, and if photography is as trustworthy there as it is at home, one step in advance will assuredly have been made.

THE PREPARATION OF GELATINE EMULSION WITHOUT WASHING.

BY C. FABRE.*

If iodide, bromide, or chloride of silver be triturated with sulphate of potash or of ammonia in the presence of a small proportion of water, combination ultimately sets in, long crystalline needles of a double salt containing single molecules of each, together with two molecules of water, being the result. The double salt in question is immediately destroyed by a moderate excess of water, as one may readily see by the change of colour which is instantly effected by the action of the fluid, the greenish yellow tint of the granular bromide becoming immediately visible. The bromide thus formed is identical with that which is produced when a solution of bromide of silver in ammonia is precipitated by means of an acid.

As regards the preparation of emulsion, the following particulars may be given. One part of bromide of silver is triturated with two and a-quarter parts of crystallized sulphate of potassium, and when the mass is thoroughly homogeneous, distilled water is added a few drops at a

* *Bulletin de la Société Française de Photographie.*

time, care being taken only to add enough to ensure complete combination, about one-tenth of the weight of the bromide of silver being sufficient in ordinary cases. When the new double salt has set or solidified, a microscopic examination will show that it consists of minute crystalline needles. At this stage an excess of water is added to the contents of the mortar, and when the decomposition is complete, the bromide of silver is washed thoroughly, and incorporated with a solution of gelatine. Any known form of silver bromide will unite with sulphate of potassium, and react as above described. In ordinary cases, 5 grammes of bromide may be added to a solution containing from 3 to 5 grammes of gelatine to 100 grammes of water.

It will be remembered that a somewhat similar reaction between iodide of lead and sulphate of potassium has been discovered by Professor Filhol.

Selenates and chromates react in a somewhat similar manner with haloid salts, but trials with chromates proved unsatisfactory as regards the preparation of emulsion.

THE REPRODUCTION OF MAPS AND PLANS IN THE MILITARY GEOGRAPHICAL INSTITUTE OF VIENNA.

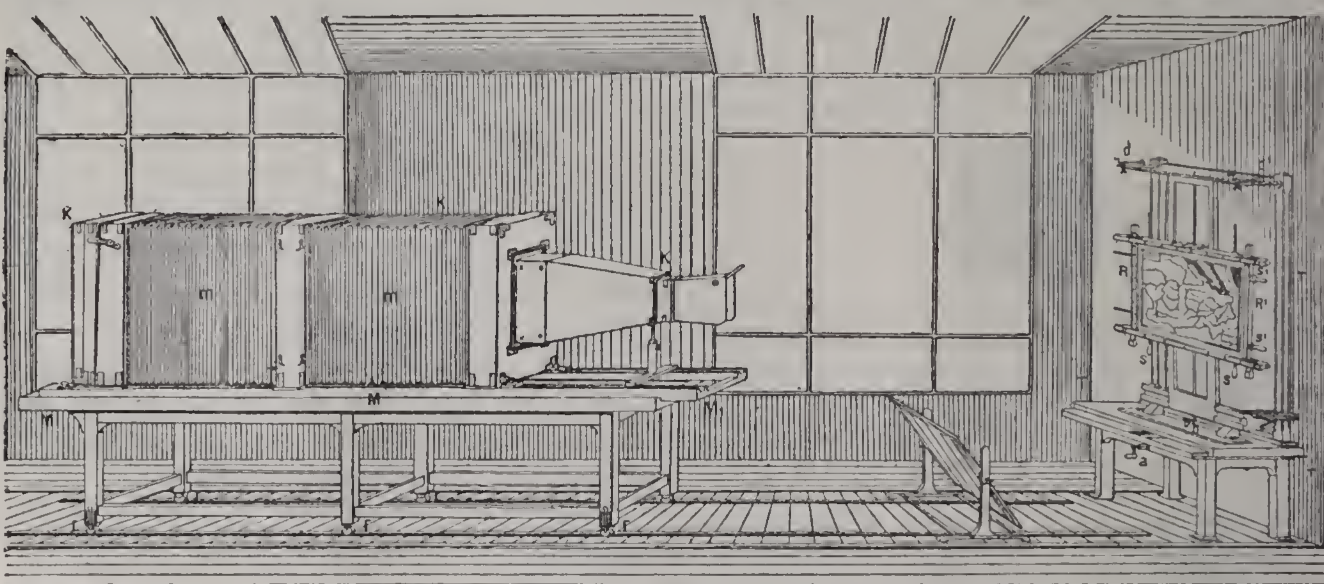
BY MAJOR VOLKMER.

We now lay before our readers an abstract of this comprehensive monograph.

Some decades ago the pantograph was the only instrument of reduction or enlargement in practical use, while copper-plate engraving and lithographic printing were almost exclusively employed for the multiplication of copies.

In the present day a variety of methods are in use for map reproduction, and among these may be specially mentioned photography in its simplest sense, lithography (including the autographic and anastatic process), photo-lithography, engraving on copper, electrotype methods, heliogravure, photo-zincography, and relief or deep etching on zinc. The selection of a process for any particular work depends entirely on the value of the original, and the time or pecuniary means which may be available for the production of copies; but in general it may be stated that important cartographic works, which are likely to possess a value during several generations, should be executed on copper-plates, while stone or zinc may well be rendered available in the case of less important reproductions.

The photographic work incident to map reproduction often presents notable difficulties in actual practice, as it but seldom happens that the original consists of clean and sharp black lines on a ground of satisfactory whiteness; but the production of a satisfactory negative is much facilitated by providing a convenient and well-designed copying camera and supports, so placed as to facilitate the proper lighting of the work; and the accompanying block



BLANSING & SONS. Photo. Process.

represents an arrangement which has been found excellent and well adapted for the rapid reproduction of negatives from originals of varying size. No further description of the engraving than the following reference notes is required:—

K K K. An ordinary camera, with body having two bellows, *m m*.

M M. Table stand for the camera, running on rails, so placed as to ensure absolute and constant parallelism of the sensitive plate with the design to be copied.

R R'. Frame on which the original is stretched equally in all directions by means of the screws, *s s'*.

a b d. Handles for controlling the forward, upward, and lateral motions respectively.

Either orthoscopic or rectilinear lenses are used, and the collodion process is employed in the production of the negatives, while the development is effected with an iron developer containing a considerable proportion of copper sulphate, the following formula being one in general use:

Sulphate of iron	2 parts
Sulphate of copper	1 part
Glacial acetic acid	2 parts
Water	64 ,,

Cyanide of potassium is used for fixing, and after fixation the image is intensified by means of a mixture of the following solution mixed at the time of using with a 1·6 per cent. solution of pyrogallic acid in water:—

Nitrate silver...	17·5 grammes
Water...	262·5 ,,

To this is added—

Nitric acid	35 grammes
Water	262·5 ,,

When the plate has been intensified, it is washed, and treated with a saturated solution of mercuric chloride in water until it is uniformly whitened, and after a renewed washing it is darkened by immersion in a hyposulphite and gold bath—

Sodium hyposulphite... ...	13 grammes
Water	350 ,,

To this add, as required, a little of the following:—

Double chloride of gold and sodium	4·37 grammes
Water	350 ,,

After mixture the solution should remain one or two hours before use, and it may then be preserved for a long time if kept in the dark. The film being then dried, is exposed to light through the glass plate until Vogel's photometer registers about 13 or 15, after which it is soaked for about a quarter of an hour in cold water, then in tepid water until a slight relief becomes visible. If the plate is once more dried, it may, after remoistening, be subjected to a fresh intensification by the method already described. The intensified plate is next flooded with a warm ten per cent. solution of gelatine, and dried horizontally after the excess has been poured off, the borders being then varnished to prevent the film separating from the glass.

Reversed negatives for heliographic processes are made by exposing through the glass plate, the film being turned away from the lens, and are best intensified by the uranium and ferrocyanide method, after which they are gelatinized by the process already described. In some cases, when reversed negatives are required, the films are stripped from the glass, and re-mounted on fresh plates.

Glass positives for etching methods are usually prepared by contact printing on an iodo-chloride emulsion, the image being printed to the full density when the light is good; but in other cases a gallic acid developer is used.

NOTE ON THE PRINCIPLE OF A NEW PHOTOGRAPHIC REVOLVER.

BY M. J. JANSSEN.*

The photographic revolver consists essentially of a rotating sensitive plate, on which are taken the images of some moving object in the successive positions it assumes during the motion. In this instrument the sensitive plate is stopped each time that an image is to be taken, and is moved on again for the purpose of impressing on the neighbouring part, which has not been exposed, the image of the next phase of the movement of the object. Such, in fact, was the arrangement adopted for the original revolver prepared for, and used on the occasion of, the observations of the Transit of Venus in 1874. While complying with this condition of arresting the motion of the plate during its exposure, it is always possible to take a certain number of photographs in the course of a second, and to this extent has M. Marey been successful in his investigation of the phenomena of the flight of birds, which he has recently communicated to the Academy. It will, however, be seen that this condition puts a limit to the number of images that can be taken in a second of time; in fact, that number can scarcely be made to exceed a dozen.

This is due to the excessive difficulty there is in arresting suddenly, and for a very short space of time, a body which is in rapid motion. For example, to obtain with sufficient fidelity a correct representation of the different stages of an insect's flight, a number of successive images must be taken at extremely short intervals, probably not exceeding in length the $\frac{1}{100}$th part a second, and it would be impossible by the arrangement above mentioned to cause a plate alternately to move and stop with such rapidity as this. The results obtained with the revolver, which are so interesting and promise to be so fertile in novel discoveries, would, owing to this circumstance, probably remain inoperative, unless the difficulty of ensuring sufficiently rapid stoppages and motions of the instrument could be surmounted.

It is now some years ago that I first entertained the idea of using the photographic revolver for investigating the conditions of animal movement, and it struck me that it might be possible to take images on a plate in motion. Analysing the question, it will be found that there is a relation, dependent on the degree of delicacy in the image, between the motion which may be impressed on the plate, and the time of the luminous action. M. Marey, having again called my attention to these investigations, I have attempted to obtain an experimental demonstration of this principle, and I have succeeded in carrying it out with images of the sun.

The granulation of the solar surface is well known to be one of the most difficult objects to detect with glasses, and only very recently has it been found possible to reproduce it by photography. To get, therefore, a perfectly reliable proof of the principle in question, I tried to obtain an impression of the granulation on a plate moving with a velocity of from 0·15 to 0·20 metre per second. The success of this experiment fully realised my expectation. I have now the pleasure of submitting to the notice of the members of the Academy a plate on which it will be seen are reproduced two images of the same portion of the sun's surface. One of these images was taken on the plate while it was at rest, the other while it was moving at the rate of about 0·15 metre per second. A comparison of the two images shows that the motion of the plates has not prevented the reproduction of the granulation—that is to say, of one of the most delicate phenomena of astronomical photography. As I desire only to demonstrate the principle, I need not at present enlarge further on this point.

Since the establishment of this fact releases us from the necessity of submitting the movement of this instrument to a series of successive pauses, it will be readily understood that nothing will now limit the number of images which the revolver may be made to furnish in a given time. It will only be necessary to discover the correct relation existing between the degree of detail in the image, the velocity of the sensitive plate, and the duration of the luminous action. In the arrangement which I have contrived, the frame on which the sensitive plate rests, and the shutter with slits, has each a continuous motion of rotation, and it is the magnitude of these movements and the relation between them that determine the rapidity with which the images are successively obtained, as well as the conditions of their formation. From a few simple calculations, I have been for some time certain that it will be easy to get images of any objects in motion, succeeding each other at intervals of $\frac{1}{100}$th of a second, and even less than that.

* Communicated to the *Academie des Sciences* at the meeting of the 3rd of April last.

LANDSCAPE LENSES FOR INSTANTANEOUS PHOTOGRAPHY.

BY G. A. KENYON, M.B.*

It is now twenty years since, wishing to make portraits with a landscape lens, I removed the small stop from the lens mount, and substituted a piece of cardboard with an opening twice the diameter of the original. With a little patience on the part of my sitters I was thus enabled to take portraits on wet collodion plates out of doors without difficulty. With the rapid plates of the present day, of course, results are far more easily attainable.

Last November I called upon Mr. George Smith, and he pointed out to me that landscape lenses such as those sent out with the scenograph camera, fitted with the small stop, gave pictures unnecessarily and, indeed, even disadvantageously sharp; also, which I well knew, that they covered a larger angle than could be profitably employed for portraiture. Further: that if a smaller angle of view only were employed, a very much larger stop could be used without loss of definition, and with great increase of rapidity in action; in fact, that precisely the same aperture of lens, with practically the same definition, and the same angle of view as is afforded by lenses of the rapid rectilinear and rapid symmetrical type when used to the best advantage, is thus attainable, and the only deficiency on the part of the single lens, namely, not giving straight lines correctly, is not appreciable in a small angle of view, and certainly not in portraiture. A scenograph lens of six and five-eighths inches focal length, and aperture enlarged by Mr. Smith to three-quarters in $\frac{f}{9}$, covers perfectly a quarter plate, and gives an image so sharp as to be capable of enlargement to the extent of at least four diameters; and with this lens in bright sunshine I have taken portraits instantaneously.

The other lenses I show are a ten and a-half inch focus lens and a seventeen inches focus lens by Lancaster. With the former aperture about one-tenth of the pictures sent round were

* A communication to the Liverpool Amateur Photographic Association.

taken—those who are accustomed to work with rapid symmetrical or rectilinear lenses will be able to judge how far successfully. A comparatively small angle, such as is thus utilised, is often necessary, and not inconvenient in instantaneous photography; for it is desirable to be at a fair distance from the object photographed for several reasons, and in many cases the object is so distant that unless a tolerably long-focus lens be used the image will be too small.

If instantaneous pictures are to be taken with a wide angle of view, there is nothing for it but to follow Mr. Williams, and look for increased rapidity of plate to work with a portable symmetrical lens. Of course, this lens is easily rapid enough for sea and river views; but for ordinary views and portraiture to be taken instantaneously the utmost amount of focal aperture and the most brilliant light are essential with commercial rapid plates.

The shutter shown with the scenograph lens, made by Mr. George Smith, is on Mr. Noton's principle, and commends itself for its extreme portability.

Correspondence.

DARK-ROOM DISEASE.

SIR,—Permit me to add my evidence of the venomous nature of pyrogallic acid. I am an amateur photographer in a small way, but a sufferer from pyrogallic poisoning in a large way. I am troubled with a patch of exczema on the leg, of many years' standing, and which is sometimes quite unbearable with itching. Last November, when packing up my traps for the winter, I applied with a brush some pyrogallic dissolved in spirit to the skin disease, thinking that the evaporation of the spirit would give me temporary relief, and was so pleased with the result that I continued using the solution until the end of the year. During this time I got completely out of sorts, and was in a low way. On New Year's day I found a rose-coloured patch on my leg just above the skin disease, which also itched, and to which I applied the pyrogallic solution also. During the night inflammation struck in my elbow joint, which had been previously hurt by a fall on the ice-covered street, and from appearances I feared it was erysipelas, and so hurried off to a doctor. He was puzzled with the elbow, and, from the fluid which exuded, he thought that the joint lubricant was escaping.

Becoming suspicious of the pyrogallic, I now discontinued its use, but the doctor had much trouble with the elbow, and during his treatment the arm had an outbreak of pimples large and small. The rose-coloured patch on the leg became very sore meanwhile, and finally a boil formed under it, but from which very little matter was thrown out, and the hole grew larger and larger until there was a very sore ulcer the size of a shilling. This ulcer had its peculiarites, and objected to any sort of treatment beyond being covered with a rag smeared with lard or vaseline. The doctor attended to the elbow, and the leg was left to nature, but neither sore was healed under about six weeks, during which time I slowly became more like my accustomed self. I suppose nature took this time to eliminate the pyrogallol from my system, and to throw out the oxidised blood corpuscles which had accumulated during the time I had applied the pyrogallol. I am about beginning photography again, but I shall be very careful with this compound.—Yours, A SUFFERER.

SIR,—Seeing so many complaints of injury supposed to be caused to photographers by contact with pyrogallic acid, I beg to suggest a simple plan by which such contact may be almost entirely avoided, *i.e.*, by lifting the plates out of the developing-dish by means of a small piece of wood, the end of which is cut into the shape of a wedge, the whole shaped like a chisel. By slipping this under the plate, it may be raised out of the developer without immersing the fingers. The blade of an old penknife would answer the purpose as well. Staining the fingers is also avoided by this method. AN AMATEUR.

DEAR SIR,—Referring to the remarks in your journal as to the injuriousness to health and sight of the deep ruby light with which it is theoretically necessary to work in the dark-room, I enclose you a print from a rapid gelatine negative which was developed by the light of a candle without the intervention of any glass or paper. The candle was, in fact, placed behind a plate-box, and the light reflected from the walls, &c., sufficed for watching the development.

Formerly, I was most careful to procure good ruby glass, always selecting it by the aid of the spectroscope; but now I have found this extreme caution unnecessary, and believe that it is the *direct* rays of light only of which we need be afraid, reflected rays being almost harmless.—Yours truly, WILLIAM J. ALLSUP.

HYDROFLUORIC ACID FOR CLEANING PLATES.

SIR,—Seeing in the NEWS a suggestion of Mr. Plener, that hydrofluoric acid might be used for cleaning glass, I wish to state, for the benefit of your readers, that I have used it for some time, and it answers the purpose exceedingly well if used in a proper state of dilution; the proper and safe proportions are 20 parts of water to 1 of acid. This will also remove metalic oxides and carbonate formed in glass bottles as if by magic, when all other means would be found useless. Hydrofluoric acid is usually kept in gutta-percha bottles; but a glass bottle warmed and coated with paraffin wax will answer the purpose. The acid fumes should be kept away from all other chemicals, and in a place by itself.—Yours truly, J. MOULE.

EXPRESSION OF THE EMOTIONS.

SIR,—I am sure you would wish to give "honour to whom honour is due," and therefore I venture to inform you that at least one of the photographs reproduced in your last issue from Darwin's "Expressions of the Emotions" was not by Rejlander. The "Laughing Child" (No. 4) was by Dr. Wallich, himself a personal friend of Mr. Darwin. It was a portrait of one of his own children, and I still have in my album a print of it, which he gave me himself. In those ante-gelatine days, he was naturally proud of a portrait that evidently had been all but instantaneous. In looking at the original print to make sure before writing, I could not but regret the inability of a woodcut to give any adequate idea of its delicate lines, and of the natural grace of the child's unforced laugh. HENRY GEARY.

THE NEW COPYRIGHT ACT.

DEAR SIR,—I am very surprised that no notice seems to be taken of the proposed Copyright Act, either in your columns, or in those of any other journal that I have seen, in respect to its dealings with photographs and photographers.

As far as I can understand it, it simply means ruin to every photographer in the kingdom, as it prohibits them using any specimen pictures whatsoever without the consent in writing of the person photographed, a thing impossible to obtain; and if you do use one, you have to give it up, negative and all, for the person's own benefit. Why, we should have our places full all day of people demanding their negatives (as I see by Clause 9 that the Act is to be retrospective); we should have to take large quantities of specimen pictures, and pay heavily for doing so; and have to put away all our best work, or else give up the negatives. I consider the proposed clauses so fatal to photography as a business, that I think all photographers ought to band together and present a petition, or get the clauses altered or amended in some way. As they stand at present, they are very unfair and unjust, and far more strict than is required for the due protection of the public.

I do not advocate selling photographs without permission; but as to not being allowed to use them as specimens, I think it monstrous and unjust, as the very person who would not let you show his own or child's picture, is just the one who would want to see a large number of specimens.

Hoping to see this matter taken up with spirit and energy, I remain, yours faithfully, ED. W. H. COX.

[All the clauses bearing either directly or indirectly on photography were reproduced in our issue of April 21st last.—ED. P. N.]

SMALL STOPS.

SIR,—In Mr. Addenbrooke's paper on a new instantaneous shutter, printed in your last, a doctrine is broached new to me, and which I venture to think erroneous, on the use of small stops. He says (p. 236), "By using small stops we greatly increase the proportionate difference between the amount of light which falls on the central and marginal portions of the picture."

Three causes of this difference are well known, which are independent of the size of the stop. First, the distance from stop to plate increases with the obliquity of the pencils, as they approach the margin of a picture. Secondly, the stop which is circular to the direct pencil, presents an elliptic aperture to oblique ones; its major axis being the diameter of the stop, while its minor axis diminishes with the increasing obliquity, thus reducing the effective area. Thirdly, the loss of light by reflection from the surfaces of the lenses increases also with the obliquity of incidence. This difference is minimised with ordinary doublets, but of more importance when the back combinations are on the Petzval principle. I assume, of course, that the stops are properly made, their inner edge having no appreciable thickness. There is also a fourth difference, where the full aperture is used, or a stop so large in proportion to the diameter of the lens that the margins of the plate are only illuminated by partial pencils. But this fault is cured, not aggravated, by using a small stop. I must confess my ignorance of any reason which will support the new doctrine. If not merely a misconception, I trust Mr. Addenbrooke will favour your readers with an explanation of his theory.

While on the subject of small stops, permit me to add a few words on what I venture to think an error, long more or less pervalent—that the physical effect of diffraction is practically injurious to definition, even with stops no smaller than any usually supplied.

Our knowledge of this injurious effect is obtained from astronomical observation. It is found practically that one inch is the smallest aperture which will separate double stars 5″ apart, with any magnifying power; while to divide stars only one 1″ apart requires 5 inches. Thus a stop $\frac{1}{10}$ inch diameter would not divide more closely than 50″. But it must be remembered that with points of intense light seen on a black ground, this error is at its maximum. In circumstances more resembling an ordinary photographic image, it is much less sensibly injurious. To derive a formula for photographic use would be easy, had we an accepted coefficient of satisfactory definition. For my own part, theory and practice alike lead me to the conclusion that if we can keep out stray light from the camera, secure it from tremor, and have time for adequate exposure, we need not fear diffraction, even with far smaller stops than those commonly supplied. I should place the practical limit at about $\frac{1}{200}$ of the focal length. With a lens of 20 inches focus, and a stop of $\frac{1}{10}$ inch, the limit of diffraction ($=50''$ with $r=20$ inches) would be $\frac{1}{200}$ of an inch. It should be remembered that if any part of the image is sharp, diffraction can have done no harm. On the other hand, a blurring of the whole image may be caused by tremor.—I am, sir, yours truly, W. S. WHEELER.

Proceedings of Societies.

CAMBRIDGE UNIVERSITY PHOTOGRAPHIC SOCIETY.

THIS Society, which was formed last term, held its first meeting this term in Mr. Scott's rooms, Trinity College, on April 28th.

The SECRETARY made a statement of the accounts, and also informed the Society what had been done in the way of fitting up the necessary dark rooms, &c., in connection with the studio.

Mr. SCOTT, the President of the Society, then read a very interesting paper on the discovery and progress of photography. The Society's premises (26, Park Street) are expected to be in working order this week, and to be found very convenient for all its members.

The officers for the term are—

President—M. Scott, M.A. (Trinity).
Vice-President—W. S. Frost (Caius).
Secretary and Treasurer—F. S. Willie (Pembroke).
Committee—Brogden, Downing, J. S. Cox Downing, F. W. Hilliard (Jesus), M. Miley (Trinity).

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE last general meeting of the session was held on Thursday, the 27th prox., in the Religious Institution Rooms, Mr. JOHN URIE in the chair.

The minutes of last meeting were read and approved of, after which the election of office-bearers for the ensuing session took place, resulting as follows:—

President—Mr. John Parker.
Vice-President—Messrs. Robertson and A. Mactear.
Treasurer—Mr. Geo. Bell. *Secretary*—Mr. W. Craig Ramsay.
Assistant Secretary—Mr. John Y. McLellan.
Council—Messrs. Skinner, Paton, Reid, Moran, Urie, and Dodd.

It was then decided that the next out-door meeting should be held on the 19th inst. at Finnech Glen.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting of this Association was held at the Free Library, on Thursday evening, the 27th ult., Mr. E. ROBERTS, President, in the chair.

The minutes of the March meeting having been read and confirmed, Messrs. P. W. Baker and T. Crooks were elected members of the Association.

The HON. SECRETARY presented his report of the Society's excursion on April 19th. The first party of members met at the "Oak," at Bettws-y-Coed, on the 18th ult., and, on the following morning, in spite of difficulties of wind and weather, were early afield at Pandy Mill and Lledr Bridge. The noon train brought a further addition to the party, and a pleasant drive to Dolgarrog followed. The falls were certainly exceedingly fine, but they are so shut in by big trees that a good picture of them proved to be an impossibility. After several negatives had been secured the drive was continued to Tal-y-Cafn Ferry, where Mr. Bruce took an instantaneous picture of the party in the boat.

The CHAIRMAN called the attention of the members present to the apparatus book—a useful institution at the meetings which had fallen into disuse of late.

The Rev. H. J. PALMER passed round some negatives taken in Enloe Glen, near Hawarden, and offered to pilot thither any of the members who desired a short excursion to good and accessible subjects.

Dr. KENYON read a paper on "Landscape Lenses for Instantaneous Photography" (see page 253).

Mr. T. W. BRUCE complained of flare and blurring from a landscape lens he had used.

Mr. W. H. WILSON said that the want of coincidence between chemical and optical foci was an evil to which landscape lenses were specially subject.

Dr. KENYON had obtained no better results with rapid symmetrical doublets of large size and aperture than with the single landscape lenses before the meeting.

Mr. H. N. ATKINS exhibited a home-made instantaneous shutter of simplest construction, which could be adjusted to any length of exposure—from a fraction of a second upwards.

Mr. W. H. KIRKBY showed a photograph taken with his shutter from a train in motion at the rate of fifteen miles an hour. The picture was a seascape, and the ripple of the waves was well defined.

Mr. A. K. BEAN exhibited some prints presented to the Society's album by Mr. J. Meyer.

Mr. J. H. T. Ellerbeck passed round a gelatine negative, of which a portion had received very decided intensification by being accidentally placed near a fire before desiccation had been completed.

Mr. H. Houlgrave showed a print from a negative, taken and developed in Ceylon, on an emulsion which had been made in the island.

Mr. J. H. Day exhibited a shutter made in wood, on the principle of the Rev. H. J. Palmer's cardboard exposer.

The Rev. H. J. Palmer gave a demonstration of the intensification of a gelatine negative. The plate in question was cut into four parts—one portion being treated with Moryson's intensifier, a second with Houlgrave's silver method, and a third with Edwards' mercury intensifier. It was thought that the Moryson portion was the most successful. Not only was the density of a very weak negative rendered satisfactory, but a slight fog which was noticeable on the original negative was cleared off in the operation of intensifying.

Mr. Blanchard exhibited a picture taken in Old Calabar, but developed and printed in England.

Mr. E. Phipps asked if anyone present could report on the advantage or disadvantage of sulphite of soda in the developer.

The Chairman said he he had used it with considerable success. Mr. Kirkby also gave his verdict in its favour.

Messrs. Bruce, Gorst, and Palmer exhibited a number of negatives and prints taken at Bettws and Dolgarrog at the last excursion.

Mr. Kirkby showed a very perfect instantaneous picture of a hen and chickens; Mr. Ellerbeck some fine prints from negatives taken at the lakes; and the Rev. H. J. Palmer some good 9 by 7 prints from negatives of Dolgelly, and some pictures printed by the Autotype Company from negatives of Swiss subjects.

The Chairman anounced that Tuesday next, the 9th inst., would be the last of Mr. Ellerbeck's "at homes" for the present.

A vote of thanks to Dr. Kenyon was carried unanimously, and the meeting adjourned to the last Thursday in May.

Bolton Photographic Society.

An extra-ordinary meeting of this Society was held on Thursday, 20th April, Mr. R. Harwood in the chair.

After the minutes of committee meetings with reference to recent open meeting had been passed, and Treasurer's statement of expenses had been passed, Mr. J. H. Wright was elected a member of the Society.

On the motion of the Hon. Secretary, it was resolved to hold the open meeting annually, about March or April.

It was also resolved that the best thanks of the Society be tendered to Mr. Perry and his glee party, for their services, it being remarked "that their performances enhanced the pleasures of the evening very much."

The Hon. Secretary read a letter from Mr. Carvalho, of N.Y., referring to the formation of an International Society. It was proposed that this be laid on the table until information be obtained.

Talk in the Studio.

Photographic Society of Great Britain.—The next meeting of this Society will take place on Tuesday next, May 9th, at 8 p.m., in the Gallery, 5A, Pall Mall East, when a paper will be read by Captain Abney, R.E., F.R.S. Some tents will be shown for developing any plates in, and methods of artificial light for developing shown and discussed.

Cantor Lectures.—Mr. J. Comyns Carr will deliver the last Course of Cantor Lectures for the present session at the Society of Arts, on Mondays, May 8, 15, and 22, the subject being "Book Illustration, Old and New." In the first lecture Mr. Carr will treat of the proper relations of printed text and illustrated design, and of the history of early wood engraving. The second lecture will be devoted to the consideration of the various modes of book illustration, and the modern development of wood engraving. Modern processes of illustration, and the influeuce of photography upon the art, will be considered in the last lecture.

A Photographers' Ball.—On Thursday, the 27th instant, a ball was held at Seyd's Hotel, Finsbury Square, about 100 persons being present. An agreeable evening was passed, but the cordial cheerfulness which characterised a similar assembly held last year under the auspices of the Photographic Club was absent—a circumstance which may have partly arisen from the fact that many of those present were strange to each other, as only a few of those gentlemen who are regularly seen at the ordinary photographic meetings attended. Numerous songs were sung, and one of Mr. Cobb's characteristic topical effusions was received with a genuine expression of approval. It is understood that any profits which may result will be handed over to the Photographers' Benevolent Association.

A Non-Electric Incandescent Lamp.—A new incandescent lamp has been recently invented by Dr. Regnard, and is suitable for projections where electricity or limelight cannot be had, as well as for other purposes. In it a mixture of air and petroleum vapour is burnt on a piece of platinum net, which is thus raised to a white heat. The lamp consists of a Bunsen burner, the mouth of which is closed by a small cage of platinum wire. The burner is connected below by means of caoutchouc tubing with a stoppered jar holding petroleum; the stopper supports a longer and a shorter glass tube, the former dipping in the liquid, and being connected with bellows or other blowing apparatus; the other connected with the lamp. With a continuous air-current, several of the lamps may be kept in action at once, to light halls, &c., and the aspect resembles that of a Swan lamp.

Violent Hailstorm.—The severe hail and thunderstorm which broke over Hereford and the district on Wednesday afternoon has done much damage to several photographic studios, and we receive similar accounts from Wolverhampton. The German system of insurance against hail is not urgently required in this country, as severe storms are not nearly so frequent in our island as in Germany; but, considering that a small premium only would be required to cover the risk, it might be desirable for some such system to be introduced here.

To Correspondents.

*** Mr. Plener's Method of Isolating the Sensitive Constituent of Emulsion.—We have received a letter from Captain Abney in which he is good enough to give some interesting details of Mr. Plener's method as seen by him at the house of a mutual friend, in whose hands Mr. Plener had placed one of his apparatus. Captain Abney does not appear to gather from our leader of last week that we had repeatedly seen Mr. Plener's process carried out, and that we delayed the publication of the method at Mr. Plener's request, as the publication of a process prior to the application for certain foreign patents may render these of doubtful validity. We must therefore allow Captain Abney's interesting communication to stand over for a short time.

P. D. R.—It is probable that you might hear of what you require through the medium of an advertisement.

Chemical.—1. A rinse in the benzoline used for lighting purposes will be found useful as a finish after the turpentine. 2. The paper should be sized with a weak and warm solution of gelatine in order to prevent the penetration of the oil mediums. 3. There is no book which comprehends them all, but a moderate acquaintance with chemistry would render such a work unnecessary.

Beta.—1. Yes, if kept clean. 2. We do not know if any are in the market; but if prepared according to Dr. Eder's directions no difficulty is likely to arise. 3. You might try Dr. Vogel's emulsion, which is, we believe, obtainable from Messrs. Rouch and Co. 4. Probably before long.

A. F.—It should doubtless read thus:—4 parts chloride of potassium, 1 part chloride of cadmium, 240 parts of water.

I. A. N.—You will find it decidedly better to purchase the higher priced article in this case; as when a second-rate objective is used every picture suffers, and you can never rise above the limit imposed on you by the quality of your lens. Another matter is that instruments by the best makers always have a certain second-hand value, perhaps a trifle over half the original cost.

X. Y. Z.—Prussian blue as prepared for the use of water colour painters is the best material. You will require a sable brush of good quality, so that the tip can be worked up to a fine point.

Alpha.—See Notes in Photographic News of Nov. 18 last.

T. L. M. C.—The proportions are quite right; but the weak solution of hyposulphite is best used fresh.

Henry Turner.—1. The Autotype Manual will probably answer your purpose very well. 2. With a small stop it will answer fairly well, provided you can place the camera a fair distance from the objects, and in this case you should work on a plate one size smaller than the lens is supposed to cover.

Charles Belton.—The picture was exhibited the year before last, and we believe that a considerable number of copies were sold, 2. The address as you have it is correct.

M. T. M.—Although it contains a large proportion of sulphur, there is no danger as long the surface is good and uncorroded.

THE PHOTOGRAPHIC NEWS.

Vol. XXVI. No. 1236.—*May* 12, 1882.

CONTENTS.

MR. PLENER'S METHOD OF ISOLATING THE SENSITIVE CONSTITUENT OF GELATINO-BROMIDE EMULSION.

A fortnight ago we intimated to our readers that Mr. Plener had, by a remarkable and rapidly executed mechanical process, succeeded in isolating the sensitive constituent of gelatino-bromide emulsion, and we are now in a position to give detailed particulars.

A strong circular metal bottle, having a flat bottom, and sides which gradually slope inwards towards the centre, where they merge into a neck, is fixed on a vertical spindle which can be rotated with enormous velocity. Under these circumstances, any emulsion which may be contained in the rotating vessel rapidly becomes separated mechanically, the solid particles being driven to the extreme outer edge of the centrifugal separator, where they agglomerate into a tolerably compact mass, which may, in its turn, be broken up and washed several times with water or other fluid, the separation being each time effected by the same method.

The centrifugal tendencies of rapidly rotating bodies have proved of great value in many industrial operations, and our readers are doubtless aware that crystals of sugar are separated from the syrup in which they are formed by rapid rotation in a cage of wire work; the crystals being retained, while the syrup is driven through the meshes of the wire-work. The centrifugal machine, or hydro-extractor, is also largely used for partially drying various other chemical products, and also textile fabrics; while the process of manufacturing crown glass is a further illustration of the principle. Assuming Mr. Plener's centrifugal separator to be one foot in diameter, the speed of revolution required in ordinary cases would be no less than 4,000 revolutions per second, while in the case of a vessel eight inches across it would be necessary to increase the rate to 6,000. It is scarcely necessary to remark that continued rotation at such a velocity necessitates the highest quality of work as regards the mandril and bearings; while the tendency of the heavy metal vessel to fly to pieces becomes so considerable under the enormous centrifugal force developed, that any unequal disposition of the weight must be most carefully avoided. The most important aspect of Mr. Plener's process is that it enables one to put fresh and undeteriorated gelatine in the place of that which has been partially decomposed by heat or other agencies, the tendency to green fog and frilling being therefore practically eliminated; it is also likely to prove very valuable as allowing the sensitive compound to be prepared on a manufacturing scale, so that the process of emulsion making may be simplified and made more certain for amateurs and plate makers.

We subjoin Mr. Plener's final specification, and hope before long to return to the subject.

My invention consists substantially of the following particulars:—

According to the first part of my invention, given an emulsion of chloride, iodide, or bromide of silver prepared in the usual way with gelatine, gum, or any colloidal body, or any mixture of some of these emulsions, I operate upon some preferably just after it has been made sensitive by any known means, and before any further operation has been proceeded with, I melt this emulsion by heating, if it is set, and place it in a metallic vessel, preferably having the form of a truncated cone (although the shape may be different), silver-plated inside, which I make to rotate with the speed of about four thousand revolutions per minute, if the vessel is one foot in diameter; but should the diameter be larger, then the number of revolutions must be in inverse ratio of the diameter. During the rotation of the vessel I heat it with a flame of gas or a lamp to prevent setting of emulsion, should it have a tendency to it. By the effect of centrifugal force the heavy salts are driven to and deposited on the circumference of the bottom of the vessel, and in about ten minutes the separation of powder and liquid is effected. The time varies with the quantity and the state of decomposition of gelatine in the emulsion, also with the size of the grains of silver salts. I then slowly stop the rotation, draw out the solution by means of a syphon, pour into the vessel some warm water, and with a brush mix the powder with water, make the vessel rotate again, and so on. I repeat this operation till all traces of gelatine and soluble salts are eliminated. The remaining powder of sensitive silver salts to make emulsion of I mix with fresh gelatine, collodion, or any substance destined to serve as vehicle for it in subsequent operations. To prepare the collodion emulsion I mix well the powder isolated from gelatine with about half of its weight of glycerine, and emulsify the mixture in a large quantity of alcohol, allow the powder to settle, pour off the supernatant liquid, repeat the operation with fresh quantity of alcohol, and the dry powder so obtained I mix with plain collodion.

According to the second part of my invention, if the emulsion to be worked upon gives through over-boiling or over-digesting foggy plates, then I proceed thus:—I place it in the said vessel and cause the latter to rotate for (say) about fifteen minutes, at a speed of between two and three thousand revolutions per minute, more or less. In this case only the largest grains of silver salts, those which are more sensitive to developer than to the light, and which produce fog, are deposited as before described. Having stopped the vessel I draw out the emulsion, which I treat afterwards as described in the first part of this specification.

According to third part of my invention, in cases where the sensitiveness of the washed emulsion is insufficient, be it through faulty preparation or action upon it by some oxidising solutions known in photography as fog destroyers, then I add about five grains of ammonium bromide to each ounce of emulsion, and digest or boil it in the usual way, till the desired degree of sensitiveness is reached. After this I treat it as described in the first part of this specification.

Having now particularly described and ascertained the nature and object of the said invention, and in what manner the same is to be performed or put in practice, I hereby declare that I claim the invention of improvements in the preparation of photographic emulsions, wherein the following are particular and important points or features :—

1. The application of centrifugal force for the isolation of silver salts from an emulsion as described in the first part of this specification.

2. The application of the same force for the division of an emulsion into several parts, according to the different size of the grains of silver salts as described in the second part of this specification.

3. The emulsion may be made to contain during the boiling or digesting unlimited quantity of water and gelatine, and thus is obtained the fine granular state of the silver salts in emulsion.

4. By eliminating the decomposed gelatine, and replacing it by fresh gelatine, all the defects in dry plates caused by the decomposition of gelatine, viz., frilling, weakness of images, &c., are got rid of.

5. The silver salts eliminated from emulsion so as not to be liable to change under long keeping, whereby the storing of same, and mixing up in great quantity, become possible, and thus uniformity of dry plates may be secured.

6. When the emulsion gives foggy plates, the same may be restored to good quality, as described in the second part of this specification.

7. To increase the sensitiveness by boiling or digesting, which may be repeated as described in the third part of this specification.

8. The silver salts once isolated from gelatine, so as to serve for the preparation of collodion emulsion, as described in the first part of this specification.

In witness whereof I, the said Joseph Plener, have hereunto set my hand and seal, this fifth day of May, in the year of our Lord one thousand eight hundred and eighty-two,

(Signed) Joseph Plener.

A NEW METHOD OF PREPARING IODIDE AND BROMIDE EMULSION.

In a recent number of the *Archiv*, Dr. Liesegang makes some interesting remarks upon the preparation of a sensitive emulsion in the old-fashioned manner with collodion, and he points out how a similar proceeding may be applied to the modern gelatine process. He says :—Eighteen years ago I referred to the circumstance that a collodion capable of being used without a silver bath might be prepared by mixing a plain collodion with a saturated solution of iodide of potassium, in which as much iodide of silver had been dissolved as the liquid was capable of taking up. Under these circumstances, the collodion becomes milky or turbid, and it is scarcely necessary to remark that plates coated with it must be soaked in water, to remove the alkaline iodide ; and the use of a tannin preservative was recommended. The above-described process may be very much simplified by the modern proceeding of precipitation of the emulsion with water, and re-solution in a mixture of alcohol and ether, the following details being recommended to the notice of those who desire to try the process practically.

The ordinary iodizing solution for a litre of collodion, as ordinarily employed for the wet process, is precipitated with a moderate excess of aqueous silver nitrate solution, and the mixed iodide and bromide of silver is thoroughly washed by decantation, the last wash water being poured off as completely as possible. Powdered iodide of lithium is then added, with constant stirring, until the precipitate dissolves ; when the solution is mixed with a litre of plain collodion, or, rather, half a litre of collodion made up with a double quantity of pyroxyline ; as by this latter modification the amount of alcohol and ether wasted is reduced to one-half. Contrary to expectation, the collodion remains clear ; but the next step, which consists in pouring it into a considerable excess of water with constant stirring, serves to precipitate all solid constituents, except the soluble iodide of lithium. After the precipitate of the flocculent matter has been thoroughly washed and dried, it is dissolved in a mixture of half a litre of alcohol and half a litre of ether ; the resulting emulsion being used in the ordinary way, and ferrous oxalate being well adapted for development. The pictures may be easily intensified, after fixation, with the usual pyrogallic acid and silver intensifier.

Gelatino-bromide emulsion may be prepared in a similar manner, the details being as follows :—Twenty grammes of bromide of potassium and twenty-eight grammes of silver nitrate are separately dissolved in water and mixed. After thorough washing, the last water is poured off until 140 cubic centimetres remain, and then eighty grammes of powdered bromide of potassium is added. When the whole has dissolved, 28 grammes of gelatine is soaked in the liquid until well softened, after which the heat of a water-bath is applied. A clear gelatino-bromide mixture is obtained ; but, when it is washed in the usual way, it becomes milky ; and, after being once more melted, it is ready for use.

A PHOTOGRAPHIC LAWSUIT IN FRANCE.

The French legal organ "La Loi" of the 4th instant gives the decision of the Tribunal of the Seine as to an alleged infraction of Pellet's Cyanofer Patent by M. Ad. Joltrain, who recently patented and worked commercially a process in which a mixture of ferric salts and gum formed the sensitive material, as is the case of Pellet's method. A second indictment was made against the defendant, namely, that of perfidious competition (concurrence déroyale), an offence unknown in English law courts.

It appears that Miss Joltrain, a sister of the defendant, was the proprietor of the business founded for the commercial working of Pellet's process, and that the defendant had acted as her manager or as director of the factory. Not long ago the business of Miss Joltrain was removed to fresh premises, and the defendant, who left her service about this time, took the original works, engaged some of the old hands, and commenced the manufacture of the prepared paper which formed the subject of this action ; the new business being also carried on under the name of Joltrain.

It is impossible to look over the evidence and the pleadings without being struck by the greater facility which is afforded in France for arriving at a conclusion in such a case ; and the finding of the Court is in reality a complete history or abstract of the case. The judgment enters minutely into the photographic principles involved in most copying processes of an analogous nature, points out that the method patented by Joltrain is essentially identical with that of Pellet, and briefly reviews the earliest contact printing methods, at the same time pointing out in what respects Pellet's method differs from them. The defendant is then ordered to pay to his sister compensation for the losses occasioned by his infringement ; and the confiscation of all appliances used by him in his manufacturing operations is decreed. The defendant was also ordered to pay for advertising the decision in three journals to be chosen by Miss Joltrain ; but the accusation of perfidious competition was not considered to be sufficiently proved, as there was no evidence that the defendant had personally endeavoured to do business with the plaintiff's customers.

At Home.

MR. J. E. MAYALL'S ELECTRIC STUDIO IN BOND STREET.

Electric studios are increasing apace. London now counts four such studios, if we include that of Messrs. Negretti and Zambra at the Crystal Palace, while in Paris, St. Petersburgh, Brussels, and Vienna, studios lighted by electricity are to be found. It is a sign of the times none should fail to note, and he would be a bold man indeed who expressed an opinion against the likelihood of electric studios not becoming general in a year or two. If we are to have electric lighting everywhere in our houses, instead of gas-jets, as seems pretty certain, then photographic studios incapable of illumination by electricity will certainly be the exception, and not the rule. Mr. Van der Weyde, as everybody knows, was the first to show how well electricity could be used for lighting the sitter, and it is only just and fair to state that the simple arrangements he contrived some six years ago, are now, with some slight modification, universally adopted.

Mr. Mayall's fine studio in Bond Street marks a new departure in many ways, and may be taken as a model of what we may expect, in the future, a first-class photographic studio to be. That neither expense nor trouble have been spared in its installation and decoration is to say but little; and when we add that only a few months ago the studio was fitted for the taking of daylight portraits, with reception rooms on the upper floors, not far removed from the glass-rooms on the roof, all of which arrangements are now thrown out of gear and demolished, to make way for the new order of things, the costliness of the undertaking may well be imagined. The well-lighted glass-rooms have been given over to artists and retouchers, and the handsome drawing room on the first floor, its decorations hardly complete, has been dismantled and cut up into laboratories.

Mr. Mayall's studio now occupies the whole building in Bond Street from floor to basement, the premises previously occupied by Messrs. Ross and Co., the well-known opticians, serving as a handsome bureau. Mr. Mayall takes portraits by electricity, and by electricity alone, for his experiments at once proved how suitable was this artificial illumination for the purpose. He has taken the cabinet portrait as his standard picture. and so thoroughly effective is his lighting, that the pose rarely exceeds three or four seconds. But he does not confine himself to cabinet pictures. Here are groups and figures larger than any we have yet seen produced in an electric studio. This group picture of Mr. and Mrs. Kendal, both at full length, measures twelve inches by eight, and whether for softness or brilliancy, is not to be surpassed. Really, until we actually pay a visit to the electric studios, and find no other locale available for portrait taking in the building, we have our doubts whether so large a surface can be equally and harmoniously lighted for camera work by the electric light, as this and other pictures prove to be. Here is a large head—four inch—of Dean Bradley, taken direct by the electric light, to show another phase of the process, and here theatrical scenes from "The Lights o' London," "The Squire," &c. So that electric photography is no longer in its infancy, but has been tried in well-nigh every branch of the art already.

Before leaving the bureau—in which, by the way, we notice the first medal given in this country for portraits by electricity, awarded to Mr. Mayall at the Exhibition of the Brighton Health Congress—we enquire the terms of the new studio. For cabinet pictures, the charge is three guineas a dozen enamelled, or, if unenamelled, two guineas, while cartes-de-visite are a guinea and a half and one guinea respectively. The glazing is most exquisitely done, reminding one of the best Russian work, and it would be impossible to give higher praise. There is glazing and glazing, as all photographers know, and it is only when the translucent surface is highly brilliant and perfectly colourless, that all trace of vulgarity disappears.

We proceed to the studios in company with Mr. Mayall's amiable manager, M. Rémandas. We have not far to go. In fact, by simply crossing the bureau or reception room, and without ascending a single stair, we arrive at our first destination. Our guide opens a mirrored door, and we step in. "This is our invalid studio," M. Rémandas remarks. It is a small apartment, not seventeen feet long, we should think, with sombre walls and without any direct daylight at all. There is no pretence about the electric light helping to eke out the daylight here; what light is employed must come from the umbrella-like apparatus that is swinging aloft. This umbrella is the reflector; it is lined on the inside with white glazed paper, and measures, perhaps, four feet across, or a little more. Where the handle of the umbrella would be, if it were a rain-defier, is a four-inch metal cup—not a semi-transparent saucer—and in this cup the carbon points are brought together to produce the light. The cup has a two-fold object; it prevents fragments of hot carbon falling, and it does not permit the sitter to see the carbon points at all, and saves him all inconvenience of glare.

Mr. Mayall makes use of very powerful illumination. The light of his electric arc is equal to no less than 12,000 candles, and it may be worthy of note that the gas engine in the basement employed to develop sufficient force to grind out this amount of electricity from the magneto-electric machine moves with so little vibration that one has no idea of its existence. A delicate violet tint suffuses itself over the interior of the reflector during the illumination, and makes it appear as if coloured paper, and not white, is being employed for reflection. This effect, we cannot help thinking, subdues in a measure the light to the eyes of the sitter.

We proceed to the first floor—up a circular staircase handsomely decorated in Japanese style of art—to a second studio. This also is nothing more than an ordinary room, except that it is a very sombre one. This apartment is pretty long, but probably not more than ten feet wide; its narrowness gives the idea that it has been sought to keep the light concentrated by confining it. M. Rémandas proposes we shall go through the ordeal of having a portrait taken, that we may be the better able to judge of the lighting. To this we readily consent—for the sake of our readers. Some white screens, made simply of white paper, are employed for reflecting the light, which is cast from the umbrella apparatus, this being suspended to the right and in front of the sitter. This primary reflector, as we have said, swings from the ceiling, and an assistant taking it in his hand can move it about, heighten or lower it, as he pleases. Thus, it is not rigidly fixed during the exposure, and all hard shadows are avoided. At the time of exposure, the reflector is probably about three feet above the sitter's head and two yards off; on his left, also somewhat to his front, is placed the principal paper screen.

In our own case, an exposure of but three seconds was given for a cabinet bust portrait. "We like to over-expose slightly," says M. Rémandas, "as thereby we obtain softness and delicacy to a degree, while to strengthen our negative I use tannic acid and silver, the details of which I will give you presently." We enquired if gelatine plates of his own make were being used. "Oh, no; the plates of all makers in the market have answered our purpose very well; this present one is a Paget."

The posing and exposing is very quickly over, for the simple reason that the work is admirably subdivided. One assistant attends to the reflector, and another to the focussing of the image and to the introduction of the plate, so that M. Rémandas can give his whole attention to posing and judging the effect of lighting; beyond that, he simply takes off the cap and replaces it. The light of the room is so subdued behind the camera, that there is no need of a cloth either to focus or to cover up the dark slide.

We make a journey to the top of the house, where, by reason of the new arrangements, artists and retouchers may revel in plenty of light. Some magnificent carbon enlargements—from negatives taken by the electric light—are here in course of finishing; as enlargements err usually in being a little too vigorous and hard, the exquisitely soft electric negatives are found to be decidedly advantageous in amplifying. For retouching the film, a little "medium" is used, and a finely pointed HB pencil.

Finally, we pay a visit to the basement to make a call upon the electric engineer, and to visit some dark-rooms which M. Rémaudas has just constructed. It is not until one reaches the basement and sees the energetic little engine spinning round, that its presence is revealed, and even here there is no vibration of any moment. Farther on in these cool cellar-like quarters are the laboratories, which could not be more advantageously located. We enter one of the little rooms; it is light enough now, for daylight enters through a hole a foot square, that looks into the passage. By simply bringing across a frame glazed with ruby glass —the rabbett of which is inside the dark room—every ray of white light is at once shut off. There is no artificial light inside the room to heat it and fill it with noxious vapour; if a lamp is necessary, this is at once provided by a gas bracket outside the window, and when ruby light is no longer imperative, the window is slipped on one side, and the flaming gas bracket pulled within, if its presence in the room is desirable. A more simple and effective plan of illuminating a dark room could not be devised.

The formula for strengthening gelatine negatives in use in Mr. Mayall's studio is as follows:—

Solution A.—Tannic acid...	... ...	2 drams
Water	... ...	10 ounces
Solution B.—Nitrate of silver	... ...	15 grains
Water	... ...	1 ounce

A few drops of the tannic acid solution are mixed with the silver and applied to the fixed, washed, and alumed plate.

The "By-the-Bye" next week will be "Paris and the Salon."

FRENCH CORRESPONDENCE.

PRINTING IN HALF-TONES WITH BITUMEN OF JUDÆA—PHOTOGRAPHIC REVOLVER—REMEDY FOR DISCOLOURATION OF NEGATIVES DEVELOPED BY PYROGALLIC—ACCIDENTS AND DISEASES TO WHICH PHOTOGRAPHERS ARE LIABLE—COMMITTEE FOR THE POITEVIN MONUMENT.

Application of the Process of Printing in Half-tones with Bitumen of Judæa.—In my last letter I described Captain Biny's interesting process for taking a positive in bitumen, in which the modelling was absolutely perfect, and similar in effect to that obtained with salts of silver, so far, at least, as the printing and continuity of the half-tones are concerned. At the meeting of the Photographic Society of France I had the opportunity of exhibiting a whole series of these remarkable prints. It stands to reason that if, instead of using a negative, we were to start with a positive in gelatino-bromide, we should have a negative counter-proof in bitumen of Judæa. At first, no doubt, it is difficult to appreciate all the applications of which this new process is capable, and at the meeting in question several persons who happened to be standing near me were asking what could be done with prints in bitumen. I do not pretend to be able to give precise information on this subject, but I think I could point out several important methods in which the process might be advantageously utilised. It is well known that bitumen of Judæa has a much greater power of resistance to the action of acids than any of the bichromatised mucilages (such as gelatine and albumen) after being acted on by light; it is for this reason that bitumen holds a high place among the substances used in chemical photo-engraving. But up to the present, prints in which bitumen forms the protecting agent against the etching liquid can only be used in copying subjects in line or hatching; it remains, therefore, to be seen whether we cannot improve photo-typography by the employment of plates in bitumen in which the images are expressed in half-tones. I have full hope that this may ultimately be the case. The image in bitumen would be the result of direct transformation, either from a negative or from a positive on collodion (not in gelatine), according to circumstances, and previous to flowing the collodion over the plate the latter should be coated with some insulating substance, such as tallow or one of the resins. When the transformation is quite complete, the film of collodion supporting the image in bitumen above the glass plate should be removed, and the transfer to the zinc or copper plate should be effected by heating the latter sufficiently to soften the layer of bitumen, and cause it to adhere completely. After this has been done, the collodion pellicle should be destroyed in the same way as this is effected in the process of photographic enamels, by dipping it in a mixture of equal parts of alcohol and ether; and finally the plate should be exposed to the action of dilute acid, which would penetrate the bitumen in proportion to the depth of tone—that is to say, not at all in the thick parts, and, in the other parts, more or less in proportion to the thicknesses of the bitumen. There appears to be no reason why a slight resinous grain should not be impressed on the print to be transformed before printing on the layer of bitumen, and the result would be a regular granulation, which would have scarcely any injurious consequence on the continuity of the modelling, but would be quite sufficient to heighten the typographic effect. A curious point in this process is that the action of copper bichloride and of sodium hyposulphite are produced through the layer of bitumen; these substances must, therefore, penetrate through the bitumen, and this confirms me in the opinion that there is a highly favourable prospect for the introduction of these half-tone prints into the photo-engraving process. It might be possible to mix with the bitumen varnish a small quantity of some inert powder of a suitable degree of density, and this would contribute directly to the required amount of graining. The powder would remain imprisoned in the bitumen in greater or less quantity according as the action of light should have been more or less intense. By transfer of the bitumen image to glass, or enamel, or glazed porcelain, the subjects might be etched in with hydrofluoric acid, and this would afford an easy means of obtaining a result which in other ways costs a deal of labour and trouble. From the above indications the numerous applications of which Captain Biny's process seems to be capable will readily be understood.*

Photographic Revolver.—Dr. Marey has just shown me his photographic revolver, by means of which he is able to take photographs of a bird in its flight, and so to produce means for the investigation of its movements. The specimens produced with this instrument by M. Marey have, up to the present, only a rudimentary value, but hopes may be entertained that more successful results will soon follow.

Remedy for the Discolouration of Negatives which have been developed with Pyrogallic Acid.—The method employed by M. Alfred Chardon for curing the discolouration produced by the use of pyrogallic acid in developing negatives would seem to promise very highly. His first rule is that it is absolutely necessary to fix and wash the negative in a place where no white light can penetrate. After the last washing he plunges the plate into a bath of 25 grammes of citrate of ammonia dissolved in 500 grammes of water. In a few minutes the greenish tint of the image disappears, and its place is taken by the neutral tint of wet collodion plates. He then washes again thoroughly in water, and he is able to guarantee perfect permanence.

Investigation of the Accidents and Diseases to which Photographers are Liable.—Dr. Duchesne has undertaken an inquiry into the causes and treatment of those special complaints from which photographers so often suffer, and he hopes to be able to publish a work on this interesting branch of pathology. Any having made a study of the action on the human subject of the chemicals most used in the laboratory are asked to submit their observations

* We remember seeing a number of bitumen prints in half-tone, which were exhibited on the occasion of a lecture on "Photo-Engraving" which was delivered at the Society of Arts some three or four years ago. The bitumen film was spread on a pellicle through which the exposure was made; and development was effected by a mixture of turpentine and benzole.

to the learned doctor, who will include them in his valuable work. I am quite at the service of the readers of the Photographic News to transmit to Dr. Duchesne any communication on the subject which may be addressed to me.

Nomination of the Committee for the Poitevin Memorial.—The committee to raise a subscription in aid of a monument commemorative of Poitevin has been nominated, and will shortly be appointed. Half of the number are nominated by the Photographic Society, and half by the *Chambre Syndicale.* The former consist of Messrs. Davanne, Franck, Tourand, Stebbing, and Londe; the latter, of Messrs. Lévy, Léon Vidal, Guilleminot, Berthaud, and Audouin. A considerable sum has already been raised, and so soon as the committee is regularly appointed, subscriptions may be expected to flow in freely as well from France as from foreign countries, and it is hoped that a sufficient amount will be realised to render the monument worthy of Poitevin's reputation. To honour our great men is to honour ourselves! Leon Vidal.

COLOURED TRANSPARENCIES FROM SILVER IMAGES.

BY C. R. WOODS.*

(Second Paper).

A few months since I had the honour of calling your attention to certain methods of toning or colouring transparencies by replacing the silver, wholly or in part, by other substances. The results of a few additional experiments in the same direction may, perhaps, be of sufficient interest to warrant my placing them before you.

The substances that most easily lend themselves to this purpose are the compounds of the metals with the double cyanides of iron and potassium; of these, those metals whose ferrocyanides are insoluble in water and dilute acids, and whose ferricyanides are soluble, are most easy to manipulate. These are iron, uranium, lead, aluminium, antimony, mercury, tin (stannicum), and zinc. The pictures obtained by pouring solutions of the ferricyanides of these metals over a silver image may be further modified by the use of other suitable reagents.

The first three, iron, uranium, and lead, are the only ones that seem hitherto to have received any attention; the last mentioned of these three having been utilized by Eder and Tóth to intensify negatives. A solution of nitrate of lead and ferricyanide of potassium—

Plumbic nitrate	... ...	20 grains
Potassic ferricyande	... ...	30 ,,
Water	... ...	1 ounce

are poured over a plate, and the white image thus produced is treated with sulphide of ammonium. Instead of ammonic sulphide, if a solution of potassic chromate, preferably slightly acidulated with acetic acid, be used, a brilliant yellow image may be obtained. It has recently been stated (Leon Vidal, Photographic News, vol. xxvi, p. 107), that if a solution of potassic chromate, rendered strongly alkaline with ammonia, be used, a red image is produced. By this formula, however, I have only succeeded in obtaining yellow, and not red, pictures; and if it be the red subchromate of lead that is desired, I have been unable to obtain it even with somewhat violent means. If the plumbic ferricyanide solution and the ferric ferricyanide solution be used alternately, and then potassic chromate, a green picture may be obtained, but it is exceedingly dark and dense, and the original picture must be somewhat weak. Yellow pictures may also be produced by treating the white image, formed by Eder and Tóth's formula, with a solution of potassic iodide.

The image formed by treating a picture with potassic ferricyanide and an aluminium salt is white; and as all the insoluble compounds of aluminium produced by wet methods are white, nothing is to be gained by the use of salts of this metal.

The image produced by a solution of potassic ferricyanide and a salt of antimony is also white, but a red picture may be produced by converting this white image into red sulphide of antimony by a solution of sulphuretted hydrogen slightly acidulated with hydrochloric acid. A readier method of obtaining these red pictures, however, is that already known, viz., by the use of Schlippe's salts (sodic sulphantimoniate).

* Read before the Photographic Society of Great Britain.

Mercuric salts give no precipitate with potassic ferricyanide, but a white precipitate with potassic ferricyanide; this precipitate, after a time, turns blue. Mercurous salts give a brown precipitate with potassic ferricyanide, which after a time turns white. If a solution of mercuric chloride and potassic ferricyanide be poured over a silver image, both these compounds are produced, the second preponderating; and a brown picture is obtained, which, as might be expected, turns a bluish grey. I hoped to obtain a colour suitable for cloud-pictures by this means, but the colour is far too dense. It might be used as an intensifier; but as it would possess no advantages over the mercury intensifiers now in use, no formula need be given. A solution of iodine poured over this film gives an orange picture in mercuric iodide. An orange picture may also be produced by treating a picture produced by mercuric chloride and potassic ferricyanide with chromic acid, after it has turned to the bluish grey referred to. The orange picture is due to a mixture of ferric and mercuric chromates. If the brown image be treated with chromic acid or potassic chromate before its colour has changed, a yellow picture is obtained.

The pictures produced by zinc and stannic salts, with ferricyanide of potassium, are also white. Salts of the former metal are of no use for obtaining coloured pictures, for the same reasons for which aluminic salts may be discarded. Yellow transparencies might be obtained by converting a white image of stannous ferrocyanide into a yellow one of stannous sulphide by a solution of sulphuretted hydrogen, but yellow pictures are easily obtained by readier processes.

There are various other metals whose compounds with potassic ferricyanide are of suitable colours, but owing to the insolubility of their compounds with potassic ferro-cyanide they cannot be readily utilised, and somewhat roundabout methods have to be resorted to.

Copper gives a reddish-brown precipitate with potassic ferrocyanide, and a dirty green precipitate with potassic ferricyanide. If the green precipitate with a cupric salt in excess comes into contact with silver immediately on precipitation, the brown cupric ferrocyanide is produced. A convenient method of obtaining chocolate-red pictures with copper salts is the following:—30 grains of cupric sulphate are dissolved in 1 ounce of water, and enough ammonia is added to nearly, but not quite, re-dissolve the precipitate produced. A second solution is made, containing 30 grains of potassic ferricyanide to the ounce. Three parts of the first to one of the second solution should be mixed just before flowing over the image; the solution should be just slightly turbid. Another method of producing these chocolate-brown pictures is to bleach a picture by cupric bromide by the usual formula:—

Sulphate of copper	... ...	50 grains
Bromide of potassium	... ...	30 ,,
Water	... ...	2 ounces

by which means sub-bromide of silver and cuprous bromide are formed, and, after washing the plate, to immerse it in a solution of potassic ferricyanide of 30 grains to the ounce. The picture subsequently darkens by the reduction of the bromide of silver. Iodide of potassium is to be preferred to bromide, both on account of the greater insolubility of the cuprous salt formed, and the less liability to darken in the light. The former method, however, in which no haloid salt of silver need be left in the film, gives a more transparent chocolate-red; but both methods may find their applications, as neither colour is identical with that produced by uranium. These methods of obtaining pictures in salts of copper may, perhaps, be turned to account by burning the pictures into the glass, the metal being suitable for the purpose.

Another brown colour may be produced by the use of salts of molybdenum, the colour possessing a rather olive tone. Both molybdous and molybdic salts produce a brown precipitate with potassic ferricyanide; but we have higher salts still in the form of molybdates. Ten grains of ammonic molybdate are dissolved in about half-an-ounce of water, and a drop of nitric acid added. Four parts of this are mixed with one part of a solution of potassic ferricyanide, 30 grains to an ounce, just before pouring over the film.

Ferricyanide of silver may be obtained in a film by treating a blue picture obtained with ferric chloride and potassic ferricyanide with a solution of nitrate of silver (50 grains to 1 ounce of water), and, after the blue colour has disappeared, and the plate has been washed, treating it with nitric acid, or some other suitable oxidizing agent. Chromic acid produces a mixed image of silver chromate and silver ferricyanide. Red and orange pictures are thus obtained with a little trouble. Chromate of silver may also be obtained in a film by pouring a weak solution of chromic acid over a silver image in collodion, if the latter has been permitted to dry, and is wetted only just before the acid is applied, so that it is not very porous; otherwise, the image is simply carried away by the chromic acid. A picture in argentic chromate alone, however, is disappointing. Tones ranging from bronze to purple may be obtained in a mixed image of sulphide and chromate of silver. These may be obtained by first treating a silver image with ammonic sulphide, and then with a dilute solution of chromic acid; in this case, the sulphide of silver forming a protective coating, preventing the silver being dissolved out. The resulting tone depends on the length of time the picture has been subjected to the ammonic sulphide.

The reactions of other double cyanides offer very few facilities for obtaining coloured transparencies. The alkaline cobalticyanides give no precipitate with ferric and mercuric salts, but with either of these salts, when poured on a film, a white image is produced; as subsequent treatment of these white images can only result in the formation of salts of the two metals that can be easily produced by the ferricyanides, no advantage ensues from the use of cobalticyanides. The double cyanides of potassium with copper, nickel, gold, and silver offer no useful reactions. Chromi-cyanide of potassium and ferric chloride give a brick-red picture when poured over a film, but the chromicyanide of potassium is difficult to prepare, and similar colours are easily obtained by other means.

In all these methods, the picture may only be lightly toned, or completely coloured. By carefully suiting the colour and treatment to the nature of the subject, a considerable range of tone may be obtained.

ON REALISM AND IDEALISM IN PHOTOGRAPHY.

BY REV. F. F. STATHAM, M.A.*

We hear a great deal now-a-days of "realism" as it affects architecture, the drama, painting, and other of the fine arts, to say nothing of its application in a moral sense; and some writers have gone so far as to define this as a "realistic age" in which no shams or make-believes are to be allowed any more, and in which all is to be ultimately genuine and true to nature or to natural law.

Now, I am not going to "run-a-tilt" against this school of thought, although I think it has some absurdities as well as some advantages connected with its teaching. Mr. John Ruskin did a good work when he showed the thoroughness and fidelity to art principles of the mediæval and early ecclesiastical architects; when he pointed out that every flying buttress or gurgoyle had not only its ornamental, but its practical value; when he demonstrated that our domestic abodes might be just as homely and as comfortable without being quite so ugly and so commonplace as they had lately been. But, then, he rode his hobby too hard, I imagine, when he insisted that *everything* about a building should be genuine; when he inveighed against imitation-grained woods as a deception, veneering as a snare, and the gilding even of organ pipes as a delusion and a covert artifice.

And so, again, with regard to the drama. Let us by all means have correct views of the actual scenes depicted (as of Elsinore Castle in "Hamlet," for example), if they are to be procured, dresses and accoutrements in accordance with historic precedent, and even, if you will, a real cab and a real live horse (as in some recent performances) to aid the illusion of the stage. But, at the same time, let us remember that the line of demarcation between the real and the ideal must, after all, be drawn somewhere, otherwise we shall have the "supers" clamouring for genuine fowls and joints at their fictitious banquets instead of the sawdust-stuffed dummies or the pasteboard imitations now in use, or crying out for the real juice of the grape in their goblets instead of the toast-and-water or airy nothingness with which they are now filled when they sing—

"Libiamo ne lieti calici."

And in like manner with respect to painting and photography (which I take to be only another form of painting, in which we make use of a pencil of light for our delineator instead of one of a more material character): let us have as much reality as we can; let us come as near to nature as the conditions under which the several artists contend will allow, but do not let us be misled by the idea that, because absolute reality cannot at all times be secured, therefore little merit attaches to our work, or that it is not so earnest and so thoughtful as it ought to be.

For my own part, I have always thought that art generally has been very much advanced by the original discovery and the gradual improvement of the photographic process. Whilst, on the one hand, no one will deny that it lacks many of those advantages which the sister arts of painting and sculpture possess in bringing before the eye the presentment of natural objects, photography —by the minuteness of the detail which it ensures, by the correct representation *on the same scale* of all the component parts of an object or scene, and by the truthfulness of its perspective as a general rule—has habituated the eyes of artists to look more carefully to the truthful rendering of their several compositions. A conventional tree—such as we meet with in the paintings of Poussin or of Gainsborough—would scarcely pass muster in the present day. Our photographers have multiplied copies of all the treasures of our woods and forests—even to the fern brakes and thickets and dells—to so marvellous an extent that now you can generally tell in a painting what a tree is intended for, instead of, as formerly, having a kind of prettily-tinted outline to do duty, with a slight variation in the anatomy of the trunk and limbs, for an elm, an oak, a sycamore, or a lime. So, again, the steady labours of the photographer upon the sea-shore have borne their fruit, and his correct sun-pictures of the stormy beach or the rolling waves, or the dashing spray or the passing storm, have given hints to the painter how things should look; and, as the result, they do look, on the canvas of our modern artists, very differently from scenes of a similar nature attempted by painters of a bygone age.

Rendering, however, every homage to the efforts of photography in the past to the correct delineation of natural objects, and believing, as I do, that its services have been invaluable in bringing about a more realistic mode of treatment in all the sister arts, I cannot help thinking that we are in some danger of falling from the high standard which ought to be the object of our attainment, and of yielding to a temptation which the very facilities of the photographic process place in our way. I refer to the readiness with which the *true* and the *false* can be so easily blended, by a little skilful manipulation, as to present in the photographic result a picture which is anything but true to nature.

What is more common, for instance, than a painted background to a carte-de-visite, with a diminished distant doorway and a pretty perspective of country or garden beyond, which, having been placed almost immediately behind the sitter at the time of focussing, makes him look, in the outcome, like a giant in a dwarf's house, with an entrance through which he could neither go out nor come in? Why is it that we see so many stuffed cats and dogs, whose painfully-staring glass eyes betray their unnaturalness, introduced as accessories by our photographic artists? Why does that perpetual basket of shabby artificial flowers do duty so frequently for the real thing, which, after all, would not be so very expensive?

For many years I could never make out why all my friends were holding tight by a chair, as though they had had "just a wee droppie in their e'e," and were anxious to steady themselves while they were being photographed, until I found out that this was an artifice to do away with the use of the head-rest. But they didn't look natural when "taking the chair," and so I told them. Then they fell into the opposite extreme, and determined to look free and easy by throwing themselves into all manner of unnatural postures. One presented me with his carte, representing him seated upon a marble balustrade. It was a most awkward and ungainly pose, and to (say nothing of the marble balustrade, which was manifestly a "sham") my friend never before or after his visit to the artist's studio did sit upon such an uncomfortable seat.

I was looking through my friend Jones's album the other day; but, although I knew most of the family pretty well by sight in their ordinary apparel, they were so disguised and "transmogrified" in the photographic likenesses that I could scarcely recognize one of them. Jones himself had had his hair curled, and was evidently "got up regardless of expense" (as the saying is) before going to visit the operator. Then he had selected a pose with his thumbs in his waistcoat pocket holes, which was quite unusual with him; and putting on, as he imagined, at the critical moment, what he considered a smiling face, he came out in the carte such a caricature of himself that I really did not know him. His eldest son had been to a fancy ball, and had

* A communication to the South London Photographic Society.

taken the whim of being dressed up as a bandit; and there he was in the album in most correct bandit costume (at least, so far as the theatrical costumier could imitate it), but looking no more like a genuine robber than myself. "Does your idea of a bandit," said I, jokingly, "coincide with a clean, smooth-faced, rather good-looking individual (you see I did not want to offend him), with his hair parted neatly down the middle?" for he had got his bandit's hat in one hand, for effect, and was holding a braud new Martini-Henri as tightly as his kid glove would let him in the other. "No, my dear sir, there is no realism in that. You couldn't look like a bandit if you tried. Your face says as plainly as can be, by its quiet, good-natured smile, 'I couldn't cut a throat for a thousand pounds,' while a bandit's features would say as plainly, 'I'd do the job for a hundredth part of the money.' Why, then, should you seek to be unreal? Why not adopt the everyday dress, the easy manner, and, if you will, the familiar surroundings of daily life when you go to be photographed? Your friends would recognize you more easily; you would recognize yourself; and if you live to have a family and to transmit your likeness to your descendants, they will be able to form some idea of how you looked, and not of how you dressed yourself or made yourself up for a solitary occasion."

But I can imagine the ready reply of my photographic friends to these modest strictures of mine. They will say, "What can we do? The public *will* have their taste gratified. We must comply with their passing whims and fancies, and photograph them according to their desire, or else put up our shutters at once, and say 'good-bye' to business." I am not quite so sure that that would be the result. To a certain extent the photographer, like the painter, is dependent upon the caprice or the taste of his employer; but a skilful artist will soon find out how to direct and encourage a higher standard of excellence. I look forward to the time, if it should not already have arrived (and you will be better judges of this than myself), when the patron will not necessarily have to resort to the studio to be photographed, but the artist will be invited to bring his camera and operate at the patron's own home and amidst his own surroundings.

I think of some of those domestic groups of the Dutch painters, in which all the members of a family have been taken in the midst of their daily occupations.

The members of that household have long since gone to their rest, but the lineaments of their features and the calm employment of their peaceful hours is still visibly before us, creating as much interest in our minds, as strangers living years afterwards, as the picture originally did when it was first painted and presented to its living prototypes. And why is this? *Because the whole thing was genuine.* The people were dressed as they usually dressed; they were occupied in their usual occupations; they were taken with their ordinary implements in their hands, and with the natural surroundings of their ordinary homes.

I have seen photographs of a similar character, but not in any great number, in modern days—perhaps some prince, or some warrior or statesman, in his palace, camp, or study, as the case may be—but not frequently in humbler life. What I would contend for is that the surroundings should, as a general rule, be real, as well as the individual posed; that no shams should be used where the genuine articles can be procured; and that, as a leading principle, the public should be trained to prefer that which is natural to them to that which is artificial—that which sets most easily upon them from constant use, to that which, being used only for the occasion, sits stiffly, and gives them a constrained and unnatural look.

Not that I would altogether exclude the *ideal* from the province of photography. On the contrary, I think that, with certain limitations as to space and colour, the photographic artist has almost as wide a scope before him as his brother of the pencil or brush. What is to prevent the master of landscape photography from idealising his work by introducing some appropriate animate or inanimate objects? Some of Claude's most famous pictures have been dignified and immortalised in this way. They were originally only simple pastoral scenes, but by the introduction of a small group of figures—perhaps representative of some Scriptural event—life was given to the picture, interest was concentrated upon it, and the landscape, which otherwise might have seemed dull and monotonous, at once attained vigour and grace, and gave rise to thought and interest on the part of the beholders.

I know that our brethren of the camera are becoming more and more alive to the necessity of giving life and incident to their pictures by the introduction of living forms. But surely what is worth doing at all is worth doing well; and it would cost little additional trouble to carry a few suitable articles of costume in the portmanteau to be utilised in dressing up some assistant or some stray passer-by in a fashion suitable for introduction in the scene selected for exposure.

How many dozens of excellent photographic views have I seen spoiled by the intrusion of the operator himself—or sometimes of only a bit of him—by way of pretence of giving life to the scene depicted!

Sometimes you may see him standing with his back towards you, evidently counting the seconds necessary for the exposure, and ready to give the signal to his assistant to put the cap over the lens, or, with the improved modern apparatus, to give the necessary squeeze of the air vessel which is to liberate the falling shutter. Sometimes he is to be recognised sitting—still with his back towards the spectator—upon a stone or some projecting stump of a tree; and not unfrequently I have "spotted" him lying upon his stomach, as though knowing he had no business in the view at all, and, like the ostrich, imagining that he couldn't be seen if he only covered his own eyes in the earth, so that he could see nobody. That some more genuine and artistic effects may be produced by a little care I shall now be able to show by passing round a few examples—all furnished by members of our Society, but several of them notably by Mr. Henry Cooper, of Torquay, and the late lamented Mr. O. G. Rejlander. (Several clever sketches by these and other artists were then exhibited by the reader of the paper.)

Idealism has abundant scope in photography in the hands of anyone with real artistic feeling in the selection of some suitable model for definite pictorial effect. Take, for example, the works of our friend Mr. Valentine Blanchard—one instance of which, "The Zealot," by his kindness, was given as the presentation plate of our Society for the year 1866, and a copy of which I now pass round. Why is it that this clever artist gives us such scant opportunities of testing his improvement in his profession? No one who looked with admiration upon his admirable "Rachel at the Well," in one of the past exhibitions of the Photographic Society of Great Britain, can do otherwise than regret that his name is so seldom seen attached to the frames annually suspended at the Suffolk Street Gallery, in honourable competition for the suffrages of an enlightened public. "The First Night at a Pantomime," by the late Mr. Henry Cooper; "The Idle Girl," by Rejlander; and "Will He Care for Me, too?" by the latter talented artist, will fully explain what I wish to convey. I pass round at the same time examples of successful grappling with costumed models, chiefly by the same gentlemen, to show how readily, in the hands of skilful manipulators, the ideal blends into the real, till it is difficult to decide to which class of production the specimen offered for inspection may belong.

I should like to have said a few words before closing upon natural and unnatural modes of lighting—or, rather, of throwing the light upon—objects designed for photographic treatment; but I fear to weary you with any longer trespass upon your patient attention. I feel persuaded, nevertheless, that very great stress ought to be laid on this point if we wish to approach to the reality of life in our facial presentments. Light affects the eyes in so sensitive a manner that any strain upon the optic nerves by an undue or unnatural glare discomposes the features generally, and gives an auxious or a distressed look to the countenance which is subjected to it. Further: the placing of a visage (as is so common) with one side facing a strong light, and the other turned to the shade, is apt to cause a shadow along every furrow or wrinkle or even minute line in the features, so that the lens, which renders every little effect faithfully, will frequently give to a young person's countenance so treated all the lines and markings which only belong to a more mature period of life. Nay, I have heard it asserted by some very charming young ladies of my acquaintance, that even their dimples have thus been turned to their natural disadvantage, and have presented in their cartes-de-visite more the appearance of moles or warts than of the ripples with which good temper or good living—(I won't be sure which)—had fortunately endowed them. The proper management of light may, moreover, be made a most happy medium in giving character and vivacity to a picture; and I cannot do better, therefore, than conclude my paper by handing round a few examples of what I consider successful treatment from this point of view, including one small but very pretty copy of Mr. H. P. Robinson's "Little Sunshine," consisting of a young maiden plaiting straw in a strong light, and apparently languid or a little exhausted with what we are almost made to realise as the excessive heat of the day.

Notes.

The Russian Government is considering the question of appending photographic portraits to all passports it issues.

We publish this week Mr. Plener's specification relating to the separation of the sensitive constituents from gelatine emulsion, to which we referred a fortnight since.

Dr. Schuster, Mr. Norman Lockyer, and Mr. C. R. Woods, together with Mr. Black, the novelist, have arrived at their camping ground in Egypt, whence they propose to observe the Eclipse next Tuesday. Mr. Woods, whose paper on "Transparencies" appears in another column, is the photographer to the expedition.

There was a discussion on tents on Tuesday evening at the Photographic Society's meeting. Mr. Maxwell Lyte's idea is to make the tent so large and comfortable, that some one else to carry it becomes a necessity; and he covers the outside with white calico, damp fern or other leaves being also used as a set-off against undue heat.

Next week we shall publish a new process of Dr. J. M. Eder's, for intensifying gelatine plates.

Those who can realise the circumstance that truly artistic work is almost impossible unless the mind and body are at ease, would do well to take a hint.

Any plates up to 12 by 10 I can easily change in absolute darkness, says Mr. Cowan; but in order to work in comfort it is necessary to keep the eyes shut, as otherwise some inconvenience is caused by the involuntary and ineffectual efforts of the visual system to help in the work.

Work in absolute darkness is, however, much facilitated by knowing that one has a sufficient area of clear space before one; but even in the dirtiest cellar this can generally be provided for by spreading an open newspaper on the floor.

Our esteemed Paris correspondent, M. Léon Vidal, has been nominated to a professorship at Limoges, for the especial purpose of teaching the application of photography to the decoration of porcelain. Limoges enamels have been famous all the world over for centuries past, and we may well hope that an impetus will be given to modern Limoges work by this well chosen appointment.

We had an opportunity, by-the-way, of seeing M. Vidal's clever little selenium photometer in action on Monday last at his laboratory in Passy. It has been described more than once in these columns, but only those who have witnessed its delicate action can realise how readily it records the amount of light falling upon its face. A very delicate galvanometer points to 0°; allow subdued daylight to strike the selenium, and immediately the needle goes to 5°, while a piece of magnesium burnt in the immediate vicinity causes the needle to point to 22°.

Our readers will remember its action. A current of electricity, on its way to the galvanometer, is stopped by reason of a piece of selenium placed in the circuit. Selenium, under ordinary circumstances, is a non-conductor, or nearly so; but permit light to shine upon it, and it becomes a conductor—the more light at hand, the greater being its conductivity. Hence, the greater the amount of light shining upon the selenium, the more the needle of the galvanometer moves. As in the case of Crookes' radiometer, or light-mill, it is the calorific rays, and not the actinic rays, that cause the change in the selenium; but as a certain relation is doubtless to be established between these two kinds of rays, the photographer is likely to benefit by M. Vidal's instrument. Its delicacy is such, that light insufficient to set the radiometer in motion marks 3° on the Vidal photometer. Sunshine marks 60° on the galvanometer.

The other day, when we published some "Expressions" from Darwin's work on the subject, we pointed out that photographers would do well to pay more attention to the why and wherefore—anatomically—of the changes that come over their sitters' faces. It was shown in one of the sketches how the mere fall of the lower lip induces a look of care and pain, while the drawing up or down of the lines of the mouth suffices to proclaim good or bad humour.

In fact, it is the mouth more than anything else that dominates the "expression." And for this reason: there are more muscles connected with it than with any other feature of the face. The late Professor Partridge, when he occupied the anatomical chair at the Royal Academy, used to make a great point of this when lecturing to the art students. He had a composite picture to prove that the "saintly look about the eyes" that many people believe in, does not exist, and that when the mouth, and consequently lower portion of a face, however devout, is made to laugh, the eyes seem to laugh also.

Eyes have very little to do with "expression," while the play of the mouth, since this controls so many muscles, exercises a wide influence. Many people have a difficulty in breathing through their noses, and hence it happens, after a while, that the mouth opens slightly. Fritz Luckardt complains that English sitters generally show too much of their front teeth, but, unfortunately, when the lips are pressed firm, a glum and determined expression ensues. Most of us, again, have a way of drooping our heads slightly on one side or the other, especially after sitting a while. All these are points that a little anatomical study would help us to understand better.

Explosions arising from dust are not unknown in the photographic world, as when an ordinary india-rubber gas bag has long been in use for holding oxygen the interior becomes corroded, and an inflammable and friable resinous product is then formed in abundance. This resinous substance, becoming diffused through the oxygen, often causes dangerous explosions. We believe that the only way to make a dusty gas-bag safe is to moisten the interior with glycerine. The resinous oxidation product of rubber has been analysed and studied from a chemical point of view by Mr. Spiller, and we think it proved to contain about one-fourth of its weight of oxygen, while pure rubber contains none.

A photographer of our acquaintance who recently published a portrait of the Prince of Wales, and now wants to make a stir in the world, thinks of advertising pictures at ten shillings a dozen, "fixed in the same hyposulphite as that employed for His Royal Highness."

"Studies from the Sunday-Camera of an Amateur," is the title of a delightful series of thirty stereoscopic views executed in Eder's gelatino-chloride process by Mr. Rudolf Hamsa, of Vienna; a silver Voigtländer medal has been awarded to Mr. Hamsa for these pictures.

We hear that the atelier appurtenances, negatives, costumes, &c., of the late M. Adam-Salomon, are valued at 100,000 francs, or four thousand pounds, a somewhat extravagant estimate, we suspect.

To make comparison of the sensitiveness of gelatine plates by noting the time they take to develop when put side by side in the developing dish is a method open to objection, if only on account of the hardness of the gelatine itself. We recently placed two samples of film gelatine in cold water, and weighed them carefully at the end of three minutes to ascertain the amount of water absorbed. The one sample had absorbed in this period one-third more water than the other. Doubtless, if the time of immersion had been extended to three hours, there would have been less difference in the amount of water they contained, one of our samples, an old and horny air-dried film, being very repellent of water to begin with. This mechanical quality of gelatine plates is one that has never yet received proper consideration.

Writes a correspondent:—"Has any one tried the old-fashioned coffee-pot as a ready means of filtering gelatine emulsion? The warm liquid could be put into the flannel bag at the bottom of the pot—where the coffee and hot water are placed—and the bag then raised gradually by turning the handle at the top, when the gelatine would be sucked through by atmospheric action. If the flannel bag were made to fit, and the vessel itself were clean and new—the interior might be plated—a coffee pot of this description would be handy just now in a photographic laboratory. We made the suggestion a twelvemonth ago, but it will well bear repeating.

Painters paint their pictures from models, and it is not singular, therefore, that novelists should employ them in constructing stories. No doubt the character given by a novelist to his hero or heroine is very different to that actually possessed by the model, but then in a painting we have the same lack of truth; the strapping butcher who sat for Hercules, and the scullery maid who has represented Cleopatra, have little else than a fancied resemblance in common with the personages. The novelist, fortunately for himself, need not come into contact with the butcher or the scullery maid; photography helps him to secure his models without all those difficulties that attend the painter.

Indeed, for the novelist's purpose, a photograph is often better than the original. The heroine may be all his fancy paints her, so long as he has but her picture before him; he can look into her witching eyes, note her roguish dimples, and read her thoughts, without fear that she may open her mouth and dispel in a moment the thread he is weaving of her hopes and fears. She is real enough to give breath and life to the story he reads in her face, and yet her silence is a guarantee she will never deny a single conjecture he makes. Whenever in doubt as to the steps his heroine shall take in his story, he can always bring her face before him and question it.

Before a photographer's show-case. *Charles (loq.)*: "Charming girl that, and what a delightful expression!" *His Friend*: "Yes, very nice, but perhaps it is only put on; you never can tell." Was it the young lady or the photographer who put it on, we wonder?

TWELVE ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.

No. IX.—Defects and Remedies.

The photographer is sure not to practise the gelatine dry plate process very long before he comes across some of the defects which are peculiar to it. We intend, therefore, to describe these as accurately as we can, and, where possible, to give a means of either preventing the occurrence of the objectionable phenomenon, or of curing it when it has made its appearance. Where the error is of a kind due to the *preparation* of the plates, we shall not enter into the cause of it, but merely indicate the cure.
