The quantity of this fluid *necessary* to be made must depend upon the *form of trough to be used*, whether horizontal or vertical, and also upon the size of the plate. With the vertical trough a glass dipper is provided, upon which the plate rests, preventing the necessity of any handle or the fingers going into the liquid. If, however, the glass used is a little larger than required, this is not necessary. Having then obtained one or other of these two and filtered the liquid previously, the plate, free from any particle of dust, &c., is to be *immersed steadily and without hesitation*; for if a pause should be made in any part, a line is sure to be formed, which will print in a subsequent part of the process.

The plate being immersed in the solution must be kept there a sufficient time for the liquid to act freely upon the surface, particularly if a negative picture is to be obtained. *As a general rule, it will take about two minutes, but this will vary with the temperature of the air at the time of operating, and the condition of the collodion.* In cold weather, or indeed anything below 50° F., the bath should be placed in a warm situation, or a proper decomposition is not obtained under a very long time. Above 60° the plate will be certain to have obtained its maximum of sensibility by two minutes' immersion, but below this temperature it is better to *give a little extra time.*

To facilitate the action, let the temperature be what it may, the plate must be lifted out of the liquid two or three times, which also assists in getting rid of the ether from the surface, for without this is thoroughly done a uniform coating cannot be obtained; *but on no account should it be removed until the plate has been immersed about half a minute*, as marks are apt to be produced if removed sooner.

The plate is now ready to receive its impression in the camera obscura. This having been done, the picture is to be developed.

The development of image. To effect this the plate must be taken again into the dark room, and with care removed from the slide to the levelling stand.

It will be well to caution the operator respecting the removal of the plate. Glass, as before observed, is a bad conductor of heat; therefore, if in taking it out we allow it to rest on the fingers at any one spot too long, that portion will be warmed through to the face, and as this is not done until the developing solution is ready to go over, the action will be more energetic at those parts than at others, and consequently destroy the evenness of the picture. We should, therefore, handle the plate with care, as if it already possessed too much heat to be comfortable to the fingers, and that we must therefore get it on the stand as soon as possible.

Having then got it there we must next cover the face with the developing solution. This should be made as follows:

Pyrogallic acid - - - - - -	5 grains.
Glacial acetic acid - - - - -	40 minims.
Distilled water - - - - - -	10 oz.

Dissolve and filter.

Mr. Delamotte employs

Pyrogallic acid - - - - - -	9 grains.
Glacial acetic acid - - - - -	2 drachms.
Distilled water - - - - - -	3 ounces.

Now, in developing a plate, the quantity of liquid taken must be in proportion to its size. A plate measuring 5 inches by 4 will require half an ounce; less may be used, but it is at the risk of stains; therefore we would recommend that half an ounce of the above be measured out, into *a perfectly clean measure*, and to this from 8 to 12 drops of a 50-grain solution of nitrate of silver be added.

Pour this quickly over the surface, taking care not to hold the measure too high, and not to pour all on one spot, but having taken the measure properly in the fingers, begin at one end, and carry the hand forward; immediately blow upon the face of the plate, which has the effect not only of diffusing it over the surface, but causes the solution to combine more equally with the damp surface of the plate: it also has the effect of keeping any deposit that may form in motion, which, if allowed to settle, causes the picture to come out mottled. A piece of white paper may now be held under the plate, to observe the development of the picture: if the light of the room is adapted for viewing it in this manner, well; if not, a light must be held below, but in either case arrangements should be made to view the plate easily whilst under the operation: a successful result depending so much upon obtaining sufficient development without carrying it too far.

As soon as the necessary development has been obtained, the liquor must be poured off, and the surface washed with a little water, which is easily done by holding the plate over a dish, and pouring water on it; taking care, both in this and a subsequent part of the process, to hold the plate horizontally, and not vertically, so as to prevent the coating being torn by the force and weight of water.

Protosulphate of iron, which was first introduced as a photographic agent in 1840 by Robert Hunt, may be employed instead of the pyrogallic acid with much advantage. The beautiful collodion portraits obtained by Mr. Tunny of Edinburgh are all developed by the iron salt. The following are the best proportions:

Protosulphate of iron - - - - -	1 ounce.
Acetic acid - - - - - - -	12 minims.
Distilled water - - - - - - -	1 pint.

This is used in the same manner as the former solutions.

Fixing of image. This is simply the removal of iodide of silver from the surface of the plate, and is effected by pouring over it, after it has been dipped into water, a solution of hyposulphite of soda, made of the strength of 4 ounces to a pint of water. At this point daylight may be admitted into the room, and, indeed, we cannot judge well of its removal without it. We then see by tilting the plate to and fro the iodide gradually dissolve away, and the different parts left more or less transparent, according to the action of light upon them.

It then only remains to thoroughly wash away every trace of the hyposulphite of soda, for should any salt be left, it gradually destroys the picture. The plate should therefore either be immersed with great care in a vessel of clean water, or what is better, water poured gently and carefully over the surface. After this it must be placed upright to dry, or held before a fire.

The fixing processes. The most important part of Photography, and one to which the least attention has been paid, is the process of rendering permanent the beautiful images which have been obtained. Nearly all the fine photographs with which we are now familiar are not permanent. This is deeply to be regretted, especially as there appears to be no necessity for their fading away. In nearly all cases the fading of a photograph may be referred to carelessness, and it is not a little startling and certainly very annoying, to hear a very large dealer in photographic pictures declare that the finest pictures by the best photographers are the first to fade. This is, no doubt, to be accounted for by the demand which there is for their pictures, leading to a fatal rapidity in the necessary manipulatory details.

There is no necessity for a photograph to fade if kept with ordinary care. It should be at all events as permanent as a sepia drawing. The hyposulphite of soda is the true fixing agent for any of the photographic processes, be they Daguerreotype, calotype, collodion, or the ordinary process for producing positive prints. It should be understood, whichever of the salts of silver are employed, that by the action of the solar rays either oxide of silver or metallic silver is produced, and the unchanged chloride, iodide, or bromide can be dissolved out by the use of the *hyposulphite of soda*.

The photographic picture on paper, on metal, or on glass, is washed with a strong solution of the hyposulphite of soda, and the silver salt employed combines with it, forming a peculiarly sweet compound, the hyposulphite of silver; this is soluble in water, and hence we have only to remove it by copious ablutions. The usual practice is to place the pictures in trays of water and to change the fluid frequently. In this is the danger, and to it may be traced the fading of nine-tenths of the pictures prepared on paper.

Paper is a mass of linen or cotton fibre; howsoever fine the pulp may be prepared, it is still full of capillary pores, which, by virtue of the force called capillarity, hold with enormous force a large portion of the solid contents of the water. If we make a solution of a known strength of the hyposulphite of soda, and dip a piece of paper into it, it will be found to have lost more of the salt than belongs to the small quantity of water abstracted by the paper. Solid matter in excess has been withdrawn from the solution. So a photographic picture on paper holds with great tenacity one or other of the hyposulphites. By soaking there is of course a certain portion removed, but it is not possible by any system of soaking to remove it all.

The picture is, however, prepared in this manner, and slowly, but surely, under the combined influences of the solar rays and atmospheric moisture, the metallic silver loses colour, *i. e.* the photograph fades.

The only process to be relied on demands that every picture should be treated separately. First, any number may be soaked in water, and the water changed; by this means the excess of the hyposulphite of silver is removed. Then each picture must be taken out and placed upon a slab of porcelain or glass, and being fixed at a small angle, water should be allowed to flow freely over and off it. Beyond this, the operator should be furnished with a piece of soft sponge, and he should maintain for a long time a dabbing motion. By this mechanical means he disturbs the solid matter held in the capillary tubes, and eventually removes it. The labour thus bestowed is rewarded by the production of a permanent picture, not to be secured by any other means.

In this article those processes only which have become of commercial value have been noted. The Carbon process of printing, which promises well, can scarcely be said to be as yet in a perfect state; and for the other curious but less important processes, and for a full examination of the philosophy of the subject, see *Hunt's Researches on Light*, 2nd edition.

PHOTOMETRY. The measurement of light, or of illuminating power. See ILLUMINATION.

PHOTOZINCOGRAPHY. This is the name given by Colonel James, R. E., Director of the Ordnance Survey, to a process which he has lately introduced, and which has been carried out, to some extent experimentally, in the Ordnance Map Office at Southampton, for the purpose of copying ancient documents. In a report just made to the House of Commons (March, 1860), Colonel James thus describes the process. After speaking of some experiments made with the carbon printing process, he continues:—

"We have also tried a method, which is still more valuable, and by which the reduced print is in a state to be at once transferred to stone or zinc, from which any number of copies can be taken, as in ordinary lithographic or zincographic printing, or for transfer to the waxed surface of the copper plates. To effect this, the paper, after being washed over with the solution of the bichromate of potash and gum, and dried, is placed in the printing frame under the collodion negative, and after exposure to the light, the whole surface is coated over with lithographic ink, and a stream of hot water then poured over it; and as the portion which was exposed to the light is insoluble, whilst the composition in all other parts being soluble is easily washed off, we obtain at once the outline of the map in a state ready for being transferred either to stone, zinc, or the copper plate, or we can take the photograph on the zinc at once.

"This new method of printing from a negative is extremely simple and inexpensive, and promises to be of great use to us. Sheet 96, of Northumberland, has been transferred to the copper plate from impressions taken by this process, and from the perfect manner in which we are able to transfer the impressions to zinc, we can, if required, print any number of faithful copies of the ancient records of the kingdom, such as *Doomsday Book*, the *Pipe Rolls*, &c., at a comparatively speaking very trifling cost. (See specimen at the end of this Report). I have called this new method Photozincography, and anticipate that it will become very generally useful, not only to Government, but to the public at large, for producing perfectly accurate copies of documents of any kind."

PHTHALIC ACID. A crystallised substance produced by the action of nitric acid on rubian. See MADDER.

PHYTOGRAPHY. See NATURE PRINTING.

PICAMARE. Colourless oil in wood tar, discovered by Reichenbach. See DISTILLATION, DESTRUCTIVE; NAPHTHA; PYROXILIC SPIRIT.

PICKLES are various kinds of vegetables and fruits preserved in vinegar. The preparation of pickles belongs rather to a book on cookery. The peculiar and beautiful green colour which has been frequently imparted to pickles, is due in nearly all cases to the use of a salt of copper. This is in the highest degree injurious, and cannot be too strongly deprecated. The presence of copper may be detected by putting the blade of a perfectly clean knife, or, still better, a polished piece of soft iron, into the suspected pickle; it will, if copper be present, become coated in a short time with a cupreous film. It is satisfactory to find that most of our large pickle manufacturers are content to sacrifice the colour, at one time so much looked to; and they now furnish the public with pickles which are free from any metallic contamination.

PICROMEL is the name given by M. Thenard to a black bitter principle which he supposed to be peculiar to the bile. MM. Gmelin and Tiedemann have since called its identity in question.—C. G. W.

PICOLINE, $C^{12}H^{7}N$. A nitryle base, isomeric with aniline, discovered by Anderson in coal naphtha and bone oil. It is also contained in the shale naphtha and crude chinoline.—C. G. W.

PICROTOXIN (*Picrotoxic acid*) is an intensely bitter poisonous vegetable principle, extracted from the seeds of the *Menispermum cocculus*, (Cocculus Indicus). It crystallises in small white needles, dissolves in boiling water and in alcohol. It does not combine with acids, but forms combinations with alkalies. Its formula is $C^{12}H^{7}O^{5}$.—C. G. W.

PIETRA DURA. Ornamental work, executed in coloured stones, representing flowers, fruits, birds, and the like. The Florentine work and the inlaid marble work of Derbyshire are of this character.

PIGMENTS. See Colours, Paints.

PIMENTO. (*Myrtus pimenta*, Linn., *Eugenia pimenta*, De Candolle.) Allspice, or Jamaica pepper. This plant is cultivated in Jamaica in regular *Pimento walks*. The full sized fruit is gathered green and sun-dried, during which process it is frequently immersed. It is sent to the English market in bags of 1 cwt. each. This fruit consists, according to Bonastre's complicated analysis, of:—

	Shells or Capsules.	Kernels.
Volatile oil	10·0	5·0
Green oil	8·4	2·5
Concrete oil	0·9	1·2
Extract containing tannin	11·4	39·8
Gummy extract	3·0	7·2
Brown matter dissolved in potash	4·0	8·0
Resinous matter	1·2	3·2
Sugar, uncrystallised	3·0	8·0
Gallic and malic acids	0·6	1·6
Vegetable fibre	50·0	16·0
Ashes charged with salts	2·8	1·9
Moisture and loss	4·1	4·8

Our *imports* and *exports* were as follows in 1858:—

Imports, almost all from Jamaica	42,310 cwts.
Exports	24,015 „

PINANG, or Betel Nut. See Areca.

PINCHBECK. A yellow metal, composed of 3 ounces of zinc to 1 lb. of copper. See Alloy; Brass.

PINE-APPLE YARN and CLOTH. In Mr. Zincke's process, patented in December, 1836, for preparing the filaments of this plant, the *Bromelia ananas*, the leaves being plucked, and deprived of the prickles round their edges by a cutting instrument, are then beaten upon a wooden block with a wooden mallet, till a silky-looking mass of fibres is obtained, which are to be freed by washing from the green fecula. The fibrous part must next be laid straight, and passed between wooden rollers. The leaves should be gathered between the time of their full maturity and the ripening of the fruit. If earlier or later, the fibres will not be so flexible, and will need to be cleared by a boil in soapy water for some hours, after being laid straight under the pressure of a wooden grating, to prevent their becoming entangled. When well washed and dried, with occasional shaking out, they will now appear of a silky fineness. They may be then spun into porous rovings, in which state they are most conveniently bleached by the ordinary methods.

PINES. A numerous family of cone-bearing timber trees. The wood, which is extensively used, is imported under the names of American, Baltic, Dantzic, Memel, Norway, and Riga timber, Swiss deals, &c. The New Zealand pine, called also the Cowdie or Kaurie (the *Dammara Australis*), is not a true pine.

The Pinus sylvestris. The wild pine, or Scotch fir, yields the yellow deal.

The Abies excelsa. The Norway spruce fir, the white deal.

The Abies picea. The silver fir, a whitish deal, much used for flooring.

The Larix Europea. The Larch. This wood is much employed in Switzerland.

The Pinus Strobus. The Weymouth pine, is much used in the Northern United States.

The Pinus Australis. The southern pine, yellow pine, or pitch pine. Of this wood nearly all the houses of the southern United States are built. It is imported into Liverpool as the Georgia pitch pine.

There are numerous others, as the American larch, the balm of Gilead fir, the spruce firs, &c., which are employed in various districts for ship and house building, but they scarcely require any special notice here.

Our *imports*, in 1858, were: —

	Loads.	Computed real value.
Not sawn or split, or otherwise dressed except hewn - -	971,826	£2,776,808
Deals, battens, boards, &c., sawn or split - - - - -	1,255,430	£3,187,200

The duty from 10th October, 1842, on timber of British possessions, 2*s.* $1\frac{2}{10}$*d.*; and from 15th April, 1851, on foreign timber, 10*s.* per load.

PINEY TALLOW is a concrete fat obtained by boiling with water the fruit of the *Vateria indica*, a tree common upon the Malabar coast. It seems to be a substance intermediate between tallow and wax; partaking of the nature of stearine. It melts at 97½° F., is white or yellowish, has a spec. grav. of 0·926; is saponified by alkalies, and forms excellent candles. Dr. Benjamin Babington, to whom we are indebted for all our knowledge of piney tallow, found its ultimate constituents to be, 77 of carbon, 12·3 of hydrogen, and 10·7 of oxygen. See OIL.

PIN MANUFACTURE. (*Fabrique d'épingles*, Fr.; *Nadelfabrik*, Germ.) A pin is a small bit of wire, commonly brass, with a point at one end, and a spherical head at the other. In making this little article, there are no less than fourteen distinct operations.

1. *Straightening the wire.* The wire, as obtained from the drawing-frame, is wound about a bobbin or barrel, about 6 inches diameter, which gives it a curvature that must be removed. The straightening engine is formed by fixing 6 or 7 nails upright in a waving line on a board, so that the void space measured in a straight line between the first three nails may have exactly the thickness of the wire to be trimmed; and that the other nails may make the wire take a certain curve line, which must vary with its thickness. The workman pulls the wire with pincers through among these nails, to the length of about 30 feet, at a running draught; and after he cuts that off, he returns for as much more; he can thus finish 600 fathoms in the hour. He next cuts these long pieces into lengths of 3 or 4 pins. A day's work of one man amounts to 18 or 20 thousand dozen of pin-lengths.

2. *Pointing*, is executed on two iron or steel grindstones, by two workmen, one of whom roughens down, and the other finishes. Thirty or forty of the pin wires are applied to the grindstone at once, arranged in one plane, between the two forefingers and thumbs of both hands, which dexterously give them a rotatory movement.

3. *Cutting these wires into pin-lengths.* This is done by an adjusted chisel. The intermediate portions are handed over to the *pointer*.

4. *Twisting of the wire for the pin-heads.* These are made of a much finer wire, coiled into a compact spiral, round a wire of the size of the pins, by means of a small lathe constructed for the purpose.

5. *Cutting the heads.* Two turns are dexterously cut off for each head, by a regulated chisel. A skilful workman may turn off 12,000 in the hour.

6. *Annealing the heads.* They are put into an iron ladle, made red-hot over an open fire, and then thrown into cold water.

7. *Stamping or shaping the heads.* This is done by the blow of a small ram, raised by means of a pedal lever and a cord. The pin-heads are also fixed on by the same operative, who makes about 1500 pins in the hour, or from 12,000 to 15,000 per diem, exclusive of one-thirteenth, which is always deducted for waste in this department, as well as in the rest of the manufacture. Cast heads, of an alloy of tin and antimony, were introduced by patent, but never came into general use.

8. *Yellowing or cleaning the pins*, is effected by boiling them for half an hour in sour beer, wine lees, or solution of tartar; after which they are washed.

9. *Whitening or tinning.* A stratum of about 6 pounds of pins is laid in a copper pan, then a stratum of about 7 to 8 pounds of grain tin; and so alternately till the vessel be filled; a pipe being left inserted at one side, to permit the introduction of water slowly at the bottom, without deranging the contents. When the pipe is withdrawn, its space is filled up with grain tin. The vessel being now set on the fire, and the water becoming hot, its surface is sprinkled with 4 ounces of cream of tartar; after which it is allowed to boil for an hour. The pins and tin grains are, lastly, separated by a kind of cullender.

10. *Washing the pins*, in pure water.

11. *Drying and polishing them*, in a leather sack filled with coarse bran, which is agitated to and fro by two men.

12. *Winnowing*, by fanners.

13. *Pricking the papers* for receiving the pins.

14. *Papering*, or fixing them in the paper. This is done by children, who acquire the habit of putting up 36,000 per day.

The pin manufacture is one of the greatest prodigies of the division of labour; it furnishes 12,000 articles for the sum of three shillings, which have required the united diligence of fourteen skilful operatives.

The above is an outline of the mode of manufacturing pins by hand labour, but several beautiful inventions have been employed to make them entirely, or in a great measure, by machinery; the consumption for home sale and export amounting to 15 millions daily, for this country alone. A detailed description of it will be found in the 9th volume of *Newton's London Journal.* The following outline will give the reader an idea of the structure of Mr. L. W. Wright's ingenious machine for pin making.

The rotation of a principal shaft mounted with several cams, gives motion to various sliders, levers, and wheels, which work the different parts. A slider pushes pincers forwards, which draw wire from a reel, at every rotation of the shaft, and advance such a length of wire as will produce one pin. A die cuts off the said length of wire by the descent of its upper chap; the chap then opens a carrier, which takes the pin to the pointing apparatus. Here it is received by a holder, which turns round, while a bevel-edged file-wheel rapidly revolves, and tapers the end of the wire to a point. The pin is now conducted by a second carrier to a finer file-wheel, in order to finish the point by a second grinding. A third carrier then transfers the pin to the first heading die, and by the advance of a steel punch, the end of the pin wire is forced into a recess, whereby the head is partially swelled out. A fourth carrier removes the pin to a second die, where the heading is perfected. When the heading-bar retires, a forked lever draws the finished pin from the die, and drops it into a receptacle below.

The following is a further detail of this very interesting manufacture: —

In pin making the wire is brass, (a compound of copper and zinc): it is reduced by the ordinary process of wire drawing to the requisite thickness: in this process it is necessarily curved. To remove this it is re-wound, and pulled through between a number of pins arranged at the draw or straightening bench; it is then cut into convenient lengths for removal, and finally reduced to just such a length as will make two pins. The pointing is done upon steel mills (revolving wheels), the circumference of which is cut with teeth, the one fine, the other coarse. Thirty or forty lengths are packed up at once, and, as in needle-making, the cast of hand given by the workman makes them revolve, and the whole are pointed at once; the same operation is performed with the other end. The process of heading is next performed as follows: a number of the pointed wires now cut in two, are placed in the feeder of the machine; one drops, is firmly seized, and by means of a pair of dies, a portion of the metal is forced up into a small bulb; by a beautifully simple and automatic arrangement, it is passed into another, when a small horizontal hammer gives it a sharp tap, which completes the head. The white colour is produced by boiling in a solution of cream of tartar and tin. They are then dried, and passed into the hands of the wrappers-up. The preparation or marking of the paper is peculiar, and is done by means of a moulded piece of wood, the moulds corresponding to those portions which represent the small folds of paper through which the pins are passed, and thereby held. The pins are then taken to the paperers, who are each seated in front of a bench, to which is attached a horizontally hinged piece of iron, the edge of which is notched with a corresponding number of marks to the number of pins to be stuck; the small catch which holds together the two parts of the iron is released, the paper introduced, and a pin inserted at every mark; the paper is then released, and the task of examination follows, which is the work of a moment. The paper of pins is held so that the light strikes upon it: those defective are immediately detected by the shade, are taken out, and others substituted in their stead. An ancient edict of Henry VIII. held that "no one should sell any pins but such as were double-headed, or the heads soldered fast on."

An improved pin has been introduced, in which iron or steel wires have been employed. The iron or steel wire employed should be very round, and, to protect it from rust, it should at the last drawing be lubricated by means of a sponge saturated with oil, placed between the draw-plate and reel.

The following is the process adopted with those: — The wire being cut into pins, and these headed and pointed, all according to the usual methods, the pins are thrown into a revolving cylinder of wood containing a bath of soap and water in a hot state. It is of the capacity of about $9\frac{1}{2}$ gallons, but should not contain more than about $1\frac{1}{2}$ gallons of water, with about 2 ounces of soap dissolved therein, as this quantity will be sufficient for the treatment of about $13\frac{1}{2}$ lbs. weight of pins at a time. The cylinder, when thus charged, is made to revolve for about a quarter of an hour; at the expiration of which time the pins are found free from the oil with which they were previously coated, and also very much smoothed and polished by their rubbing one against the other.

The pins are next dried by transferring them to another cylinder partially filled with well-dried sawdust (preferring for the purpose the sawdust of poplar wood), and causing this cylinder to revolve for about ten minutes; or, instead of employing a cylinder of this description, the pins may be thrown into a bag or bags partially filled with the sawdust, and the requisite friction produced by swinging or rolling these bags about for the same length of time.

Into a glass or stone vase, there are put about $1\frac{1}{2}$ gallons of soft water, $\frac{7}{10}$ of a pound of sulphuric acid, $\frac{6}{100}$ lb. of salt of tin, $\frac{8}{100}$ lb. of crystallised sulphate of zinc, and 108 grs. of pure sulphate of copper. This mixture is left to work for about 24 hours, so that the salts and sulphates may be properly dissolved.

The mixture, prepared as directed, is introduced into another revolving cylinder, and pins about $13\frac{1}{2}$ lbs. weight are thrown into the midst of it. The cylinder is then caused to revolve for about half an hour, which serves at once to remove any verdigris from the pins, to impart a high polish to them, and to give a beginning to the copper coating process. At the end of the half hour or thereabouts 232 grs. of crystallised sulphate of copper in coarse powder, and 150 grs. of crystallised sulphate of zinc, previously dissolved in soft water, are added to the mixture in the cylinder, and the whole again agitated for about a quarter of an hour. The pins are by this operation not only completely coated, but acquire a very considerable degree of polish. The copper liquors being drawn off, the pins are washed with cold water in the rotating cylinder, and afterwards in a tub with soap and water out of contact with air, where they are well shaken. The contents of the tub are then emptied into a wooden strainer, having a perforated bottom of tin plate iron. The pins are finally dried by agitation with dry sawdust.

The tinning and blanching are performed by laying the pins upon plates of very thin tin placed one above another, in a tinned copper boiler containing a solution of about $4\frac{2}{5}$ lbs. of crude tartar or cream of tartar, in about 22 gallons of water, and then setting the whole to boil for about 12 hours. The tartar solution should be prepared at least 24 hours previously. A little more cream of tartar improves the brilliancy of the pins.

PIPERIDINE, $C^{10}H^{11}N$. A volatile base, discovered by Anderson, by acting with potash on the product of the action of nitric acid on piperine. It may also be procured by treating piperine with potash. It has been chiefly studied by Cahours.—C. G. W.

PIPERINE is a crystalline principle extracted from black pepper, by means of alcohol. It is colourless, has hardly any taste, fuses at 212° F.; is insoluble in water, but soluble in acetic acid, ether, and most readily in alcohol.

PITCH, MINERAL. is the same as BITUMEN and ASPHALT, which see.

PITCH *of wood-tar* (*Poix*, Fr.; *Pech*, Germ.) is obtained by boiling tar in an open iron pot, or in a still, till the volatile matters are driven off. Pitch contains pyroligneous resin, along with colophany (common rosin), but its principal ingredient is the former, called by Berzelius pyretine. It is brittle in the cold, but softens and becomes ductile with heat. See TAR.

PIPECLAY. A silicate of alumina, found in Devonshire and some other parts, much used in the manufacture of tobacco pipes. See PORCELAIN CLAY.

PITCH BLENDE. An ore of URANIUM, which see.

PITCH-STONE. A glassy trappean rock, similar to, and often classed with obsidian.

PITCOAL. See COAL.

PITTACAL, from two Greek words, signifying *fine pitch*, is one of the principles detected in wood-tar by Reichenbach. It is obtained by adding barytes water to a solution of *picamar*, or of oil of tar deprived of its acid, when the pittacal falls. It is a dark-blue solid substance, somewhat like indigo, and assumes a metallic lustre on friction. It is void of taste and smell, not volatile; carbonises at a high heat without emitting an ammoniacal smell; is soluble or rather very diffusible in water; gives a green solution, with a cast of crimson, in sulphuric acid, with a cast of red blue in muriatic acid, and with a cast of aurora red in acetic acid. It is insoluble in alkalies, and in alcohol and ether. It dyes a fast blue upon linen and cotton goods with tin and aluminous mordants.

PLANE TREE. Maple or Plane. (*Erable*, Fr.; *Ahorn*, Germ.) The *Platanus occidentalis*, about the largest of the American trees. The wood of the plane tree is much used in this country for quays. It is also employed for musical instruments, and for other works requiring a clean light coloured wood.

PLASMA. A translucent chalcedony, of a greenish colour, and a glittering lustre.

PLASTER. See MORTAR.

PLASTER OF PARIS. See ALABASTER and GYPSUM.

PLASTIC CLAY. Any clay which, when in a moist state, may be kneaded between the fingers, and admits of being moulded into a definite form, so as to be converted into pottery.

Hence plastic clay is not confined to any particular strata, and is found in secondary and tertiary formations, and also in deposits derived from the decomposition of other rocks.

In geological nomenclature, however, the term Plastic Clay is applied to those portions of the Lower Tertiary or Eocene strata which intervene between the Chalk and the London clay, in consequence of some of the beds of clay of which they are composed being of a plastic nature. Some of the earliest pottery made in this country was manufactured from these clays, dug up at Crendle Common, near Cranborne, in Dorsetshire, where, as well as at Newport in the Isle of Wight, Fareham in Hants, &c., the clay is still dug up and converted into pottery. The clay from the Plastic Clay series is generally of a bright brick-red colour, frequently mottled with white, but sometimes (as at Crendle) it is dark purple or nearly black towards the lower part, and this clay is said to be the best as regards quality. The clays of the plastic clay burn to a red colour, and are manufactured into bricks, tiles, flower-pots, and other coarse pottery.—H. W. B.

PLATE-CLEANING. Boil 30 grms. of finely powdered and calcined hartshorn in a quart of water, and while on the fire put as many silver articles in the vessels used for boiling as it will hold, and leave them there for a short time; then withdraw them, and dry them over the fire; continue this until all the articles have been treated in the same manner; then introduce into the hartshorn water clean woollen rags, and allow them to remain until saturated, after which dry them, and use them for polishing the silver. This is also the best substance for cleaning locks and brass handles of room doors. When the silver articles are perfectly dry, they must be carefully rubbed with a soft leather. This mode of cleaning is excellent, and much preferable to the employment of any powder containing mercury, as mercury has the effect of rendering the silver so brittle as to break on falling.—*C. Gaz.* 1849, p. 362.

PLATED MANUFACTURE. (*Fabrique de plaqué*, Fr.; *Silber plattirung*, Germ.) The silver in this case is not applied to ingots of pure copper, but to an alloy consisting of copper and brass, which possesses the requisite stiffness for the various articles.

The furnace used for melting that alloy, in black lead crucibles, is a common air-furnace, like that for making brass.

The ingot-moulds are made of cast-iron, in two pieces, fastened together; the cavity being of a rectangular shape, 3 inches broad, $1\frac{1}{2}$ thick, and 18 or 20 long. There is an elevated mouth-piece or gate, to give pressure to the liquid metal, and secure solidity to the ingot. The mould is heated, till the grease with which its cavity is besmeared merely begins to smoke, but does not burn. The proper heat of the melted metal for casting, is when it assumes a bluish colour, and is quite liquid. Whenever the metal has solidified in the mould, the wedges that tighten its rings are driven out, lest the shrinkage of the ingot should cause the mould to crack. See BRASS.

The ingot is now dressed carefully with the file on one or two faces, according as it is to be single or double plated. The thickness of the silver plate is such as to constitute one fortieth of the thickness of the ingot; or when this is an inch and a quarter thick, the silver plate applied is one thirty-second of an inch; being by weight a pound troy of the former, to from 8 to 10 pennyweights of the latter. The silver, which is slightly less in size than the copper, is tied to it truly with iron wire, and a little of a saturated solution of borax is then insinuated at the edges. This salt melts at a low heat, and excludes the atmosphere, which might oxidise the copper, and obstruct the union of the metals. The ingot thus prepared is brought to the plating furnace.

The furnace has an iron door with a small hole to look through; it is fed with coke laid upon a grate at a level with the bottom of the door. The ingot is placed immediately upon the cokes, the door is shut, and the plater watches at the peep-hole the instant when the proper soldering temperature is attained. During the union of the silver and copper, the surface of the former is seen to be drawn into intimate contact with the latter, and this species of *rivetting* is the signal for removing the compound bar instantly from the furnace. Were it to remain a very little longer, the silver would become alloyed with the copper, and the plating be thus completely spoiled. The adhesion is, in fact, accomplished here by the formation of a film of true silver-solder at the surfaces of contact.

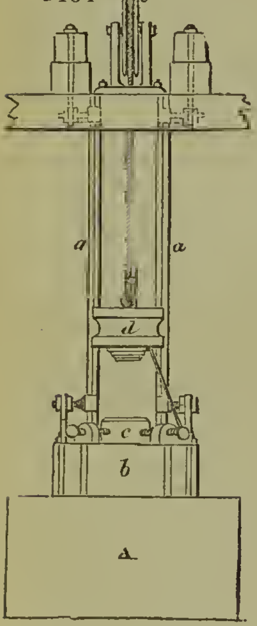
The ingot is next cleaned, and rolled to the proper thinness between cylinders, as described under MINT; being in its progress of lamination frequently annealed on a small reverberatory hearth. After the last annealing, the sheets are immersed in hot dilute sulphuric acid, and scoured with fine Calais sand; they are then ready to be fashioned into various articles.

In plating copper wire, the silver is first formed into a tubular shape, with one edge projecting slightly over the other; through which a redhot copper cylinder being somewhat loosely run, the silver edges are closely pressed together with a steel burnisher, whereby they get firmly united. The tube thus completed is cleaned inside, and put on the proper copper rod, which it exactly fits. The copper is left a little longer than its coating tube, and is grooved at the extremities of the latter, so that the silver edges, being worked into the copper groove, may exclude the air from the surface of the rod. The compound cylinder is now heated redhot, and rubbed briskly over with the steel burnisher in a longitudinal direction, whereby the two metals get firmly united, and form a solid rod, ready to be drawn into wire of any requisite fineness and form; as flat, half-round, fluted, or with mouldings, according to the figure of the hole in the draw-plate. Such wire is much used for making bread-baskets, toast-racks, snuffers, and articles combining elegance with lightness and economy. The wire must be annealed from time to time during the drawing, and finally cleaned, like the plates, with dilute acid.

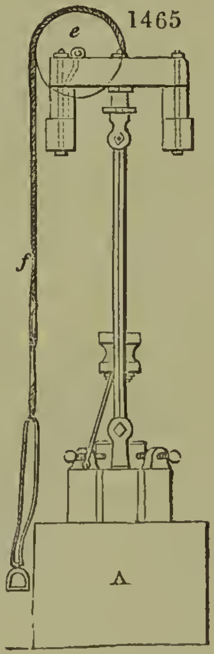
Formerly the different shaped vessels of plated metal were all fashioned by the hammer; but every one of simple form is now made in dies struck with a drop-hammer or stamp. Some manufacturers employ 8 or 10 drop machines.

Fig. 1464 and 1465 are two views of the stamp: A is a large stone, the more massy

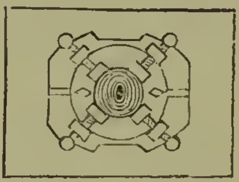
1464



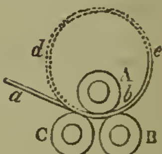
1465



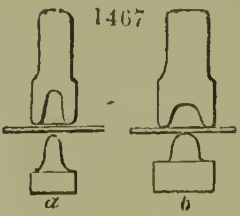
1466



1469



1467



1468

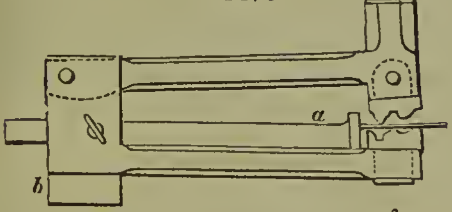
the better; *b*, the anvil on which the die *c* is secured by four screws, as shown in the ground plan, *fig.* 1466. In *fig.* 1464, *a a* are two upright square prisms, set diagonally with the angles opposed to each other; between which the hammer or drop *d* slides truly, by means of nicely fitted angular grooves or recesses in its sides. The hammer is raised by pulling the rope *f*, which passes over the pulley *e*, and is let fall from different heights, according to the impulse required. Vessels which are less in diameter at the top and bottom than in the middle, must either be raised by the stamp in two pieces, or raised by a hand hammer. The die is usually made of *cast* steel.

When it is placed upon the anvil, and the plated metal is cut into pieces of proper size, the top of the die is then surrounded with a lute, made of oil and clay, for an inch or two above its surface; and the cavity is filled with melted lead. The under face of the stamp-hammer has a plate of iron called the *licker-up* fitted into it, about the area of the die. Whenever the lead has become solid, the hammer is raised to a certain height, and dropped down upon it; and as the under face of the licker-up is made rough like a rasp, it firmly adheres to the lead, so as to lift it afterwards with the hammer. The plated metal is now placed over the die, and the hammer mounted with its lead is let fall repeatedly upon it, till the impression on the metal is complete. If the vessel to be struck be of any considerable depth, two or three dies may be used of progressive sizes in succession. But it occasionally happens that when the vessel has a long conical neck, recourse must be had to an auxiliary operation, called *punching*. See the embossing punches, *fig.* 1467. These are made of cast steel, with their hollows turned out in the lathe. The pieces *a*, *b*, are of lead. The punching is performed by a series of these tools, of different sizes, beginning with the largest, and ending with the least. By this means a hollow cone, 3 or 4 inches deep, and an inch diameter, may be raised out of a flat plate. These punches are struck with a hand hammer also, for small articles of too great delicacy for the drop. Indeed it frequently happens that one part of an article is executed by the stamp and another by the hand.

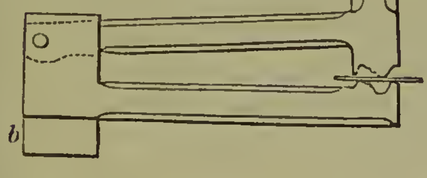
Cylindrical and conical vessels are mostly formed by bending and soldering. The bending is performed on blocks of wood, with wooden mallets; but the machine so much used by the tin-smiths, to form their tubes and cylindric vessels (see the end sections *figs.* 1468, 1469), might be employed with advantage. This consists of 3 iron rollers fixed in an iron frame. A, B, C are the three cylinders, and *a*, *b*, *c*, *d*, the riband or sheet of metal passed through them to receive the cylindrical or conical curvature. The upper roller A, can be raised or lowered at pleasure, in order to modify the diameter of the tube; and when one end of the roller is higher than the other, the conical curvature is given. The edges of the plated cylinders or cones are soldered with an alloy composed of silver and brass. An alloy of silver and copper is somewhat more fusible; but that of brass and silver answers best for plated metal, the brass being in very small proportion, lest the colour of the plate be affected. Calcined borax mixed with sandiver (the salt skimmed from the pots of crown glass) is used along with the alloy, in the act of soldering. The seam of the plated metal being smeared with that saline mixture made into a pap with water, and the bits of laminated solder, cut small with scissors, laid on, the seam is exposed to the flame of an oil blowpipe, or to that of charcoal urged by bellows in a little forge-hearth, till the solder melts and flows evenly along the junction. The use of the sandiver seems to be, to prevent the iron wire that binds the plated metal tube from being soldered to it.

Mouldings are sometimes formed upon the edges of vessels, which are not merely ornamental, but give strength and stiffness. These are fashioned by an instrument called a *swage*, represented in *figs.* 1470, 1471. The part A lifts up by a joint, and

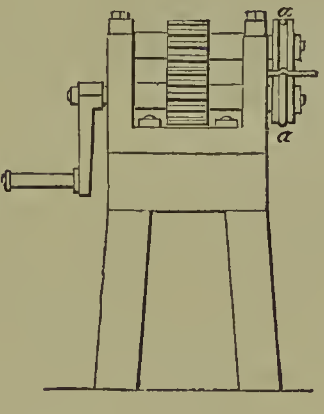
1470



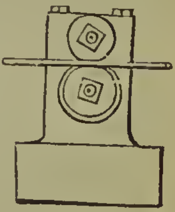
1471



1472



1474



1473

the metal to be *swaged* is placed between the dies, as shown in the figures; the tail *b*, being held in the jaws of a vice, while the shear-shaped hammer rests upon it. By striking on the head A, while the metal plate is shifted successively forwards, the beading is formed. In *fig.* 1470, the tooth *a* is a guide to regulate the distance between the bead and the edge. A similar effect is produced of late years in a neater and more expeditious manner by the rollers, *figs.* 1472, 1474. *Fig.* 1473 is a section to show the form of the bead. The two wheels *a, a, fig.* 1472, are placed upon axes, two of which are furnished with toothed pinions in their middle; the lower one being turned by the handle, gives motion to the upper. The groove in the upper wheel corresponds with the bead in the lower, so that the slip of metal passed through between them assumes the same figure.

The greatest improvement made in this branch of manufacture, is the introduction of silver edges, beads and mouldings, instead of the plated ones, which from their prominence had their silver surface speedily worn off, and thus assumed a brassy look. The silver destined to form the ornamental edging is laminated exceedingly thin; a square inch sometimes weighing no more than 10 or 12 grains. This is too fragile to bear the action of the opposite steel dies of the swage above described. It is necessary, therefore, that the sunk part of the die should be steel, and the opposite side lead, as was observed in the stamping; and this is the method now generally employed to form these silver ornaments. The inside shell of this silver moulding is filled with soft solder, and then bent into the requisite form.

The base of candlesticks is generally made in a die by the stamp, as well as the neck, the dish part of the nozzle or socket, and the tubular stem or pillar. The different parts are united, some with soft and others with hard solder. The branches of candlesticks are formed in two semi-cylindrical halves, like the feet of tea-urns. When an article is to be engraved on, an extra plate of silver is applied at the proper part, while the plate is still flat, and fixed by burnishing with great pressure over a hot anvil. This is a species of welding.

The last finish of plated goods is given by burnishing tools of bloodstone, fixed in sheet-iron cases, or hardened steel, finely polished.

The ingots for lamination might probably be plated with advantage by the delicate pressure process employed for silvering copper wire. See Electro-Metallurgy.

PLATINUM is a metal of a greyish-white colour. It is harder than silver, and of about double its density, being of specific gravity 21. It is so infusible, that no considerable portion of it can be melted by the strongest heats of our furnaces. It is unchangeable in the air and water; nor does a white heat impair its polish. The only acid which dissolves it, is the nitro-muriatic.

Native Platinum in the natural state is never pure, being alloyed with several other metals. It occurs only under the form of grains, which are usually flattened, and resemble in shape the gold *pepitas*. Their size is in general less than linseed, although in some cases they equal hempseed, and, occasionally, peas. One piece brought from Choco, in Peru, and presented to the Cabinet of Berlin, by M. Humboldt, weighs 882½ grains, or more than 2 oz. avoirdupois. A lump of native platinum is in the Royal Museum of Madrid, which was found in 1814 in the gold mine of Condoto, province of Novita, at Choco. Its size is greater than a Turkey's egg, (about 2 inches one diameter, and 4 inches the other,) and its weight 11,641 grains. In 1827 a specimen was found in the Ural Mountains which weighed 11·57 pounds troy; the largest yet obtained being in the Demidoff Cabinet, weighing 21 pounds.

The colour of the grains of native platinum is generally a greyish white, like tarnished steel. The cavities of the rough grains are often filled with earthy and ferruginous matters, or sometimes with small grains of black oxide of iron, adhering to the surface of the platinum grains. Their specific gravity is also much lower than that of forged pure platinum; varying from 15 in the small particles, to 18·94 in M. Humboldt's large specimen. This relative lightness is owing to the presence of iron, copper, lead, and chrome; besides its other metallic constituents, palladium, osmium, rhodium, and iridium.

Its main localities in the New Continent are the three following districts:—

1. At Choco, in the neighbourhood of Barbacoas, and generally on the coasts of the South Sea, or on the western slopes of the Cordillera of the Andes, between the 2nd and the 6th degrees of north latitude. The gold-washings that furnish most platinum are those of Condoto, in the province of Novita; those of Santa Rita, or Viroviro, of Santa Lucia, of the ravine of Iro, and Apoto, between Novita and Taddo. The deposit of gold and platinum grains is found in alluvial ground, at a depth of about 20 feet. The gold is separated from the platinum by picking with the hand, and also by amalgamation; formerly, when it was imagined that platinum might be used to debase gold, the grains of the former metal were thrown into the rivers, through which mistaken opinion an immense quantity of it was lost.

2. Platinum grains are found in Brazil, but always in the alluvial lands that contain gold, particularly in those of Matto-Grosso. The ore of this country is somewhat different from that of Choco. It is in grains, which seem to be fragments of a spongy substance. The whole of the particles are nearly globular, exhibiting a surface formed of small spheroidal protuberances strongly cohering together, whose interstices are clean, and even brilliant. This platinum includes many small particles of gold, but

none of the magnetic iron-sand or of the small zircons which accompany the Peruvian ore. It is mixed with small grains of native palladium, which may be recognised by their fibrous or radiated structure, and particularly by their chemical characters.

3. Platinum grains are found in Hayti, or Saint Domingo, in the sand of the river Jacky, near the mountains of Sibao. Like those of Choco, they are in small brilliant grains, as if polished by friction. The sand containing them is quartzose and ferruginous. This native platinum contains, like that of Choco, chromium, copper, osmium, iridium, rhodium, palladium, and probably titanium. Vauquelin could find no gold among the grains.

4. Platinum is largely produced in the Russian territories, in the auriferous sands of Kuschwa, 250 wersts from Ekaterinebourg, and consequently in a geological position which seems to be analogous with that of South America. It also occurs at Nische, Tagilsk, and Goroblagodat in the Ural in alluvial and drift material.

These auriferous sands are, indeed, almost all superficial; they cover an argillaceous soil; and include, along with gold and platinum, debris of dolerite (a kind of greenstone), protoxide of iron, grains of corundum, &c. The platinum grains are not so flat as those from Choco, but they are thicker; they have less brilliancy, and more of a leaden hue. This platinum, by M. Laugier's analysis, is similar in purity to that of Choco; but the leaden-grey grains, which were taken for a mixture of osmium and iridium, are merely an alloy of platinum, containing 25 per cent. of these metals. In Russia platinum has been formed into coins of eleven and twenty-two rubles each; and this country affords annually about 800 cwt. of platinum, which is nearly ten times the amount from Brazil, Colombia, St. Domingo, and Borneo.

M. Vauquelin found nearly 10 per cent. of platinum in an ore of argentiferous copper, which was transmitted to him as coming from Guadalcanal in Spain. This would be the only example of platinum existing in a rock, and in a vein. The same thing has not again been met with, even in other specimens from Guadalcanal.

Platinum has been known in Europe only since 1748, though it was noticed by Ulloa in 1741. It was compared at first to gold; and was, in fact, brought into the market under the name of white gold. The term platinum, however, is derived from the Spanish word, *plata*, silver, on account of its resemblance in colour to that metal.

The whole of the platinum ore from the Urals is sent to St. Petersburg, where it is treated by the following simple process:—

One part of the ore is put in open platina vessels, capable of containing from 6 to 8lbs., along with 3 parts of muriatic acid at 25° B. and 1 part of nitric acid at 40°. Thirty of these vessels are placed upon a sand-bath covered with a glazed dome with movable panes, which is surmounted by a ventilating chimney to carry the vapours out of the laboratory. Heat is applied for 8 or 10 hours, till no more red vapours appear; a proof that the whole nitric acid is decomposed, though some of the muriatic remains. After settling, the supernatant liquid is decanted off into large cylindrical glass vessels, the residuum is washed, and the washing is also decanted off. A fresh quantity of nitro-muriatic acid is now poured upon the residuum. This treatment is repeated till the whole solid matter has eventually disappeared. The ore requires for solution from 10 to 15 times its weight of nitro-muriatic acid, according to the size of its grains.

The solutions thus made are all acid; a circumstance essential to prevent the iridium from precipitating with the platinum, by the water of ammonia, which is next added. The deposit being allowed to form, the mother waters are poured off, the precipitate is washed with cold water, dried, and calcined in crucibles of platinum.

The mother-waters and the washings are afterwards treated separately. The first being concentrated to one-twelfth of their bulk in glass retorts, on cooling they let fall the iridium in the state of an ammoniacal chloride, constituting a dark-purple powder, occasionally crystallised in regular octahedrons. The washings are evaporated to dryness in porcelain vessels; the residuum is calcined and treated like fresh ore; but the platinum it affords needs a second purification.

For agglomerating the platinum, the spongy mass is pounded in bronze mortars; the powder is passed through a fine sieve, and put into a cylinder of the intended size of the ingot. The cylinder is fitted with a rammer, which is forced in by a coining press, till the powder is much condensed. It is then turned out of the mould, and baked 36 hours in a porcelain kiln, after which it may be readily forged, if it be pure, and may receive any desired form from the hammer. It contracts in volume from 1-6th to 1-5th during the calcination.

For Dr. Wollaston's process, see *Phil. Trans.* 1829, Part I.

Platinum furnishes most valuable vessels to both analytical and manufacturing chemists. It may be beaten out into leaves of such thinness as to be blown about with the breath. Dr. Wollaston succeeded in obtaining a wire not exceeding the two-thousandth of an inch in diameter. A wire of this metal of $\frac{1}{8}$ inch in diameter will support a weight of 361 lbs.

This metal is applied to porcelain by two different processes; sometimes in a rather coarse powder, applied by the brush, like gold, to form ornamental figures; sometimes in a state of extreme division, obtained by decomposing its nitro-muriatic solution, by means of an essential oil, such as rosemary or lavender. In this case, it must be evenly spread over the whole ground. Both modes of application give rise to a steely lustre.

The properties possessed in common by gold and platinum have several times given occasion to fraudulent admixtures, which have deceived the assayers. M. Vauquelin having executed a series of experiments to elucidate this subject, drew the following conclusions:—

If the platinum do not exceed 30 or 40 parts in the thousand of the alloy, the gold does not retain any of it when the parting is made with nitric acid in the usual way; and when the proportion of platinum is greater, the fraud becomes manifest, 1st, by the higher temperature required to pass it through the cupel, and to form a round button; 2nd, by the absence of the lightning, fulguration, or coruscation; 3rd, by the dull white colour of the button and its crystallised surface; 4th, by the straw-yellow colour which platinum communicates to the aquafortis in the parting; 5th, by the straw-yellow colour, bordering on white, of the cornet after it is annealed. If the platinum amounts to one fourth of the gold, we must add to the alloy at least 3 times its weight of fine silver, laminate it very thin, anneal somewhat strongly, boil it half an hour in the first aquafortis, and at least a quarter of an hour in the second, in order that the acid may dissolve the whole of the platinum.

Were it required to determine exactly the proportions of platinum contained in an alloy of copper, silver, gold, and platinum, the amount of the copper may be found in the first place by *cupellation*, then the respective quantities of the three other metals may be learned by the processes founded, 1, upon the property possessed by sulphuric acid of dissolving silver without affecting gold or platinum; and, 2, upon the property of platinum being soluble in the nitric acid, when it is alloyed with a certain quantity of gold and silver.

The value of the platinum *imported* in 1858 was 8,285*l.*

PLATINUM, ALLOYS OF. This metal will alloy with iron; the alloy is malleable and possesses much lustre.

Copper and platinum in certain proportions form a brilliant alloy.

* The Russian pood is 36 lbs. 1 oz. 11 drs. Troy. The pood contains 40 Russian pounds; 63 poods make a ton.

Silver is much hardened by platinum: although platinum is not soluble in nitric acid, it will, when alloyed with silver, dissolve in that acid.

Some other alloys are known, but none of them are employed.

PLATINUM BLACK. This interesting preparation, which so rapidly oxidises alcohol into acetic acid, &c., by what has been called in chemistry the catalytic or contact action, is most easily prepared by the following process of M. Bœttger:—the insoluble powder of potassa-chloride or ammonia-chloride of platinum is to be moistened with sulphuric acid (oil of vitriol), and a bit of zinc is to be laid *in* the mixture. The platinum becomes reduced into a black powder, which is to be washed first with hydrochloric acid and then with water. The fineness of this powder depends upon that of the saline powders employed to make it; so that if these be previously finely ground, the platinum black will be also very fine, and proportionally powerful as a chemical agent.

The following method of preparing igniferous black platinum, proposed by Descotil, has been recommended by M. Dobereiner:—

Melt platinum ore with double its weight of zinc, reduce the alloy to powder, and treat it first with dilute sulphuric acid, and next with dilute nitric acid, to oxidise and dissolve out all the zinc, which, contrary to one's expectations, is somewhat difficult to do, even at a boiling heat. The insoluble black-grey powder contains some osmiuret of iridium, united with the crude platinum. This compound acts like simple platinum black, after it has been purified by digestion in potash lye, and washing with water. Its oxidising power is so great as to transform not only the formic acid into the carbonic, and alcohol into vinegar, but even some osmic acid, from the metallic osmium. The above powder explodes by heat like gunpowder.

When the platinum black prepared by means of zinc is moistened with alcohol, it becomes incandescent, and emits osmic acid; but if it be mixed with alcohol into a paste and spread upon a watch-glass, nothing but acetic acid will be disengaged; affording an elegant means of diffusing the odour of vinegar in an apartment.

A yet more simple method of preparing the platinum black than either of those is the following:—Protochloride of platinum is dissolved in a concentrated solution of potash with the aid of heat; then alcohol is added by degrees, constantly stirring the solution. The platinum is precipitated as a black powder, which is boiled successively with alcohol, hydrochloric acid, and potash water.

PLATINUM, SALTS OF. The salts of platinum being rarely employed in the arts or manufactures, the reader is referred for them to *Ure's Dictionary of Chemistry.*

PLATINUM YELLOW. A pigment prepared from platina, by oxidation with acids, is sold under this name.

PLUMBAGO, commonly called Black Lead; the name *plumbago*, and its common one, being derived from the fact of this mineral resembling lead in its external appearance. See Graphite, for its mineralogical and chemical characters. In this country plumbago has been found most abundantly in Cumberland. The mountain at Borrowdale, in which the black lead is mined, is nearly 2,000 feet high, and the entrance to the mine is about 1000 feet below its summit. This valuable mineral became so common a subject of robbery about a century ago, as to have enriched, it was said, a great many persons living in the neighbourhood. Even the guard stationed over it by the proprietors was of little avail against men infuriated with the love of plunder; since in those days a body of miners broke into the mine by main force, and held possession of it for a considerable time.

The treasure was then protected by a building, consisting of four rooms upon the ground floor; and immediately under one of them is the opening, secured by a trap-door, through which alone workmen could enter the interior of the mountain. In this apartment, called the dressing-room, the miners change their ordinary clothes for their mining dress. At one time as much as 100,000*l.* was realised from the Borrowdale mine in a year, the Cumberland plumbago selling at 45*s.* per pound. This mine has not, however, been worked for many years. The last great discovery, stated to have been about 30,000*l.*'s worth, has been hoarded by the proprietors, a small quantity only being sold every year; but it is now generally understood to be nearly exhausted. Some few years since the Borrowdale Black Lead Mine was inspected by three experienced miners, but their report was far from encouraging; notwithstanding which a new company has been recently (1859) formed to work this mine.

This plumbago in Borrowdale is found in "nests" in a trap rock, partially decomposed, which runs through the clay slate. In Glenstrathfarrar in Inverness, it is found in gneiss, and at Craigman in Ayrshire it occurs in coal beds which have been formed in contact with trap. In Cornwall plumbago has been discovered in small lumps in the Elvan courses (see Elvan); and on the northern coast of that country, small pieces are picked out of the clay slate rocks, where it has been exposed by the wearing down of the cliffs. At Arendal, in Norway, it occurs with quartz. Plumbago is sometimes formed in considerable quantities in the beds of blast furnaces, especially at Cleator Moor.

Plumbago occurs in Finland. Large quantities are brought from Ceylon and the East Indies. Some considerable portions are obtained from the mines of the United States.

Mr. Brodie purifies plumbago by mixing it in coarse powder, in an iron vessel, with twice its own weight of commercial sulphuric acid, and seven per cent. of chlorate of potash, and heats the whole over a water bath until chloric oxide ceases to be evolved. By this means the compounds of iron, lime, and alumina present, are rendered for the most part soluble, and the subsequent addition of a little fluoride of sodium to the acid mixture, will decompose any silicates which may remain, and volatilise the silica present. The mass is now washed with abundance of water, dried, and heated to redness. This last operation causes the grains of the plumbago to exfoliate. The mass swells up in a surprising manner, and is reduced to a state of very minute division. It is then levigated, and obtained in a state of great purity, ready to be compressed by the method of Brockedon.—T. S. H.

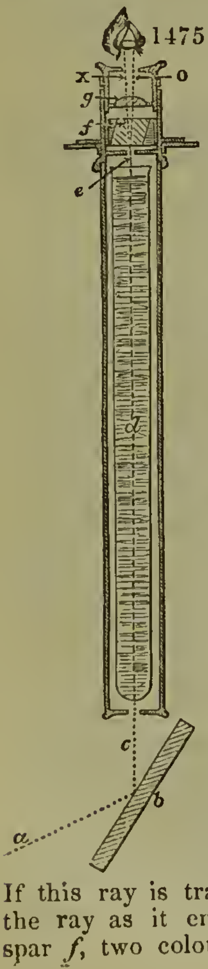
PLUSH (*Panne*, *Peluche*, Fr.; *Wollsammet*, *Plüsch*, Germ.) is a textile fabric, having a sort of velvet nap or shag upon one side. It is composed regularly of a woof of a single woollen thread, and a two-fold warp, the one, wool of two threads twisted, the other, goat's or camel's hair. There are also several sorts of plush made entirely of worsted. It is manufactured, like velvet, in a loom with three treadles; two of which separate and depress the woollen warp, and the third raises the hair-warp, whereupon the weaver, throwing the shuttle, passes the woof between the woollen and hair warp; afterwards, laying a brass brooch or needle under that of the hair, he cuts it with a knife (see FUSTIAN) destined for that use, running its fine slender point along in the hollow of the guide broach, to the end of a piece extended upon a table. Thus the surface of the plush receives its velvety appearance. This stuff is also made of cotton and silk.

POAKE. A name amongst peltmongers for the collected waste arising in the preparation of skins; it is used for manure.

POINT NET is a style of lace formerly much in vogue, but now superseded by the bobbin-net manufacture.

POLARISATION OF LIGHT. It is not the purpose of the present work to deal with any of the peculiar phenomena of the physical powers, except so far as they are involved in any of the processes of manufacture. Polarised light is employed in the sugar refinery; it therefore is necessary that some short account should be given of the phenomena so called, and of the methods of rendering it available to useful ends.

1475



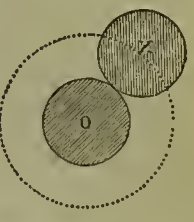
Under the term *Polarisation of Light* is comprehended a variety of very singular phenomena, which it is exceedingly difficult to explain within the space which can be devoted to this article. For anything like an exact description of these peculiar and striking phenomena, the reader is referred to works devoted specially to this branch of science. For our purpose it will be sufficient to state that if a ray of light is reflected from a plate of glass placed at an angle of about 56 degrees, it will be found to have undergone a remarkable change. If the reflected ray of light is looked at through a thin slice of *Tourmaline*, it will be found that while the ray is seen, while the reflecting plate is in one position, it can no longer be seen through the transparent crystal if the glass plate is turned round 90°, or if the crystal is turned to the same extent; although an ordinary ray of light is seen with equal intensity in whatever position the crystal may be held.

The ray of light by reflection, at or about the above-named angle, appears to have assumed the position of a polar body, *i. e.*, a body having dissimilar sides. or it may be, that the mode of motion has been altered by the reflection at the polarising angle. Light can be polarised by refraction, equally as well as by reflection.

Under some circumstances, the condition of *Circular Polarisation* is produced. (See Pereira's *Lectures on Polarised Light*). We do not attempt to explain this. The phenomena alone is all we have now to deal with. An instrument called a Polariscope is constructed upon the principles shown in the accompanying figure (*fig.* 1475).

If a ray of common light *a*, be polarised by falling upon a glass *b*, at an angle of 56° 45′, the plane polarised ray *c* is obtained. If this ray is transmitted through a pure solution of crystallisable cane sugar, and the ray as it emerges, *e*, be analysed by a double refracting rhomb of Iceland spar *f*, two coloured images are perceived, as shown in *fig.* 1476. One, *o*, is caused by ordinary refraction, and the other, *x*, by extraordinary refraction. *y* is a lens to produce a well-defined image. The colours of these images are complementary, that is, when one is *red* the other is *green*, when one is *yellow* the other is *violet*, when one is *blue* the other is *orange*. By rotating the "analyser,"—the rhomb of Iceland spar,—the colours change. If the rotation be right handed, that is, as we turn a screw or cork-screw to make it enter, the sequence of colour is *red, orange, yellow, green, blue, indigo,* and *violet red.* It will be understood that by rotating the rhomb of Iceland spar, the extraordinary ray revolves around the ordinary ray, each undergoing a change of colour. The sequence of the ordinary image being given above, and the complementary colours named, it will be seen that the sequence of colours on the extraordinary image will be *green, blue, indigo,* and *violet, red, orange, yellow, green.* In one complete revolution of the analyser, each of the colours of the spectrum occurs twice for each image. The polariscope is now used for both the qualitative and quantitative analysis of sugar. Indeed, the minutest difference in chemical character and physical constitution can be readily detected by this instrument. See SUGAR.

1476



POLISHING SLATE. A grey or yellow slate composed of microscopic infusoria. It is found abundantly in the coal measures of Bohemia, and in the Auvergne.

POLYCHROMATE. (*Æsculine.*) A compound from which a variety of colours may be prepared.

A great many vegetables give, when treated with hot water, a solution which appears yellow by transmitted light, but blue by reflected light. The inner bark of the horse-chestnut is a peculiar example of this. See FLUORESCENCE.

POPLAR. (*Peuplier*, Fr.; *Pappel*, Germ.) The wooden polishing wheels of the glass grinder are made from horizontal sections of the stem of this tree. It is used in the manufacture of toys, but not for many other purposes.

POPPY OIL. Much used in painting. See OIL.

PORCELAIN. See POTTERY.

PORCELAIN CLAY. (*Kaolin.*) Nature has, up to a certain point, provided the article which man requires for the elaboration of the most perfect production of the potter's art. The clay — China clay, as it is commonly called, or *kaolin*, as the Chinese have it — is quarried from amidst the granitic masses of Dartmoor and of Cornwall. We are not at all satisfied with any of the theories which have been put forward to account for the formation of porcelain clay. It is commonly stated to be a decomposed granite; this rock, as is well known, consisting of mica, quartz, and felspar, with sometimes shorl and hornblende. The felspar is supposed to have decomposed; and, as this forms the largest portion of the mass, the granite is disintegrated by this process. We have, therefore, the mica, quartz, and the clay, forming together a soft mass, lying but a short distance below the surface, but extending to a considerable depth. It is quite evident that this stratum is not *deposited;* had it been so, the particles constituting the mass would have arranged themselves in obedience to the law of gravity, towards which there is not the slightest attempt. But we do not know by what process the decomposition of the solid granite could have been effected to a depth from the surface of upwards of one hundred feet, and then, as it often does, suddenly to cease. This, however, is a question into which we cannot at present enter. The largest quantity of porcelain or China clay is manufactured in Cornwall, especially about St. Austell and St. Stepheus; from which, in 1859, about 60,000 tons were sent away to the potteries, and for paper-making and bleaching.

A spot being discovered where this substance abounds, the operation is commenced by removing the vegetable soil and substratum, called by the workmen the *overburden*, which varies in depth from about three to ten feet. The lowest part of the ground is then selected, in order to secure an outlet for the water used in washing the clay. The *overburden* being removed, the clay is dug up in *stopes*: that is, in successive layers or courses, and each one being excavated to a greater extent than the one immediately below it, the *stopes* resemble a flight of irregular stairs. The depth of the *china clay pits* is various, extending from twenty feet to fifty feet.

The clay when first raised has the appearance and consistence of mortar; it contains numerous grains of quartz, which are disseminated throughout in the same manner as in granite. In some parts the clay is stained of a rusty colour, from the presence of veins and imbedded portions of shorl and quartz; these are called by the workmen *weed, caple,* and *shell*, which are carefully separated. The clay is next conveyed to the floor of the washing place, and is then ready for the first operation of the process.

A heap of the clay being placed on an inclined platform, on which a little stream of water falls from the height of about six feet, the workman constantly moves it and turns it over with a *piggle* and shovel, by which means the whole is gradually carried down into an oblong trench beneath, which is also inclined, and which ends in a covered channel that leads to the *catch-pits* about to be described. In the trench the grains of quartz are deposited, but the other parts of the clay, in consequence of their greater levity, are carried away in a state of suspension.

This water is conducted into a series of pits, each of which is about eight feet long, four in breadth and in depth, and is lined on the sides and bottom with cut moorstone, laid in a waterproof cement. In these pits the porcelain earth is gradually deposited. In the first pit the grosser particles collect; and being of a mixed nature, are always rejected at the end of each day's work by an opening provided for that purpose at the bottom of the pit. When the water has filled the first pit, it overflows into the second, and in like manner into the third; and in these pits, particularly in the second, a deposit also takes place, which is often preserved, and is called by the workmen *mica.* The water, still holding in suspension the finer and purer particles of porcelain clay, next overflows into larger pits, called *ponds*, which are of the same depth as the first pits, but about three times as long and wide. Here the clay is gradually deposited, and the clear supernatant water is from time to time discharged by plug-holes on one side of the pond. This process is continued until, by successive accumulations, the ponds are filled. At this stage the clay is in the state of a thick paste; and to complete the process it only remains to be consolidated by drying, and then it is fit for the market.

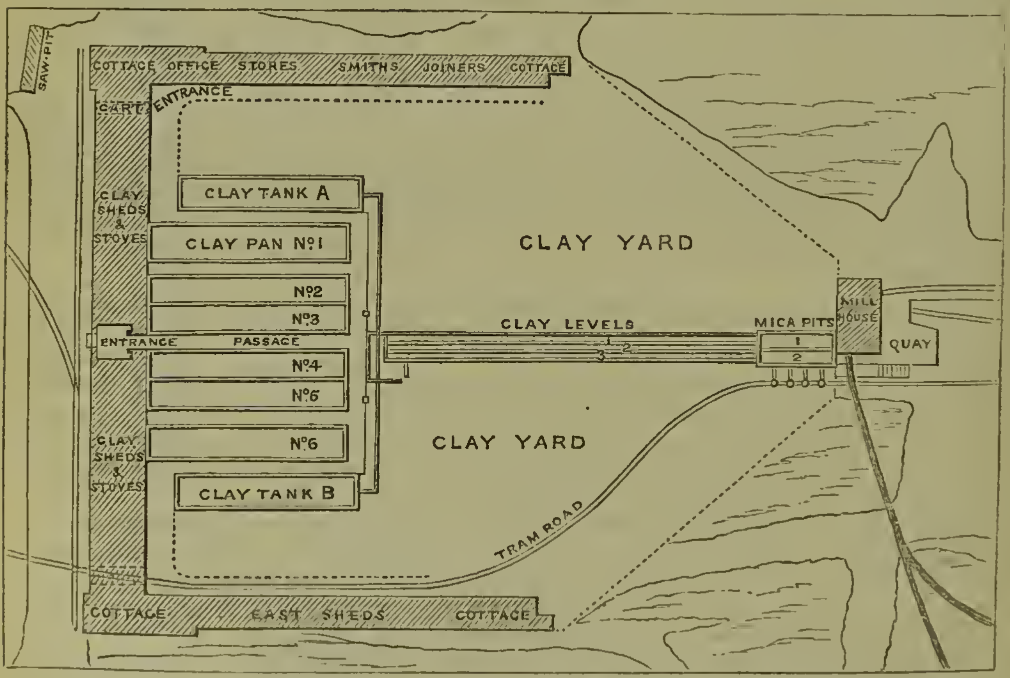
This, however, is a tedious operation in our damp climate, and is effected as follows:—The moist clay is removed in hand-barrows into *pans*, which are constructed like the *pits* and *ponds*, but are much larger, being about forty feet long, fifteen wide, and a foot and a half in depth. The above dimensions may not be quite correct, for I did not actually measure the pits; they are, however, very near the truth. When the pans are nearly filled, the clay is levelled, and is then allowed to remain undisturbed until it is nearly dry. The time required for this part of the process must depend in a great measure on the state of the weather and the season of the year, because the pans are exposed to the air. During the winter at least eight months are necessary, whilst during the summer less than half the time is sufficient.

When the clay is in a fit state, it is cut into oblong masses, and carried to the drying house,—an oblong shed, the sides of which are open wooden frames, constructed in the usual way for keeping off the rain, but admitting the free passage of the air.

The clay thus dried is next scraped perfectly clean, and is then packed up into casks, and carried to one of the adjacent ports, to be shipped for the potteries.

The porcelain earth thus prepared is of a beautiful and uniform whiteness, and is perfectly smooth and soft to the touch.—*Dr. Boase's Geology of Cornwall.*

1477



The works at Lee Moor, on the borders of Dartmoor, being, however, far more complete, we have selected them as the best for our description. See *fig.* 1477.

Here we see a quarry of this decomposed granite, shining white in the sunshine, and at the bottom of this quarry are numerous workmen employed in filling trucks placed upon a tramway. This native material is now carried off to a house, distinguished by the powerful water-wheel which revolves on one side of it, and here it undergoes its first process in manufacture. The trucks are lifted, and the contents discharged into a hopper, from which the clay falls into inclined troughs, through which a strong current of water passes, and the clay is separated from the large particles of quartz and mica, these being discharged *over* a grating, *through which* flows the water charged with the clay and the finer matter, the coarser portion sliding off the grating, and falling in a heap outside the building. The water contains not only the pure clay, but the finer particles of silica, mica, shorl, or of any other matters which may be mixed with the mass. To separate these from the clay, very complete arrangements are made. Large and deep stone tanks receive the water as it comes from the mill, in these the heavier particles settle; and when each tank becomes full, the mica, &c., is discharged through openings in the bottom, into trucks placed to receive it on a railway, and this, the refuse material of the clay works elsewhere, is here preserved for other uses, to be by-and-by described. The water, charged with its clay, now flows slowly and quietly through a great length of stone channel, and during its progress nearly all the micaceous and other particles subside; the water eventually flowing into very large pits, in which the clay is allowed slowly to deposit. The water enters in a thin sheet at one end, and gradually diffuses itself over the large area. The clay, in an impalpable powder, falls down, and perfectly clear water passes away at the other end. From the clay tanks marked A and B in the plan, the semi-fluid clay is pumped into the clay-pans, beneath which there circulates hot-water pipes, and in these the clay is finally dried. When a thickness of about eighteen inches is obtained, evaporation is promoted by the graduated artificial temperature produced by the water pipes. After a little time, the clay is sufficiently hard to be cut out, and subjected to its final drying. The clay is cut out in squares of about eight inches, so that they form parallelograms when removed from the bed. These are then placed in heated rooms, and being still further dried, are fit for the market.

The clay found near Newton in Devonshire is a clay prepared from the same source by nature, instead of by art. Of this about 20,000 tons are annually exported from Teignmouth. See Clay.

PORCELAIN JASPER. Beds of clay which have been vitrefied by the igneous rocks.

PORCELLANOUS SHELLS. See Shells.

PORPOISE OIL. See Oils.

PORPORINO. An Italian glass.

PORTER is a malt liquor, so called from being for a long period the favourite beverage of the porters of London, and indeed confined exclusively to this class of the workpeople of the metropolis. It is characterised by its dark-brown colour, its transparency, its moderately bitter taste, and peculiar aromatic flavour. At first the essential distinction of porter arose from its wort being made with highly-kilned brown malt, while other kinds of beer and ale were brewed from a paler article; but of late years, the taste of the public having run in favour of sweeter and lighter beverages, the actual porter is brewed with a less proportion of brown malt, is less strongly hopped, and not allowed to get hard by long keeping in huge ripening tuns. Some brewers colour the porter with burnt sugar; but in general the most respectable concentrate a quantity of their first and best wort to an extract, in an iron pan, and burn this into a *colouring* stuff, whereby they can lay claim to the merit of using nothing in their manufacture but malt and hops. Porter is now brewed in large quantities in other cities besides London, especially in Dublin. See Beer.

PORTLAND ARROWROOT. See Arrowroot.

PORTLAND CEMENT is so called because it resembles in colour the Portland stone. It is prepared by calcining a mixture of the clayey mud of the Thames with a proper proportion of chalk. They make equally good cement in other parts of England and France by mixing chalk or marl with other clays. The materials are reduced to fine powder, and intimately mixed, with the addition of water. The resulting paste is moulded into bricks, which are dried and burned. It is of importance that the heat in calcining be sufficiently elevated, otherwise the carbonic acid and water may be expelled, without that reaction between the lime and clay which is required for the production of a cement. It is necessary to employ a white heat, which shall agglutinate and frit the mixture. After this operation the material is assorted, and the portions which are scorified by too much heat, as well as those insufficiently calcined, being set aside, the cement is pulverised for use. It is often advantageous to grind to powder the native mixtures of limestone and clay before burning them, in order to ensure homogeneousness. It will also be seen that a calcination at a very high temperature is frequently required to develop the hydraulic character of limestones; the greater the temperature employed, the more slow is the solidification of the cement, but the harder does it become.

PORTLAND STONE. An oolitic limestone, immediately underlying the Purbeck strata; so called in consequence of its development in the island of Portland, situated off the southern coast of Dorsetshire.

St. Paul's Cathedral, and many of the public buildings of this country, have been built of stone from Portland, and it is still obtained from numerous quarries on the island for transmission to other places, and for the breakwater now in course of construction there.

The quarries from which the stone used for building St. Paul's Cathedral was obtained, were situated at the northern extremity of the island, but have been long abandoned in consequence of the stone being somewhat harder and more difficult to work than that met with in other parts of the island. The principal beds of stone quarried in the Isle of Portland are called, in descending order, *roach* or *roche*, *rubbly bed*, and *whit* (*i. e.* white) or *best* bed. These beds vary much in thickness, but they may be stated to average five, and six feet, respectively; some reaching fifteen feet.

The roach affords large blocks of a hard and durable white stone, particularly adapted for foundations of buildings, docks, breakwaters, and other constructions where great strength is required; but, owing to the numerous cavities it contains (produced by the empty casts of shells), it will not receive a close, even face, and is therefore not so well adapted for many other purposes of a more ornamental description. The rubbly bed is not much worked; but the white or best bed, when accessible, is always quarried, and affords a white oolitic freestone, which takes a smooth, even face, and works freely in all directions.

The following analysis by Professor Daniell, gives the chemical composition of this stone: —

Silica	1·20
Carbonate of lime	95·16
Carbonate of magnesia	1·20
Iron, alumina	0·50
Water and loss	1·94
Bitumen	trace
	100·00

The other principal localities where the Portland stone is quarried are the Isle of Purbeck, in Dorsetshire, where it is called Purbeck-Portland; and the Vale of Wardour, where (as at Chilmark and other places) it affords a freestone of a very superior description.

In the year 1858, about 40,000 tons of stone were raised in the Isle of Portland. See *Mineral Statistics* for 1858, by Robert Hunt.—H. W. B.

POTASH, or POTASSA. (*Potasse*, Fr.; *Kali*, Germ.) This substance was so named from being prepared for commercial purposes by evaporating in iron pots the lixivium of the ashes of wood fuel. In the crude state it consists, therefore, of such constituents of burned vegetables as are very soluble in water, and fixed in the fire. The potash salts of plants which originally contained vegetable acids, will be converted into carbonates, the sulphates will become sulphites, sulphides, or even carbonates, according to the manner of incineration; the nitrates will be changed into pure carbonates, while the muriates or chlorides will remain unaltered. Should quicklime be added to the solution of the ashes, a corresponding portion of caustic potassa will be introduced into the product, with more or less lime, according to the care taken in decanting off the clear lye for evaporation.

In America, where timber is in many places an incumbrance upon the soil, it is felled, piled up in pyramids, and burned, solely with a view to the manufacture of potashes. The ashes are put into wooden cisterns, having a plug at the bottom of one of the sides under a false bottom; a moderate quantity of water is then poured on the mass, and some quicklime is stirred in. After standing for a few hours, so as to take up the soluble matter, the clear liquor is drawn off, evaporated to dryness in iron pots, and finally fused at a red-heat into compact masses, which are grey on the outside and pink-coloured within.

Pearlash is prepared by calcining potashes upon a reverberatory hearth, till the whole carbonaceous matter, and the greater part of the sulphur, be dissipated; then lixiviating the mass, in a cistern having a false bottom covered with straw, evaporating the clear lye to dryness in flat iron pans, and stirring it towards the end into white lumpy granulations.

Dr. Ure says the best pink Canadian potashes, as imported in casks containing about 5 cwts., contain pretty uniformly 60 per cent. of absolute potassa; and the best pearlashes contain 50 per cent.; the alkali in the former being nearly in a caustic state; in the latter, carbonated.

All kinds of vegetables do not yield the same proportion of potassa. The more succulent the plant, the more does it afford; for it is only in the juices that the vegetable salts reside, which are converted by incineration into alkaline matter. Herbaceous weeds are more productive of potash than the graminiferous species, or shrubs, and these than trees; and for a like reason twigs and leaves are more productive than timber. But plants in all cases are richest in alkaline salts when they have arrived at maturity. The soil in which they grow also influences the quantity of saline matter.

The following Table exhibits the average product in potassa of several plants, according to the researches of Vauquelin, Pertuis, Kirwan, and De Saussure:—

In 1000 parts.	Potassa.	In 1000 parts.	Potassa.	In 1000 parts.	Potassa.
Pine or fir	0·45	Thistles	5·00	Bastard chamomile (*Anthemis cotula*, L.)	19·6
Poplar	0·75	Flax stems	5·00	Sunflower stalks	20·00
Trefoil	0·75	Small rushes	5·08	Common nettle	25·03
Beechwood	1·45	Vine shoots	5·50	Vetch plant	27·50
Oak	1·53	Barley straw	5·80	Thistles in full growth	35·37
Boxwood	2·26	Dry beech bark	6·00	Dry straw of wheat before earing	47·0
Willow	2·85	Fern	6·26	Wormwood	73·0
Elm and maple	3·90	Large rush	7·22	Fumitory	79·0
Wheat straw	3·90	Stalk of maize	17·5		
Barb of oak twigs	4·20	Bean stalks	20·0		

Stalks of tobacco, potatoes, chestnuts, chestnut husks, broom, heath, furze, tansy, sorrel, vine leaves, beet leaves, orach, and many other plants, abound in potash salts. In Burgundy, the well-known *cendres gravelées* are made by incinerating the lees of wine pressed into cakes, and dried in the sun; the ashes contain fully 16 per cent. of potassa.

The purification of pearlash is founded upon the fact of its being more soluble in water than the neutral salts which debase it. Upon any given quantity of that substance, in an iron pot, let one and a half times its weight of water be poured, and let a gentle heat be applied for a short time. When the whole has again cooled, the bottom will be encrusted with the salts, while a solution of nearly pure carbonate of potash will be found floating above, which may be drawn off clear by a siphon. The salts may be afterwards thrown upon a filter of gravel. If this lye be diluted with 6 times its bulk of water mixed with as much slaked lime as there was pearlash employed, and the mixture be boiled for an hour, the potash will become caustic, by giving up its carbonic acid to the lime. If the clear settled lixivium be now siphoned off, and concentrated by boiling in a covered iron pan, till it assumes the appearance of oil, it will constitute the common caustic of the surgeon, the *potassa fusa* of the shops. But to obtain potash chemically pure, recourse must be had to the bicarbonate, nitrate, or tartrate of potash, salts which, when carefully crystallised, are exempt from anything to render the potash derived from them impure. The bicarbonate having been gently ignited in a silver basin, is to be dissolved in 6 times its weight of water, and the solution is to be boiled for an hour, along with one pound of slaked lime for every pound of the bicarbonate used. The whole must be left to settle without contact of air. The supernatant lye is to be drawn off by a siphon, and evaporated in an iron or silver vessel provided with a small orifice in its close cover for the escape of the steam, till it assumes, as above, the appearance of oil, or till it be nearly red-hot. Let the fused potash be now poured out upon a bright plate of iron, cut into pieces as soon as it concretes, and put up immediately in a bottle furnished with a well-ground stopper. It is hydrate of potash, being composed of 1 atom of potassa 48, + 1 atom of water 9 = 57.

A pure carbonate of potash may be also prepared by fusing pure nitre in an earthen crucible, and projecting charcoal into it by small bits at a time, till it ceases to cause deflagration. Or a mixture of 10 parts of nitre and 1 of charcoal may be deflagrated in small successive portions in a red-hot deep crucible. When a mixture of 2 parts of tartrate of potassa, or crystals of tartar, and 1 of nitre, is deflagrated, pure carbonate of potash remains mixed with charcoal, which by lixiviation, and the agency of quicklime, will afford a pure hydrate. Crystals of tartar calcined alone yield also a pure carbonate.

Caustic potash, after being fused in a silver crucible at a red heat, retains 1 prime equivalent of water. Hence its composition in 100 parts is, potassium 70, oxygen 14, water 16. Anhydrous potash, or the oxide free from water, can be obtained only by the combustion of potassium in the open air. It is composed of 83⅓ of metal, and 16⅔ of oxygen. Berzelius's numbers are, 83·05 and 16·95.

Caustic potash may be crystallised; but in general it occurs as a white brittle substance of spec. grav. 1·708, which melts at a red heat, evaporates at a white heat, deliquesces into a liquid in the air, and attracts carbonic acid; is soluble in water and alcohol, forms soft soaps with fat oils, and soapy-looking compounds with resins and wax; dissolves sulphur, some metallic sulphurets, as those of antimony, arsenic, &c., as also silica, alumina, and certain other bases; and decomposes animal textures, as hair, wool, silk, horn, skin, &c. It should never be touched with the tongue or the fingers.

The following Table exhibits the quantity of potash in 100 parts of *caustic lye*, at the respective densities:—

Sp. gr.	Pot. in 100.	Sp. gr.	Pot. in 100.	Sp. gr.	Pot. in 100.	Sp. gr.	Pot. in 100.	Sp. gr.	Pot. in 100.
1·58	53·06	1·46	42·31	1·34	32·14	1·22	23·14	1·10	11·28
1·56	51·58	1·44	40·17	1·32	30·74	1·20	21·25	1·08	9·20
1·54	50·09	1·42	37·97	1·30	29·34	1·18	19·34	1·06	7·02
1·52	48·46	1·40	35·99	1·28	27·86	1·16	17·40	1·04	4·77
1·50	46·45	1·33	34·74	1·26	26·34	1·14	15·38	1·02	2·44
1·48	44·40	1·36	33·46	1·24	24·77	1·12	13·30	1·00	0·00

The only certain way of determining the quantity of free potash in any solid or liquid is from the quantity of a dilute acid of known strength which it can saturate.

The hydrate of potash or its lye often contains a notable quantity of carbonate, the presence of which may be detected by lime water, and its amount be ascertained by the loss of weight which it suffers, when a weighed portion of the lye is poured into a weighed portion of dilute sulphuric acid poised in the scale of a balance.

Carbonate of potash is composed of 48 parts of base, and 22 of acid, according to most British authorities; or, in 100 parts, of 68·57 and 31·43; but according to Berzelius, of 68·09 and 31·91.

Carbonate of potash, as it exists associated with carbon in calcined tartar, passes very readily into the *bicarbonate*, on being moistened with water, and having a current of carbonic acid gas passed through it. The absorption takes place so rapidly, that the mass becomes hot, and therefore ought to be surrounded with cold water.

We *imported* of pearlash and potash, in 1858, 150,432 cwts., of the computed real value of 233,724*l.*

POTASH, BICARBONATE, is prepared by passing carbonic acid through a solution of the carbonate of potash. See BICARBONATES.

POTASH, BICHROMATE OF. See CHROMATES OF POTASH.

POTASH, BINOXALATE. *Salt of wood sorrel; Salt of sorrel; Sal acetosella.* (*Sel d'oseille*, Fr.)

The *Oxalis acetosella* is an odourless plant, but in taste it is agreeably acidulous. In some parts of Germany the binoxalate of potash is obtained in large quantities from this plant by evaporating the expressed juice. Five hundred parts of the plant yield four parts of the crystallised salt; its composition is, oxalic acid two parts, potash one part, water two parts.

The salt sold under this name is however usually made by neutralising one part of oxalic acid, with carbonate of potash, and then adding three parts more of acid to it. This is a *quadroxalate* of potash.

It is sold under the name of *salt of lemons*, sometimes in a pure state, but more frequently mixed with *cream of tartar*, and is used for the removal of iron stains.

POTASH, BITARTRATE. *Cream of tartar.* This salt is a constituent of many vegetable juices, especially of the juice of the grape. All the salt of commerce is obtained during the vinous fermentation; it deposits during the process of the formation of alcohol, and accordingly as it is obtained from white or red wine it is known by the name of *white or red argol.* The acid tartar is thus prepared in the wine-making districts of France.

Argol, which occurs in crystalline cakes, and is composed of the bitartrate of potash, tartrate of lime, and colouring matter, is boiled in water; and the solution allowed to cool, by which a deposit of crystals is obtained. These are washed with cold water, and then dissolved in boiling water, in which is diffused clay and charcoal, which as they fall down receive the colouring matter. The clear liquor is allowed to cool slowly, and crystals form.

This salt consists of

Potash	25·00
Tartaric acid	70·21
Water	4·79
	100·00

If cream of tartar is heated it is decomposed, swells up, evolves gaseous products, and is converted into Black Flux, which see.

The bitartrate of potash is used in many processes of manufacture.

POTASH, CARBONATE. Salt of tartar, potashes, pearlashes. If land plants are burnt their ashes will be found to contain a considerable quantity of the carbonate of potash. See Potash.

POTASH, CHLORATE OF. See Chlorate of Potash.

POTASH, CITRATE OF. This salt is formed by neutralising citric acid with carbonate of potash. Under the names of *lemon and kali*, *effervescing lemonade*, and the like, mixtures of dry citric acid in powder and carbonate of potash, with very dry sugar, are sold. These form very agreeable and healthful beverages.

POTASH, HYDRATE OF, CAUSTIC. (*Potasse*, Fr.; *Kali*, Germ.) An oxide of potassium. It may be obtained thus:—Mix a solution of 1 part of the dry carbonate of potash with 1 part freshly prepared dry hydrate of lime, and allow it to stand in a closed vessel for 24 hours at a temperature of 68° to 78° F., frequently shaking it. The potash salt should be dissolved in 12 to 15 parts of water; the carbonate of lime separates in a granulated state, and the clear caustic lye may be decanted. A weaker lye may be obtained from the residue by fresh treatment with water.

POTASH, HYDRIODATE OF. See Potassium, Iodide of.

POTASH, NITRATE OF, KO,NO^5. Syn. *Nitre*, *Saltpetre*, *Prismatic nitre*. (*Nitrate de potasse*, Fr.; *Salpetersaures Kali*, Germ.) For the mode of purification, see Gunpowder. This well known and useful salt is found native in various parts of the world, more especially in tropical climates. The formation of nitre in the earth appears to be much facilitated by warmth.

Preparation. 1. By lixiviation of earth impregnated with the salt. The earth is heated with water in tanks or tubs with false bottoms, and after sufficient digestion the solution is run off and evaporated to crystallisation. The nitre procured by the first operation is exceedingly impure, and contains large quantities of chloride of potassium, and some sulphate of potash. By repeated crystallisations the salt may be obtained pure. If the crude product of the lixiviation contains, as is often the case, the nitrates of lime or magnesia, they may be got rid of by the addition of carbonate of potash; the earths are precipitated as carbonates, and may be filtered off, while an equivalent quantity of nitrate of potash is formed and remains in solution, thus:—

$$CaO,NO^5 + KO,CO^2 = CaO,CO^2 + KO,NO^5.$$

2. The second mode of preparing nitre which we shall consider, is from nitrate of soda and chloride of potassium. On dissolving equivalent quantities of these two salts in water, and salting down, double decomposition takes place. The chloride of sodium may be removed from the hot concentrated fluid by means of shovels, while the nitrate of potash, being much more soluble in hot than in cold water, remains in solution, but crystallises out on cooling. The decomposition takes place in accordance with the annexed equation:—

$$NaO,NO^5 + KCl = NaCl + KO,NO^5.$$

The above reaction is one of great interest and importance, inasmuch as it enables us to convert Peruvian or cubic nitre, as nitrate of soda is sometimes called, into the much more valuable salt, nitrate of potash. During the last war with Russia it was found that large quantities of chloride of potassium were exported, and found their way into that country. For some time no notice was taken, because the salt appeared too harmless to be declared contraband of war. Eventually it was found that it was entirely used in Russia for the purpose of affording nitrate of potash, by the process described. It need scarcely be said that the gunpowder made through the medium of our own chloride of potassium, was employed against our troops in the Crimea.

3. Nitre may of course be prepared by neutralising nitric acid by means of carbonate of potash, or the caustic alkali. The process is evidently too expensive to be employed, except for the purpose of experimental illustration, or under other special circumstances.

The formation of nitre in the earth of hot climates is probably in most cases due to the decomposition of nitrogenised organic matters. The subject of nitrification is one upon which some controversy has taken place. It is supposed by some chemists that the chief source of the nitric acid is the ammonia produced during the decay of nitrogenous matters. The presence of bases appears to have a remarkable tendency to increase the production of the acid. It has been asserted that the ammonia which is produced suffers partial oxidation, the acid formed uniting with the undecomposed ammonia to form the nitrate of that alkali. On the other hand, it has been argued that the ammonia does not suffer oxidation, but that the nitrogen produced during the decay of organic matter combines, at the instant of its liberation with oxygen, to form nitric acid, which unites with the bases present. Nitrate of ammonia, no matter how formed, suffers double decomposition in presence of the carbonates of the alkaline earths, the result being the production of the nitrates of lime and magnesia. It is owing to the presence of the two latter salts in the crude liquor obtained by lixiviating nitrified earth, that the addition of carbonate of potash is so important, and causes so great an increase in the produce of nitre. It has been insisted by some observers that the presence of nitrogenous organic matters is not essential to the production of nitre. In support of this it has been shown that large quantities of nitrates are often found where little or no organic matters are present. This has been explained by assuming that porous bodies have the power of absorbing water, oxygen, and nitrogen, and producing nitric acid from them. But it is evident that other forces exist capable of inducing the oxidation of atmospheric nitrogen. It has been experimentally demonstrated that nitric acid is produced during the discharge of atmospheric electricity. It is also probable that ozone plays an important part in the phenomena of nitrification. Perhaps most of the chemists who have investigated the subject, have been too anxious to assign the formation of nitre to one particular cause, whereas the phenomena which have been noticed by different observers are in favour of the idea that several agencies are at work during the production of nitrates in the earth and in artificial nitre beds.

During the time that France was fighting single-handed against the rest of Europe, great difficulty was found in obtaining sufficient nitre for the production of the vast amount of gunpowder necessary to enable her artillery to be effectively supplied with ammunition. This led the French chemists to establish artificial nitre beds in various parts of the country. The success of the process may be judged of from the fact that they yielded 2,000 tons annually.

Chemical and physical properties.—Nitre crystallises in colourless six-sided prisms. The crystals are anhydrous; large specimens when broken, however, generally show the presence of a little moisture mechanically adhering to the interstices. If wanted in fine powder, it must therefore be first coarsely bruised, and then dried, after which it may be finely pulverised and sifted, without that tendency to adhere into lumps which would otherwise be observed.

By the careful application of heat, nitrate of potash may be melted without undergoing any decomposition or loss of weight. But if the heat be raised to redness it begins to decompose, the degree to which the change takes place depending on the amount of heat and the time of exposure. By carefully heating for some time, a large quantity of nitrite of potash is formed, oxygen gas being evolved. If the heat be raised, or the exposure to a high temperature be continued, a large quantity of nitrogen accompanies the oxygen, and the nitre becomes more and more changed, until finally, a mixture of potash with peroxide of potassium is attained. If copper filings, clippings, or shreds be mixed with the nitre, the decomposition proceeds much more readily, and Wöhler has proposed to prepare pure potash by this means. At high temperatures nitre is a potent agent of oxidation, so much so, that the diamond itself is attacked and converted into carbonic acid, which unites with the potash. It was in this manner that Smithson Tennant first showed the diamond to consist of pure carbon. His mode of operating was to fuse the nitre with fragments of diamond in a tube of gold. Crystallised boron, which is said to equal if not exceed the diamond in hardness, is not attacked by fused nitre. A very striking experiment for the lecture table consists in pouring charcoal in powder into melted nitre retained at a red heat over a lamp. A violent deflagration takes place, and a considerable quantity of carbonate of potash is formed. The presence of the latter substance may be shown as soon as the capsule has become cold, by adding an acid to its contents, when a strong effervescence will take place. The oxidising power of nitre is made use of in the arts in order to obtain bichromate of potash from chrome iron ore.

Nitrate of potash is sometimes used as a source of nitric acid, but nitrate of soda is in every way more economical. This will be evident when it is considered that it takes 101 parts of nitrate of potash to yield one equivalent of dry nitric acid (54 parts), whereas 85 parts of nitrate of soda yield the same amount of acid. Moreover, if nitrate of potash be used, it is essential to employ two equivalents of sulphuric acid to decompose one equivalent of the salt, for if only one were used the residue of sulphate of potash being hard, and not very readily removable by water, considerable chances would be incurred of injuring the still; it is usual, therefore, to so adjust the proportions that the readily soluble bisulphate should be the residue. If, on the other hand, nitrate of soda be employed, the residue in the still being sulphate of soda, no difficulty is found in its removal.

Nitrate of potash is employed in blow-pipe experiments, in order to assist in the production of the green reaction characteristic of the presence of manganese. It often happens where the quantity of manganese is exceedingly small, as in rose quartz, that the green coloration with soda or platinum foil cannot be obtained; if, however, a little nitre be added, and the testing be repeated, the reaction generally appears without any trouble.

Nitrate of potash is greatly employed in the preparation of pyrotechnic mixtures. It ought always to be well dried and reduced to fine powder before being used.

Solubility of nitre in water at various temperatures.

1 part of nitre dissolves in	13,320	parts of water at	32°·0
"	4·000	"	61°·0
"	3·450	"	64°·4
"	1·340	"	113°·0
"	0·424	"	206°·6
"	0·250	"	212°·0

From the above table it is evident that the solubility of nitre in water increases very rapidly with the temperature. Nitre is not unfrequently employed by the chemist for determining the percentage of sulphur in coals. For this purpose the coal, reduced to fine powder, is mixed with nitre and carbonate of soda, and projected by small portions into a silver crucible, maintained at a red heat. A platinum crucible must not be employed, as it is attacked by nitre in a state of fusion. The sulphur in the coal is converted, by the oxidising agency of the nitre, into sulphuric acid; the latter can then be converted into sulphate of baryta, and the percentage of sulphur ascertained from its weight.

Estimation of the value of nitre.—A great number of proeesses have been devised for the determination of the percentage of pure nitrate of potash in samples of the crude salt. All these processes are more or less incorrect, and a really accurate mode of determining the value of nitre has long been felt as a want by chemists. This want has only quite recently been supplied by Messrs. Abel and Bloxam of the Woolwich Arsenal, who have devoted much labour and skill to the subject, the importance of which, in connection with the art of war, can scarcely be over-estimated. Before detailing the new and successful process of the latter chemists, we will take a brief glance at the other methods commonly used for the purpose. The French process depends upon the principle that a solution, when saturated with one salt, is still capable of dissolving a considerable quantity of saline matter differing in its nature from the first. If, therefore, a saturated solution of nitre be poured upon pure nitre, no more is dissolved if the temperature remains the same as it was when the original solution was prepared. But if, on the other hand, the saturated solution of nitre be digested with an impure sample containing the chlorides of sodium, potassium, &c., the latter salts will be dissolved, and the pure nitre remaining can, after proper draining, &c., be dried and weighed. The loss of weight obviously represents the impurities removed. This process is subject to so many sources of error that the practical details need not be entered into.

Another mode of valuing nitre consists in fusing the salt, and, after cooling, breaking the cake: the fineness or coarseness and general characters of the fracture are the means whereby the greater or less value of the salt are ascertained. This process, which is known as the Swedish or Swartz's method, is far too dependent on the individual experience and dexterity of the operator to be of any value in the hands of the chemist whose attention is only now and then directed to the valuation of saltpetre. Moreover, although those who are in the habit of using it possess some confidence in its correctness, is quite evident that it is impossible for such an operation to yield results of analytical accuracy.

The Austrian method has also been used by some, but it is quite inadmissible as a general working process. It consists in ascertaining the temperature at which the solution crystallises.

Gossart's method consists in determining the value of the nitre by measuring its power of oxidation. The latter is accomplished by finding the quantity of protoxide of iron which it can convert into peroxide. If to an acid solution of protosulphate of iron nitric acid or a nitrate be added, the proto is converted into a persalt at the expense of a portion of the oxygen of the nitric acid, thus:—

$$2(FeO,SO^3) + NO^5 + SO^3 = Fe^2O^3, 3SO^3 + NO^4.$$

Theoretically this process is unexceptionable, but in practice it is liable to great errors.

M. Pelouze endeavoured to improve the above process by using such an excess of the protosalt of iron that the nitre added should be able to convert only a portion of it into a persalt. The remaining protoxide was then converted into persalt by means of a solution of permanganate of potash of known strength. The data so obtained enabled the value of the nitre to be estimated. But even this process is liable to variations, so much so, indeed, that Messrs. Abel and Bloxam obtained the following results in eleven experiments made with pure nitre:—

Exp.	Nitre taken.	Nitre found.	Per-centage.
1	18·53	18·12	99·40
2	18·50	Result somewhat higher.	
3	20·10	17·58	87·46
4	20·16	17·81	88·33
5	20·05	17·78	88·67
6	20·18	18·45	91·42
7	20·26	19·95	98·48
8	17·83	19 71	110·55
9	17·80	19·09	107·20
10	17·64	19·33	109 50
11	14·56	16·41	112·70

In the above experiments the conditions were somewhat varied, but the results showed that very slight variations in the modes of manipulating created such enormous differences in the values obtained, that it was quite impossible to rely on the method.

The next process which we shall notice is that which the chemists alluded to have finally settled upon as yielding the best results. It is that of M. Gay-Lussac. It depends on the fact that if nitrate of potash be heated with charcoal, or, in fact, any carbonaceous matters in excess, the nitrate is converted into carbonate of potash, the amount of which may be accurately estimated by means of a standard solution of sulphuric acid. The chlorides which may be present are unacted upon by the charcoal, and do not, therefore, influence the result; but if sulphates be present they are reduced by the earbon to sulphides, which, in consequenee of being decomposed by the sulphuric acid, may cause serious errors. Fortunately the amount of sulphuric acid present in nitre is seldom sufficient to cause any great error. Any nitrate of soda present would come out in the final result as nitrate of potash, and thus become another source of error; in practice this is seldom likely to occur. The original process consists in weighing out 20 grammes (308·69 grains) of crude saltpetre, and mixing it with 5 grammes (77·17 grains) of charcoal, and 80 grammes (1234·7 grains) of chloride of sodium. The mixture is thrown little by little into a red-hot crucible, and, when the decomposition is over, allowed to cool. The residual mass is dissolved in water, filtered, and water passed through the filter until it amounts to 200 cubic centimetres (12·2 cubic inches). The amount of alkali is then ascertained with a burette and standard sulphuric acid. (See ALKALIMETER.) Messrs. Abel and Bloxam have minutely and laboriously studied this operation, and deteeted its sources of difficulty and error. Their researches have led them to employ the following modification.

Twenty grains of the sample are to be well mixed in a platinum crucible with 30 grains of finely-powdered resin, and 80 grains of pure dry common salt. The heat of a wire gauze flame is then applied, until no more vapour is given off. The crucible is then allowed to cool down a little, and 25 grains of chlorate of potash are added. A gentle heat is then applied uutil most of the chlorate is decomposed; the heat is then raised to bright redness for two or three minutes. The mass should be fluid, and free from floating charcoal. The mass, when cool, is removed to a funnel, and the crucible, &c., washed with boiling water. The mass is then dissolved in hot water, and the entire solution, coloured by litmus, is neutralised with the standard acid. In the annexed table 20 grains of pure nitre were taken for each experiment:—

Exp.	Nitre found.	Nitre per cent.
1.	20·00	100·00
2.	20·00	100·00
3.	19·97	99·85
4.	19·97	99·85
5.	20·08	100·40
6.	20·08	100·40
7.	20·08	100·40

The authors, not yet satisfied, made 53 more experiments by this method. The mean result with pure nitre was 99·7 per cent.

The mean of 25 of the above experiments was 98·7 per cent.

The mean of the remainder was 100·7 per cent.

Subsequent experiments showed that greater accuracy might be obtained by substituting for the resin, pure ignited finely divided graphite, prepared by Professor Brodie's patented process. To perform the process 20 grains of the nitre are to be mixed with 5 grains of ignited graphite and 80 grains of salt. The general process is conducted in the manner described in the operation with resin. The results are very exact, and apparently quite sufficient for all practical purposes.—C. G. W.

POTASH, NITRITE OF, KO,NO^3. When ordinary saltpetre, or nitrate of potash, is heated with sulphuric acid, in the cold, no special reaction becomes evident, as far as any evolution of gas is concerned; but if, previous to the addition of the acid, the nitre be strongly fused, it will be found, as soon as the admixture takes place, that red fumes are evolved. This arises from the fact, that nitrate of potash, when subjected to strong ignition, is decomposed with evolution of oxygen, the nitrate becoming gradually converted into the nitrite of potash, thus:—

$$KO,NO^5 = KO,NO^3 + 2O.$$

This reaction acquires great interest from the circumstance, that to its correct explanation was owing the commencement of the fame of the illustrious Swedish chemist Scheele. A pharmaceutist, at Upsala, having heated some saltpetre to redness in a crucible, happened, when it became cold, to pour vinegar over it, when, to his surprise, red fumes were evolved. Ghan was applied to for an explanation; but, unable to comprehend the matter, he applied to Bergmann; but even he was as much in the dark as Gahn. The explanation which these eminent chemists were unable to give, was supplied by the pharmaceutist's apprentice, the young Scheele. Bergmann, when informed by Gahn of Scheele's explanation, felt a strong desire to make his acquaintance, and ultimately they were introduced to each other.

Nitrite of potash has acquired some importance of late years, owing to the valuable properties, as a decomposing agent, which have been found by chemists to reside in nitrous acid.

Preparation.—Nitrate of potash is to be fused at a red heat for a considerable time. When cold, the contents of the crucible are to be dissolved out with boiling water, and the nitrate of potash remaining is to be removed as far as possible by crystallisation. The nitrite of potash may be obtained from the mother liquor by evaporation and subsequent crystallisation. It is a neutral salt, which deliquesces on exposure to the air. If a piece of strongly-fused nitre be put, when cold, into a solution of sulphate of copper, a very beautiful apple-green colour is produced, of a tint which is seldom observed except in solutions containing the nitrite of that metal.—C. G. W.

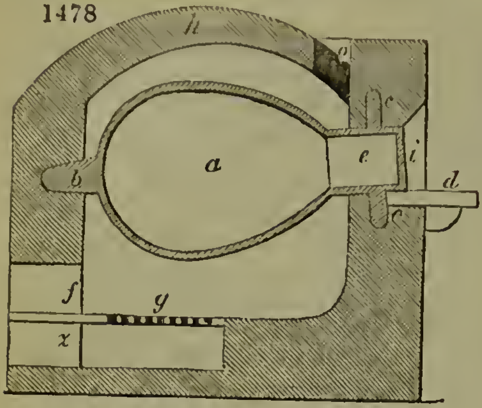
POTASH, PRUSSIATE OF. *Ferrocyanide of potassium. Yellow prussiate of potash.* $K^2FeCy^3 + 3HO$.

This salt occurs in a state of great purity in commerce, and is thus manufactured on the large scale.

Among the animal substances used for the preparation of this lixivium, blood deserves the preference, where it can be had cheap enough. It must be evaporated to perfect dryness, reduced to powder, and sifted. Hoofs, parings of horns, hides, old woollen rags, and other animal offals, are, however, generally had recourse to, as condensing most azotised matter in the smallest bulk. Dried funguses have been also prescribed. These animal matters may either be first carbonised in cast-iron cylinders, and the residual charcoal may be then taken for making the ferroprussiate; or the dry animal matters may be directly employed. The latter process is apt to be exceedingly offensive to the workmen and neighbourhood, from the nauseous vapours that are exhaled in it. Eight pounds of horn (hoofs), or ten pounds of dry blood, afford upon an average one pound of charcoal. This must be mixed well with good pearlash, (freed previously from most of the sulphate of potassa, with which it is always contaminated,) either in the dry way, or by soaking the bruised charcoal with a strong solution of the alkali; the proportion being one part of carbonate of potassa to from 1½ to two parts of charcoal, or to about eight parts of hard animal matter.

The pot for calcining the mixture of animal and alkaline matter is egg-shaped, as represented at *a*, *fig.* 1478, and is considerably narrowed at the neck *e*, to facilitate the closing of the mouth with a lid *i*. It is made of cast-iron, about two inches thick in the belly and bottom; this strength being requisite because the chemical action of the materials wears the metal fast away. It should be built into the furnace in a direction sloping downwards, (more than is shown in the figure,) and have a strong knob *b*, projecting from its bottom to support it upon the back wall, while its shoulder is embraced at the arms *c*, *c*, by the brickwork in front. The interior of the furnace is so formed as to leave but a space of a few inches round the pot, in order to make the flame play closely over its whole surface. The fire-door *f*, and the draught-hole *z*, of the ash-pit, are placed in the posterior part of the furnace, in order that the workmen may not be incommoded by the heat. The smoke-vent *o*, issues through the arched top *h* of the furnace, towards the front, and is thence led backwards by a flue to the main chimney of the factory. *d* is an iron or stone shelf, inserted before the mouth of the pot, to prevent loss in shovelling out the semi-liquid paste. The pot may be half filled with the materials.

1478



The calcining process is different, according as the animal substances are fresh or carbonised. In the first case, the pot must remain open, to allow of diligent stirring of its contents, with a slightly bent flat iron bar or scoop, and of introducing more of the mixture as the intumescence subsides, during a period of five or six hours, till the nauseous vapours cease to rise, till the flame becomes smaller and brighter, and till a smell of ammonia be perceived. At this time the heat should be increased, the mouth of the pot should be shut, and opened only once every half hour, for the purpose of working the mass with the iron paddle. When, on opening the mouth of the pot, and stirring the pasty mixture, no more flame rises, the process is finished.

If the animal ingredients are employed in a carbonised state, the pot must be shut as soon as its contents are brought to ignition by a briskly urged fire, and opened for a few seconds only every quarter of an hour, during the action of stirring. At first, a body of flame bursts forth every time that the lid is removed ; but by degrees this ceases, and the mixture soon agglomerates, and then softens into a paste. Though the fire be steadily kept up, the flame becomes less and less each time that the pot is opened ; and when it ceases, the process is at an end. The operation, with a mass of 50 pounds of charcoal and 50 pounds of purified pearlash, lasts about 12 hours the first time that the furnace is kindled ; but when the pot has been previously brought to a state of ignition, it takes only 7 or 8 hours. In a well-appointed factory the fire should be invariably maintained at the proper pitch, and the pots should be worked with relays of operatives.

The molten mass is now to be scooped out with an appropriate iron shovel, having a long shank, and caused to cool in small portions, as quickly as possible ; but not by throwing it into water, as has sometimes been prescribed, for in this way a good deal of the cyanogen is converted into ammonia. If it be heaped up and kept hot in contact with air, some of the ferrocyanide is also decomposed, with diminution of the product. The crude mass is to be then put into a pan with cold water, dissolved by the application of a moderate heat, and filtered through cloths. The charcoal which remains upon the filter possesses the properties of decolouring syrups, vinegars, &c., and of destroying smells in a pre-eminent degree. It may also serve, when mixed with fresh animal coal, for another calcining operation.

As the iron requisite for the formation of the ferrocyanide is in general derived from the sides of the pot, this is apt to wear out into holes, especially at its under side, where the heat is greatest. In this event it may be taken out of the furnace, patched up with iron-rust cement, and re-inserted with the sound side undermost. The erosion of the pot may be obviated in some measure by mixing iron borings or cinder with the other materials, to the amount of one or two hundredths of the potash.

The above lixivium is not a solution of pure ferroprussiate ; it contains not a little cyanide of potassium, which in the course of the process had not absorbed the proper dose of iron to form a ferrocyanide ; it contains also more or less carbonate of potash, with phosphate, sulphate, hydrogenated sulphuret, muriate, and sulpho-cyanide of the same base, as well as phosphate of lime ; substances derived partly from the impure potash, and partly from the incinerated animal matters. Formerly that very complex impure solution was employed directly for the precipitation of prussian blue ; but now, in all well regulated works, it is converted by evaporation and cooling into crystallised ferroprussiate of potash. The mother-water is again evaporated and crystallised, whereby a somewhat inferior ferroprussiate is obtained. Before evaporating the lye, however, it is advisable to add as much solution of green sulphate of iron to it as will re-dissolve the white precipitate of cyanide of iron which first falls, and thereby convert the cyanide of potassium, which is present in the liquor, into ferrocyanide of potassium. The commercial prussiate of potash may be rendered chemically pure by making its crystals effloresce in a stove, fusing them with a gentle heat in a glass retort, dissolving the mass in water, neutralising any carbonate and cyanide of potash that may be present with acetic acid, then precipitating the ferroprussiate of potash by the addition of a sufficient quantity of alcohol, and finally crystallising the precipitated salt twice over in water. The sulphate of potash may be decomposed by acetate of baryta, and the resulting acetate of potassa removed by alcohol.

Berry's patent process.—Reduce charcoal into bits of the size of a walnut, soak them with a solution of carbonate of potash in urine; and then pour over them a solution of nitrate or acetate of iron; dry the whole by a moderate heat and introduce them into the cast-iron tubes, presently to be described. The following proportions of constituents have been found to answer:—Ordinary potash, 30 parts; nitre, 10, acetate of iron, 15; charcoal or coke, 45 to 55; dried blood, 50. The materials, mixed and dried, are put into retorts similar to those for coal gas. The animal matter, however (the blood), is placed in separate compartments of pipes connected with the above retorts. The pipes containing the animal matter should be brought to a red heat before any fire is placed under the retorts.

In *fig.* 1479, A B C D, is a horizontal section of a furnace constructed to receive four elliptical iron pipes. The furnace is arched in the part A C B, in order to reverberate the heat, and drive it back on the pipes W, W′, W″, W‴. These pipes are placed on the plane E F, of the ellipsoid. *a a*, represents the grating or bars of the furnace to be heated with coal or coke; I I, is the pot or retort shown in *figs.* 1480, 1481, 1482.

This pot or retort is placed in a separate compartment, as seen in *fig.* 1479, which is a vertical section, taken through *fig.* 1482 at the line G, H. K, is a connecting tube, from the retort and the elliptical pipes W.

In the section, *fig.* 1480, the shape of the tube K will be better seen; also its cocks *u*, and likewise its connection with the pipes W. *l*, is a safety valve; *s*, the cover of the pot or retort; L, is the ash-pit; and *b*, the door of the furnace; X, is an open space, roofed over, or a kind of shed, close to the furnace, and under it the pipes are emptied; M, an inclined plane behind the fire bars.

The arrows indicate the direction of the current of heat. This current traverses the intervals left between the pipes, and ascends behind them, passing through the aperture *j*, in the brickwork, which is provided with a valve or damper, for closing it, as required. The heat passes through this aperture, and strikes against the sides of the pot when the valve is open. Another valve *f*, *g*, must also be open to expose the pot or retort to the direct action of the fire. The smoke escapes by a lateral passage into a chimney N.

It must be remarked, that there is a direct communication between the chimney and that compartment of the furnace which contains the pipes, so that the heat, reflected from the part V, strikes on the pot or retort only when the pipes W, W′, W″, W‴, are sufficiently heated.

In *fig.* 1481 is represented the junction-tubes, which connect the four pipes with their gas-burners Z, Z, and the cocks *m m′*. *r*, *r*, *fig.* 1482, are covers, closing the pipes, and having holes formed in them; these holes are shut by the stoppers *e*.

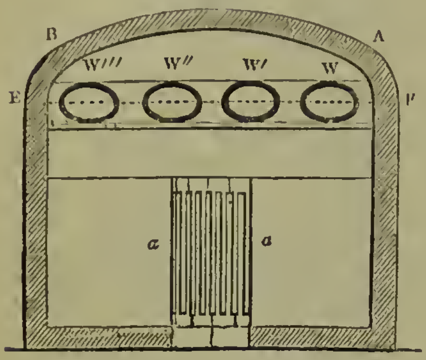
Whether the pipes are placed in the vertical or horizontal position, it is always proper to be able to change the direction of the current of gas; this is easily done by closing, during one hour (if the operation is to last two hours), the cocks *u*, *m′*, and opening those, *u′*, *m*; then the gas passes through *u′*, into the branch K, and entering W‴, passes through V, into W″, through *g*, into W′, and through 2nd *g*, and W, and finally escapes by the burner Z. During the following or other hour, the cocks *u′*, *m*, must be closed; the cocks *u*, *m′*, being opened, the current then goes from *u*, into K, W, W′, W″, W‴, and escapes by the burner Z′, where it may be ignited.

The changing of the direction of the current dispenses, to a certain degree, with the labour required for stirring with a spatula the matters contained in the pipes; nevertheless, it is necessary, from time to time, to pass an iron rod or poker amongst the substances contained in the pipes. It is for this purpose that apertures are formed, so as to be easily opened and closed.

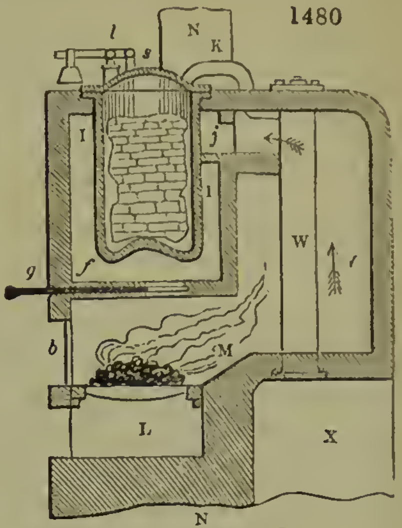
The patentee remarks, that although this operation is only described with reference to potash, for obtaining prussiate of potash, it is evident that the same process is applicable to soda; and when the above-mentioned ingredients are employed, soda being substituted for potash, the result will be prussiate of soda.

The process employed in the manufacture of *Kalium Eisen Cyanure*, by Hoffmayr and Prükner, is as follows:—The potash must be free from sulphate, for each atom of sulphur destroys an atom of the cyanide of potash. A very strong heat is advantageous. The addition of from 1 to 3 per cent. of saltpetre, is useful, when the mass is too long in fusing. A reverberatory furnace is recommended; but the flame must not beat too much upon the materials for fear of oxidising them. When the smoky

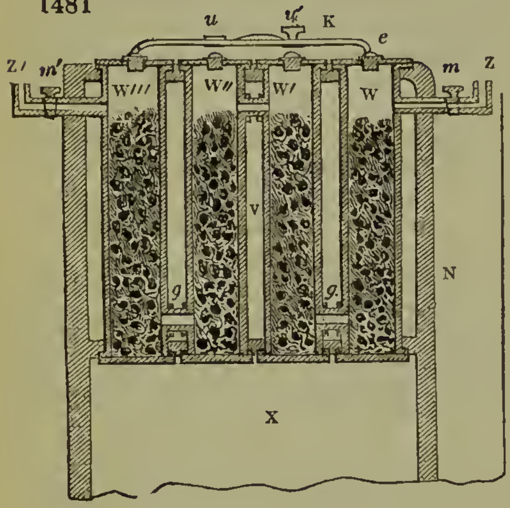
1479



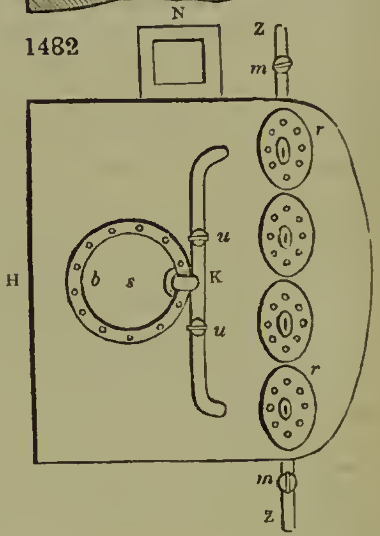
1480



1481



1482



red flame ceases, it is useful to throw in from time to time small portions of uncarbonised animal matter, particularly where the flame first beats upon the mass, whereby the resulting gases prevent oxidation by the air. The animal matters should not be too much carbonised, but left somewhat brown-coloured, provided they be readily pulverised. Of uncarbonised animal matters, the proportions may be 100 parts dried blood, to from 28 to 30 of potash (carbonate), and from 2 to 4 of hammerschlag (smithy scales), or iron filings. 2nd. 100 parts of horns or hoofs; from 33 to 35 potash; 2 to 4 iron. 3rd. 100 leather, 45 to 48 potash; and 2 to 4 iron. From blood, 8 to 9 per cent. of the prussiate are obtained; from horns, 9 to 10; and from leather, 5 to 6. The potash should be mixed in coarse particles, like peas, with the carbonised animal matter, which may be best done in a revolving pot, containing cannon-balls. Of the animal coal and potash, equal parts may be taken, except with that from leather, which requires a few more parts potash per cent. On the average, blood and horn coal should afford never less than 20 per cent. of prussiate, nor the leather than 8: but by good treatment they may be made to yield, the first 25, and the last from 10 to 11.

Dr. Ure, in the former editions of this Dictionary, discussed the chemical questions involved in the manufacture of this very important salt. As *Ure's Dictionary of Chemistry*, from which, originally, the article was derived, is again in course of publication, this subject is restored to its original place.

POTASH, RED PRUSSIATE OF. Ferridcyanide of potassium, prepared by passing chlorine gas through a solution of the ferrocyanide of potassium until it ceases to give a precipitate of prussian blue, with a persalt of iron, and no longer. Its formula is $K^3Fe^2Cy^6$.

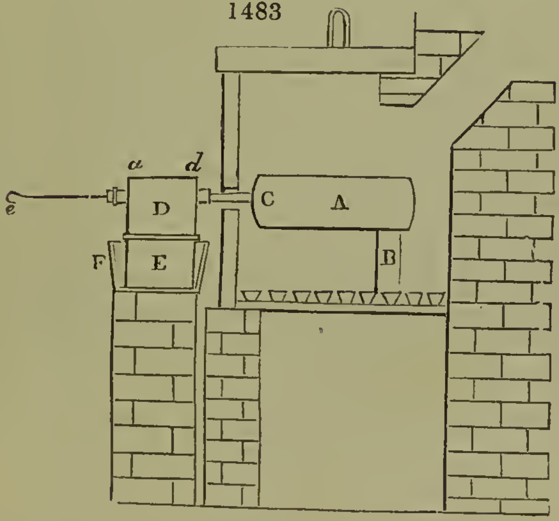
POTASSIUM (Eng. and Fr.; *Kalium*, Germ.) is a metal deeply interesting, not only from its own marvellous properties, but from its having been the first link in the chain of discovery which conducted Sir H. Davy through many of the formerly mysterious and untrodden labyrinths of chemistry. It is the metallic base of potash.

The easiest mode of obtaining this elementary substance is that contrived by Brunner. Into the orifice of one of the iron bottles, as A, *fig.* 1483 in which mercury is imported, adapt, by screwing, a piece of gun-barrel tube, 9 inches long; having brazed into its side, about three inches from its outer end, a similar piece of iron tube. Fill this retort two-thirds with a mixture of 10 parts of cream of tartar, previously calcined in a covered crucible, and 1 of charcoal, both in powder; and lay it horizontally in an air furnace, so that while the screw orifice is at the inside wall, the extremity of the straight or nozzle tube may project a few inches beyond the brick-work, and the tube brazed into it at right angles may descend pretty close to the outside wall, so as to dip its lower end a quarter of an inch beneath the surface of some rectified naphtha contained in a copper bottle surrounded by ice-cold water. By bringing the condenser vessel so near the furnace, the tubes along which the potassium vapour requires to pass, run less risk of getting obstructed. The horizontal straight end of the nozzle tube should be shut by screwing a stopcock air-tight into it. By opening the cock momentarily, and thrusting in a hot wire, this tube may be readily kept free, without permitting any considerable waste of potassium. The heat should be slowly applied at first, but eventually urged to whiteness, and continued as long as potassuretted hydrogen continues to be disengaged. The retort and the part of the nozzle tube exposed to the fire should be covered with a good refractory lute, as described under the article PHOSPHORUS. The joints must be perfectly air-tight; and the vessel freed from every trace of mercury, by ignition, before it is charged with the tartar-ash.

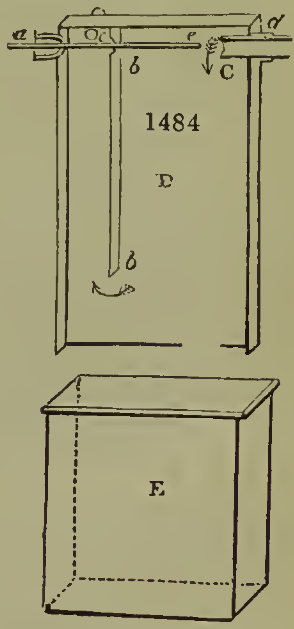
Tartar skilfully treated in this way will afford 3 per cent. of potassium; and when it is observed to send forth green fumes, it has commenced the production of the metal. Instead of the construction above described, the following form of apparatus may be employed.

A, *fig.* 1483 represents the iron bottle, charged with the incinerated tartar; and B is a fire-brick support. A piece of fire-tile should also be placed between the bottom of

1483



1484



the bottle and the back wall of the furnace, to keep the apparatus steady during the operation. Whenever the moisture is expelled, and the mass faintly ignited, the tube C should be screwed into the mouth of the bottle, through a small hole left for this purpose in the side of the furnace. That tube should be no longer, and the front wall of the furnace no thicker, than what is absolutely necessary. As soon as the reduction is indicated by the emission of green vapours, the receiver must be adapted, *d*, *a*, D, E, shown in a large scale in *fig.* 1484.

This is a condenser, in two pieces, made of thin sheet copper; D, the upper part, is a rectangular box, open at bottom, about 10 inches high, by 5 or 6 long and 2 wide; near to the side *a*, it is divided inside into two equal compartments, up to two-thirds of its height, by a partition, *b*, *b*, in order to make the vapours that issue from C pursue a downward and circuitous path. In each of its narrow sides, near the top, a short tube is soldered, at *d* and *a*; the former being fitted air-tight into the end of the nozzle of the retort, while the latter is closed with a cork traversed by a stiff iron probe *e*, which passes through a small hole in the partition *b*, *b*, under *c*, and is employed to keep the tube C, clear, by its drill-shaped steel point. In one of the broad sides of the box, D, near the top, a bit of pipe is soldered on at *c*, for receiving the end of a bent glass tube of safety, which dips its other and lower end into a glass containing naphtha. E, the bottom copper box, with naphtha, which receives pretty closely the upper case, D, is to be immersed in a cistern of cold water, containing some lumps of ice.

For an account of the chemical action by which potassa is reduced, see *Ure's Chemical Dictionary*.

Pure potassium, as procured in Sir H. Davy's original method, by acting upon fused potash under a film of naphtha, with the negative wire of a powerful voltaic battery, is a soft metal, which can be cut like wax with a knife, and its newly cut surface possesses great brilliancy. It is fluid at 120° F. At 50° it is malleable, and has the lustre of polished silver; at 32° it is brittle, with a crystalline fracture; and at a heat approaching to redness, it begins to boil, is volatilised, and converted into a green-coloured gas, which condenses into globules upon the surface of a cold body. Its specific gravity in the purest state is 0·865 at 60°. When heated in the air, it takes fire, and burns very vividly. It has a stronger affinity for oxygen than any other known substance; and is hence very difficult to preserve in the metallic state. At a high temperature it reduces almost every oxygenised body. When thrown upon water, it kindles, and moves about violently upon the surface, burning with a red flame, till it be consumed; that is to say, converted into potash. When thrown upon a cake of ice, it likewise kindles, and melts a hole in it. If a globule of it be laid upon wet turmeric paper, it takes fire, and runs about, marking its desultory paths with red lines. The flame observed in these cases is owing chiefly to hydrogen, for it is at the expense of the water that the potassium burns, potassuretted hydrogen being formed.

POTASSIUM, IODIDE OF. Iodide of potassium is usually prepared by digesting 2 parts of iodine, and 1 part of pure iron filings, in 10 parts of water, till they have combined to form a solution of a pale green colour, which is a solution of the iodide of iron.

This solution is decomposed with exactly the requisite quantity of carbonate of potash, and iodide of potassium is held in solution, the iron salt being precipitated. The iodide is then crystallised out. *Iodide of potassium* is much used in photography to obtain the iodide of silver; and for this purpose its purity is of great importance. The iodide of potassium of commerce frequently contains carbonate of potash, caustic potash, and the bromide and chloride of potassium. In the *Chemical Gazette*, Mr. Penny gives the following method of detecting these adulterations. His plan consists in ascertaining the amount of a solution containing a known weight of the iodide which is required to decompose a given quantity of bichromate of potash, dissolved in water acidulated with hydrochloric acid. The point at which the chromic acid is completely reduced is indicated by dipping a glass rod into the solution, and touching a drop of a solution of protosulphate of iron and sulphocyanide of potassium placed upon a white plate; when a red colour is no longer produced the decomposition is complete; 10 grains of KO^2CrO correspond to 33 grains of KI. For other methods, see *Ure's Chemical Dictionary*.

POST. A north of England term for any bed of firm rock. It is generally applied to sandstone.

POTATO. (*Pomme de terre*, Fr.; *Kartoffel*, Germ.) The well-known root of the *Solanum tuberosum*.

Many methods have at different times been tried for preserving potatoes in an unchangeable state, and always ready to be dressed into a wholesome and nutritious dish, but none with such success as the plan of Mr. Downes Edwards, for which he obtained a patent in August, 1840. The potatoes, being first clean washed, are boiled in water or steamed, till their skins begin to crack, then peeled, freed from their specks and eyes, and placed in an iron cylinder, tinned inside, and perforated with many holes one-eighth of an inch in diameter. The potatoes are forced through these by the pressure of a piston. The pulp is finally dried on well-tinned plates of copper, moderately heated by steam, into a granular meal. When this is mixed into a pulp with hot water, and seasoned with milk, &c., it forms a very agreeable food — like fresh mashed potatoes. See STARCH.

POTATO STARCH. *English arrowroot*. See STARCH.

POTATO SUGAR. See SUGAR.

POTSTONE, a magnesian mineral of the character of steatite and serpentine. It is used in Germany for ornamental purposes.—H. W. B.

POT METAL, an inferior metal composed of lead and copper, used for making large vessels. See ALLOY.

POTTERY, PORCELAIN. EARTHENWARE, STONEWARE. (Engl. and Fr.; *Steingut, Porcellan*, Germ.) The French call this art *céramique*, from the Greek noun *κεραμος*, an earthen pot, or *burned clay*. In reference to chemical constitution, there are only two genera of baked stoneware. The first consists of a fusible earthy mixture, along with an infusible, which when combined are susceptible of becoming semi-vitrified and translucent in the kiln. This constitutes true porcelain or china-ware; which is also called *hard* and *genuine*, or *tender* and *spurious*, according to the quality and quantity of the fusible ingredients. The *tender* porcelain is an earthy body which is covered with and penetrated by a transparent glaze. The second kind consists of an infusible mixture of earths, which is refractory in the kiln and continues opaque. This is pottery, properly so called; but it comprehends several sub-species, which graduate into each other by imperceptible shades of difference. To this head belong earthenware, stoneware, flint-ware, *fayence*, delftware, iron-stone china, &c.

The glazed bricks from Babylon,—the enamelled tiles from the ruined cities of the desert,—and the glazed coffins from those Assyrian cities of the dead discovered by Mr. Kennet Loftus, prove, contrary to the received ideas, that the earliest attempts to make a compact earthenware, with a painted glaze, did not originate with the Arabians in Spain about the ninth century; but it is certain that the art passed thence into Majorca, in which island they were carried on with no little success. In the 14th century, these articles, and the art of imitating them, were highly prized by the Italians, under the name of Majolica, and *porcelana*, from the Portuguese word for a cup. The first manufactory of this ware possessed by them was erected at Fayenza, in the ecclesiastical state, whence the French term *fayence* is derived. The body of the ware was usually a red clay, aud the glaze was opaque, being formed of the oxides of lead and tin, along with potash and sand, which glaze was in all probability the discovery of Luca della Robbia, which he had found "after experiments innumerable." Bernard Palissy, about the middle of the 16th century, manufactured the Palissy ware,—which is remarkable for its beautiful glaze, and the imitation of plants and animals,—at Saintes, in France; and not long afterwards the Dutch produced a similar article, of substantial make, under the name of Delftware, and Delft *porcelain*, but destitute of those graceful forms and paintings for which the ware of Fayenza was distinguished. Common fayence may be, therefore, regarded as a strong, well-burned, but rather coarse-grained kind of earthenware.

The English East India Company was formed in 1600, and in 1631 they imported China ware into England. The Dutch, however, in 1586, appear to have traded in this true porcelain. There was naturally a desire to imitate this beautiful manufacture. In this Böttcher made the first advance in 1709. Böttcher was working in the laboratory of Tschirnhaus, an alchemist, at Dresden, and it is stated that some crucibles prepared by him assumed the character of Chinese porcelain. Böttcher made first a red ware, but eventually, by employing white clays (*Kaolin*) which were found near Schneeberg in the Erzgebirge, he made a true porcelain at Meissen. Eventually the manufacture spread to Dresden, Munich, and other places, and the celebrated Sèvres Pottery was established.

Coarse ware was manufactured in Staffordshire as early, if not earlier, than 1500. Dr. Shaw says, "there exist documents which imply that during many centuries considerable quantities of common culinary articles were manufactured of red, brown, and mottled pottery."—*History of Staffordshire Potteries.*

It was in 1670 that a work for making earthenware of a coarse description, coated with a common lead glaze (butter pots), was formed at Burslem, which may be considered as the germ of the vast potteries now established Staffordshire. The manufacture was improved about the year 1690, by two Dutchmen, the brothers Elers, who were compelled to leave the Potteries in 1710, and it is said they settled in Chelsea. The introduction of the use of salt for glazing took place in 1690 at Palmer's pottery at Bagnall. It is to the late Josiah Wedgewood that this country and the world at large are mainly indebted for the great modern advancement of the *ceramic* art. It was he who first erected magnificent factories, where every resource of mechanical and chemical science was made to co-operate with the arts of painting, sculpture, and statuary, in perfecting this valuable department of the industry of nations. So sound were his principles, so judicious his plans of procedure, and so ably have they been prosecuted by his successors in Staffordshire, and especially by the late Herbert Minton, that a population of upwards of 100,000 operatives now derives a comfortable subsistence within a district formerly bleak and barren, of 8 miles long by 6 broad, which contains 250 kilns, and is significantly called The Potteries. The discovery of the Cornish China clay by Cookworthy must be considered as the primary cause which advanced the art.

Of the Materials of Pottery, and their Preparation.

Clay.—The best clay from which the Staffordshire ware is made comes from Pool in Dorsetshire, and a second quality from near Newton in Devonshire; but both are well adapted for working, being refractory in the fire, and becoming very white when burnt. The clay is cleaned as much as possible by hand, and freed from loosely adhering stones at the pits where it is dug. For the manufacture of porcelain, and of the finer kinds of earthenware, the China clay is used. See Porcelain Clay. In the factory the clay is cut to pieces, and then kneaded into a pulp with water, by engines; instead of being broken down with pickaxes, and worked with water by hand-paddles, in a square pit or water-tank, an old process, called *blunging*. The clay is now thrown into a cast-iron cylinder, 20 inches wide, and 4 feet high, or into a cone 2 feet wide at top, and 6 feet deep, in whose axis an upright shaft revolves, bearing knives as radii to the shaft. The knives are so arranged, that their flat sides lie in the plane of a spiral line; so that by the revolution of the shaft, they not only cut through everything in their way, but constantly press the soft contents of the cylinder or cone obliquely downwards, on the principle of a screw. Another set of knives stands out motionless, at right angles from the inner surface of the cylinder, and projects nearly to the central shaft, having their edges looking opposite to the line of motion of the revolving blades. Thus the two sets of slicing implements, the one active, and the other passive, operate like shears in cutting the clay into small pieces, while the active blades, by their spiral form, force the clay in its comminuted state out at an aperture at the bottom of the cylinder or cone, whence it is conveyed into a cylindrical vat, to be worked into a pap with water. This cylinder is tub-shaped, being about 4 times wider than it is deep. A perpendicular shaft turns also in the axis of this vat, bearing cross spokes one below another, of which the vertical set on each side is connected by upright staves, giving the movable arms the appearance of two or four opposite square paddle-boards revolving with the shaft. This wooden framework, or large *blunger*, as it is called, turns round amidst the water and clay lumps, so as to beat them into a fine pap, from which the stony and coarse sandy particles separate, and subside to the bottom. Whenever the pap has acquired a cream-consistenced uniformity, it is run off through a series of wire, lawn, and silk sieves, of different degrees of fineness, which are kept in continual agitation backwards and forward by a crank mechanism; and thus all the grosser parts are completely separated, and hindered from entering into the composition of the ware. This clay liquor is set aside in proper cisterns, and diluted with water to a standard density.

Flints.—These are obtained in great quantities from the chalk formations.

Chert, which is a flinty substance, found in the Mountain Limestone, is also employed. These are calcined and ground.

Felspar.

Bone.—Bone ashes, phosphate of lime, also enters into the composition of pottery.

Steatite, or *Soap stone,* is occasionally employed.

China stone.—A decomposed granite.

These may be regarded as the substances which enter into the body of the ware. See Porcelain Clay.

Clay alone cannot form a proper material for pottery, on account of its great contractility by heat, and the consequent cracking and splitting in the kiln of the vessels made of it; for which reason a siliceous substance incapable of contraction must enter into the body of pottery. For this purpose, ground flints, called flint powder by the potters, is universally preferred. The nodules of flint extracted from the chalk formation are washed, heated redhot in a kiln, like that for burning lime, and thrown in this state into water, by which treatment they lose their translucency, and become exceedingly brittle. They are then reduced to a coarse powder in a stamping-mill or a crushing-mill. The pieces of flint are laid on a strong grating, and pass through its meshes whenever they are reduced by the stamps to a certain state of comminution. This granular matter is now transferred to the proper flint-mill, which consists of a strong cylindrical wooden tub, bottomed with flat pieces of massive *chert*, or hornstone, over which are laid large flat blocks of similar chert, that are moved round over the others by strong iron or wooden arms projecting from an upright shaft made to revolve in the axis of the mill-tub. Sometimes the active blocks are fixed to these cross arms, and thus carried round over the passive blocks at the bottom. Into this cylindrical vessel a small stream of water constantly trickles, which facilitates the grinding motion and action of the stones, and works the flint powder and water into a species of pap. Near the surface of the water there is a plughole in the side of the tub, by which the creamy-looking flint liquor is run off from time to time, to be passed through lawn or silk sieves, similar to those used for the clay liquor; while the particles that remain on the sieves are returned into the mill. This pap is also reduced to a standard density by dilution with water; whence the weight of dry siliceous earth present may be deduced from the measure of the liquor.

The standard clay and flint liquors are now mixed together, in such proportion by measure, that the flint powder may bear to the dry clay the ratio of one to five, or occasionally one to six, according to the richness or plasticity of the clay; and the liquors are intimately incorporated in a revolving churn, similar to that employed for making the clay-pap. This mixture is next freed from its excess of water by evaporation in oblong stone troughs, called *slip-kilns*, bottomed with fire-tiles, under which a furnace flue runs. The breadth of this evaporating trough varies from 2 to 6 feet; its length from 20 to 50; and its depth from 8 to 12 inches, or more.

By the dissipation of the water, and careful agitation of the pap, an uniform doughy mass is obtained; which, being taken out of the trough, is cut into cubical lumps. These are piled in heaps, and left in a damp cellar for a considerable time; that is, several months, in large manufactories. Here the dough suffers disintegration, promoted by a kind of fermentative action, due probably to some vegetable matter in the water and the clay; for it becomes black, and exhales a fetid odour. The argillaceous and siliceous particles get disintegrated also by the action of the water, in such a way that the ware made with old paste is found to be more homogeneous, finer grained, and not so apt to crack or to get disfigured in the baking, as the ware made with newer paste.

But this chemical comminution must be aided by mechanical operations; the first of which is called the potter's *slapping* or *wedging*. It consists in seizing a mass of clay in the hands, and, with a twist of both at once, tearing it into two pieces, or cutting it with a wire. These are again slapped together with force, but in a different direction from that in which they adhered before, and then dashed down on a board. The mass is once more torn or cut asunder at right angles, again slapped together, and so worked repeatedly for 20 or 30 times, which ensures so complete an incorporation of the different parts, that if the mass had been at first half black and half white clay, it would now be of a uniform grey colour. A similar effect is produced in some large establishments by a slicing machine, like that used for cutting down the clay lumps as they come from the pit.

In the axis of a cast iron cylinder or cone, an upright shaft is made to revolve, from which the spiral-shaped blades extend, with their edges placed in the direction of rotation. The pieces of clay subjected to the action of these knives (with the reaction of fixed ones) are minced to small morsels, which are forced pell-mell by the screw-like pressure into an opening of the bottom of the cylinder or cone from which a horizontal pipe about 6 inches square proceeds. The dough is made to issue through this outlet, and is then cut into lengths of about 12 inches. These clay pillars or prisms are thrown back into the cylinder, and subjected to the same operation again and again, till the lumps have their particles perfectly blended together. This process may advantageously precede their being set aside to ripen in a damp cellar. In France the earthenware dough is not worked in such a machine; but after being beat with wooden mallets, a practice common also in England, it is laid down on a clean floor, and a workman is set to tread upon it with naked feet for a considerable time, walking in a spiral direction from the centre to the circumference, and from the circumference to the centre. In Sweden, and also in China (to judge from the Chinese paintings which represent their manner of making porcelain), the clay is trodden to a uniform mass by oxen. It is afterwards, in all cases, kneaded like baker's dough, by folding back the cake upon itself, and kneading it out alternately.

Although we have abundant evidence proving to us the importance of the so-called fermenting process, of the treading operation, and of the slapping, we are not in possession of any explanation, which is in the slightest degree reliable, as to any one of the changes which may be effected in the mass by these manipulations.

The basis of the English earthenware is a clay, brought from Dorsetshire and Devonshire, which lies at the depth of from 25 to 30 feet beneath the surface. It is composed of about 24 parts of alumina, and 76 of silica, with other ingredients in very small proportions. This clay is very refractory in high heats, a property which, joined to its whiteness when burned, renders it peculiarly valuable for pottery. It is also the basis of all the yellow biscuit ware called *cream colour*, and in general of what is called the *printing body;* as also for the semi-vitrified porcelain of Wedgewood's invention, and of the tender porcelain.

The constituents of the stoneware are, Dorsetshire clay, the powder of calcined flints, and of the decomposed granite called Cornish stone. The proportions are varied by the different manufacturers. The following are those generally adopted in one of the principal establishments of Staffordshire:—

For *cream colour*,	Silex or ground flints - - - - -	20 parts.
	Clay - - - - - - - - -	100 „
	Cornish stone - - - - - - -	2 „

Composition of the Paste for receiving the Printing Body under the Glaze.

For this purpose the proportions of the flint and the felspar must be increased. The substances are mixed separately with water into the consistence of a thick cream, which weighs per pint, for the flints 32 ounces, and for the Cornish stone 28. The China Clay is added to the same mixture of flint and felspar, when a finer pottery or porcelain is required. That clay-cream weighs 24 ounces per pint. These 24 ounces in weight are reduced to one-third of their bulk by evaporation. The pint of dry porcelain clay weighs 17 ounces, and in its first pasty state 24, as just stated. The dry flint powder weighs 14½ ounces per pint; which when made into a cream weighs 32 ounces. To 40 measures of Teignmouth clay-cream there are added,

13	measures of	flint liquor.
12	—	porcelain clay ditto.
1	—	Cornish stone ditto.

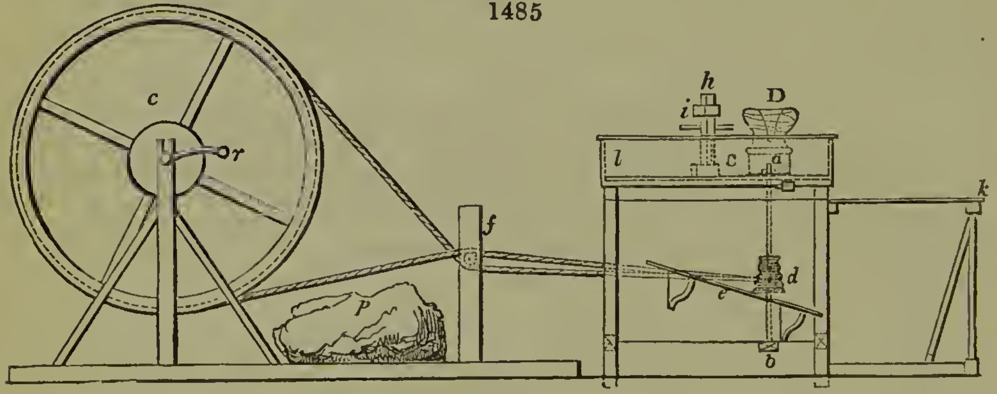
The whole are well mixed by proper agitation, half dried in the *troughs* of the slip-kiln, and then subjected to the machine for cutting up the clay into junks. The above paste, when baked, is very white, hard, sonorous, and susceptible of receiving all sorts of impressions from the paper engravings. When the silica is mixed with the alumina in the above proportions, it forms a compact ware, and the impression remains fixed between the biscuit and the glaze, without communicating to either any portion of the tint of the metallic colour employed in the engraver's press. The felspar gives strength to the biscuit, and renders it sonorous after being baked; while the china clay has the double advantage of imparting an agreeable whiteness and great closeness of grain.

We must now proceed to a consideration of the manufacture. The clay being prepared is submitted to the potter, who employs at the present day a wheel of the same description as that used in the days of Moses.

Throwing is performed upon a tool called the potter's lathe. This consists of an upright iron shaft, about the height of a common table, on the top of which is fixed, by its centre, a horizontal disc or circular piece of wood, of an area sufficiently great for the largest stoneware vessel to stand upon. The lower end of the shaft is pointed, and runs in a conical step, and its collar, a little below the top-board, being truly turned, is embraced in a socket attached to the wooden frame of the lathe. The shaft has a pulley fixed upon it, with grooves for 3 speeds, over which an endless band passes from a fly-wheel, by whose revolution any desired rapidity of rotation may be given to the shaft and its top-board. This wheel, when small, may be placed alongside, as in the turner's lathe, and then it is driven by a treadle and crank; or when of larger dimensions, it is turned by the arms of a labourer.

Fig. 1485 is the profile of the ordinary potter's lathe, for blocking out round ware; C is the table or tray; *a* is the head of the lathe, with its horizontal disc; *a*, *b*,

1485



is the upright shaft of the head; *d*, pulleys with several grooves of different diameters, fixed upon the shaft, for receiving the driving-cord or band; *k* is a bench upon which the workman sits astride; *e*, the treadle foot-board; *l* is a ledge-board, for catching the shavings of clay which fly off from the lathe; *h* is an instrument, with a slide-nut *i*, for measuring the objects in the blocking out; *c* is the fly-wheel with its winch-handle *r*, turned by an assistant; the sole-frame is secured in its place by the heavy stone *p*; *f* is the oblong guide-pulley, having also several grooves for converting the vertical movement of the fly-wheel into the horizontal movement of the head of the lathe.

D is one of the intermediate forms given by the potter to the ball of clay, as it revolves upon the head of the lathe.

In large potteries, the whole of the lathes, both for throwing and turning, are put in motion by a steam engine. The vertical spindle of the lathe has a bevel wheel on it, which works in another bevel-toothed wheel fixed to a horizontal shaft. This shaft is provided with a long conical wooden drum, from which a strap ascends to a similar conical drum on the main lying shaft. The apex of the one cone corresponds to the base of the other, which allows the strap to retain the same degree of tension, while it is made to traverse horizontally, in order to vary the speed of the lathe at pleasure. When the belt is at the base of the driving-cone, it works near the vortex of the driven one, so as to give a maximum velocity to the lathe, and *vice versâ.*

During the throwing of any article, a separate mechanism is conducted by a boy, which makes the strap move parallel to itself along these conical drums, and nicely regulates the speed of the lathe. When the strap runs at the middle of the cones, the velocity of each shaft is equal. By this elegant contrivance of parallel cones reversed, the velocity rises gradually to its maximum, and returns to its minimum or slower motion when the workman is about to finish the article thrown. The strap is then transferred to a pair of loose pulleys, and the lathe stops. The vessel is now cut off at the base with a small wire; is dried, turned on a power lathe, and polished as above described.

The same degree of dryness which admits of the clay being turned on the lathe, also suits for fixing on the handles and other appendages to the vessels. The parts to be attached being previously prepared, are joined to the circular work by means of a thin paste which the workmen call *slip*, and the seams are then smoothed off with a wet sponge. They are now taken to a stove-room heated to 80° or 90° F., and fitted up with a great many shelves. When they are fully dried, they are smoothed over with a small bundle of hemp, if the articles be fine, and are then ready for the kiln, which is to convert the tender clay into the hard *biscuit.*

At a certain stage of the drying, called the *green state*, the ware possesses a greater tenacity than at any other, till it is baked. It is then taken to another lathe, called the turning lathe, where it is attached by a little moisture to the vertical face of a wooden chuck, and turned nicely into its proper shape with a very sharp tool, which also smooths it. After this it is slightly burnished with a smooth steel surface. A great variety of pottery wares, however, cannot be fashioned on the lathe, as they are not of a circular form. These are made by two different methods, the one called *press-work*, and the other *casting.* The press-work is done in moulds made of Paris plaster, the one half of the pattern being formed in the one side of the mould, and the other half in the other side: these moulding-pieces fit accurately together. All vessels of an oval form, and such as have flat sides, are made in this way. Handles of tea-pots, and fluted solid rods of various shapes, are formed by pressure also; viz., by squeezing the dough contained in a pump-barrel through different shaped orifices at its bottom, by working a screw applied to the piston rod. The worm-shaped dough, as it issues, is cut to proper lengths, and bent into the desired form. Tubes may be also made on the same pressure principle, only a tubular opening must be provided in the bottom plate of the clay-forcing pump. The temperature of the various rooms in a pottery is as follows:—

Plate-makers' hothouse - - - - - -	108° Fahr.
Dish-makers' hothouse - - - - - -	106 „
Printers' shop - - - - - - -	90 „
Throwers' hothouse - - - - - -	98 „

The branches against which the temperature of the hothouse is placed, require that heat for drying their work and getting it off their moulds. The outer shops in which they work may be from five to ten degrees less.

The other method of fashioning earthenware articles is called *casting*, and is, perhaps, the most elegant for such as have an irregular shape. This operation consists in pouring the clay, in the state of pap or slip, into plaster moulds, which are kept in a desiccated state. These moulds, as well as the pressure ones, are made in halves, which nicely correspond together. The slip is poured in till the cavity is quite full, and is left in the mould for a certain time, more or less, according to the intended thickness of the vessel. The absorbent power of the plaster soon abstracts the water, and makes the coat of clay in contact with it quite doughy and stiff, so that the part still liquid being poured out, a hollow shape remains, which when removed from the mould constitutes the half of the vessel, bearing externally the exact impress of the mould. The thickness of the clay varies with the time that the paste has stood upon the plaster. These *cast* articles are dried to the green state, like the preceding, and then joined accurately with *slip.* Imitations of flowers and foliage are elegantly executed in this way. This operation, which is called *furnishing*, requires very delicate and dexterous manipulation.

The saggers for the unglazed coloured stoneware should be covered inside with a glaze composed of 12 parts of common salt and 30 of potash, or 6 parts of potash and 14 of salt; which may be mixed with a little of the common enamel for the glazed pottery saggers. The bottom of each sagger has some bits of flints sprinkled upon it, which become so adherent after the first firing as to form a multitude of little prominences for setting the ware upon, when this does not consist of plates. It is the duty of the workmen belonging to the glaze kiln to make the saggers during the intervals of their work; or if there be a relay of hands, the man who is not firing makes the saggers.

When the ware is sufficiently dry, and in sufficient quantity to fill a kiln, the next process is placing the various articles in the baked fire-clay vessels, which may be either of a cylindrical or oval shape; called *gazettes*, Fr.; *kapseln*, Germ. These are from 6 to 8 inches deep, and from 12 to 18 inches in diameter. When packed full of the dry ware, they are piled over each other in the kiln. The bottom of the upper sagger forms the lid of its fellow below; and the junction of the two is luted with a ring of soft clay applied between them. These dishes protect the ware from being suddenly and unequally heated, and from being soiled by the smoke and vapours of the fuel. Each pile of saggers is called a *bung*.

Plan of an English Pottery.

A pottery should be placed by the side of a canal or navigable river, because the articles manufactured do not well bear land carriage.

A Staffordshire pottery is usually built as a quadrangle, each side being about 100 feet long, the walls 10 feet high, and the ridge of the roof 5 feet more. The base of the edifice consists of a bed of bricks, 18 inches high, and 16 inches thick; upon which a mud wall in a wooden frame, called *pisé*, is raised. Cellars are formed in front of the buildings, as depôts for the pastes prepared in the establishment. The wall of the yard or court is 9 feet high, and 18 inches thick.

A, *fig.* 1486, is the entrance door; B, the porter's lodge; C, a particular warehouse; D, workshop of the plaster-moulder; E, the clay depôt; F, F, large gates, 6 feet 8 inches high; G, the winter evaporation stove; H, the shop for sifting the paste liquors; I, sheds for the paste liquor tubs; J, paste liquor pits; K, workshop for the moulder of hollow ware; L, ditto of the dish or plate moulder; M, the plate drying-stove; N, workshop of the biscuit-printers; O, ditto of the biscuit, with o', a long window; P, passage leading to the paste liquor pits; Q, biscuit warehouse; R, place where the biscuit is cleaned as it comes out of the biscuit-kilns, S S; T, T, enamel or glaze kilns; U, long passage; V, space left for supplementary workshops; X, space appointed as a depôt for the sagger fire-clay, as also for making the saggers; Z, the workshop for applying the glaze liquor to the biscuits; *a*, apartment for cleaning the glazed ware; *b*, *b*, pumps; *c*, basin; *d*, muffles; *e*, warehouse for the finished stoneware; *f*, that of the glazed goods; *g*, *g*, another warehouse; *h*, a large space for the smith's forge, carpenter's shop, packing room, depôt of clays, saggers, &c. The packing and loading of the goods are performed in front of the warehouse, which has two outlets, in order to facilitate the work; *i*, a passage to the court or yard; *l*, a space for the wooden sheds for keeping hay, clay, and other miscellaneous articles; *m*, room for putting the biscuit into the saggers; m', a long window; *n*, workshop with lathes and fly-wheels; *o*, drying-room; *p*, room for mounting or furnishing the pieces; *q*, repairing room; *r*, drying room of the goods roughly turned; *s*, rough turning or blocking-out room; *t*, room for beating the paste or dough; *u*, counting-house.

Pottery Kiln of Staffordshire.

Figs. 1487, 1488, 1489, 1490, 1491, represent the kiln for baking the biscuit, and also for running the glaze, in the English potteries.

a, *a*, *figs.* 1487, 1488, 1489, are the furnaces which heat the kiln; of which *b*, in *fig.* 1487, are the upper mouths, and b' the lower; the former being closed more or less by the fire-tile *z*, shown in *fig.* 1491.

f is one fireplace; for the manner of distributing the fuel in it, see *fig.* 1491.

g, *y*, *figs.* 1487, 1491, are the horizontal and vertical flues and chimneys for conducting the flame and smoke. *l* is the laboratory, or body of the kiln; having its floor *k* sloping slightly downwards from the centre to the circumference. *x*, *y*, is the slit of the horizontal register, leading to the chimney flue *y* of the furnace, being the first regulator; *x*, *u*, is the vertical register conduit, leading to the furnace or mouth *f*, being the second regulator; *v* is the register slit above the furnace, and its vertical flue leading into the body of the kiln; v', *c*, slit for regulating flue at the shoulder of

1486

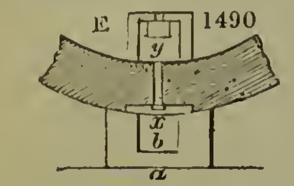
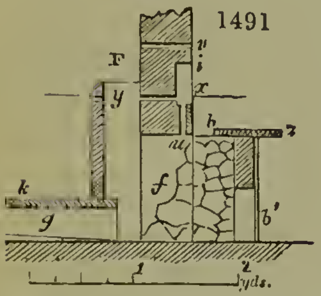
the kiln; *i* is an arch which supports the walls of the kiln, when the furnace is under repair; *c*, *c*, are small flues in the vault *s* of the laboratory. *h*, *fig.* 1488, is the central flue, called *lunette*, of the laboratory.

T, T, is the conical tower or *howell*, strengthened with a series of iron hoops. o′ is the great chimney or *lunette* of the tower; *p* is the door of the laboratory, bound inside with an iron frame.



1490



1491

A, is the complete kiln and *howell*, with all its appurtenances.

B, *fig.* 1488, is the plan at the level *d*, *d*, of the floor, to show the arrangement and distribution of all the horizontal flues, both circular and radiating.

C, *fig.* 1489, is a plan at the level *e*, *e*, of the upper mouths *b*, of the furnaces, to show the disposition of the fireplaces of the vertical flues, and of the horizontal registers, or peep-holes.

D, *fig.* 1489, is a bird's-eye view of the top of the vault or dome *s*, to show the disposition of the vent-holes *c*, *c*.

E, *fig.* 1490, is a detailed plan at the level *c*, *c*, of one furnace and its dependencies.

F, *fig.* 1491, is a transverse section, in detail, of one furnace and its dependencies.

The same letters indicate the same objects in all the figures.

Charging of the kiln.—The saggers are piled up first in the space between each of the upright furnaces, till they rise to the top of the flues. These contain the smaller articles. Above this level, large fire tiles are laid, for supporting other saggers, filled with teacups, sugar-basins, &c. In the bottom part of the pile, within the preceding, the same sorts of articles are put; but in the upper part all such articles are placed as require a high heat. Four piles of small saggers, with a middle one 10 inches in height, complete the charge. As there are 6 piles between each furnace, and as the biscuit kiln has 8 furnaces, a charge consequently amounts to 48 or 50 *bungs*, each composed of from 18 to 19 saggers. The inclination of the bungs ought always to follow the form of the kiln, and should therefore tend towards the centre, lest the strong draught of the furnaces should make the saggers fall against the walls of the kiln, an accident apt to happen were these piles perpendicular. The last sagger of each bung is covered with an unbaked one, three inches deep, in place of a round lid. The watches are small cups, of the same biscuit as the charge, placed in saggers, four in number, above the level of the flue-tops. They are taken hastily out of the saggers, lest they should get smoked, and are thrown into cold water.

When the charging is completed, the firing is commenced, with coal of the best quality. The management of the furnaces is a matter of great consequence to the success of the process. No greater heat should be employed for some time than may be necessary to agglutinate the particles which enter into the composition of the paste, by evaporating all the humidity; and the heat should never be raised so high as to endanger the fusion of the ware, which would make it very brittle.

Whenever the mouth or door of the kiln is built up, a child prepares several fires in the neighbourhood of the *howell*, while a labourer transports in a wheelbarrow a supply of coals, and introduces into each furnace a number of lumps. These lumps divide the furnace into two parts; those for the upper flues being placed above, and those for the ground flues below, which must be kept unobstructed.

The fire-mouths being charged, they are kindled to begin the baking, the regulator tile, *z*, *fig.* 1491, being now opened; an hour afterwards the bricks at the bottom of the furnace are stopped up. The fire is usually kindled at 6 o'clock in the evening, and progressively increased till 10, when it begins to gain force, and the flame rises half-way up the chimney. The second charge is put in at 8 o'clock, and the mouths of the furnaces are then covered with tiles; by which time the flame issues through the vent of the tower. An hour afterwards a fresh charge is made; the tiles *z*, which cover the furnaces, are slipped back; the cinders are drawn to the front, and replaced with small coal. About half-past 11 o'clock the kiln-man examines his furnaces, to see that their draught is properly regulated. An hour afterwards a new charge of coal is applied; a practice repeated hourly till 6 o'clock in the morning. At this moment he takes out his first *watch*, to see how the baking goes on. It should be at a very pale-red heat; but the watch of 7 o'clock should be a deeper red. He removes the tiles from those furnaces which appear to have been burning too strongly, or whose flame issues by the orifices made in the shoulder of the kiln; and puts tiles upon those which are not hot enough. The flames glide along briskly in a regular manner. At this period he draws out the watches every quarter of an hour, and compares them with those reserved from a previous standard kiln; and if he observes a similarity of appearance, he allows the furnaces to burn a little longer; then opens the mouths carefully and by slow degrees; so as to lower the heat and finish the round.

The baking usually lasts from 40 to 42 hours; in which time the biscuit kiln may consume 14 tons of coals; of which four are put in the first day, seven the next day and following night, and the four last give the strong finishing heat.

Emptying the kiln.—The kiln is allowed to cool very slowly. On taking the ware out of the saggers, the biscuit is not subjected to friction, as in the foreign potteries, because it is smooth enough; but is immediately transported to the place where it is to be dipped in the glaze or enamel tub. A child makes the pieces ring, by striking with the handle of the brush, as he dusts them, and then immerses them into the glaze cream; from which tub they are taken out by the enameller, and shaken in the air. The tub usually contains no more than 4 or 5 inches depth of the glaze, to enable the workman to pick out the articles more readily, and to lay them upon a board, whence they are taken by a child to the glaze kiln.

Of Porcelain.

Porcelain is a kind of pottery ware whose paste is fine grained, compact, very hard, and faintly translucid; and whose biscuit softens slightly in the kiln. Its ordinary whiteness cannot form a definite character, since there are porcelain pastes variously coloured. There are two species of porcelain, very different in their nature, the essential properties of which it is of consequence to establish; the one is called *hard*, and the other *tender*: important distinctions, the neglect of which has introduced great confusion into many treatises on this elegant manufacture.

Hard porcelain is essentially composed, first, of a natural clay containing some silica, infusible, and preserving its whiteness in a strong heat; this is almost always a true kaolin; secondly, of a flux, consisting of silica and lime, composing a quartzose felspar rock, called *pe-tun-tse*. The glaze of this porcelain, likewise earthy, admits of no metallic substance or alkali.

The biscuit of the hard porcelain made at the French national manufactory of Sèvres is generally composed of a kaolin clay, and of a decomposed felspar rock; analogous to the china clay of Cornwall, and Cornish stone. Both of the above French materials come from Saint Yrieux-la-perche, near Limoges.

After many experiments, the following composition has been adopted for the *service paste* of the Royal manufactory of Sèvres; that is, for all the ware which is to be glazed: silica, 59; alumina, 35·2; potash, 2·2; lime, 3·3. The conditions of such a compound are pretty nearly fulfilled by taking from 63 to 70 of the washed kaolin or china clay, 22 to 15 of the felspar; nearly 10 of flint powder, and about 5 of chalk. The glaze is composed solely of solid felspar, calcined, crushed, and then ground fine at the mill. This rock pretty uniformly consists of silica 73, alumina 16·2, potash 8·4, and water 0·6.

The kaolin is washed at the pit, and sent in this state to Sèvres, under the name of *decanted earth*. At the manufactory it is washed and elutriated with care; and its slip is passed through fine sieves. This forms the plastic, infusible, and opaque ingredient to which the substance must be added which gives it a certain degree of fusibility and semi-transparency. The felspar rock used for this purpose, should contain neither dark mica nor iron, either as an oxide or sulphide. It is calcined to make it crushable, under stamp-pestles driven by machinery, then ground fine in hornstone (chert) mills. This pulverulent matter being diffused through water, is mixed in certain proportions, regulated by its quality, with the argillaceous *slip*. The mixture is deprived of the chief part of its water in shallow plaster pans without heat; and the resulting paste is set aside to ripen, in damp cellars, for many months.

When wanted for use, it is placed in hemispherical pans of plaster, which absorb the redundant moisture; after which it is divided into small lumps, and completely dried. It is next pulverised, moistened a little, laid on a floor, and trodden upon by a workman marching over it with bare feet in every direction; the parings and fragments of soft moulded articles being intermixed, which improve the plasticity of the whole. When sufficiently tramped, it is made up into masses of the size of a man's head, and kept damp till required.

The dough is now in a state fit for the potter's lathe; but it is much less plastic than stoneware paste, and is more difficult to fashion into the various articles; and hence one cause of the higher price of porcelain.

The round plates and dishes are shaped on plaster moulds; but sometimes the paste is laid on as a crust, and at others it is turned into shape on the lathe. When a crust is to be made, a moistened sheep-skin is spread on a marble table; and over this the dough is extended with a rolling pin, supported on two guide-rules. The crust is then transferred over the plaster mould, by lifting it upon the skin; for it wants tenacity to bear raising by itself. When the piece is to be fashioned on the lathe, a lump of the dough is thrown on the centre of the horizontal wooden disc, and turned into form as directed in treating of stoneware, only it must be left much thicker than in its finished state. After it dries to a certain degree on the plaster mould, the workman replaces it on the lathe, by moistening it on its base with a wet sponge, and finishes its form with an iron tool. A good workman at Sèvres makes no more than from 15 to 20 porcelain plates in a day; whereas an English potter, with two boys, makes from 1000 to 1200 plates of stoneware in the same time. The pieces, which are not round, are shaped in plaster moulds, and finished by hand. When the articles are very large, as wash-hand basins, salads, &c., a flat cake is spread above a skin on the marble slab, which is then applied to the mould with the sponge, as for plates; and they are finished by hand.

The projecting pieces, such as handles, beaks, spouts, and ornaments, are moulded and adjusted separately; and are cemented to the bodies of china-ware with slip, or porcelain dough thinned with water. In fact, the mechanical processes with porcelain and the finer stoneware are substantially the same; only they require more time and greater nicety. The least defect in the fabrication, the smallest bit added, an unequal pressure, the cracks of the moulds, although well repaired, and seemingly effaced in the clay shape, re-appear after it is baked. The articles should be allowed to dry very slowly; if hurried but a little, they are liable to be spoiled. When quite dry, they are taken to the kiln.

The kiln for hard porcelain at Sèvres is a kind of tower in two flats, constructed of fire-bricks; and resembles, in other respects, the stoneware kiln already figured and described. The fuel is young aspen wood, very dry, and cleft very small; it is put into the apertures of the four outside furnaces or fire-mouths, which discharge their flame into the inside of the kiln; each floor being closed in above, by a dome pierced with holes. The whole is covered in by a roof with an open passage, placed at a proper distance from the uppermost dome. There is, therefore, no chimney proper so called.

The raw pieces are put into the upper floor of the kiln; where they receive a heat of about the 60th degree of Wedgewood's pyrometer, and a commencement of baking, which, without altering the shape, or causing a perceptible shrinking of their bulk, makes them completely dry, and gives them sufficient solidity to bear handling. By this preliminary baking, the clay loses its property of forming a paste with water; and the pieces become fit for receiving the glazing coat, as they may be dipped in water without risk of breakage.

The glaze of hard porcelain is a felspar rock; this being ground to a very fine powder, is worked into a paste with water mingled with a little vinegar. All the articles are dipped into this milky liquid for an instant; and as they are very porous, they absorb the water greedily, whereby a layer of the felspar glaze is deposited on their surface, in a nearly dry state, as soon as they are lifted out. Glaze-pap is afterwards applied with a hair brush to the projecting edges, or any points where it had not taken; and the powder is then removed from the part on which the article is to stand, lest it should get fixed to its support in the fire. After these operations it is replaced in the kiln, to be completely baked.

The articles are put into saggers, like those of fine stoneware; and this operation is one of the most delicate and expensive in the manufacture of porcelain. The saggers are made of the plastic or potter's clay of Abondant, to which about a third part of cement of broken saggers has been added.

As the porcelain pieces soften somewhat in the fire, they cannot be set above each other, even were they free from glaze; for the same reason, they cannot be baked on tripods, several of them being in one case, as is done with stoneware. Every piece of porcelain requires a sagger for itself. They must, moreover, be placed on a perfectly flat surface, because in softening they would be apt to conform to the irregularities of a rough one. When therefore any piece, a soup plate for example, is to be *saggered*, there is laid on the bottom of the case a perfectly true disc or round cake of stoneware, made of the sagger material, and it is secured in its place on three small props of a clay-lute, consisting of potter's clay mixed with a great deal of sand. When the cake is carefully levelled, it is moistened, and dusted over with sand, or coated with a film of fire-clay slip, and the porcelain is carefully set on it. The sand or fire-clay hinders it from sticking to the cake. Several small articles may be set on the same cake, provided they do not touch one another.

The saggers containing the pieces thus arranged, are piled up in the kiln over each other, in the columnar form, till the whole space be occupied; leaving very moderate intervals between the columns to favour the draught of the fires. The whole being arranged with these precautions, and several others, too minute to be specified here, the door of the kiln is built up with three rows of bricks, leaving merely an opening 8 inches square, through which there is access to a sagger with the nearest side cut off. In this sagger are put fragments of porcelain intended to be withdrawn from time to time, in order to judge of the progress of the baking. These are called time-pieces or watches (*montres*). This opening into the watches is closed by a stopper of stoneware.

The firing begins by throwing into the furnace-mouths some pretty large pieces of white wood, and the heat is maintained for about 15 hours, gradually raising it by the addition of a larger quantity of the wood, till at the end of that period the kiln has a cherry-red colour within. The heat is now greatly increased by the operation termed *covering the fire.* Instead of throwing billets vertically into the four furnaces, there is placed horizontally on the openings of these furnaces, aspen wood of a sound texture, cleft small, laid in a sloping position. The brisk and long flame which it yields dips into the tunnels, penetrates the kiln, and circulates round the sagger-piles. The heat augments rapidly, and, at the end of 13 or 15 hours of this firing, the interior of the kiln is so white that the watches can hardly be distinguished. The draught, indeed, is so rapid at this time, that one may place his hand on the slope of the wood without feeling incommoded by the heat. Everything is consumed, no small charcoal remains, smoke is no longer produced, and even the wood-ash is dissipated. It is obvious that the kiln and the saggers must be composed of a very refractory clay, in order to resist such a fire. The heat in the Sèvres kilns mounts so high as the 134th degree of Wedgewood.

At the end of 15 or 20 hours of the great fire; that is, after from 30 to 36 hours' firing, the porcelain is baked; as is ascertained by taking out and examining the watches. The kiln is suffered to cool during 3 or 4 days, and is then opened and discharged. The sand strewed on the cakes to prevent the adhesion of the articles to them, gets attached to their sole, and is removed by friction with a hard sandstone; an operation which one woman can perform for a whole kiln in less than 10 days; and is the last applied to hard porcelain, unless it needs to be returned into the hot kiln to have some defects repaired.

The materials of fine porcelain are very rare; and there would be no advantage in making a grey-white porcelain with coarser and somewhat cheaper materials, for the other sources of expense above detailed, and which are of most consequence, would still exist; while the porcelain, losing much of its brightness, would lose the main part of its value.

Its pap or dough, which requires tedious grinding and manipulation, is also more difficult to work into shapes, in the ratio of 80 to 1, compared to fine earthenware. Each porcelain plate requires a separate sagger; so that 12 occupy in the kiln a space sufficient for at least 38 earthenware plates. The temperature of a hard porcelain kiln being very high, involves a proportionate consumption of fuel and waste of saggers. With 40 cubic metres of wood, 12,000 earthenware plates may be completely fired, both in the biscuit and glaze kilns; while the same quantity of wood would bake at most only 1000 plates of porcelain.

The process of bisque firing is as follows: the ware being finished from the hands of the potter is brought by him upon boards to the "green-house," so called from its being the receptacle for ware in the "green" or unfired state. It is here gradually dried for the ovens; when ready it is carried to the "sagger-house" in immediate connection with the oven in which it is to be fired, and here it is placed in the "saggers:" these are boxes made of a peculiar kind of clay (a native marl) previously fired, and infusible at the heat required for the ware, and of form suited to the articles they are to contain. A little dry pounded flint is scattered between them of china, and sand of earthenware to prevent adhesion. The purpose of the sagger is to protect the ware from the flames and smoke, and also for its security from breakage, as in the clay state it is exceedingly brittle, and when dry, or what is called white, requires great care in the handling. A plate sagger will hold twenty plates placed one on the other of earthenware, but china plates are fired separately in "setters" made of their respective forms. The "setters" for china plates and dishes answer the same purpose as the saggers, and are made of the same clay. They take in one dish or plate each, and are "reared" in the oven in "bungs," one on the other.

The hovels in which the ovens are built form a very peculiar and striking feature of the pottery towns, and forcibly arrest the attention and excite the surprise of the stranger, resembling as they closely do a succession of gigantic beehives. They are constructed of bricks about 40 feet in diameter, and about 35 feet high, with an aperture at the top for the escape of the smoke. The "ovens" are of a similar form, about 22 feet diameter, and from 18 to 21 feet high, heated by fireplaces or "mouths," about nine in number, built externally around them. Flues in connection with these converge under the bottom of the oven to a central opening, drawing the flames to this point, where they enter the oven; other flues termed "bags" pass up the internal sides to the height of about 4 feet, thus conveying the flames to the upper part.

When "setting in" the oven, the firemen enter by an opening in the side, carrying the saggers with the ware placed as described; these are piled one upon another, from bottom to top of the oven, care being taken to arrange them so that they may receive the heat (which varies in different parts) most suited to the articles they contain. This being continued till the oven is filled, the aperture is then bricked up. The firing of earthenware bisque continues sixty hours, and of china forty-eight.

The quantity of coals necessary for a "bisque" oven is from 16 to 20 tons; for a "glost" oven from $4\frac{1}{2}$ to 6 tons.

The ware is allowed to cool for two days, when it is drawn in the state technically called "biscuit" or bisque, and is then ready for "glazing," except when required for printing or a common style of painting, both of which processes are done on the bisque prior to being "glazed."

Tender porcelain, or soft china-ware, is made with a vitreous frit, rendered less fusible and opaque by an addition of white marl or bone-ash. The frit is, therefore, first prepared. This, at Sèvres, is a composition, made with some nitre, a little sea salt, Alicant barilla, alum, gypsum, and much siliceous sand or ground flints. That mixture is subjected to an incipient pasty fusion in a furnace, where it is stirred about to blend the materials well; and thus a very white spongy frit is obtained. It is pulverised, and to every three parts of it, one of the white marl of Argenteuil is added; and when the whole are well ground, and intimately mixed, the paste of tender porcelain is formed.

As this paste has no tenacity, it cannot bear working till a mucilage of gum or black soap be added, which gives it a kind of plasticity, though even then it will not bear the lathe. Hence it must be fashioned in the press, between two moulds of plaster. The pieces are left thicker than they should be; and when dried, are finished on the lathe with iron tools.

In this state they are baked, without any glaze being applied; but as this porcelain softens far more during the baking than the hard porcelain, it needs to be supported on every side. This is done by baking on earthen moulds all such pieces as can be treated in this way, namely, plates, saucers, &c. The pieces are reversed on these moulds, and undergo their shrinkage without losing their form. Beneath other articles, supports of a like paste are laid, which suffer in baking the same contraction as the articles, and of course can serve only once. In this operation saggers are used, in which the pieces and their supports are fired.

The kiln for the tender porcelain at Sèvres is absolutely similar to that for the common stoneware; but it has two floors; and while the biscuit is baked in the lower story, the glaze is fused in the upper one; which causes considerable economy of fuel. The glaze of soft porcelain is a species of glass or crystal prepared on purpose. It is composed of flint, siliceous sand, a little potash or soda, and about two-fifth parts of lead oxide. This mixture is melted in crucibles or pots beneath the kiln. The resulting glass is ground fine, and diffused through water mixed with a little vinegar to the consistence of cream. All the pieces of biscuit are covered with this glazy matter, by pouring this slip over them, since their substance is not absorbent enough to take it on by immersion.

The pieces are encased once more each in a separate sagger, but without any supports; for the heat of the upper floor of the kiln, though adequate to melt the glaze, is not strong enough to soften the biscuit. But as this first vitreous coat is not very equal, a second one is applied, and the pieces are returned to the kiln for the third time. See Stone, Artificial, for a view of this kiln.

The manufacture of soft porcelain is longer and more difficult than that of hard; its biscuit is dearer, although the raw materials may be found everywhere; and it furnishes also more refuse. Many of the pieces split asunder, receive fissures, or become deformed in the biscuit-kiln, in spite of the supports; and this vitreous porcelain, moreover, is always yellower, more transparent, and incapable of bearing rapid transitions of temperature, so that even the heat of boiling water frequently cracks it. It possesses some advantages as to painting, and may be made so gaudy and brilliant in its decorations, as to captivate the vulgar eye.

The best English porcelain is made from a mixture of the Cornish and Devonshire kaolin (called china clay), ground flints, ground Cornish stone, and calcined bones in powder, or bone-ash, besides some other materials, according to the fancy of the manufacturers. A liquid pap is made with these materials, compounded in certain proportions, and diluted with water. The fluid part is then withdrawn by the absorbent action of dry stucco basins or pans. The dough, brought to a proper stiffness, and perfectly worked and kneaded on the principles detailed above, is fashioned on the lathe, by the hands of modellers, or by pressure in moulds. The pieces are then baked to the state of biscuit in a kiln, being enclosed, of course, in saggers.

This biscuit has the aspect of white sugar, and being very porous, must receive a vitreous coating. The glaze consists of ground felspar or Cornish stone. Into this, diffused in water, along with a little fire-powder and potash, the biscuit ware is dipped, as already described. The pieces are then fired in the glaze-kiln, care being taken, before putting them into their saggers, to remove the glaze powder from their bottom parts, to prevent their adhesion to the fire-clay vessel.

Mortar body, is a paste composed of 6 parts of clay, 3 of felspar, 2 of silex, and 1 of china clay.

Ironstone China. Some of the English porcelain has been called ironstone china. This is composed usually of 60 parts of Cornish stone, 40 of china clay, and 2 of flint glass; or 42 of felspar, the same quantity of clay, 10 parts of flints ground, and 8 of flint glass.

The glaze for the first composition is made with 20 parts of felspar, 15 of flints, 6 of red lead, and 5 of soda, which are fritted together; with 44 parts of the frit, 22 parts of flint glass, and 15 parts of white lead, are ground.

The glaze for the second composition is formed of 8 parts of flint glass, 36 of felspar, 40 of white lead, and 20 of silex (ground flints).

The English manufacturers employ three sorts of compositions for the porcelain biscuit; namely, two compositions not fritted; one of them for the ordinary table service; another for the dessert service and tea dishes; the third, which is fritted, corresponds to the paste used in France for sculpture; and with it all delicate kinds of ornaments are made.

	First composition.	Second composition.		Third composition.	
Ground flints - - -	75	- -	66	Lynn sand	150
Calcined bones - -	180	- -	100	- -	300
China clay - - -	40	- -	96	- -	100
Clay - - - -	70	Granite	80	Potash	107

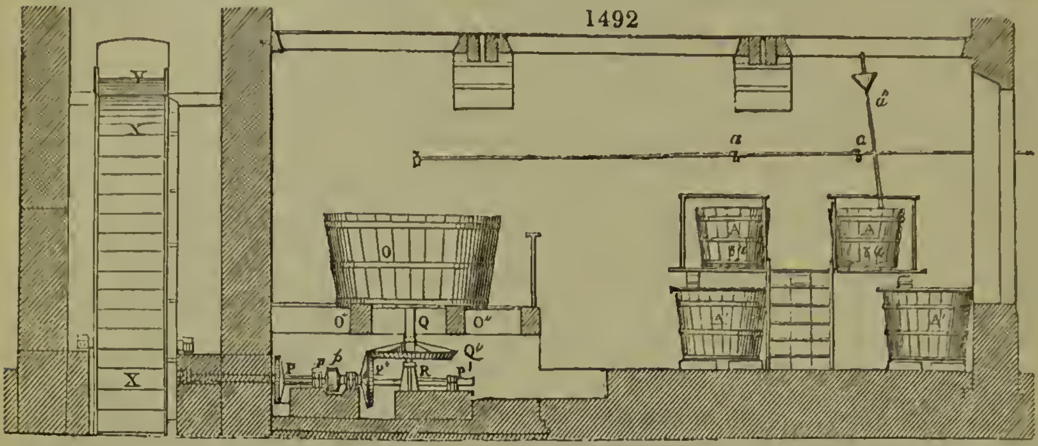
The glaze for the first two of the preceding compositions consists of, felspar 45, flints 9, borax 21, flint glass 20, nickel 4. After fritting that mixture, add 12 parts of red lead. For the third composition, which is the most fusible, the glaze must receive 12 parts of ground flints, instead of 9; and there should be only 15 parts of borax, instead of 21.

Description of the Porcelain Mill.

1. The following figures of a felspar and flint mill (*figs.* 1492, 1493) are taken from plans of apparatus lately constructed by Mr. Hall of Dartford, and erected by him in the royal manufactory of Sèvres. There are two similar sets of apparatus, which may be employed together or in succession; composed each of an elevated tub A, and of three successive vats of reception A′, and two behind it, whose top edges are upon a lower level than the bottom of the casks A, A, to allow of the liquid running out of them with a sufficient slope. A proper charge of kaolin is first put into the cask A, then water is gradually run into it by the gutter adapted to the stopcock *a*, after which the mixture is agitated powerfully in every direction by hand with the stirring-bar, which is hung within a hole in the ceiling, and has at its upper end a small tin-plate funnel to prevent dirt or rust from dropping down into the clay. The stirrer may be raised or lowered so as to touch any part of the cask. The semi-fluid mass is left to settle for a few minutes, and then the finer argillaceous pap is run off by the stopcock *a′*, placed a little above the gritty deposit, into the zinc pipe which conveys it into one of the tubs A′; but as this semi-liquid matter may still contain some granular substances, it must be passed through a sieve before it is admitted into the tub. There is, therefore, at the spot upon the tub where the zinc pipe terminates, a wire-

cloth sieve, of an extremely close texture, to receive the liquid paste. This sieve is shaken upon its support, in order to make it discharge the washed argillaceous kaolin.

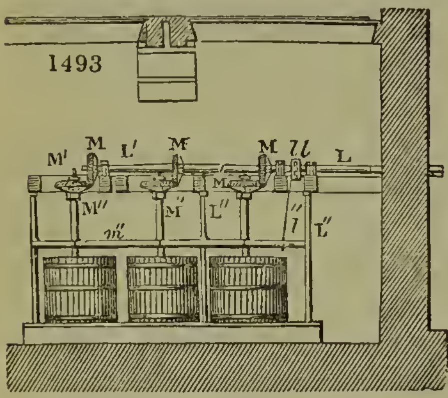
1492



After the clay has subsided, the water is drawn off from its surface by a zinc siphon. The vats A′ have covers, to protect their contents from dust. In the pottery factories of England the agitation is produced by machinery instead of the hand. A vertical shaft, with horizontal or oblique paddles, is made to revolve in the vats for this purpose.

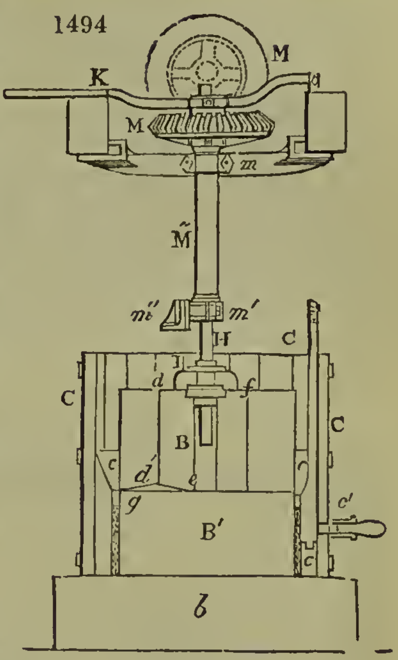
The small triturating mill is represented in *fig.* 1493. There are three similar grinding-tubs on the same line. The details of the construction are shown in *fig.* 1494, where it is seen to consist principally of a revolving millstone, B (*fig.* 1495), of a fast or sleeper millstone, B′, and of a vat, C, hooped with iron, with its top raised above the upper millstone. The lower block of hornstone rests upon a very firm basis, *b′*; it is surrounded immediately by the strong wooden circle *c*, which slopes out funnel-wise above, in order to throw back the earthy matters as they are pushed up by the attrition of the stones. That piece is hollowed out, partially to admit the key C, opposite to which is the faucet and spigot *c′*, for emptying the tub. When one operation is completed, the key C is lifted out by means of a peg put into the holes at its top; the spigot is then drawn, and the thin paste is run out into vats. The upper grindstone, B *d*, like the lower one, is about two feet in diameter, and must be cut in a peculiar manner. At first there is scooped out a hollowing in the form of a sector, denoted by *d e f*, *fig.* 1495; the arc *d f* is about one-sixth of the circumference, so that the vacuity of the turning grindstone is one-sixth of its surface; moreover, the stone must be channelled, in order to grind or crush the hard gritty substances. For this purpose, a wedge-shaped groove *d e g*, about an inch and a quarter deep, is made on its under face, whereby the stone, as it turns in the direction indicated by the arrow, acts with this inclined plane upon all the particles in its course, crushing them and forcing them in between the stones, till they be triturated to an impalpable powder. When the grindstone wears unequally on its lower surface, it is useful to trace upon it little furrows, proceeding from the centre to the circumference, like those shown by the dotted lines *e′ e″*. It must, moreover, be indented with rough points by the hammer.

1493



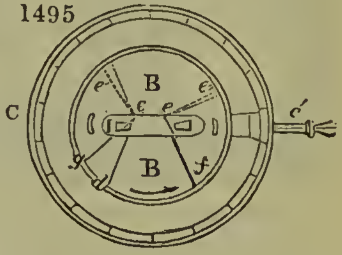
The turning hornstone-block is set in motion by the vertical shaft H, which is fixed by the clamp-iron cross I to the top of the stone. When the stone is new, its thickness is about 14 inches, and it is made to answer for grinding till it be reduced to about 8 inches, by lowering the clamp I upon the shaft, so that it may continue to keep its hold of the stone. The manner in which the grindstones are turned, is obvious from inspection of *fig.* 1493, where the horizontal axis L, which receives its impulsion from the great water-wheel, turns the prolonged shaft L′, or leaves it at rest, according as the clutch *l*, *l′* is locked or open. This second shaft bears the three bevel wheels M, M, M. These work in three corresponding bevel wheels M′M′M′, made fast respectively to the three vertical shafts of the millstones, which pass through the cast-iron guide tubes M″ M″. These are fixed in a truly vertical position by the collar-bar m'', m', *fig.* 1494. In this figure we see at m how the strong cross-bar of cast iron is made fast to the wooden beams which support all the upper mechanism of the mill work. The bearing m' is disposed in an analogous manner; but it is supported against two cast-iron columns, shown at L″ L″, in *fig.* 1493. The guide tubes M″ are bored smooth for a small distance from each of their extremities, and their interjacent calibre is wider, so that the vertical shafts touch only at two places. It is obvious, that whenever the shaft L′ is set agoing, it necessarily turns the wheels M and M′, and their guide tubes M″; but the vertical shaft may remain either at rest, or revolve, according to the position of the lever click or catch K, at the top, which is made to slide upon the shaft, and can let fall a finger into a vertical groove cut in the surface of that shaft, The clamp-fork of the click is thus made to catch upon the horizontal bevel-wheel M′, or to release it, according as the lever K is lowered or lifted up. Thus each millstone may be thrown out of or into gear at pleasure.

1494



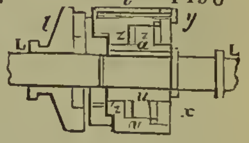
These stones make upon an average 11 or 12 turns in a minute, corresponding to 3 revolutions of the water-wheel, which moves through a space of 3 feet 4 inches in the second, its outer circumference being 66 feet. The weight of the upper stone, with its iron mountings, is about 6 cwt. when new. The charge of each mill in dry material is 2 cwt.; and the water may be estimated at from one-half to the whole of this weight; whence the total load may be reckoned to be at least 3 cwt.; the stone by displacement of the magma, loses fully 400 pounds of its weight, and weighs therefore in reality only 2 cwt. It is charged in successive portions, but it is discharged all at once. When the grinding of the siliceous or felspar matters is nearly complete, a remarkable phenomenon occurs; the substance precipitates to the bottom, and assumes in a few seconds so strong a degree of cohesion, that it is hardly possible to restore it again to the pasty or magma state; hence if a millstone turns too slowly, or if it be accidentally stopped for a few minutes, the upper stone gets so firmly cemented to the under one, that it is difficult to separate them. It has been discovered, but without knowing why, that a little vinegar added to the water of the magma almost infallibly prevents that sudden stiffening of the deposit and stoppage of the stones. If the mills come to be set fast in this way, the shafts or gearing would be certainly broken, were not some safety provision to be made in the machinery against such accidents. Mr. Hall's contrivance to obviate the above danger is highly ingenious. The clutch l, l', *fig.* 1493, is not a locking crab, fixed in the common way, upon the shaft L; but it is composed, as shown in *figs.* 1496, 1497, 1498, 1499, of a hoop, u, fixed upon the shaft by means of a key, of a collar v, and of a flat ring or washer x, with four projections, which are fitted to the collar v by four bolts, y. *Fig.* 1497 represents the collar v seen in front; that is, by the face which carries the clutch teeth; and *fig.* 1498 represents its other face, which receives the flat ring x, *fig.* 1499, in four notches corresponding to the four projections of the washer-ring. Since the ring u is fixed upon the shaft L, and necessarily turns with it, it has the two other pieces at its disposal, namely the collar v, and the washer x, because they are always connected with it by the four bolts y, so as to turn with the ring u, when the resistance they encounter upon the shaft L′ is not too great, and to remain at rest, letting the ring u turn by itself, when that resistance increases to a certain pitch. To give this degree of friction, we need only interpose the leather washers z, z', *fig.* 1496; and now, as the collar *coupling-box* v slides pretty freely upon the ring u, it is obvious that by tightening more or less the screw bolts y, these washers will

1495

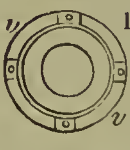


1497

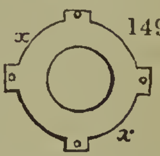
1496



1498



1499



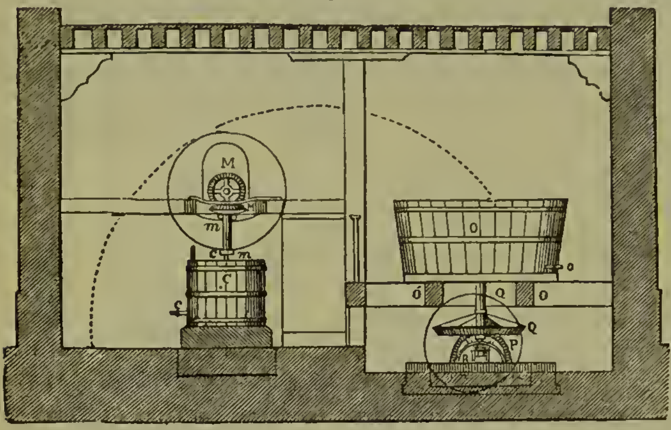
become as it were a lateral brake, to tighten more or less the bearing of the ring *u*, to which they are applied: by regulating this pressure, everything may be easily adjusted. When the resistance becomes too great, the leather washers, pressed upon one side by the collar *v*, of the washer *x*, and rubbed upon the other side by the prominence of the ring *u*, get heated to such a degree, that they are apt to become carbonised, and require replacement.

This safety clutch may be recommended to the notice of mechanicians, as susceptible of beneficial application in a variety of circumstances.

Great porcelain mill.—The large felspar and kaolin mill, made by Mr. Hall, for Sèvres, has a flat bed of hornstone, in one block, laid at the bottom of a great tub, hooped strongly with iron. In most of the English potteries, however, that bed consists of several flat pieces of chert or hornstone, laid level with each other. There is as usual a spigot and faucet at the side, for drawing off the liquid paste. The whole system of the mechanism is ver y substantial, and is supported by wooden beams.

The following is the manner of turning the upper blocks. In *fig.* 1492 the main horizontal shaft P bears at one of its extremities a toothed wheel, usually mounted upon the periphery of the great water-wheel (*fig.* 1500 shows this toothed wheel by a dotted line) at its other end; P carries the fixed portion *p* of a coupling-box, similar to the one just described as belonging to the little mill. On the prolongation of P, there is a second shaft P′, which bears the movable portion of that box, and an upright bevel wheel P″. Lastly, in *figs.* 1492 and 1500, there is shown the vertical shaft Q, which carries at its upper end a large horizontal cast-iron wheel Q, not seen in this view, because it is sunk within the upper surface of the turning hornstone, like the clamp *d*, *f*, in *fig.* 1494. At the lower end of the shaft Q, there is the bevel wheel Q″, which receives motion from the wheel P″, *fig.* 1492.

1500



The shaft P always revolves with the water-wheel; but transmits its motion to the shaft P′ only when the latter is thrown into gear with the coupling-box *p*′, by means of its forked lever. Then the bevel wheel P′ turns round with the shaft P′, and communicates its rotation to the bevel wheel Q″, which transmits it to the shaft Q, and to the large cast-iron wheel, which is sunk into the upper surface of the revolving hornstone.

The shaft Q is supported and centred by a simple and solid adjustment; at its lower part, it rests in a step R, which is supported upon a cast-iron arch Q′, seen in profile in *fig.* 1492; its base is solidly fixed by four strong bolts. Four set screws above R, *fig.* 1492, serve to set the shaft Q truly perpendicular: thus supported, and held securely at its lower end, in the step at R, *figs.* 1492 and 1500, it is embraced near the upper end by a brass bush or collar, composed of two pieces, which may be drawn closer together by means of a screw. This collar is set into the summit of a great truncated cone of cast-iron, which rises within the tub through two-thirds of the thickness of the hornstone bed; having its base firmly fixed by bolts to the bottom of the tub, and having a brass collet to secure its top. The iron cone is cased in wood. When all these pieces are well adjusted and properly screwed up, the shaft Q revolves without the least vacillation, and carries round with it the large iron wheel Q′, cast in one piece, and which consists of an outer rim, three arms or radii, and a strong central nave, made fast by a key to the top of the shaft Q, and resting upon a shoulder nicely turned to receive it. Upon each of the three arms, there are adjusted, with bolts, three upright substantial bars of oak, which descend vertically through the body of the revolving mill to within a small distance of the bedstone; and upon each of the three arcs of that wheel-ring, comprised between its three strong arms, there are adjusted, in like manner, five similar uprights, which fit into hollows cut in the periphery of the moving stone. They ought to be cut to a level at their lower part, to suit the slope of the bottom of the tub *o*, *figs.* 1492 and 1500, so as to glide past it pretty closely, without touching.

The speed of this large mill is eight revolutions in the minute. The turning hornstone describes a mean circumference of 141⅓ inches (its diameter being 45 inches), and of course moves through about 100 feet per second. The tub o, is 52 inches wide at bottom, 56 at the surface of the sleeper block (which is 16 inches thick), and 64 at top, inside measure. It sometimes happens that the millstone throws the pasty mixture out of the vessel, though its top is 6 inches under the lip of the tub *o*; an inconvenience which can be obviated only by making the pap a little thicker; that is, by allowing only from 25 to 30 per cent. of water; then its density becomes nearly equal to 2·00, while that of the millstones themselves is only 2·7; whence, supposing them to weigh only 2 cwt., there would remain an effective weight of less than ½ cwt. for pressing upon the bottom and grinding the granular particles. This weight appears to be somewhat too small to do much work in a short time; and therefore it would be better to increase the quantity of water, and put covers of some convenient form over the tubs. It is estimated that this mill will grind nearly 5 cwt. of hard kaolin or felspar gravel, in 24 hours, into a proper pap.

STONEWARE.

It is with great difficulty that any satisfactory distinction can be made between the different kinds of ware; they slide by nice degrees into one another. Stoneware of the ordinary kind, such as we see in jars, drain-pipes, and the variety of chemical utensils which are made in the Lambeth potteries, is constituted of the plastic clay, united in various proportions with some felspathic mineral, sands of different kinds, and in some cases with cement—stone, or chalk; these mixtures being subjected to a heat which is sufficient to produce a partial fusion of the mass,—this condition of semi-fusion being the distinguishing character of stoneware. The finer varieties of stoneware are made from well-selected clays, which when burnt will not have much colour. These are united with some fluxing material, by which that condition of semi-fusion is obtained which is necessary to the production of stoneware. The glaze of stoneware was always a salt glaze; it has, however, recently been the practice to glaze with a mixture of Cornish stone, flint, &c., as for earthenware.

EARTHENWARE.

This ware is exemplified in the Majolica ware, the Fayence of the French, the Dutch or Delf ware, and by the common varieties of pottery which are at present in general use in this country.

All the varieties of earthenware — and they are many — consist of clay bodies, coated with an easily-fusible glaze, containing lead or borax.

Poole clay, Devonshire clay, Cornish clay, and many of the clays from the coal measures, and other geological formations, enter into the composition of earthenware. These are combined with certain proportions of ground flint. Porous vessels for cooling water and wine, now made extensively in many parts of this country, are similar to the ancient Spanish cooling vessels.

The Spanish *alcarazzas*, or cooling vessels, are made porous, to favour the exudation of water through them, and maintain a constantly moist evaporating surface. Lasteyrie says, that granular sea salt is an ingredient of the paste of the Spanish alcarazzas; which being expelled partly by the heat of the baking, and partly by the subsequent watery percolation, leaves the body very open. The biscuit should be charged with a considerable portion of sand, and very moderately fired.

With what has been already said in reference to the modes of manufacture, added to the remarks on printing, glazing, &c., which are to follow, the general principles which obtain in the manufacture of pottery, will, we think, be sufficiently understood.

PRINTING AND PAINTING.

There are two distinct methods of printing in use for china and earthenware; one is transferred on the bisque, and is the method by which the ordinary printed ware is produced, and the other is transferred on the glaze. The first is called "press printing" and the latter "bat printing." The engraving is executed upon copper plates, and for press printing is cut very deep to enable it to hold a sufficiency of colour to give a firm and full transfer to the ware. The printer's shop is furnished with a brisk stove having an iron plate on the top immediately over the fire, for the convenience of warming the colour while being worked, also a roller press and tubs. The printer has two female assistants called "transferers," and also a girl called a "cutter." The copper plate is charged with colour mixed with thick boiled oil by means of a knife and "dabber," while held on the hot stove plate for the purpose of keeping the colour fluid; and the engraved portion being filled, the superfluous colour is scraped off the surface of the copper by the knife, which is further cleaned by being rubbed with a boss made of leather. A thick firm oil is required to keep the different parts of the design from flowing into a mass or becoming confused while under the pressure of the rubber, in the process of transferring. A sheet of paper of the necessary size and of a peculiarly thin texture, called "pottery tissue," after being saturated with a thin solution of soap and water, is placed upon the copper plate, and being put under the action of the press, the paper is carefully drawn off again, (the engraving being placed on the stove,) bringing with it the colour by which the plate was charged, constituting the pattern. This impression is given to the "cutter," who cuts away the superfluous paper about it; and if the pattern consists of a border and a centre the border is separated from the centre, as being more convenient to fit to the ware when divided. It is then laid by a transferrer upon the ware and rubbed first with a small piece of soaped flannel to fix it, and afterwards with a rubber formed of rolled flannel. This rubber is applied to the impression very forcibly, the friction causing the colour to adhere firmly to the bisque surface, by which it is partially imbibed; it is then immersed in a tub of water, and the paper washed entirely away with a sponge, the colour, from its adhesion to the ware and being mixed with oil, remaining unaffected. It is now necessary, prior to "glazing," to get rid of this oil, which is done by submitting the ware to heat in what are called "hardening kilns," sufficient to destroy it and leave the colour pure. This is a necessary process, as the glaze, being mixed with water, would be rejected by the print, while the oil remained in the colour.

The printing under the stoneware glaze is generally performed by means of cobalt, and has different shades of blue according to the quantity of colouring matter employed. After having subjected this oxide to the processes requisite for its purification, it is mixed with a certain quantity of ground flints and sulphate of baryta, proportioned to the dilution of the shade. These materials are fritted and ground; but before they are used, they must be mixed with a flux consisting of equal parts by weight of flint glass and ground flints, which serves to fix the colour upon the biscuit, so that the immersion in the glaze liquor may not displace the lines printed on, as also to aid in fluxing the cobalt.

The "bat printing" is done upon the glaze, and the engravings are for this style exceedingly fine, and no greater depth is required than for ordinary book engravings. The impression is not submitted to the heat necessary for that in the bisque, and the medium of conveying it to the ware is also much purer. The copper plate is first charged with linseed oil, and cleaned off by hand, so that the engraved portion only retains it. A preparation of glue being run upon flat dishes about a quarter of an inch thick, is cut to the size required for the subject, and then pressed upon it, and being immediately removed, draws on its surface the oil with which the engraving was filled. The glue is then pressed upon the ware, with the oiled part next the glaze, and being again removed, the design remains; though, being in a pure oil, scarcely perceptible. Colour finely ground is then dusted upon it with cotton wool, and a sufficiency adhering to the oil leaves the impression perfect, and ready to be fired in the enamel kilns.

The following are the processes usually practised in Staffordshire for printing under the glaze.

The cobalt, or whatever colour is employed, should be ground upon a porphyry slab, with a varnish prepared as follows:—A pint of linseed oil is to be boiled to the consistence of thick honey, along with 4 ounces of rosin, half a pound of tar, and half a pint of oil of amber. This is very tenacious, and can be used only when liquefied by heat; which the printer effects by spreading it upon a hot cast-iron plate.

The printing plates are made of copper, engraved with pretty deep lines in the common way. The printer, with a leathern muller, spreads upon the engraved plate, previously heated, his colour, mixed up with the above oil varnish, and removes what is superfluous with a pallet knife; then cleans the plate with a dossil filled with bran, tapping and wiping as if he were removing dust from it. This operation being finished, he takes the paper intended to receive the impression, soaks it with soap-water, and lays it moist upon the copper-plate. The soap makes the paper part more readily from the copper, and the thick ink part more readily from the biscuit. The copper-plate is now passed through the engraver's cylinder press, the proof leaf is lifted off and handed to the women, who cut it into detached pieces, which they apply to the surface of the biscuit. The paper best fitted for this purpose is made entirely of linen rags; it is very thin, of a yellow colour, and unsized, like tissue blotting-paper.

The stoneware biscuit never receives any preparation before being imprinted, the oil of the colour being of such a nature as to fix the figures firmly. The printed paper is pressed and rubbed on with a roll of flannel, about an inch and a half in diameter, and 12 or 15 inches long, bound round with twine, like a roll of tobacco. This is used as a burnisher, one end of it being rested against the shoulder, and the other end being rubbed upon the paper; by which means it transfers all the engraved traces to the biscuit. The piece of biscuit is laid aside for a little, in order that the colour may take fast hold; it is then plunged into water, and the paper is washed away with a sponge.

When the paper is detached, the piece of ware is dipped into a caustic alkaline lye to saponify the oil, after which it is immersed in the glaze liquor, with which the printed figures readily adhere. This process, which is easy to execute, and very economical, is much preferable to the old plan of passing the biscuit into the muffle after it had been printed, for the purpose of fixing and volatilising the oils. When the paper impression is applied to pieces of porcelain, they are heated before being dipped in the water, because, being already semi-vitrified, the paper sticks more closely to them than to the biscuit, and can be removed only by a hard brush.

The impression above the glaze is done by quite a different process, which dispenses with the use of the press. A quantity of fine clean glue is melted and poured hot upon a large flat dish, so as to form a layer about a quarter of an inch thick, and of the consistence of jelly. When cold it is divided into cakes of the size of the copper-plates it is intended to cover.

The operative (a woman) rubs the engraved copper-plate gently over with linseed oil boiled thick, immediately after which she applies the cake of glue, which she presses down with a silk dossil filled with bran. The cake licks up all the oil out of the engraved lines; it is then cautiously lifted off, and transferred to the surface of the glazed ware which it is intended to print. The glue cake being removed, the enamel surface must be rubbed with a little cotton, whereby the metallic colours are attached only on the lines charged with oil: the piece is then heated under the muffle. The same cake of glue may serve for several impressions.

Ornaments and colouring.—Common stoneware is coloured by means of two kinds of apparatus; the one called the blowing-pot, the other the worming-pot. The ornaments made in relief in France, are made hollow (intaglio) in England, by means of a mould engraved in relief, which is passed over the article. The impression which it produces is filled with a thick clay paste, which the workman throws on with the blowing-pot. This is a vessel like a tea-pot, having a spout, but it is hermetically sealed at top with a clay plug, after being filled with the pasty liquor. The workman by blowing in at the spout, causes the liquor to fly out through a quill pipe which goes down through the clay plug into the liquor. The jet is made to play upon the piece while it is being turned upon the lathe; so that the hollows previously made in it by the mould or stamp are filled with a paste of a colour different from that of the body. When the piece has acquired sufficient firmness to bear working, the excess of the paste is removed by an instrument called a *tournas n*, till the ornamental figure produced by the stamp be laid bare; in which case merely the colour appears at the bottom of the impression. By passing in this manner several layers of clay liquor of different colours over each other with the blowing-pot, net-work and decorations of different colours and shades are very rapidly produced.

The serpentine or snake pots, established on the same principle, are made of tin plate in three compartments, each containing a different colour. These open at the top of the vessel in a common orifice, terminated by small quill tubes. On inclining the vessel, the three colours flow out at once in the same proportion at the one orifice, and are let fall upon the piece while it is being slowly turned upon the lathe, whereby curious serpent-like ornaments may be readily obtained. The clay liquor ought to be in keeping with the stoneware paste. The blues succeed best when the ornaments are made with the finer pottery mixtures given above.

White and yellow figures upon dark-coloured grounds are a good deal employed. To produce yellow impressions upon brown stoneware, ochre is ground up with a small quantity of antimony. The flux consists of flint glass and flints in equal weights. The composition for white designs is made by grinding silex up with that flux, and printing it on as for blue colours, upon brown or other coloured stoneware, which shows off the light hues.

Metallic lustres applied to stoneware.—The metallic lustre being applied only to the outer surface of vessels, can have no bad effect on health, whatever substances be employed for the purpose; and as the glaze intended to receive it is sufficiently fusible, from the quantity of lead it contains, there is no need of adding a flux to the metallic coating. The glaze is in this case composed of 60 parts of litharge, 36 of felspar, and 15 of flints.

The silver and platina lustres are usually laid upon a white ground, while those of gold and copper, on account of their transparency, succeed only upon a coloured ground. The dark-coloured stoneware is, however, preferable, as it shows off the colours to most advantage; and thus the shades may be varied by varying the colours of the ornamental figures applied by the blowing-pot.

The gold and platina lustre is almost always applied to a paste body made on purpose, and coated with the above-described lead glaze. This paste is brown, and consists of 4 parts of clay, 4 parts of flints, and equal quantity of kaolin (china clay), and 6 parts of felspar. To make brown figures in relief upon a body of white paste, a liquor is mixed up with this paste, which ought to weigh 26 ounces per pint, in order to unite well with the other paste, and not to exfoliate after it is baked.

Preparation of gold lustre.—Dissolve first in the cold, and then with heat, 48 grains of fine gold in 288 grains of aqua regia, composed of 1 ounce of nitric acid and 3 ounces of muriatic acid; add to that solution 4½ grains of grain tin, bit by bit; and then pour some of that compound solution into 20 grains of balsam of sulphur diluted with 10 grains of oil of turpentine. The balsam of sulphur is prepared by heating a pint of linseed oil, and 2 ounces of flowers of sulphur, stirring them continually till the mixture begins to boil; it is then cooled, by setting the vessel in cold water; after which it is stirred afresh, and strained through linen. The above ingredients, after being well mixed, are to be allowed to settle for a few minutes; then the remainder of the solution of gold is to be poured in, and the whole is to be triturated till the mass has assumed such a consistence that the pestle will stand upright in it; lastly, there must be added to the mixture 30 grains of oil of turpentine, which being ground in, the gold lustre is ready to be applied. If the lustre is too light or pale, more gold must be added, and if it have not a sufficiently violet or purple tint, more tin must be used.

Platina lustre.—Of this there are two kinds; one similar to polished steel, another lighter and of a silver-white hue. To give stoneware the steel colour with platina, this metal must be dissolved in aqua regia composed of 2 parts of muriatic acid, and 1 part of nitric. The solution being cooled, and poured into a capsule, there must be added to it, drop by drop, with continual stirring with a glass rod, a *spirit of tar*, composed of equal parts of tar and sulphur boiled in linseed oil and filtered. If the platina solution be too strong, more spirit of tar must be added to it; but if too weak, it must be concentrated by boiling. Thus being brought to the proper pitch, the mixture may be spread over the piece, which being put into the muffle, will take the aspect of steel.

The oxide of platina, by means of which the silver lustre is given to stoneware, is prepared as follows:—After having dissolved to saturation the metal in an aqua regia composed of equal parts of nitric and muriatic acid, the solution is to be poured into a quantity of boiling water. At the same time, a capsule, containing solution of sal-ammoniac, is placed upon a sand-bath, and the platina solution being poured into it, the metal will fall down in the form of the well-known yellow precipitate, which is to be washed with cold water till it is perfectly edulcorated, then dried, and put up for use.

This metallic lustre is applied very smoothly by means of a flat camel's hair brush. It is then to be passed through the muffle kiln; but it requires a second application of the platinum to have a sufficient body of lustre. The articles sometimes come black out of the kiln, but they get their proper appearance by being rubbed with cotton.

These lustres are applied with most advantage upon chocolate and other dark grounds. Much skill is required in their firing, and a perfect acquaintance with the quality of the glaze on which they are applied.

Dead silver on porcelain is much more easily affected by fuliginous vapours than burnished. It may, however, by the following process, be completely protected. The silver must be dissolved in very dilute acid, and slowly precipitated; and the metallic precipitate well washed. The silver is then laid (in wavy lines ?) upon the porcelain before being coloured (or if coloured, the colour must not be any preparation of gold) in a pasty state and left for 24 hours, at the expiration of which time the gold is to be laid on and the article placed in a moderate heat. The layer of gold must be very thin, and laid on with a brush over the silver before firing it; when, by the aid of a flux and a cherry-red heat, the two metals are fixed on the porcelain.

An iron lustre is obtained by dissolving a bit of steel or iron in muriatic acid, mixing the solution with the spirit of tar, and applying it to the surface of the ware.

Aventurine glaze.—Mix a certain quantity of silver leaf with the above-described soft glaze, grind the mixture along with some honey and boiling water, till the metal assume the appearance of fine particles of sand. The glaze being naturally of a yellowish hue, gives a golden tint to the small fragments of silver disseminated through it. Molybdena may also be applied to produce the aventurine aspect.

The granite-like gold lustre is produced by throwing lightly with a brush a few drops of oil of turpentine upon the goods already covered with the preparation for gold lustre. These cause it to separate and appear in particles resembling the surface of granite. When marbling is to be given to stoneware, the lustres of gold, platina, and iron are used at once, which blending in the fusion, form veins like those of marble.

Pottery and stoneware of the Wedgewood colour.—This is a kind of semi-vitrified ware, called *dry bodies*, which is not susceptible of receiving a superficial glaze. This pottery is composed in two ways; the first is with barytic earths, which act as fluxes upon the clays, and form enamels: thus the Wedgewood *jasper* ware is made.

The white vitrifying pastes, fit for receiving all sorts of metallic colours, are composed of 47 parts of sulphate of barytes, 15 of felspar, 26 of Devonshire clay, 6 of sulphate of lime, 15 of flints, and 10 of sulphate of strontites. This composition is capable of receiving the tints of the metallic oxides and of the ochreous metallic earths. Manganese produces the dark purple colour; gold precipitated by tin, a rose colour; antimony, orange; cobalt, different shades of blue; copper is employed for the browns and the dead-leaf greens; nickel gives, with potash, greenish colours.

One per cent. of oxide of cobalt is added; but one half, or even one quarter, of a per cent. would be sufficient to produce the fine Wedgewood blue, when the nickel and manganese constitute 3 per cent., as well as the carbonate of iron. For the blacks of this kind, some English manufacturers mix black oxide of manganese with the black oxide of iron, or with ochre. Nickel and umber afford a fine brown. Carbonate of iron, mixed with bole or *terra di Sienna*, gives a beautiful tint to the paste; as also manganese with cobalt, or cobalt with nickel. Antimony produces a very fine colour when combined with the carbonate of iron in the proportion of 2 per cent., along with the ingredients necessary to form the above-described vitrifying paste.

The following is another vitrifying paste, of a much softer nature than the preceding:— Felspar, 30 parts; sulphate of lime, 23; silex, 17; potter's clay, 15; kaolin of Cornwall (china clay), 15; sulphate of baryta, 10.

These vitrifying pastes are very plastic, and may be worked with as much facility as English pipe-clay. The round ware is usually turned upon the lathe. It may, however, be moulded, as the oval pieces always are. The more delicate ornaments are cast in hollow moulds of baked clay, by women and children, and applied with remarkable dexterity upon the turned and moulded articles. The coloured pastes have such an affinity for each other, that the detached ornaments may be applied not only with a little gum water upon the convex and concave forms, but they may be made to adhere without experiencing the least cracking or chinks. The coloured pastes receive only one fire, unless the inner surface is to be glazed; but a gloss is given to the outer surface. The enamel for the interior of the black Wedgewood ware, is composed of 6 parts of red lead, 1 of silex, and 2 ounces of manganese, when the mixture is made in pounds' weight.

The operation called *smearing*, consists in giving an external lustre to the unglazed semi-vitrified ware. The articles do not in this way receive any immersion, nor even the aid of the brush or pencil of the artist; but they require a second fire. The saggers are coated with the salt glaze already described. These cases, or saggers, communicate by reverberation the lustre so remarkable on the surface of the English stoneware; which one might suppose to be the result of the glaze tub, or of the brush. Occasionally also a very fusible composition is thrown upon the inner surface of the muffle, and 5 or 6 pieces called *refractories* are set in the middle of it, coated with the same composition. The intensity of the heat converts the flux into vapour; a part of this is condensed upon the surfaces of the contiguous articles, so as to give them the desired brilliancy.

Enamel colours for painting on porcelain are metallic oxides incorporated with a fusible flux. Gold precipitated by tin furnishes the crimson, rose, and purple; oxides of iron and chrome produce reds; the same oxides yield black and brown, also obtained from manganese and cobalt; orange is from oxides of uranium, chrome, antimony, and iron; greens from oxides of chrome and copper; blue from oxides of cobalt and zinc. The fluxes are borax, flint, oxides of lead, &c. They are worked in essential oils and turpentine, and a very great disadvantage under which the artist labours, is that the tints upon the palette are in most cases different to those they assume when they have undergone the necessary heat, which not only brings out the true colour, but also, by partially softening the glaze and the flux, causes the colour to become fixed to the ware. This disadvantage will be immediately apparent in the case where a peculiar delicacy of tint is required, as in flesh tones for instance. But the difficulty does not end here, for as a definite heat can alone give to a colour a perfect hue, and as the colour is continually varying with the different stages of graduated heat, another risk is incurred; that resulting from the liability of its receiving the heat in a greater or less degree than is actually required, termed "over-fired" and "short-fired." As an instance of its consequence, we cite rose colour or crimson, which when used by the painter is a dirty violet or drab; during the process of firing it gradually varies with the increase of heat from a brown to a dull reddish hue, and from that progressively to its proper tint. But if by want of judgment or inattention of the fireman the heat is allowed to exceed that point, the beauty and brilliancy of the colour are destroyed beyond remedy, and it becomes a dull purple. On the other hand, should the fire be too slack, the colour is presented in one of its intermediate stages, as already described, but in this case extra heat will restore it. Nor must we forget to allude to casualties of cracking and breaking in the kilns by the heat being increased or withdrawn too suddenly, a risk to which the larger articles are peculiarly liable. These vicissitudes render enamel painting in its higher branches a most unsatisfactory and disheartening study, and enhance the value of those productions which are really successful and meritorious.

In enamelling, ground-laying is the first process, in operating on all designs to which it is applied; it is extremely simple, requiring principally lightness and delicacy of hand. A coat of boiled oil adapted to the purpose being laid upon the ware with a pencil, and afterwards levelled, or as it is technically termed "bossed," until the surface is perfectly uniform; as the deposit of more oil on one part than another would cause a proportionate increase of colour to adhere, and consequently produce a variation of tint. This being done, the colour, which is in a state of fine powder, is dusted on the oiled surface with cotton wool; a sufficient quantity readily attaches itself, and the superfluity is cleared off by the same medium. If it be requisite to preserve a panel ornament or any object white upon the ground, an additional process is necessary, called "stencilling." The stencil (generally a mixture of rose-pink, sugar, and water) is laid on in the form desired with a pencil, so as entirely to protect the surface of the ware from the oil, and the process of "grounding," as previously described, ensues. It is then dried in an oven to harden the oil and colour, and immersed in water, which penetrates to the stencil, and, softening the sugar, is then easily washed off, carrying with it any portion of colour or oil that may be upon it, and leaving the ware perfectly clean. It is sometimes necessary, where great depth of colour is required, to repeat these colours several times. The "ground-layers" do generally, and should always, work with a bandage over the mouth to avoid inhaling the colour-dust, much of which is highly deleterious. Bossing is the term given to the process by which the level surfaces of various colours so extensively introduced upon decorated porcelain are effected. The "boss" is made of soft leather.

The process of gilding is as follows: — The gold (which is prepared with quicksilver and flux) when ready for use, appears a black dust; it is used with turpentine and oils similar to the enamel colours, and like them worked with the ordinary camels' hair pencil. It flows very freely, and is equally adapted for producing broad massive bands and grounds, or the finest details of the most elaborate design.

To obviate the difficulty and expense of drawing the pattern on every piece of a service, when it is at all intricate, a "pounce" is used, and the outline dusted through with charcoal, — a method which also secures uniformity of size and shape. Women are precluded from working at this branch of the business, though from its simplicity and lightness it would appear so well adapted for them. Firing restores the gold to its proper tint, which first assumes the character of "dead gold," its after brilliancy being the result of another process termed "burnishing."

Glazing.—A good enamel is an essential element of fine stoneware; it should experience the same dilatation and contraction by heat and cold as the biscuit which it covers. The English enamels contain nothing prejudicial to health, as many of the foreign glazes do; no more lead being added to the former than is absolutely necessary to convert the siliceous and aluminous matters with which it is mixed into a perfectly neutral glass.

Three kinds of glazes are used in Staffordshire; one for the common pipe-clay or cream-coloured ware; another for the finer pipe-clay ware to receive impressions, called *printing body;* a third for the ware which is to be ornamented by painting with the pencil.

The glaze of the first or common ware is composed of 53 parts of white lead, 16 of Cornish stone, 36 of ground flints, and 4 of flint glass; or of 40 of white lead, 36 of Cornish stone, 12 of flints, and 4 of flint or crystal glass. These compositions are not fritted; but are employed after being simply triturated with water into a thin paste.

The following is the composition of the glaze intended to cover all kinds of figures printed in metallic colours; 26 parts of white felspar are fritted with 6 parts of soda, 2 of nitre, and 1 of borax; to 20 pounds of this frit, 26 parts of felspar, 20 of white lead, 6 of ground flints, 4 of chalk, 1 of oxide of tin, and a small quantity of oxide of cobalt, to take off the brown cast, and give a faint azure tint, are added.

The following recipe may also be used. Frit together 20 parts of flint glass, 6 of flints, 2 of nitre, and 1 of borax; add to 12 parts of that frit, 40 parts of white lead, 36 of felspar, 8 of flints, and 6 of flint glass; then grind the whole together into an uniform cream-consistenced paste.

As to the stoneware which is to be painted, it is covered with a glaze composed of 13 parts of the printing-colour frit, to which are added 50 parts of red lead, 40 of white lead, and 12 of flint; the whole having been ground together.

The above compositions produce a very hard glaze, which cannot be scratched by the knife, is not acted upon by vegetable acids, and does no injury to potable or edible articles kept in the vessels covered with it. It preserves for an indefinite time the glassy lustre, and is not subject to crack and exfoliate, like most of the Continental stoneware made from common pipe-clay.

In order that the saggers in which the articles are baked, after receiving the glaze, may not absorb some of the vitrifying matter, they are themselves coated, as above mentioned, with a glaze composed of 13 parts of common salt, and 30 parts of potash, simply dissolved in water, and brushed over them.

Glaze kiln.—This is usually smaller than the biscuit kiln, and contains no more than 40 or 45 bungs or columns, each composed of 16 or 17 saggers. Those of the first bung rest upon round tiles, and are well luted together with a finely ground fire-clay of only moderate cohesion; those of the second bung are supported by an additional tile. The lower saggers contain the cream-coloured articles, in which the glaze is softer than that which covers the blue printed ware; this being always placed in the intervals between the furnaces, and in the uppermost saggers of the columns. The bottom of the kiln, where the glazed ware is not baked, is occupied by printed biscuit ware.

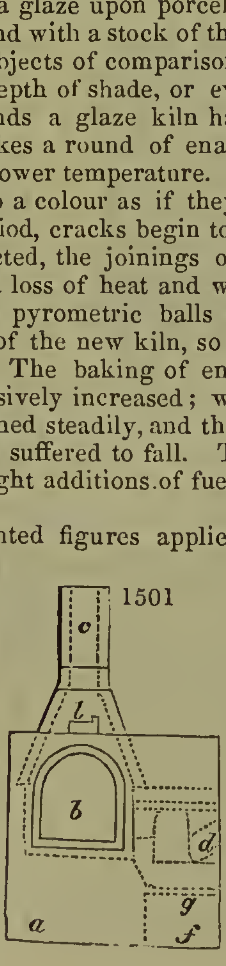
Pyrometric balls of red clay, coated with a very fusible lead enamel, are employed in the English potteries to ascertain the temperature of the glaze kilns. This enamel is so rich, and the clay upon which it is spread is so fine-grained and compact, that even when exposed for three hours to the briskest flame, it does not lose its lustre. The colour of the clay alone changes, whereby the workman is enabled to judge of the degree of heat within the kiln. At first the balls have a pale red appearance; but they become browner with the increase of the temperature. The balls, when of a slightly dark-red colour, indicate the degree of baking for the hard glaze of pipe-clay ware; but if they become dark brown, the glaze will be much too hard, being that suited for *ironstone* ware; lastly, when they acquire an almost black hue, they show a degree of heat suited to the formation of a glaze upon porcelain.

The *glazer* provides himself at each round with a stock of these ball *watches*, reserved from the preceding baking, to serve as objects of comparison; and he never slackens the firing till he has obtained the same depth of shade, or even somewhat more; for it may be remarked, that the more rounds a glaze kiln has made, the browner the balls are apt to become. A new kiln bakes a round of enamel-ware sooner than an old one; as also with less fuel, and at a lower temperature. The watch-balls of these first rounds have generally not so deep a colour as if they were tried in a furnace three or four months old. After this period, cracks begin to appear in the furnaces; the horizontal flues get partially obstructed, the joinings of the brickwork become loose; in consequence of which there is a loss of heat and waste of fuel; the baking of the glaze takes a longer time, and the pyrometric balls assume a different shade from what they had on being taken out of the new kiln, so that the first watches are of no comparable use after two months. The baking of enamel is commenced at a low temperature, and the heat is progressively increased; when it reaches the melting point of the glaze, it must be maintained steadily, and the furnace mouths be carefully looked after, lest the heat should be suffered to fall. The firing is continued 14 hours, and then gradually lowered by slight additions of fuel; after which the kiln is allowed from 5 to 6 hours to cool.

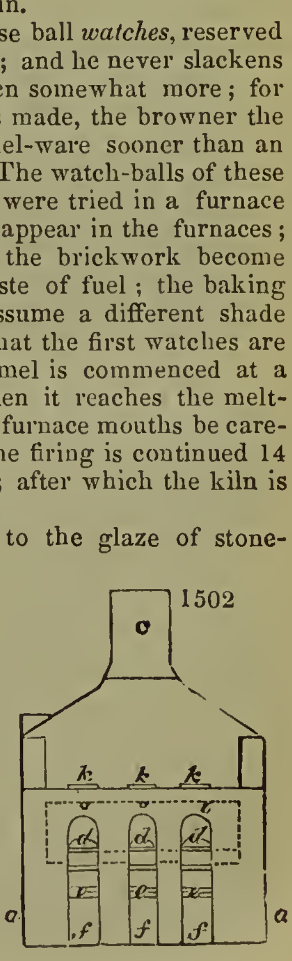
Muffles.—The paintings and the printed figures applied to the glaze of stoneware and porcelain are baked in muffles of a peculiar form. *Fig.* 1501 is a lateral elevation of one of these muffles; *fig.* 1502 is a front view. The same letters denote the same parts in the two figures.

a is the furnace; *b*, the oblong muffle, made of fire-clay, surmounted with a dome pierced with three apertures, *k*, *k*, *k*, for the escape of the vaporous matters of the colours and volatile oils with which they are ground up; *c* is the chimney; *d*, *d*, feed-holes, by which the fuel is introduced; *e*, the fire-grate; *f*, the ash-pit; channels are left in the bottom of the

1501



1502

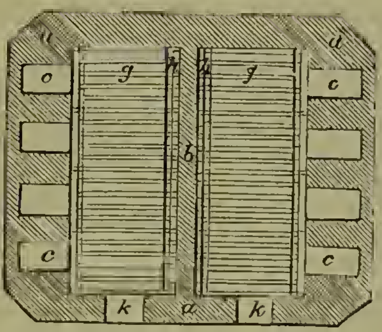


furnace to facilitate the passage of the flame beneath the muffle; *g* is a lateral hole which makes a communication across the furnace in the muffle, enabling the kiln man to ascertain what is passing within; *k*, *k*, are the lateral chinks for observing the progress of the firing or flame; *l* is an opening scooped out in the front of the chimney to modify its draught.

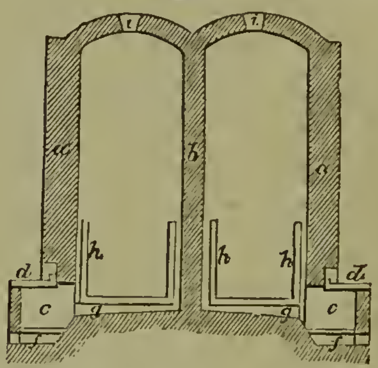
The articles which are printed or painted upon the glaze are placed in the muffle without saggers, upon tripods, or movable supports furnished with feet. The muffle being charged, its mouth is closed with a fire-tile well luted round its edges. The fuel is then kindled in the fire-places *d*, *d*, and the door of the furnace is closed with bricks, in which a small opening is left for taking out samples, and for examining the interior of the muffle. These sample or trial pieces, attached to a strong iron wire, show the progress of the baking operation. The front of the fireplaces is covered with a sheet-iron plate, which slides to one side, and may be shut whenever the kiln is charged. Soon after the fire is lighted, the flame, which communicates laterally from one furnace to another, envelopes the muffle on all sides, and thence rises up the chimney.

A patent was obtained by Mr. W. Ridgway for the following construction of oven, in which the flames from the fire-places are conveyed by parallel flues, both horizontal and vertical, so as to reverberate the whole of the flame and heat upon the goods after its ascension from the flues. His oven is built square instead of round, a fire-proof partition wall being built across the middle of it, dividing it into two chambers, which are covered in by two parallel arches. The fire-places are built in the two sides of the oven opposite to the partition wall: from which fire-places narrow flues rise in the inner face of the wall, and distribute the flame in a sheet equally over the whole of its surface. The other portion of the heat is conveyed by many parallel or diverging horizontal flues, under and across the floor or hearth of the oven, to the middle or partition wall; over the surface of which the flame which ascends from the numerous flues in immediate contact with the wall is equally distributed. This sheet of ascending flame strikes the shoulder of the arch, and is reverberated from the saggers beneath, till it meets the flame reverberated from the opposite side of the arch, and both escape at the top of the oven. The same construction is also applied to the opposite chamber. In *figs.* 1503 and 1504, *a* represents the square walls or body of the oven; *b*, the partition wall; *c*, the fire-places or

1503



1504



furnaces with their iron boilers; *d*, the mouths of the furnaces for introducing the fuel; *f*, the ash-pits; *g*, the horizontal flues under the hearth of the oven; *h*, the vertical flues; *i*, the vents in the top of the arches; and *k*, the entrances to the chambers of the ovens.

Before this article is concluded it is necessary that we should notice the attempts which have been made, with various degrees of success, to employ porcelain as a means for multiplying the productions of high art in a cheap form. Under the various terms of Statuary Porcelain, Parian, Carrara, &c., are produced numerous works of art, many of which are distinguished by their beauty. As the most direct method of illustrating the process of making these figures, let us suppose the object under view to be a figure or group, and this we will assume to be 2 feet high in the model. The clay, which is of the most perfect character, is mixed with flint, as in the case of manufacturing the finest stoneware china, and it is used in a semi-liquid state about the consistency of cream: this is poured into the moulds forming the various parts of the subject (sometimes as many as fifty): the shrinking that occurs before these casts can be taken out of the mould, which is caused by the absorbent nature of the plaster of which the mould is composed, is equal to a reduction of one inch and a half in the height. The moulds are made of plaster of Paris, which, when properly prepared, has the property of absorbing water so effectually that the moisture is extracted from the clay, and the ware is enabled to leave the mould, or "deliver" with care and rapidity. Prior to use the plaster (gypsum) is put into long troughs, having a fire running underneath them, by which means the water is drawn off, and it remains in a state of soft powder; and if its own proportion of water be again added to it, it will immediately set into a firm compact body, which is the case when it is mixed to form the mould. These casts are then put together by the "figure-maker," the seams (consequent upon the marks caused by the subdivisions of the moulds) are then carefully removed, and the whole worked upon to restore the cast to the same degree of finish as the original model. The work is then thoroughly dried to be in a fit state for firing, as if put in the oven while damp the sudden contraction consequent upon the great degree of heat instantaneously applied, would be very liable to cause it to crack; in the process it again suffers a further loss of one inch and a half by evaporation, and it is now but 1 foot 9 inches. Again in the "firing" of the bisque oven, its most severe ordeal, it is diminished 3 inches, and is then but 18 inches high, being 6 inches or one-fourth less than the original. Now as the contraction should equally affect every portion of the details of the work, in order to realise a faithful copy, and as added to this contingency are the risks in the oven of being "over-fired" by which it would be melted into a mass, and of being "short-fired," by which its surface would be imperfect, it is readily evident that a series of difficulties present themselves which require considerable practical experience successfully to meet. Indeed the difficulties which surround the manufacture of Parian, prevent its being rendered to the public at such a price as those would desire who wish to secure the introduction, amongst the people, of all examples which are calculated to refine their tastes. A biscuit china is, by a somewhat similar process, employed in several of the porcelain manufactories on the continent for the production of statuettes, busts, &c., but in colour and character they are all inferior to the English Parian. See Bricks; Clay; Porcelain Clay; Tiles; Stone, Artificial, &c.

The value of *exports* of British manufacture, in 1857 was £1,492,236, and in 1858 £1,153,579.

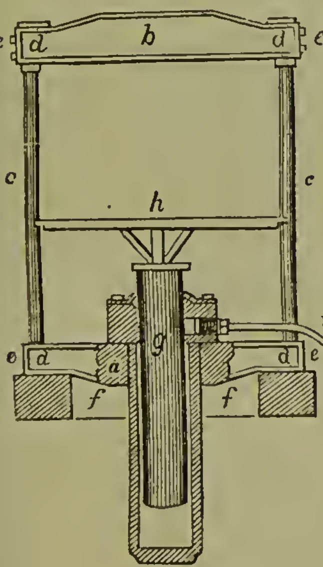
PRECIPITATE is any matter separated in minute particles from a fluid holding matter in solution, which subsides to the bottom of the vessel in a pulverulent form.

PRECIPITATION is the actual subsidence of a precipitate.

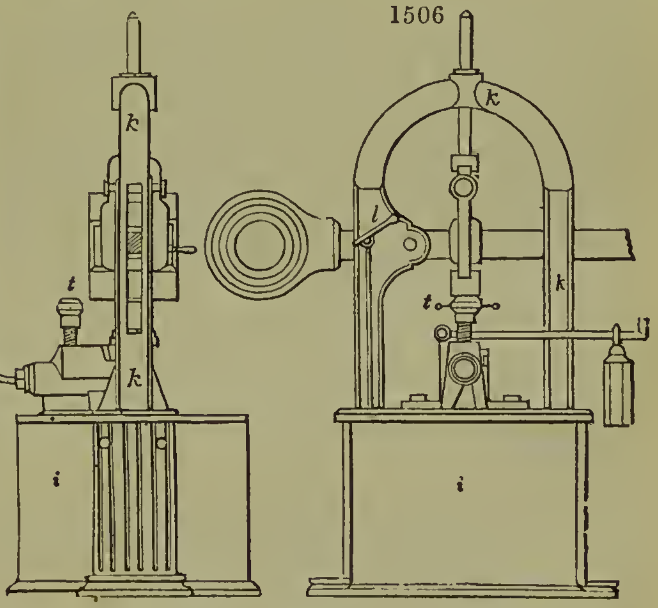
PRESERVED MEATS. See Meats, Preserved.

PRESS, HYDRAULIC. Though the explanation of the principles of this powerful machine belongs to a work upon mechanical engineering, rather than to one upon

1505



1506

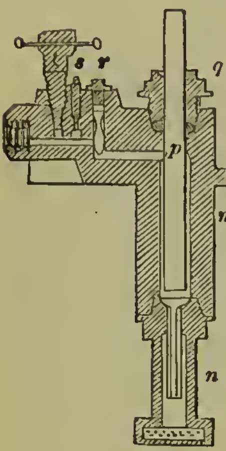


manufactures, yet as it is often referred to in this volume, a brief description of it cannot be unacceptable to many of our readers.

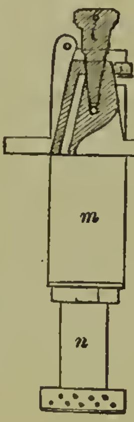
The framing consists of two stout cast-iron plates, *a*, *b*, which are strengthened by projecting ribs, not seen in the section, *fig.* 1505. The top or crown plate *b*, and the base-plate *a*, *a*, are bound most firmly together by 4 cylinders of the best wrought iron, *c*, *c*, which pass up through holes near the ends of the said plates, and are fast wedged in them. The flat pieces *e*, *e*, are screwed to the ends of the crown and base-plates, so as to bind the columns laterally. *f*, is the hollow cylinder of the press, which, as well as the ram *g*, is made of cast-iron. The upper part of the cavity of the cylinder is cast narrow, but is truly and smoothly rounded at the boring-mill, so as to fit pretty closely round a well-turned ram or piston; the under part of it is left somewhat wider in the casting. A stout cup of leather, perforated in the middle, is put upon the ram, and serves as a valve to render the neck of the cylinder perfectly water-tight by filling up the space between it and the ram; and since the mouth of the cup is turned downwards, the greater the pressure of water upwards, the more forcibly are the edges of the leather valve pressed against the insides of the cylinder, aud the tighter does the joint become. This was Bramah's beautiful invention.

Upon the top of the ram, the press-plate, or table, strengthened with projecting ridges, rests, which is commonly called the follower, because it follows the ram closely in its descent. This plate has a half-round hole at each of its four corners, corresponding to the shape of the four iron columns along which it glides in its up-and-down motions of compression and relaxation.

1507



1508



h, *h*, *figs.* 1505 and 1506, is the framing of a force pump with a narrow barrel; *i* is the well for containing water to supply the pump. To spare room in the engraving, the pump is set close to the press, but it may be removed to any convenient distance by lengthening the water-pipe *u*, which connects the discharge of the force pump with the inside of the cylinder of the press. *Fig.* 1507 is a section of the pump and its valves. The pump *m*, is of bronze; the suction pipe *n*, has a conical valve with a long tail; the solid piston or plunger *p*, is smaller than the barrel in which it plays, and passes at its top through a stuffing-box *q*; *r* is the pressure-valve, *s* is the safety-valve, which, in *fig.* 1506, is seen to be loaded with a weighted lever; *t* is the discharge-valve, for letting the water escape from the cylinder beneath the ram, back into the well. See the winding passages in *fig.* 1508, *u* is the tube which conveys the water from the pump into the press-cylinder. In *fig.* 1506, two centres of motion for the pump-lever are shown. By shifting the bolt into the centre nearest the pump-rod, the mechanical advantage of the workman may be doubled. Two pumps are generally mounted in one frame for one hydraulic press: the larger to give a rapid motion to the ram at the beginning, when the resistance is small; the smaller to give a slower but more powerful impulsion, when the resistance is much increased. A pressure of 500 tons may be obtained from a well-made hydraulic press with a ten-inch ram, and a two and a one inch set of pumps. See Water Pressure Machine.

PRINCE'S METAL, or Prince Rupert's metal, is a modification of brass.

PRINTING. (*Imprimerie*, *typographie*, Fr.; *Buchdrückerkunst*, Germ.) The art of taking impressions from types and engravings in relief.

History.—The art itself is of comparatively modern origin, only 400 years having elapsed since the first book, properly so called, issued from the press; but we cannot doubt that its essence was known to the ancients. It has certainly been practised in the East from a very early period, and in a manner similar to our own first attempts. That a rude kiud of printing was known to the Babylonians is evident from the undecayed bricks of that city which have been found stamped with various symbolical and hieroglyphic characters; but, as the stamp itself was in one piece or block, it was inapplicable to the propagation of knowledge, from its cost and tediousness of production.

The Chinese are the only people who have continued this primitive mode of printing to the present time. Their earliest attempts are stated in the chronicles to have been made about 50 years before the Christian era; but it was not till the reign of the Emperor Ming-tsong (927—934 A.D.) that any great advance was made in printing large numbers of comparatively cheap books. The name of the Chinese Caxton was Tong-tao. He obtained permission of the emperor in 932 to print and circulate copies of the "Classical Works," as they are called, by taking impressions from stone plates, the letters cut into them, so that the impression ou the paper was black, and the letters themselves left white. This is still the case in all Chinese lithographic printing. Tong-tao, however, subsequently obtained the emperor's sanction to cut in wood and print an edition of the nine "King," or classical books, for the use of the Imperial College in Pekin. This was completed in 952; and, although intended only for the pupils of the college, it was made purchasable by any person in the empire. The process pursued in the printing of this work is precisely the same as at the present day; the following being the *modus operandi*:—The work intended to be printed is handed to a caligraphist, who writes the separate pages on fine tracing paper; these are given to the engraver, who glues them face downwards upon a thin plate of hard wood, called *li*, resembling that of the pear tree, and he cuts away with a sharp instrument all those parts of the wood on which nothing is traced, leaving the transcribed characters in relief and ready for printing. The Chinese printer then, having no notion of the printing-press, makes use of two fine brushes, both held in the right hand, one of which contains ink, the other dry. With the former he blackens the letters; the latter he passes gently over the paper which has been laid on them. By this means an expert workman can take a large number of impressions in one day. As the Chinese paper is thin and transparent, it is printed on one side only, two pages side by side, and the sheet has a black line down the middle, as a guide to the binder, who folds it double, and fastens the open leaves together. Various attempts have been made in the Celestial Empire to substitute movable types for the wooden blocks, but they have always terminated in a return to the old method.

The ancient Romans made use of metal stamps, with characters engraved in relief, to mark their articles of trade and commerce; and Cicero, in his "De Naturâ Deorum," has a passage from which Toland imagines the moderns have taken the hint of printing. Cicero orders the types to be made of metal, and calls them *formæ literarum*, the very words used by the first printers to express them. In Virgil's time, too, brands, with letters, were used for marking cattle, &c., with the owner's name. Landseer (*Lectures on the Art of Engraving*, 8vo. 1807) observes, "Had the modern art of making paper been known to the ancients, we had probably never heard the names of Faust and Finiguerra; for with the same kind of stamps which the Romans used for their pottery and packages, books might also have been printed; and the same engraving which adorned the shields and pateras of the more remote ages, with the addition of paper, might have spread the rays of Greek and Etrurian intelligence over the world of antiquity. Of the truth of this assertion I have the satisfaction to lay before you the most decided proofs, by exhibiting engraved Latin inscriptions, both in cameo and intaglio, from the collection of Mr. Douce, with impressions taken from them at Mr. Savage's letter-press but yesterday [1805]. One of them is an intaglio stamp, with which a Roman oculist was used to mark his medicines; the other, which is of metal, and in cameo, is simply the proper name of the tradesman by whom it has probably been used, 'T[itus] Valagini Mauri.'" The following impression (*fig.* 1509) is a facsimile of the latter stamp:—

1509

Books before the invention of printing.—The value of books and the esteem in which they were held before the invention of printing, were such, that notaries were employed to make the conveyance with as much care and attention as if estates were to be transferred. It was then thought the worthy occupation of a life either to copy or collect an amount of reading which modern improvements now present to us for a few shillings. Galen tells us that Ptolemy Philadelphus gave the Athenians 15 talents, with exemption from all tribute, and a great convoy of provisions, for the autographs and originals of the tragedies of Æschylus, Sophocles, and Euripides. "Pisistratus is said to have been the first among the earliest of the Greeks who projected an immense collection of the works of the learned, and is supposed to have been the collector of the scattered works which passed under the name of Homer." (*D'Israeli, Cur. of Lit.*)

Among the Romans the bulk or goodness of a man's library was the distinguishing mark of his excellence and wisdom. Middleton (*Life of Cicero*), speaking of Cicero himself, says, "Nor was he less eager in making a collection of Greek books, and forming a library, by the same opportunity of Atticus's help. This was Atticus's own passion; who, having free access to all the Athenian libraries, was employing his slaves in copying the works of their best writers, not only for his own use, but for sale also, and the common profit both of the slave and the master.

The passion for the enjoyment of books has in all ages led their lovers to cover them with the most costly and ornamental bindings. The ancients commonly adorned them with pendent ornaments of variously coloured cloth, and the covers were stained with scarlet or purple colour: "Hirsutus sparsis ut videare comis" (*Ovid*), and "Purpureo fulgens habitu, radiantibus uncis" (*Martial*). The *unci* were rollers of wood or ivory, round which the books were rolled to prevent injury to their fronts. Ovid and Tibullus call them *cornua*, from the similarity of their ends to horns. Epistles differed from books in this: the leaves were folded together, tied round with linen tape, and sealed with *creta Asiatica*, while books were "bound" as above. If, however, there were more epistles than one, "or if one epistle was to be preserved in the library, it was enclosed and turned round, and not folded: hence the word *volumen*" (*Arts of the Greeks and Romans*). "Video quod agas: tuas quoque epistolas vis referam in volumina." (*Cicero.*)

The orders respecting books in the "Close Rolls" of the Middle Ages are interesting, not only as illustrating the literary taste of the age, but principally because they generally contain some circumstance which shows the scarcity and value of the article. It was not until a period considerably subsequent to the invention of printing that the cost and rarity of books ceased to obstruct the advancement of learning and the diffusion of knowledge.

Incredible difficulties were encountered by those who undertook first to lay open the stores of ancient learning, from the scarcity of MSS.; for the literary treasures of antiquity had suffered from the malice of men as well as from the hand of time.

Block Books.—The time had now come, however, when the world's inheritance of the knowledge of Greece and Rome was to be secured from any further destruction. The art of printing books from engraved blocks of wood was no doubt invented in Holland; and, apart from the great interest created by the object for which the block books were designed, namely, the propagation of the Scriptures (being, as it were, the forerunner of the Reformation), they are extremely valuable as exhibiting the first attempts at engraving on wood in the form of books, many of them having preceded the art of printing by movable types. (*Sotheby's Block Books.*)

But that prints without text, or letterpress as it is termed, were in common use at a period considerably anterior to that of the block books, there is abundant evidence. It is related by Papillon (*Traité Historique et Pratique de la Gravure en Bois*) that the heroic actions of Alexander the Great were engraved on wood by the two Cunio, Alexander Alberic, and his sister Isabella, and impressions printed from the blocks as early as 1285; and his statement has been supported by Ottley (*Early Hist. of Engraving upon Copper and Wood, &c.*, 2 vols. 4to. 1816) and Singer (*Hist. of Playing Cards, &c.*, London, 4to. 1816). But Jackson (*Hist. of Wood Engraving*) takes some trouble to prove that Papillon was excessively credulous, if not deranged. Towards the end of the 14th century, too, playing cards were engraved and printed for the amusement of Charles VI. King of France, who reigned from 1380 to 1421. The print of St. Christopher carrying the infant Saviour on his back across the sea, in the collection of Earl Spencer, bears an inscription and the date 1423 at the bottom of the same block; but one in the possession of Mr. J. A. G. Weigel of Leipsic is supposed to be the work of even an earlier artist.* These circumstances, together with the fact that the government of Venice published a decree, dated October 11, 1441, wherein the art and mystery of making "playing cards and coloured figures printed" are stated to have fallen into decay in consequence of the great quantity which had been made out of that state, and which were now prohibited under pain of forfeiture and fine †, all prove that the knowledge and practice of printing, although not applied to the spread of knowledge and the multiplication of books, had yet an existence in Europe long before the time to which it is usually attributed.

When the substructure had been completed, the work was pursued with the utmost eagerness. Great numbers of books were produced, evidently in the Chinese manner above described; for the diversity of the characters found in block books has been a never-ending puzzle to those who have endeavoured to ascertain the printer by comparison of the formation of the letters used. The workmanship of many of these picture books was of a coarse description, without shadowing or "cross-hatching," tastelessly daubed over with broad colours, especially those printed for circulation amongst the poorer classes. Those best known of this class were called *Biblia Pauperum*, poor men's books, or rather books for poor preachers, and consisted of a series of rude engravings, each occupying a page, but divided into compartments containing pictorial illustrations of the most remarkable incidents mentioned in the books of Moses, the Gospels, and the Apocalypse.

Invention of movable types.—Gutenberg.—About the year 1438, while the learned Italians were eagerly deciphering their recently-discovered MSS., and slowly circulating them from hand to hand, it fell to the lot of a few obscure Germans to perfect the greatest discovery recorded in the annals of mankind. The notion of printing by movable types, and thereby saving the endless labour of cutting new blocks of letters for every page, was reserved for John Gutenberg of Mayence. Born in that city about the beginning of the century, he settled at Strasburg about 1424, and commenced printing in the house of one Dritzehen. But having been

* A copy of Mr. Weigel's print may be seen in Sotheby's "Block Books," vol. ii. p, 161.
† This must be regarded as the earliest authentic document respecting printing.

engaged in a lawsuit connected with Dritzehen's family, and exhausted his means, he returned to Mentz, where he resumed his typographic employment in partnership with a wealthy goldsmith, named John Fust or Faust. After many experiments with his presses and movable types, Gutenberg succeeded in printing an edition of the Vulgate, the Mentz or Mazarin Bible, so called from a copy having been discovered in the library of Cardinal Mazarin in Paris. The work was done between the years 1450 and 1455, and was printed on vellum; but there are several paper copies in England, France, and Germany. The partnership between Gutenberg and Fust having been dissolved, and the former being unable to repay part of the capital advanced by the wealthy goldsmith, the whole of the printing apparatus fell into the hands of Fust, who "printed off a considerable number of copies of the Bible, to imitate those which were commonly sold as MSS.; and he undertook the sale of them at Paris. It was his interest to conceal this discovery, and to pass off his printed copies for MSS. But, enabled to sell his bibles at sixty crowns, while the other scribes demanded five hundred, this raised universal astonishment; and still more when he produced copies as fast as they were wanted, and even lowered his price. The uniformity of the copies increased the wonder. Informations were given in to the magistrates against him as a magician; and in searching his lodgings a great number of copies were found. The red ink, — and Fust's red ink is peculiarly brilliant, — which embellished his copies, was said to be his blood; and it was solemnly adjudged that he was in league with the infernals. Fust at length was obliged, to save himself from a bonfire, to reveal his art to the Parliament of Paris, who discharged him from all prosecution in consideration of the wonderful invention. (*D'Israeli, Cur. of Lit.*)

This Bible was printed with large *cut* metal types; but in 1457 a magnificent edition of the "Psalter" appeared, printed by Fust and his assistant and son-in-law, Peter Schœffer, who had been taken into partnership. In this book the new invention was announced to the world in "a boasting colophon, though certainly not unreasonably bold. Another edition of the 'Psalter,' one of an ecclesiastical book, Durand's account of liturgical offices *, one of the Constitutions of Pope Clement V., and one of a popular treatise on general science, called the Catholicon †, filled up the interval till 1462, when the second Mentz Bible proceeded from the same printers. This, in the opinion of some, is the earliest book in which *cast* metal types were employed; those of the Mazarin Bible having been cut with the hand. But this is a controverted point. In 1465 Fust and Schœffer published an edition of Cicero's 'Offices,' the first tribute of the new art to polite literature." (*Hallam, Europe during the Middle Ages*, vol. iii. p. 470.)

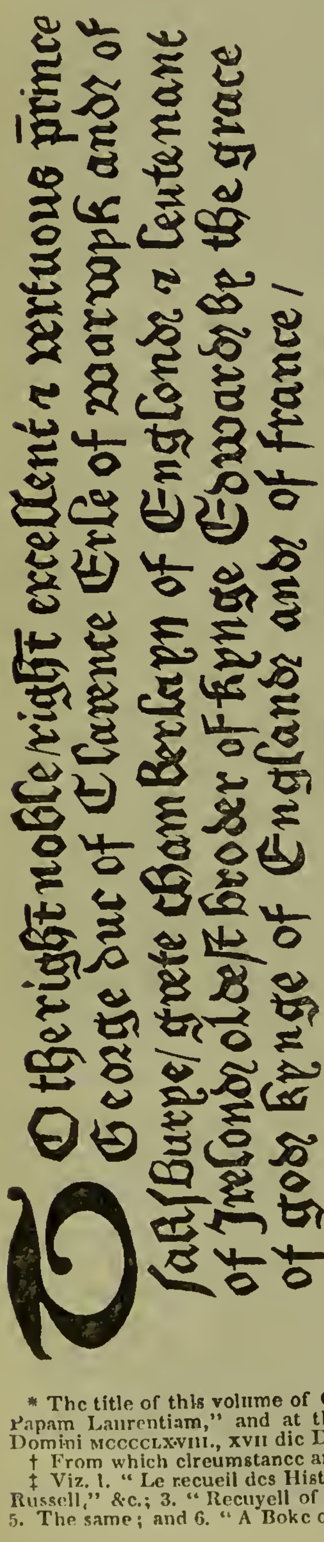
After the lapse of a few years the pupils and workmen of Fust and Schœffer, dispersed into various countries by the sacking of Mentz, under the Archbishop Adolphus, the invention was thereby publicly made known, and the art spread over all parts of Europe. Before the year 1500, printing presses had been set up in 220 places, and a multitude of editions of the classical writers given to the world. Santander ("*Dictionnaire Bibliographique choisi du quinzième Siècle*," &c., Bruxelles 1805, 3 vols.), in his interesting and masterly work, gives at the end of his first volume a chronological table of 200 places where the art was practised during the 15th century, with the names of the printers and of the first productions of their presses. We cannot afford room for this list; but must be content to state that from Mentz the art was transplanted to Haarlem and Strasburg; from Haarlem to Rome, in 1466, by Sweynheym and Pannartz, who were the first to make use of Roman types; to Paris in 1469; to England in 1474; and to Spain in 1475; and spread so rapidly that, between the years 1469 and 1475, most towns in Germany, Italy, and the Netherlands had made successful attempts in the production of printed copies of the most valued authors of the time.

Printing in England. — Until about the period of the Restoration, William Caxton was universally acknowledged to have introduced the art of printing into this country, in or about the year 1471. But, in 1664, a Mr. Richard Atkyns, in a work called "The Original and Growth of Printing," &c., brought before the notice of the curious a little book, printed at Oxford, bearing the date 1468, three years before the period usually assigned to the labours of Caxton. This work took literary men by surprise, and gave rise to the most violent discussions. It is related by Atkyns that a Dutchman of the name of Frederic Corsellis was induced to desert his employers in the Low Countries, and that one Richard Turnour, an agent of King Henry VI., assisted by William Caxton, who was well known in Holland as a merchant, and therefore likely to throw the jealous possessors of the new art off their guard, brought him to England, where at Oxford he was set to work by Archbishop

* "Rationale Divinorum Officiorum" of William Durand, 1459.
† "Catholicon Januensis," 1460, in the King's Library.

Bourchier, ten years before the date of Caxton's first book.* But the silence of Caxton on a subject in which he took the utmost interest, and in which it is stated on this occasion he was an important actor, is a strong argument against the authenticity of the story. Indeed, M. Santander (vol. i. p. 328) does not for a moment entertain the pretensions of Corsellis, and agrees with Dr. Conyers Middleton in considering that the date MCCCCLXVIII. ought to have been MCCCCLXXVIII., an X having been by accident omitted by the compositor:—"Voilà ce que Richard Atkyns imagina, et les moyens dont il se servit, en 1664, pour soutenir contre le corps des libraires de Londres, que l'imprimerie était un droit de la couronne en Angleterre. Mais le docteur Middleton, dans sa 'Dissertation sur l'Origine de l'imprimerie en Angleterre,' imprimée à Cambridge, en 1735, in 4°, a prouvé démonstrativement, que l'impression d'Oxford, de 'l'Expositio S. Jeronimi in simbolum Apostolorum,' est de l'an 1478, le compositeur ayant omis un X dans la date de la souscription (faute typographique dont nous avons plusieurs exemples dans les impressions du XV^e siècle)." Amongst other examples of blunders of this description, the learned doctor observes:—"But whilst I am now writing, an unexpected instance is fallen into my hands, to the support of my opinion; an 'Inauguration Speech of the Woodwardian Professor, Mr. Mason,' just fresh from the press, with its date given ten years earlier than it should have been, by the omission of an X, viz. MDCCXXIV.; and the very blunder exemplified in the last piece printed at Cambridge, which I suppose to have happened in the first from Oxford."

1510



Whether, however, Caxton was or was not the first English printer, it is quite certain that he was the first who made use of cast metal types, the works of Corsellis having been executed with merely wooden ones. During a long residence abroad, he had acquired a practical knowledge of the art; and on his return to England in 1471, set up a press at Westminster Abbey, in an old chapel† adjoining that edifice; and was for many years engaged in translating and printing books on a variety of subjects. His first work is, "Le Recueil des Histoires de Troyes" of Raoul le Fevre, chaplain to the Duchess of Burgundy; but "The Dictes and Sayinges of the Philosophers" is the earliest book known to have issued from his press with the date and place of printing; and we have no proof at all that his six earlier works‡ were printed in this country. Indeed, it is stated in the Life of Caxton, in Ames's "Typ. Antiquities," p. xcv., that the French and English editions of the "Histories of Troy" are justly "admitted to have been printed abroad."

The types used in Caxton's works, as well as in those of most of the early printers, were the Gothic or *black-letter* characters, said to have been invented by Ulphilas, first bishop of the Mœso-Goths. A facsimile of Caxton's types is here annexed, *fig.* 1510, showing the formation of his letters; and proving to our mind that, as compared with the specimens we have seen of the characters used by the Oxford printer Corsellis, they have an undoubted claim to the greater antiquity.

Caxton is said to have printed 64 books; and was followed by his pupils or assistants, Theodore Rood, John Lettou, William Machilinia, and Wynkyn de Worde, all foreigners, and Thomas Hunt, an Englishman. All these pioneers of the art worthily maintained the honour of their master's name; and Wynkyn de Worde is especially remarkable for his improvements and typographical excellence, and as having been the first printer in England who introduced the Roman letter. He printed 410 works.

* The title of this volume of Corsellis is, "Exposicio Sancti Jeronimi in Simbolum Apostolorum ad Papam Laurentiam," and at the end, "Explicit Exposicio, &c. Impressa Oxonie, et finita Anno Domini MCCCCLXVIII., XVII die Decembris."

† From which circumstance an assemblage of printers is to this day called a "chapel."

‡ Viz. 1. "Le recueil des Histoires de Troyes;" 2. "Propositio Clarissimi oratoris Magistri Johannis Russell," &c.; 3. "Recuyell of the Histories of Troye;" 4. "The Game and Playe of the Chesse;" 5. The same; and 6. "A Boke of the hoole Lyf of Jason."

The spirit and taste of the patrons of the first printers are shown in the character of their earliest works, religious books and romances constituting the greater part of the productions of the father of English printing. But the art, although at first countenanced by the clergy, was soon looked upon with extreme jealousy by the church. Efforts were made towards the publication of the Word of God; but for the first 60 or 70 years all copies of the Scriptures were printed in the Latin or some other language, not understood by the generality of the people. A new era had, however, arrived. The doctrines of the Reformation had proclaimed the Bible as man's best guide and teacher, and the people yearned to possess Bibles. Wickliffe's translation was never printed. The part of the Sacred Writings in the English language first produced by the printing press, was the New Testament, translated by William Tindal, assisted by Miles Coverdale, afterwards Bishop of Exeter: it was printed at Antwerp, in 1526; but as it gave offence to Wolsey and the church, the whole impression was bought up and burnt. The first complete English Bible printed by authority, was Tindal's version, revised and compared with the original by Coverdale, and afterwards examined by Cranmer, who wrote a preface for it. Of this edition, hence called " Cranmer's Bible," 500 copies were printed by Grafton and Whitchurch, to whom Henry VIII., in letters patent dated November 13, 1539, granted the sole right of printing the Bible for five years. It was ordered by royal proclamation to be set up in all churches throughout the kingdom, under a penalty of 40*s.* a month in every case of neglect. So great was the demand for copies of the Scriptures in the 16th century, that we have in existence 326 editions of the English Bible, or parts of the Bible, printed between 1526 and 1600.

The progress of the art in the first century of its existence was remarkable ; but the earliest English printers did not attempt what the Continental ones were doing for the ancient classics. " Down to 1540, no Greek book had appeared from an English press; Oxford had only printed a part of Cicero's epistles; Cambridge, no ancient writer whatever. Only three or four old Roman writers had been reprinted, at that period, throughout England. But a great deal was done for public instruction by the course which our early printers took ; for, as one of them says: — 'Divers famous clerks and learned men translated and made many noble works into our English tongue, whereby there was much more plenty and abundance of English used than there was in times past.' The English nobility were, probably, for more than the first half century of English printing, the great encouragers of our press: — They required translations and abridgments of the classics, versions of French and Italian romances, old chronicles, and helps to devout exercises. Caxton and his successors abundantly supplied these wants, and the impulse to most of their exertions was given by the growing demand for literary amusement on the part of the great. Caxton, speaking of his 'Boke Eneydos,' says — 'This present book is not for a rude uplandish man to labour therein, nor read it; but only for a clerk and a noble gentleman, that feeleth and understandeth in feats of arms, in love, and in noble chivalry.' But a great change was working in Europe; the 'rude uplandish man,' if he gave promise of talent, was sent to school. The priests strove with the laity for the education of the people ; and not only in Protestant but in Catholic countries were schools and universities everywhere founded. Here, again, was a new source of employment for the press — A, B, C's, or Absies, Primers, Catechisms, Grammars, Dictionaries, were multiplied in every direction. Books became, also, during this period, the tools of professional men. There were not many works of medicine, but a great many of law. The people, too, required instruction in the ordinances they were called upon to obey ; and thus the statutes, mostly written in French, were translated and abridged by Rastell, our first law-printer.

" After all this rush of the press of England towards the diffusion of existing knowledge, it began to assist in the production of new works, but in very different directions. Much of the poetry of the 16th century, which our press spread around, will last for ever: its controversial divinity has, in great part, perished. Each, however, was a natural supply, arising out of the demand of the people ; as much as the chronicles, and romances, and grammars were a natural supply; and as the almanacks. and mysteries, and ballads, which the people then had, were a natural supply. Taken altogether, the activity of the press of England, during the first period of our enquiry, was very remarkable. Ames and Herbert have recorded the names of 350 printers in England and Scotland, or of foreign printers engaged in producing books for England, that flourished between 1471 and 1600. The same authors have recorded the titles of nearly 10,000 distinct works printed amongst us during the same period. Many of these works, however, were only single sheets, but, on the other hand, there are, doubtless, many not here registered. Dividing the total number of books printed during these 130 years, we find that the average number of distinct works produced each year was 75." (*Penny Magazine.*)

The first book in which Greek types occur is Cicero's "Offices," printed in the year 1465, in which the characters are so imperfect that the words are with difficulty deciphered; but the first work printed wholly with Greek types is a Greek Grammar written by the learned Constantine Lascaris, printed in Milan by Dionysius Paravisinus, in 1476, in 4to. It went through several editions in Italy, France, and Switzerland. One of them, that of Aldus, printed in Venice in 1495, is the first Aldine book printed with a date. One of the most elegant specimens of ancient Greek typography, valued not only for its beauty, but also for its rarity and the accuracy of its text, is the "Argonautica, Flor. ap. Junta, 1500," 4to, editio princeps.

It was not unusual for the early printers of Greek, as well as of other works, to endeavour to imitate the characters of the MSS. of the age. In this they were more or less successful. An exceedingly beautiful specimen of this kind of printing is the editio princeps of Isocrates, "Orat. à Demetrio Chalcondyla, Gr. Mediol. ap. Henr. Germanus et Sebastianus ex Pontremula," 1493, fol. The text of this edition is said to be remarkably accurate. Fabricius considers it more so than that of the Aldine edition of 1513.

The first Greek book printed in Rome was the works of Pindar: "Pindari Opera, Gr. cum Scholiis Callieggi." Rome, 1515, 4to. This is also remarkable as the first edition with the Scholia. The first Greek work printed at Cambridge was Plato's "Menexenus, sive Funebris Oratio, exhortatio ad Patriam amaudam atque defendam. Cantab." Greek types were not introduced into Scotland till after the middle of the 16th century. In a 4to volume printed in Edinburgh in 1563, entitled, "The Confutation of the Abbote of Crosraguel's Masse," there is an Epistle by the Printer to the Reader, apologising for his want of Greek characters, which he was obliged to supply by manuscript.

The first work printed with Roman types was Cicero's "Epistolæ Familiares," by Sweynheym and Pannartz, at Rome, in 1467. Italic type was invented by Aldus Manutius, about 1500.

Italy has the honour also of having printed the first Hebrew Bible, at Soncino, a small city in the Duchy of Milan, in 1488, under the superintendence of two Jewish rabbins, named Joshua and Moses. The edition of Brescia, of 1494, was used by Luther in making his German translation. But Hebrew types were not introduced into England for many years after this period; for we find that in 1524, Dr. Robert Wakefield, chaplain to Henry VIII., complains, in his "Oratio de Laudibus," &c., that he was obliged to omit his whole third part, as the printer (Wynkyn de Worde) had no Hebrew types. Towards the end of the 16th century, various works were printed in Syriac, Arabic, Persian, Armenian, and Coptic, or modern Egyptian types; some to gratify the curiosity of the learned, and others for the liturgic uses of the Christians in the Levant.

In the 16th century the broils consequent on the Reformation, although that event stimulated religious inquiry, did much to impede the progress of the art in England. But the civil wars and the gloomy religious spirit which succeeded to the pedantry and verbal criticism of the reign of James I., and which prevailed till the Restoration, interrupted still more the production of works calculated to cultivate the understanding. Indeed, we cannot but regard this period as the least favourable to the diffusion of knowledge of any period in the history of our literature. In the British Museum is a collection of controversial and quibbling tracts amounting to the enormous number of 30,000*, while the impressions of new books printed during these stormy times were very few. Dr. Johnson has well remarked that the nation, from 1623 to 1664, was satisfied with two editions of Shakspeare's plays, which, probably, together did not amount to a thousand copies. But during this period we must not forget the present authorised version of the Bible, translated by the forty-seven distinguished scholars appointed by James I., and printed in 1611, which is allowed by competent judges to be one of singular merit, and indeed the most perfect ever produced. An unfavourable effect was also produced on our national literature, and on the progress of the press, by the licentiousness introduced by the literary parasites and courtezans of the Restoration. Under such a state of mental depression, Milton could obtain only 15*l.* for the MS. of his immortal "Paradise Lost," and an Act of Parliament was actually in force enacting that only twenty printers should practise their art in the whole kingdom! Burton, who lived near this time, has drawn a miserable picture of the abject condition of literary men when they had such patrons to rely upon: — "Rhetoric only serves them to curse their bad fortunes; and many of them, for want of means, are driven to hard shifts. From grass-hoppers they turn humble-bees and wasps, plain parasites, and make the Muses mules, to satisfy their hunger-starved paunches and get a meal's meat."

In addition to these impediments, the Crown endeavoured, in the reign of Charles II., to destroy the activity of the press; "and in this it had the example not only of all for-

* Tomlinson's Collection.

mer reigns (in which nothing had been legally published without a license), but of the Long Parliament itself, which had laid severe restrictions upon the printing of 'scandalous and unlicensed papers.' At one time, indeed, it was ordered that no printing should be carried on anywhere but in the City of London and the two Universities; and all London printers were to enter into a bond of 300*l.* not to print anything against the Government, or without the name of the author (or at least of the licenser) on the title-page, in addition to their own."—(*Eccleston's Eng. Antiquities*, p. 325.)

It has been ascertained by counting that the whole number of books printed during the fourteen years from 1666 to 1680, was 3550, of which 947 were divinity, 420 law, and 153 physic, so that two-fifths of the whole were professional books; 397 were school-books, and 253 on subjects of geography and navigation, including maps. Taking the average of these fourteen years, the total number of works produced yearly was 253; but deducting the reprints, pamphlets, single sermons, and maps, we may fairly assume that the yearly average of new books was much under 100. Of the number of copies constituting an edition we have no record; we apprehend it must have been small, for the price of a book, so far as we can ascertain it, was considerable.

The period from the accession of George III. to the close of the 18th century is marked by the rapid increase of the demand for popular literature, rather than by any prominent features of originality in literary production. Periodical literature spread on every side; newspapers, magazines, reviews, were multiplied; and the old system of selling books by hawkers was extended to the rural districts and small provincial towns. Of the number-books thus produced, the quality was indifferent, with a few exceptions; and the cost of these works was considerable. The principle, however, was then first developed, of extending the market, by coming into it at regular intervals with fractions of a book, so that the humblest customer might lay by each week in a savings'-bank of knowledge. This was an important step, which has produced great effects, but which is even now capable of a much more universal application than it has ever yet received. Smollet's 'History of England' was one of the most successful number-books; it sold to the extent of 20,000 copies.

We may exhibit the rapid growth of the publication of new books, by examining the catalogues of the latter part of the eighteenth century, passing over the earlier years of the reign of George III. In the 'Modern Catalogue of Books,' from 1792 to the end of 1802, eleven years, we find that 4096 new works were published, exclusive of reprints not altered in price, and also exclusive of pamphlets: deducting one-fifth for reprints, we have an average of 372 new books per year. This is a prodigious stride beyond the average of 93 per year of the previous period. But we are not sure that our literature was in a more healthy condition. From some cause or other, the selling price of books had increased, in most cases 50 per cent., in others, 100 per cent. The 2*s.* 6*d.* duodecimo had become 4*s.*; the 6*s.* octavo, 10*s.* 6*d.*; and the 12*s.* quarto, 1*l.* 1*s.* It would appear from this that the exclusive market was principally sought for new books; that the publishers of novelties did not rely upon the increasing number of readers; and that the periodical works constituted the principal supply of the many. The aggregate increase of the commerce in books must, however, have become enormous, when compared with the previous fifty years; and the effect was highly beneficial to the literary character. The age of patronage was gone. (*Penny Magazine.*)

According to the last census, upwards of 26,000 persons are employed in printing, and 11,000 in bookbinding.

Printing was introduced into Scotland, and begun in Edinburgh about 30 years after Caxton had brought it into England. Mr. Watson, in his 'History of Printing,' says that the art was introduced into Scotland from the Low Countries by the priests who fled thither from the persecutions at home. Be this as it may, we find James IV. granting a patent in 1507 to Walter Chapman, a merchant of Edinburgh, and Andrew Mollar, a workman, to establish a press in that city. According to bibliographers, the most ancient specimen of printing in Scotland extant is a collection, entitled the 'Porteus of Nobleness,' Edinburgh. In 1509, a 'Breviary of the Church of Aberdeen' was printed at Edinburgh; and a second part in the following year. Very few works, however, appear to have issued from the Scottish press for the next 30 years; but from 1541, the date from which we find James V. granting licenses to print, the art has been pursued with success in the metropolis. At present, and from the beginning of the present century, it is perhaps the most distinguished craft in the city, being conducted in all its departments of typefounding, printing, publishing, and, we may add, paper-making at the mills in the vicinity.

Printing was not known in Ireland till about the year 1551, when a book in black letter was issued from a press in Dublin; but till the year 1700, very little printing was executed in Ireland, and even since that period, the country has acquired little celebrity in this department of the arts, although possessing some respectable printing establishments.

The art of printing has readily taken root and flourished among the civilised inhabitants of North America. The first printing-press established in the American colonies was one set up at Cambridge, in Massachusetts, in the year 1638, the era of the foundation of Harvard College of that place. It was only established by the exertions and joint contributions of different individuals in Europe and America; and there is no doubt that the mechanism and types were imported from England. The first work which issued from this press was the 'Freeman's Call,' and the second the 'Almanac for New England,' both in 1639; the first book printed was the New England version of the Psalms, an octavo volume of 300 pages. In 1676, books began to be printed at Boston; in 1686, printing became known in Philadelphia; and in 1693, in New York. In the year 1700 there were only four printing presses in the colonies. Since that period, and especially since the revolution, which removed everything like a censorship of the press, the practice of the art has undergone enormous expansion. Among the occupations enumerated in the census of 1850 were 14,740 printers, and 3414 bookbinders. In their style of typography and bookmaking, the Americans are still inferior to the English, sacrificing beauty and durability to economy and despatch. (*Chambers's Inform.*)

The activity of the French press has very greatly increased since the time of the first Napoleon. Count Daru, in 1827 (*Notions Statistiques sur la Libraire*), estimated the number of printed sheets (exclusive of newspapers) produced by the French press in 1816, at 66,852,883; and it appears that in 1836 the number of printed sheets (exclusive of newspapers) had increased to 118,857,000; so that it may now be fairly estimated at from 130,000,000 to 140,000,000 of sheets. The quality of many of the works which have issued from the French press is also very superior, such as the "Biographie Universelle," the "Art de vérifier les Dates," and "Bayle's Dictionary;" and it is doubted whether such books could have been published in any other country.

The German printing press is always in a state of the greatest activity; and the trade in books is very much facilitated by the book fairs of Leipsic, the Easter fair especially being frequented by all the booksellers of Germany, besides those of France, Switzerland, Denmark, Livonia, &c., in order to settle their mutual concerns and form new connections. In 1814 began a literary deluge, which still continues to increase. For the 5000 works which then sufficed for the annual demand, we have now from 6000 to 8000. Private libraries are diminishing, and the public ones are daily increasing.

In Austria the printing press has made rapid strides of late years. The Imperial printing office in Vienna, under the able management of M. Auer, has become an establishment of the highest interest. At the Exhibition of 1851, he presented to the notice of the public a collection of the Lord's Prayer, printed with Roman type in 608 languages and dialects, the second section of which contained 206 languages and dialects, printed in the characters proper to the language of the respective nation. He has collected together the following founts, many of which are, however, to be found in the British type foundries :—

Types.—Although most of the early printers were type-founders themselves, it does not appear in any prologue or colophon to the books printed by Caxton that he lays claim to the title of type-founder. It would appear that he obtained his type, which is precisely of the same character as that of John Brito of Bruges, from that city, or from the same founders who supplied or manufactured it for John Valdener of Utrecht. But as the art extended the workmanship became inferior; "so that while the productions of the first printers were executed in a very superior style, and the embellishments showed a great proficiency both in design and engraving, the productions of their competitors had all the crudeness and imperfection of a new invention; and in the 17th century it had retrograded to a very low state. At the commencement of the 18th century, Caslon made great improvements in types; as also, Baskerville of Birmingham, in 1750, both in types and printing, which were subsequently carried on by Besley, Bulmer, Clowes, Corrall, Davison, McCreery, Spottiswoode, Whittingham, and a few others in London; by the Foulis, in Glasgow; the Ballantynes, in Edinburgh; by Bodoni at Parma; by Didot in Paris;" and by Brockhaus in Leipsic.

Newspapers, &c.—The period of the English Revolution will be ever memorable in the literary history of this country for the establishment in great part of periodical literature. But English newspapers, properly so called, date from the first year of the Long Parliament, the oldest that has been discovered being a quarto pamphlet of a few leaves, entitled "The Diurnal Occurrences, or Daily Proceedings of both houses in this great and happy Parliament, from the 3rd November, 1640, to the 3rd of November, 1641. London: printed for William Cooke, and are to be sold at his shop at Furnival's Inn Gate, in Holborn, 1641." (*Fig.* 1511.) More than 100 papers

1511.

with different titles appear to have been published from this time to the death of the king, and upwards of 80 from that date to the Restoration. These were at first published weekly; but, as the interest increased, twice or thrice a week; and even, it would seem, daily, at least for a time. Such were the "French Intelligences," the "Dutch Spy," the "Scots Dove," &c.; but "Mercuries" of all sorts were the favourite title. Thus they had "Mercurius Acheronticus," "Mercurius Democritus," "Aulicus," "Britannicus," "Laughing Mercury," and "Mercurius Mastix," which last faithfully lashed all the rest. The great newspaper editors of the day were Marchmont Needham on the Presbyterian, and Sir John Birkenhead on the royalist side. These were followed by Sir Roger l'Estrange, who has also been ranked amongst the patriarchs of the newspaper press. Pamphlets were also issued in prodigious numbers during those troubled times; the average being calculated at four or five new ones every day. (*Eccleston's Eng. Antiq.*)

In 1709, one daily paper, fifteen three times a week, and one twice a week, papers, were published in the metropolis. In 1724 there were three daily, six weekly, and ten three times a week papers, in London; and provincial newspapers had been established in various places. The reign of Queen Anne also witnessed a new and most successful species of literature—the issue of the "Guardian," "Spectator," and other such literary sheets, published at short intervals. The strong good sense of Cave, the printer, originated the "Gentleman's Magazine," which completely established the principle that the patronage of men of letters is best confided to the people, and not the great and fashionable. This publication soon had rivals to contend with in the "Monthly," "European," "London," and "Critical;" but it has survived them all; and a complete set of "The Gentleman" is highly prized at the present day, and is extremely amusing and valuable.

The first newspaper published in Scotland was the "Caledonian Mercury," in 1660, under the title of "Mercurius Caledonius;" but its publication was soon after interrupted. In 1750 a newspaper was, for the first time, attempted in Glasgow.

The increase of newspapers in America has been much more rapid than in this country; in consequence partly, no doubt, of the greater increase of population in the Union, but more probably of their freedom from taxation, and of the violence of party contests. According to a return published some few years back, the aggregate circulation of papers and other publications was about 5,000,000; and the entire number of copies printed annually in the United States amounted to about 422,600,000 annually.

The first newspaper published in the West Indies is said to have been the "Barbadoes Mercury." It was established in 1733, and died in 1852.

Practice of Printing.—The workmen principally employed in printing are of two kinds: *compositors*, who *set up* the types into lines and pages according to the MS. or *copy* furnished by the author; and *pressmen*, who apply ink to the surface of the *form* of types, and take off the impressions upon paper.

Composition.—The mode of proceeding described hereafter is that which is pursued in most of the extensive establishments in London:—The first thing to be done, when the sizes of page, type, and paper, are determined on, is to look over the MS., and see that it is correctly paged. It is then handed to a *clicker*, or foreman of a *companionship*, or certain number of compositors, each of whom has a *taking of copy*, or convenient portion of MS., given to him, to be set up in type.

Printers' types are of great variety in size, amounting to forty or fifty; the smallest is called *Brilliant*, but is seldom used; *Diamond* is a size larger, and *Pearl* larger still, which latter type is used for printing the smallest Bibles and Prayer Books. The following is a view of the comparative sizes used in printing books:—

Diamond . . .	To the art of printing it is acknowledged we owe the Reformation It has been justly remarked that
Pearl	To the art of printing it is acknowledged we owe the Reformation. It has been justly re-

The larger sizes, used for printing bills posted in the streets, are usually called *Double Pica, Two-line Pica, Two-line English, Five-line Pica, Ten-line Pica*, and so on. A complete assortment of printing types of one size is called a *fount*, and the fount may be regulated to any weight. Type-founders have a scale, or *bill*, as it is called, of the proportional quantity of each letter required for a fount. The letter *c*, as will be seen from the following *bill*, is used more, and the letter *z* less frequently than others:—

BILL OF PICA.—WEIGHT 800 POUNDS.—ITALIC $\frac{1}{10}$TH.

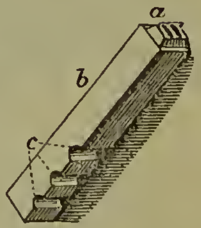
In setting up indexes and similar matter, the capitals mentioned would be considerably deficient. This would also be the case with French and Italian works, where accented letters are used in great numbers.

The type itself is a thin metallic bar, an inch in length, like the following engraving (*fig.* 1512), which represents the letter *m*; *a* is the *face*, *b* the *body*, and *c* the *nicks* or notches. Whatever size of type is used, each letter must be perfectly true in its angles, otherwise the form could never be *locked up*. Besides letters, there are types for commas, periods, quotation marks, semicolons, and all other characters used in printing.

1512



The types are arranged, each sort by itself, in two *cases*,—an upper and lower,—in little cells or *boxes*. The upper case, having ninety-eight boxes, contains the capital and small capital letters, figures, accents, and other types not used so frequently as the smaller letters; and in the lower case, having fifty-four boxes, are disposed the small letters, together with the points, spaces, quadrats, &c. The boxes in the cases are arranged in the best possible manner for facilitating the work of the compositor, and enabling him to pick up the types rapidly,—the letters most frequently used being placed nearest to his hand.

Pair of Cases according to the modern Method.

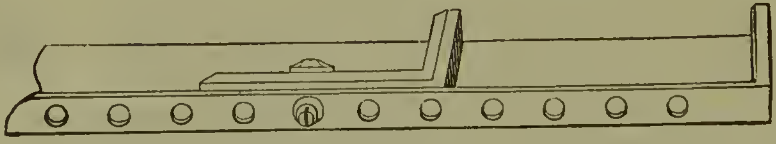
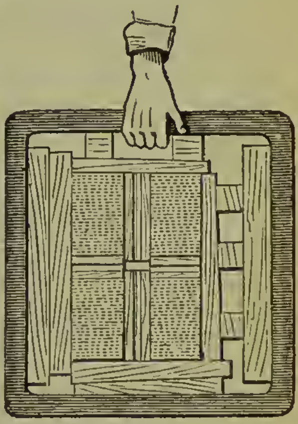
In *setting up* or *composing*, the compositor stands opposite to his cases; and, having received directions respecting the size of the type, the width of the page, the author's wishes as to punctuation, capitals, italics, &c., places his copy or MS. before him, on a spare part of the upper case, and holds in his left hand a small instrument called a *composing stick*, usually made of iron, with a movable slide, capable, by means of a screw, of being adjusted to the different widths required in miscellaneous printing, as seen in the illustration. With the right hand he picks up the types, and arranges them one by one in his composing stick. He does not look at the face, but only glances at the nick (*fig.* 1512, *e*), and takes it for granted that if it come from the

1513



right box it must be the right letter. He secures each letter with the thumb of the left hand, as the types are placed side by side in line from left to right; and, when he comes to the end of his line, and finds that he has a syllable or word which will not fill out the measure, he has to perform a task which requires considerable care and taste. This is called *justification*. The first and last letters must be at the extremities of the line; and there must not be wide spaces between some words and crowding in others, but the distances between them must be made as nearly as possible uniform by changing the *spaces* (or short blank types, not so high as the letters, and therefore giving no impression), and thus *getting in* or *driving out* part or whole of a word. The first line being thus justified, the compositor proceeds with the setting up of the next, and so on with a sufficient number of lines to fill his stick, and then lifts the *handful*, or mass of types, out of the stick, and places them upon a *galley*, or oblong tray of wood or metal, having an edge at the left side and top half an inch in height. This operation of filling and emptying the stick is repeated till the galley is sufficiently full, or the taking of copy is finished; when the *matter*, as it is then called, is taken away by the clicker, who divides it into the required lengths of pages, placing head-lines, signatures, &c., and binding them round tightly with cord. The clicker then *lays down* the pages in their proper positions on the *imposing stone*,—a flat, smooth slab of stone, or, better, of iron. The *chase*, a frame of iron, divided into compartments like the sashes of a window, is put round the pages, and the form *dressed* thus:—a set of *furniture*, consisting of slips of wood or metal, about half an inch in height, and of various thicknesses, is placed, some at the head, called *head-sticks*, some between the pages, called *gutters*, and others at the sides and feet, called *side* and *foot-sticks*. The side and foot-sticks are larger at one end than at the other, so that small wedges of wood, or *quoins*, may be driven tightly between them and the sides of the chase, locking up the types so firmly, that the *form*, as the mass is then called, may be carried from place to place with perfect safety. A form of eight pages of this Dictionary contains between 40,000 and 50,000 separate letters and spaces.

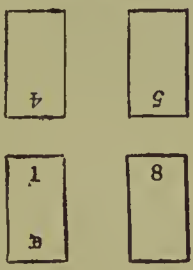
1514



The sizes of books are reckoned by the number of leaves into which a sheet of paper is folded. Thus the largest size is *broadside*, or the whole size of the sheet; *folio*, or half the sheet; *quarto*, or a sheet folded into four leaves; *octavo*, or the sheet folded into eight leaves; *duodecimo*, or the sheet folded into twelve leaves; and so on. In imposing, the pages are of course laid down in positions the reverse of those they will take when printed. The following tables show the mode of imposing some of the most common sizes:—

Sheet of Quarto.

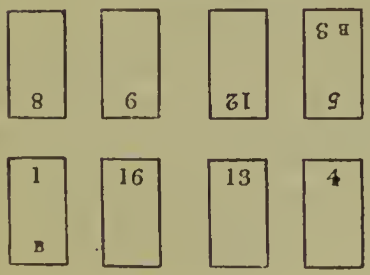
Outer Form.



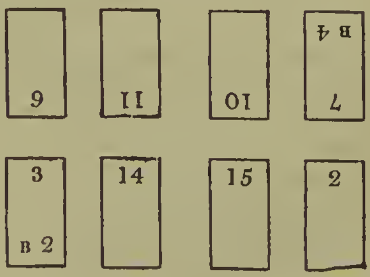
Inner Form.

Sheet of Octavo.

Outer Form.

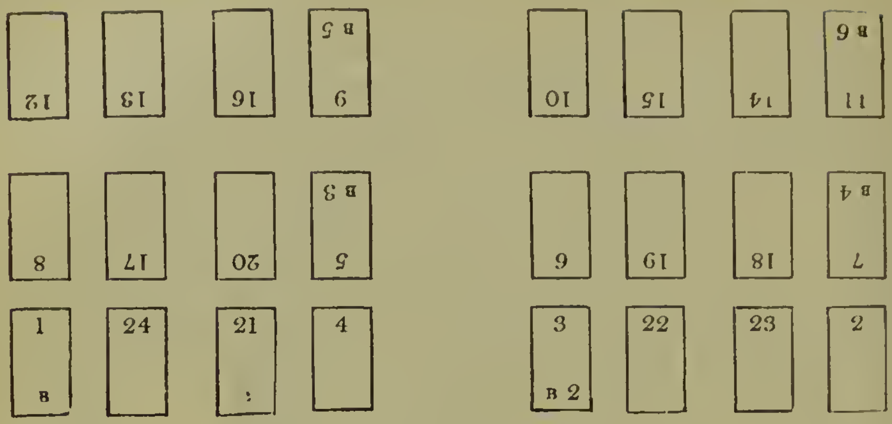


Inner Form.



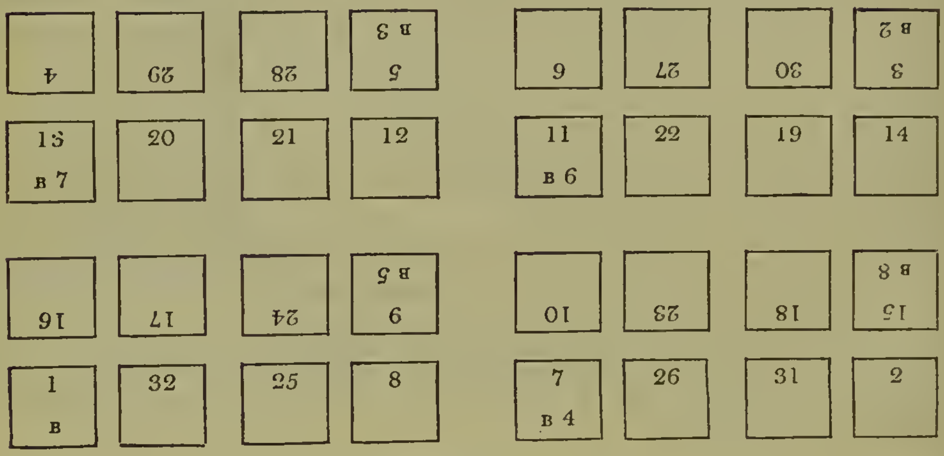
Sheet of Twelves.

Outer Form. Inner Form.



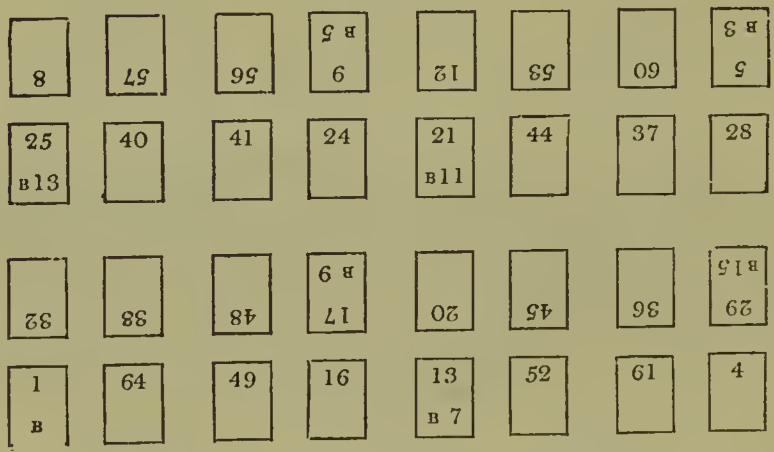
Sheet of Sixteen

Outer Form. Inner Form.



Sheet of Thirty-twos.

Outer Form.



(The inner form is the reverse of this.)

When this process of imposing is completed the form is carried to a press, and an impression is taken, called the *first proof*. This proof, with the MS., is handed to the corrector of the press, or *reader*, and a *reading boy* reads the copy to him while he examines the proof and marks the necessary corrections and errors of the compositor. In correcting a proof sheet a set of symbols are used for the purpose of calling the attention of the compositor to the several kinds of errors, and to direct him how they are to be amended. These marks are best shown by the following specimen of a corrected proof from Brande's "Dictionary," the explanation of each mark being given in the left-hand column:—

Where a word is to be changed from small let- to capitals, draw three lines under it, and write . in the margin.
Where there is a wrong letter draw the pen ugh that letter, and make the right one opposite ie margin.
A letter turned upside down.
The substitution of a comma for another point, or a letter put in by mistake.
The insertion of a hyphen.
To draw the letters of a word close together.
To take away a superfluous letter or word the is struck through it, and a round top *d* made oppo- being the contraction of *deleatur*, to expunge.
Where a word has to be changed to Italic draw ne under it, and write *Ital.* in the margin; and re a word has to be changed from Italic to Ro- ı, write *Rom.* opposite.
When words are to be transposed three ways of king them are shown; but they are not usually ibered except more than three words have their er changed.
). The transposition of letters in a word.]
. To change one word for another.
:. The substitution of a period or a colon for any er point. It is customary to encircle these two nts with a line.
3. The substitution of a capital for a small letter.
l. The insertion of a word, or a letter.
). When a paragraph commences where it is not nded. connect the matter by a line, and write in margin opposite *run on*.
. Where a space or a quadrat stands up and ap- -s, draw a line under it and make a strong per- dicular line in the margin.
When a letter of a different size to that used, or different face, appears in a word, draw a line er through it or under it, and write opposite *wf.*, wrong fount.
3. The marks for a paragraph, when its com- icement has been omitted.
). When one or more words have been struck and it is subsequently decided that they shall re- n, make dots under them, and write the word *stet* he margin.
). The mark for a space where it has been omitted veen two words.
. To change a word from small letters to small tals make two lines under the word, and write *caps.* opposite. To change a word from small tals to small letters make one line under the d, and write in the margin *lo. ca.* for lower case
:. The mark for the apostrophe; and also the ks for turned commas, which designate extracts.
3. The manner of marking an omission, or an in- ion, when it is too long to be written in the side gin. When this occurs it may be written either he top or the bottom of the page.
l. Marks when lines or words are not straight.
he subjoined specimen, when corrected, would be ollows:—

ANTIQUITY, like every other quality t attracts the notice of mankind, has un- ıbtedly votaries that *reverence* it, not from son, but from prejudice. Some seem to nire indiscriminately whatever has been g preserved, without considering that ie has sometimes co-operated with chance: perhaps are more willing to honour past n present excellence; and the mind con- ıplates genius through the shades of age, the eye surveys the sun through artificial ıcity. The great contention of criticism o find the faults of the moderns, and the ıuties of the ancients. While an author ret living, we estimate his powers by his rst performances; and when he is dead, rate them by his best.

To works, however, of which the excel- ce is not absolute and definite, but gradual l comparative; to works, not raised upon nciples demonstrative and scientifick, but ealing wholly to observation and experi- e, no other test can be applied than LENGTH luration and continuance of esteem.

we rate them by his best./ 23

When the reader has read his proof it is handed to the compositor, who unlocks the form and makes the corrections in the types, by lifting out the wrong letters by means of a sharp awl, or *bodkin*, and putting in right ones in their places. The form is then locked up again, taken to the press, and another proof is *pulled.* This is termed *the revise*, and is sent to the reader, with his first proof, that he may see that all the corrections have been properly made, put queries against doubtful matters for the author's consideration, and send it, thenceforth called a *clean proof*, with the MS., to the author. When the author returns his proof and revise, and is satisfied that the sheet is correct, the form, after having been finally read with care for press, is taken to the press or machine to have the requisite number of impressions struck off. Before this is done, however, care is taken that the matter at the beginning of the sheet connects with that at the end of the preceding, that the pages are correct, and that the "signatures" are in order. The signatures are generally small capital letters placed at the foot of the first page of each sheet, commencing with B, and omitting the J, V, and W. They are said to have been first used by John Koelhof, at Cologne, in 1472; but they exist in an edition of *Terence*, printed by Antonio Zorat, at Milan, in 1470. There is a Venetian edition of "Baldi Lectura Super Codic," &c., printed by John de Colonia and Jo. Manthen de Gherretzem, in 1474, in which it is evident that these printers had only just become acquainted with the use of signatures, as these marks were not introduced till one-half of the work had been printed. The following tables show the signatures and folios of any given number of sheets, in 8vo, 12mo, and 18mo:—

The paper used in printing is always damped before being sent to the press, wet paper taking the ink considerably better than dry. The warehouseman delivers the proper quantity of paper to the wetter, which is wetted thus :—The quire of paper is opened, its back broken, and divided into three, four, or five portions, or *dips*, drawn through a trough of clean water and laid on a board, dip after dip, till a convenient heap is made. This is put into a screw-press, a little pressure applied, and the next day the whole is *turned* and slightly pressed again, so that fresh surfaces of the paper coming into contact, the moisture is equally diffused throughout the heap. The paper used in printing is of three kinds: *imperfect paper*, consisting of 20 quires of 24 sheets, or 480 sheets to the ream; *perfect paper* (that most generally used) consisting of 21½ quires, or 516 sheets; and *news paper*, consisting of 20 quires of 25 sheets each to the ream, or 500 sheets. The *stamped sheets* of news paper (generally called *stamps*, and the plain paper *blanks*) are always received and delivered by the net number without allowing for spoilage in the press work; but in book work it is the practice to allow 16 sheets in each ream for "tympan sheet" and spoiled sheets. The following table shows the quantity of perfect and imperfect paper required for one sheet of 16 pages of a work like "Ure's Dictionary," from 12 to 10,000 copies:—

Quantity required of *perfect* paper.			Quantity required of *imperfect* paper.			For printing 1 sheet of 16 pages.	Total number of copies the paper will make.

Presswork.—The pressman first lays the inner form on the press, and prints one copy, which is called a *press revise;* this he takes to the person appointed to revise it, and while that is being done proceeds to secure the form on the table of the press by means of quoins; to place his tympan sheet; to fix the points which make small holes in the paper that enable him to cause the pages to fall precisely on the back of each other when the second side of the paper is printed, and to produce an even and uniform impression in all the pages. He then cuts his frisket, which preserves the margin of the paper clean, and, when the revise is corrected, proceeds to ink the surface of the types by means of rollers. When the whole impression of one side of the paper is printed, he lifts the form off the press, washes the ink off the face of the type with lye, and rinses it with water. He then proceeds in a similar manner with the outer form, which completes the sheet. This process is continued sheet after sheet till the work is complete.

When the sheet is printed the compositor lays it up, distributes the type, and proceeds, sheet after sheet, till the body of the work is finished; then the title, dedication, preface, introduction, contents, and any other prefatory matter is proceeded with, these being always printed the last. This distribution of the types, or putting back the letters into the several compartments of the case where they belong, is performed with the greatest rapidity. The compositor wets the whole page or form, and takes up a number of lines on his composing rule. This wetting causes the types to adhere slightly together, and renders the manipulation easy. He then takes up a few words between his right hand finger and thumb, and by a dexterous motion he throws off the several letters into their various boxes. Distribution is performed four times faster than composition.

After the sheets have been printed on both sides, the warehouseman takes them away, and hangs them up on poles to dry, varying the number of sheets hung up together from five or six to ten or eleven, according to the heat of the room, or the pressure of business. When dry the sheets are taken down from the poles, carefully knocked up, and put away in the warehouse in piles; and when the book is nearly finished from ten to fourteen consecutive sheets are laid upon the gathering board in order, and collected sheet by sheet by boys, who deposit each *gathering* in a heap at the end of the table, so constructed that when a boy has deposited his gathering he has only to turn himself and begin again. These gatherings are then carefully *collated*, to ascertain that the different sheets are correct and in order, and folded up the middle. When the work is finished the gatherings are put together, or *in books*, one of each, which forms a copy of the work, and pressed. The work is now completed, and awaits the order of the bookseller, &c., to deliver the copies to the bookbinder.

Printing in colours. — In many of the old printed books, the initial letters, and occasionally other parts, were printed in red. This was done by two workings at press, and was an imitation of the earlier fashion of illuminating MSS. The practice is still followed in some almanacs, the saints' days and holidays being "red-letter days." Some ingenious contrivances have been devised for working in various colours; and a few years since a curious book was written and published on the subject by Mr. Savage. Still more recently, printing in gold and other metals has been practised. This is done by printing with a sort of size, and afterwards applying the metal leaf. But the specimens of printing in colours produced by Mr. Kronheim are really beautiful as works of art. The copy picture is made in colours, and the blocks for printing each colour and shade are cut in relief on "surface-metal" plates, consisting of perfectly smooth plates of type metal. These plates are then printed by the ordinary method, great care, however, being taken that each colour falls in its right place.

The following is the mode of printing two or more "rainbow tints" at the same time: — Take the cut, ink it well and rather full, with black ink, and get a perfect impression on paper not very damp; then lay the face of the printed paper carefully on the surface of the block prepared for engraving the whites on the tinted ground, and give it a good soft pull. This will transfer to the tint block a facsimile of the wood-engraving itself. This block is then handed over to the engraver, who cuts out the whites for the clouds, shadows, water, &c., according to his taste, and with a view to effect. The tint-block is printed first, and then the black block is put to press, and the pressman must be careful in distributing his different inks to make them fade away and blend at the given points. This is an easy matter after a little practice.

Laws affecting the Press. — As to the laws relating to the press, see 39 Geo. III. c. 79, amended by 51 Geo. III. c. 65, and 2 & 3 Vict. c. 12. There is no censorship over the press, which is, however, amenable to the remedy of an injured party, or to the correction of criminal justice (*Wharton's Law Lex.* 2nd ed. 1860).—R. J. C.

PRINTING BLOCKS—ELECTRO. While this book has been passing through the press, Mr. H. G. Collins has taken out two patents, which are likely to prove of essential service to the publishing world. By the one he is enabled to take on vulcanised caoutchouc, prepared with an equally elastic surface, an impression in transfer from any steel or copper plate, wood block, stereotype, lithographic stone, or, in fact, from an original drawing, if done in transfer ink on transfer paper, and increase or reduce the same to any required size. This is effected by expanding the Indian rubber in one case, after it has received the impression; and in the other, before the impression is made. In the first instance the impression is enlarged as the elastic material expands, in the other it is reduced by allowing the already expanded Indian rubber to contract in its frame; then laying the expanded or contracted copy down upon stone, and treating it after the usual manner of lithography. This presents a vast field for adapting the plates of any work of acknowledged merit which may have cost some hundreds or thousands of pounds, and years to produce, to the wants of the public in these days of cheap and well illustrated literature, by bringing out the same works in a reduced size, which, but for this plan, no publisher would think of attempting. Many plates, also, such as portraits, public buildings, or landscapes, may be enlarged and issued separately. This last application is particularly suitable for maps, as any one, from the size of a school atlas, may be taken and made to serve for large wall maps without the cost of engraving the same. The rapidity with which this alteration of size can be accomplished is not among the least of its recommendations; for an engraving that would take several months in the ordinary mode may be completed in from two to three days.

This patent offers the same facilities to a vast number of the manufactures of the country, such as the lace trade, cotton printers, damask and moreen houses, potteries, paper-hangings; in fact, to all and every one who employ *art* or *design* in their calling. It will be well to observe that the size cannot only be enlarged or diminished, as the case may be, but the pattern can be altered in form; thus a circular design can be made into an oval, if required. Mr. Collins, by his second patent, is enabled, after these impressions are once upon the stone, to make them into electro blocks, thus reducing also the cost of printing engraved plates, which is effected in the following manner:—The impression being placed on the lithographic stone or the zinc plate—either one or the other can be employed—acid is applied to abrase to a certain extent the stone or metal over the unprotected portions; when this is sufficiently deep a mould is taken in wax, the surface of which being prepared is subjected to the electrotype process, and thus a copper block is obtained.

Mr. C. has also a provisional specification for a third patent, by which he can by the assistance of photography, produce blocks for surface printing (without the aid of the engraver) in the course of a few hours. The whole of these patents are being brought into practical operation by the "Electro Printing-block Company." See Photozincography.

PRINTING INK. (*Encre d'imprimerie*, Fr.; *Buchdrückerfarbe*, Germ.) After reviewing the different prescriptions given by Moxon, Breton, Papillon, Lewis, those in Nicholson's and the Messrs. Aikins' Dictionaries, in Rees' Cyclopædia, and in the French Printer's Manual, Mr. Savage * says, that the Enclycopædia Britannica is the only work, to his knowledge, which has given a recipe by which a printing ink might be made that could be used, though it would be of inferior quality, as acknowledged by the editor; for it specifies neither the qualities of the materials, nor their due proportions. The fine black ink made by Mr. Savage has, he informs us, been pronounced by some of our first printers to be unrivalled; and has procured for him the large medal from the Society for the Encouragement of Arts.

1. *Linseed oil.*—Mr. S. says that the linseed oil, however long boiled, unless set fire to, cannot be brought into a proper state for forming printing ink; and that the flame may be most readily extinguished by the application of a pretty tight tin cover to the top of the boiler, which should never be more than half full. The French prefer nut oil to linseed; but if the latter be old, it is fully as good, and much cheaper, in this country at least.

2. *Black rosin* is an important article in the composition of good ink; as by melting it in the oil, when that ingredient is sufficiently boiled and burnt, the two combine, and form a compound approximating to a natural balsam, like that of Canada.

3. *Soap.*—This is a most important ingredient in printer's ink, which is not even mentioned in any of the recipes prior to that in the *Encyclopædia Britannica*. For want of soap ink accumulates upon the face of the types, so as completely to clog them up after comparatively few impressions have been taken; it will not wash off without alkaline lyes, and it skins over very soon in the pot. Yellow rosin soap is the best for black inks; for those of light and delicate shades, white curd soap is preferable. Too much soap is apt to render the impression irregular, and to prevent the ink from drying quickly. The proper proportion has been hit, when the ink works clean, without clogging the surface of the types.

4. *Lamp black.*—The vegetable lamp black, sold in firkins, takes by far the most varnish, and answers for making the best ink. See Black.

5. *Ivory black* is too heavy to be used alone as a pigment for printing ink; but it may be added with advantage by grinding a little of it upon a muller with the lamp black, for certain purposes; for instance, if an engraving on wood is required to be printed so as to produce the best possible effect.

6. *Indigo* alone, or with an equal weight of prussian blue, added in small propor-

* In his work on the Preparation of Printing Ink; 8vo, London, 1832.

tion, takes off the brown tone of certain lamp-black inks. Mr. Savage recommends a little Indian red to be ground in with the indigo and prussian blue, to give a rich tone to the black ink.

7. *Balsam of capivi*, mixed, by a stone and a muller, with a due proportion of soap and pigment, forms an extemporaneous ink, which the printer may employ very advantageously when he wishes to execute a job in a peculiarly neat manner.

After the smoke begins to rise from the boiling oil, a bit of burning paper stuck in the cleft end of a long stick should be applied to the surface, to set it on fire, as soon as the vapour will burn; and the flame should be allowed to continue (the pot being meanwhile removed from over the fire, or the fire taken from under the pot,) till a sample of the varnish, cooled upon a pallet-knife, draws out into strings of about half an inch long between the fingers. To six quarts of linseed oil thus treated, six pounds of rosin should be gradually added, as soon as the froth of the ebullition has subsided. Whenever the rosin is dissolved, one pound and three quarters of dry brown soap, of the best quality, cut into slices, is to be introduced cautiously, for its water of combination causes a violent intumescence. Both the rosin and soap should be well stirred with a spatula. The pot is to be now set upon the fire again, in order to complete the combination of all the constituents.

Put next of well-ground indigo and prussian blue, each $2\frac{1}{2}$ ounces, into an earthen pan, sufficiently large to hold all the ink, along with 4 pounds of the best mineral lamp black, and $3\frac{1}{2}$ pounds of good vegetable lamp black; then add the warm varnish by slow degrees, carefully stirring, to produce a perfect incorporation of all the ingredients. This mixture is next to be subjected to a mill, or slab and muller, till it be levigated into a smooth uniform paste.

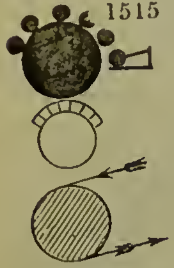
One pound of a superfine printing ink may be made by the following recipe of Mr. Savage:—Balsam of capivi, 9 oz.; lamp black, 3 oz.; indigo and prussian blue together, p. æq. $1\frac{1}{4}$ oz.; Indian red, $\frac{3}{4}$ oz.; turpentine (yellow) soap, dry, 3 oz. This mixture is to be ground upon a slab, with a muller, to an impalpable smoothness. The pigments used for colouring printing inks are, carmine, lakes, vermilion, red lead, Indian red, Venetian red, chrome yellow, chrome red or orange, burnt *terra di Sienna*, gall-stone, Roman ochre, yellow ochre, verdigris, blues and yellows mixed for greens, indigo, Prussian blue, Antwerp blue, umber, sepia, &c.

PRINTING MACHINE. (*Typographie mécanique*, Fr.; *Druckmaschine*, Germ.) No improvement had been introduced in these important machines, from the invention of the art of printing, till the year 1798, a period of nearly 350 years. In Dr. Dibdin's interesting account of printing, in the *Bibliographical Decameron*, may be seen representations of the early printing-presses, which exactly resemble the wooden presses in use a few years back.

For the first essential modification of the old press, the world is indebted to the late Earl Stanhope. His press is formed of iron, without any wood; the table upon which the form of types is laid, as well as the *platen* or surface which immediately gives the impression, is of cast-iron, made perfectly level; the platen being large enough to print a whole sheet at one pull. The compression is applied by a beautiful combination of levers, which give motion to the screw, cause the platen to descend with progressively increasing force till it reaches the type, when the power approaches the maximum; upon the infinite lever principle, the power being applied to straighten an obtuse-angled jointed lever. This press, however, like all its flat-faced predecessors, does not act by a continuous, but a reciprocating motion; nor does it much exceed the old presses in productiveness, since it can turn off only 250 impressions per hour; but it is capable of producing much finer presswork than any steam or hand machine yet invented, for this reason:—the best work requires the best ink, which is stiff, and requires a longer time in distributing over and beating into the form of types than the thin, oily, and consequently browner ink required by the rapidly moving machine. It is a remarkable fact that the *Penny Magazine* was printed at the hand press, although the editor assured his readers that the cylindrical form of machine was capable of printing the finest impressions from woodcuts. The machine, however, has the advantage of uniformity of colour in inking throughout a whole impression. The iron platen of the Stanhope press was supposed at one time to wear out types much sooner than the old wooden one, but experience does not warrant us in supporting this statement.

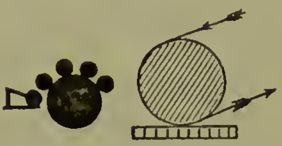
The first person who publicly projected a self-acting printing-press, was Mr. William Nicholson, the able editor of the *Philosophical Journal*, who obtained a patent in 1790, 1, for imposing types upon a cylindrical surface (see *fig.* 1515); 2, for applying the ink upon the surface of the types, &c., by causing the surface of a cylinder smeared with the colouring-matter to roll over them; or else causing the types to apply themselves to the cylinder. For the purpose of spreading the ink evenly over this cylinder, he proposed to apply three or more distributing-rollers longitudinally against the inking-cylinder, so that they might be turned by the motion of the latter. 3. " I perform," he says, " *all my impressions by the action* of a cylinder or cylindrical surface; that is, I cause the paper to pass between two cylinders, one of which has the form of types attached to it, and forming part of its surface; and the other is faced with cloth, and serves to press the paper so as to take off an impression of the colour previously applied; or otherwise I cause the form of types, previously coloured, to pass in close and successive contact with the paper wrapped round a cylinder with woollen." See *figs.* 1515, and 1516.*

1515



Nicholson's for arched type.

1516



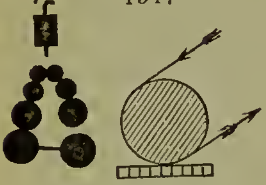
Nicholson's for common type.

The first operative printing machine was undoubtedly contrived by, and constructed under the direction of, M. König, a clock-maker from Saxony, who, so early as the year 1804, was occupied in improving printing-presses. Having failed to interest the continental printers in his views, he came to London soon after that period, and submitted his plans to Mr. T. Bensley and Mr. G. Woodfall, well known printers, and to Mr. R. Taylor, late one of the editors of the *Philosophical Magazine*.

These gentlemen afforded Mr. König, and his assistant Bauer, a German mechanic, liberal pecuniary support. In 1811, he obtained a patent for a method of working a common hand-press by steam power, and 3000 copies of signature H of the *New Annual Register* were printed by it; but after much expense and labour he was glad to renounce the scheme. He then turned his mind to the use of a cylinder for communicating the pressure, instead of a flat plate; and he finally succeeded, sometime before the 28th November, 1814, in completing his printing automaton; for on that day the editors of the *Times* informed their readers that they were perusing for the first time a newspaper printed by steam-impelled machinery; it is a day, therefore, which will be ever memorable in the annals of typography.

In that machine the form of type was made to traverse horizontally under the pressure cylinder, with which the sheet of paper was held in close embrace by means of a series of endless tapes. The ink was placed in a cylindrical box, from which it was extruded by means of a powerful screw, depressing a well-fitted piston; it then fell between two iron rollers, and was by their rotation transferred to several other subjacent rollers, which had not only a motion round their axes, but an alternating traverse motion (endwise.) This system of equalising rollers terminated in two which applied the ink to the types. (See *fig.* 1517.) This plan of inking evidently involved a rather complex mechanism, was hence difficult to manage, and sometimes required two hours to get into good working trim.

1517

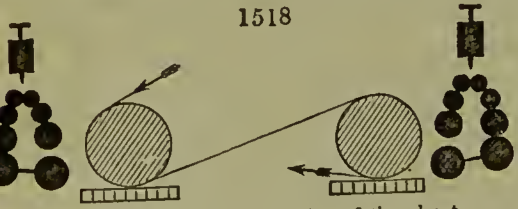


König's single, for one side of the sheet.

In order to obtain a great many impressions rapidly from the same form, a paper-conducting cylinder (one embraced by the paper) was mounted upon each side of the inking apparatus, the form being made to traverse under both of them. This double-action machine threw off 1100 impressions per hour when first finished; and by a subsequent improvement, no less than 1800.

Mr. König's next feat was the construction of a machine for printing both sides of the newspaper at each complete traverse of the forms. This resembled two single machines, placed with their cylinders towards each other, at a distance of two or three feet; the sheet was conveyed from one paper cylinder to another, as before, by means of tapes; the track of the sheet exactly resembled the letter S laid horizontally, thus, ∽; and the sheet was turned over or reversed in the course of its passage. At the first paper cylinder it received the impression from the first form, and at the second it received it from the second form; whereby the machine could print 750 sheets of book letter-press on both sides in an hour. This new register apparatus was erected for Mr. T. Bensley, in the year 1815, being the only machine made by Mr. König for printing upon both sides. See *fig.* 1518.

1518



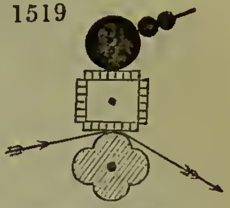
König's double, for both sides of the sheet.

Messrs. Donkin and Bacon had for some years previous to this date been busily engaged with printing machines, and had indeed, in 1813, obtained a patent for an

* The black parts in these little diagrams, 1515, 1516, indicate the inking apparatus; the diagonal lines, the cylinders upon which the paper to be printed is applied; the perpendicular lines, the plates or types; and the arrows show the track pursued by the sheet of paper.

apparatus, in which the types were placed upon the sides of a revolving prism; the ink was applied by a roller, which rose and fell with the eccentricities of the prismatic surface, and the sheet was wrapped upon another prism fashioned so as to coincide with the eccentricities of the type prism. One such machine was erected for the University of Cambridge. (See *fig.* 1519.) It was a beautiful specimen of ingenious contrivance and good workmanship. Though it was found to be too complicated for common operatives, and defective in the mechanism of the inking process; yet it exhibited for the first time the elastic inking rollers, composed of glue combined with treacle, which alone constitute one of the finest inventions of modern typography.

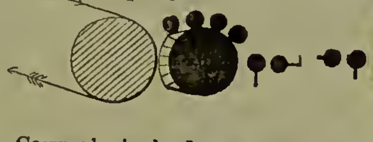
1519



Donkin and Bacon's for type.

In the year 1815, Mr. Cowper turned his mind to the subject of printing machines, and in co-operation with his partner, Mr. Applegath, carried them to an unlooked-for degree of perfection. In 1815, Mr. Cowper obtained a patent for curving stereotype plates, for the purpose of fixing them on a cylinder. Several machines so mounted, capable of printing 1000 sheets per hour upon both sides, are at work at the present day. See *figs.* 1520, and 1521. In these machines, Mr. Cowper places two paper cylinders side by side, and against each of them a cylinder for holding the plates; each of these four cylinders is about two feet in diameter. Upon the surface of the stereotype-plate cylinder, four or five inking rollers of about three inches in diameter are placed; they are kept in their position by a frame at each end of the said cylinder, and the axles of the rollers rest in vertical slots of the frame, whereby having perfect freedom of motion, they act by their gravity alone, and require no adjustment.

1520



Cowper's single, for curved stereotype.

1521

Cowper's double, for both sides of the sheet.

The frame which supports the inking rollers, called the waving-frame, is attached by hinges to the general framework of the machine; the edge of the stereotype-plate cylinder is indented, and rubs against the waving-frame, causing it to vibrate to and fro, and consequently to carry the inking rollers with it, so as to give them an unceasing traverse movement. These rollers distribute the ink over three-fourths of the surface of the cylinder, the other quarter being occupied by the curved stereotype plates. The ink is contained in a trough, which stands parallel to the said cylinder, and is formed by a metal roller revolving against the edge of a plate of iron; in its revolution it gets covered with a thin film of ink, which is conveyed to the plate cylinder by a distributing roller vibrating between both. The ink is diffused upon the plate cylinder, as before described; the plates in passing under the inking rollers become charged with the coloured varnish; and as the cylinder continues to revolve, the plates come into contact with a sheet of paper on the first paper cylinder, which is then carried by means of tapes to the second paper cylinder, where it receives an impression upon its opposite side from the plates upon the second cylinder. Thus the printing of the sheet is completed.

In order to adapt this method of inking to a flat type-form machine, it was merely requisite to do the same thing upon an extended flat surface or table, which had been performed upon an extended cylindrical surface. Accordingly, Messrs. Cowper and Applegath constructed a machine for printing both sides of the sheet from type, including the inking apparatus, and the mode of conveying the sheet from the one paper cylinder to the other, by means of drums and tapes. It is highly creditable to the scientific judgment of these patentees, that in new-modelling the printing machine, they dispensed with forty wheels, which existed in Mr. König's apparatus, when Mr. Bensley requested them to apply their improvements to it.

1522

Cowper's inking table and roller.

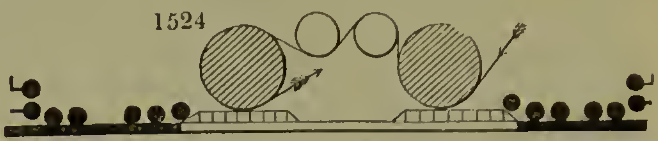
The distinctive advantages of these machines, and which have not hitherto been equalled, are the uniform distribution of the ink, the equality as well as delicacy with which it is laid upon the types, the diminution in its expenditure, amounting to one half upon a given quantity of letterpress, and the facility with which the whole mechanism is managed. The hand inking-roller and distributing-table, now so common in every printing-office in Europe and America, is the invention of Mr. Cowper, and was specified in his patent. The vast superiority of the inking apparatus in his machines, over the balls used of old, induced him to apply it forthwith to the common press, and most successfully. See *fig.* 1522.

To construct a printing machine which shall throw off two sides at a time with exact register, that is, with the second side placed precisely upon the back of the first, is a very difficult problem, which was practically solved by Messrs. Applegath and

1523

Applegath and Cowper's single.

1524

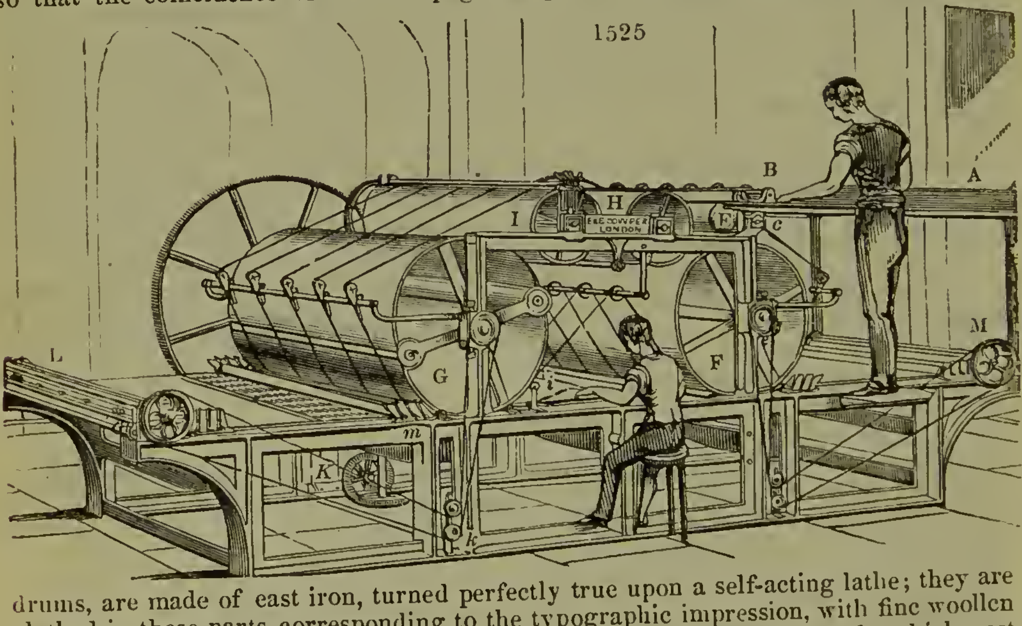


Applegath and Cowper's double.

Cowper. It is comparatively easy to make a machine which shall print the one side of a sheet of paper first, and then the other side, by the removal of one form, and the introduction of another; and thus far did Mr. König advance. A correct register requires the sheet, after it has received its first impression from one cylinder, to travel round the peripheries of the cylinders and drums, at such a rate as to meet the types of the second side at the exact point which will ensure this side falling with geometrical nicety upon the back of the first. For this purpose, the cylinders and drums must revolve at the very same speed as the carriage underneath; hence the least incorrectness in the workmanship will produce such defective typography as will not be endured in book-printing at the present day, though it may be tolerated in newspapers. An equable distribution of the ink is of no less importance to beautiful letterpress. See *figs.* 1523, 1524.

The machines represented in *figs.* 1525, 1526, 1527, are different forms of those which have been patented by Messrs. Applegath and Cowper. That shown in *figs.* 1525, 1527, prints both sides of the sheet during its passage, and is capable of throwing off nearly 1000 finished sheets per hour. The moistened quires of blank paper being piled upon a table, A, the boy, who stands on the adjoining platform, takes up one sheet after another, and lays them upon the feeder B, which has several linen girths passing across its surface, and round a pulley at each end of the feeder; so that whenever the pulleys begin to revolve, the motion of the girths carries forward the sheet, and delivers it over the entering roller E, where it is embraced between two series of endless tapes, that pass round a series of tension rollers. These tapes are so placed as to fall partly between, and partly exterior to, the pages of the printing; whereby they remain in close contact with the sheet of paper on both of its sides during its progress through the machine. The paper is thus conducted from the first printing cylinder F, to the second cylinder G, without having the truth of its register impaired, so that the coincidence of the two pages is perfect. These two great cylinders, or

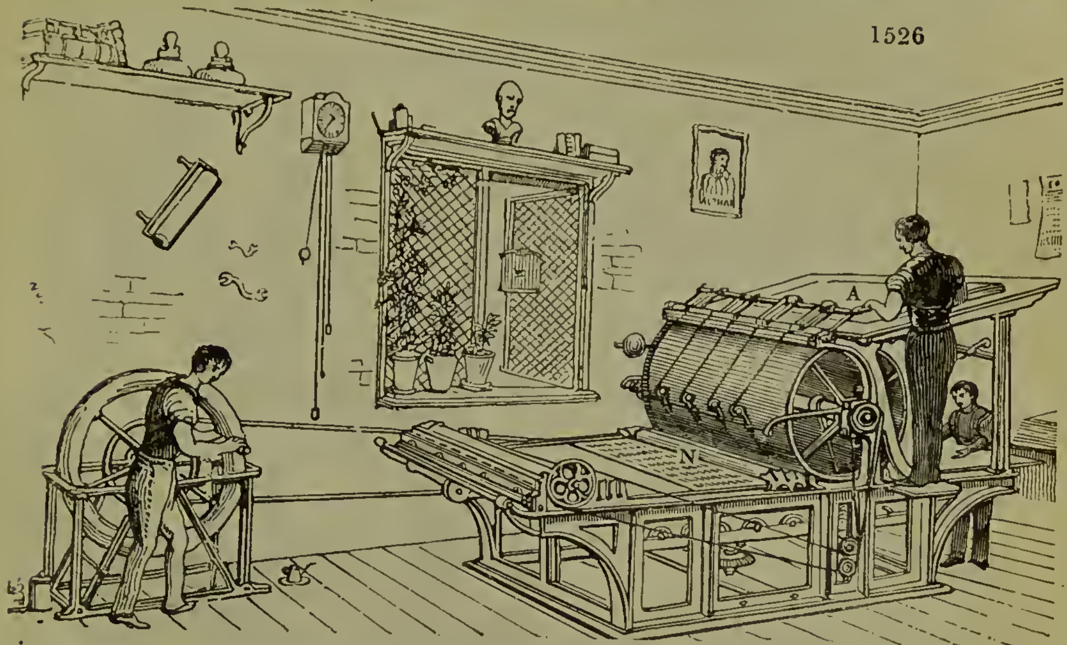
1525



drums, are made of cast iron, turned perfectly true upon a self-acting lathe; they are clothed in these parts, corresponding to the typographic impression, with fine woollen cloth, called *blankets* by the pressmen, and revolve upon powerful shafts which rest in brass bearings of the strong framing of the machine. These bearings, or plummer blocks, are susceptible of any degree of adjustment, by set screws. The drums H and I are made of wood; they serve to conduct the sheet evenly from the one printing cylinder to the other.

One series of tapes commences at the upper part of the entering drum E, proceeds in contact with the right-hand side and under surface of the printing cylinder F, passes next over the carrier-drum H, and under the carrier-drum I; then encompassing the left-hand side and under portion of the printing drum G, it passes

1526

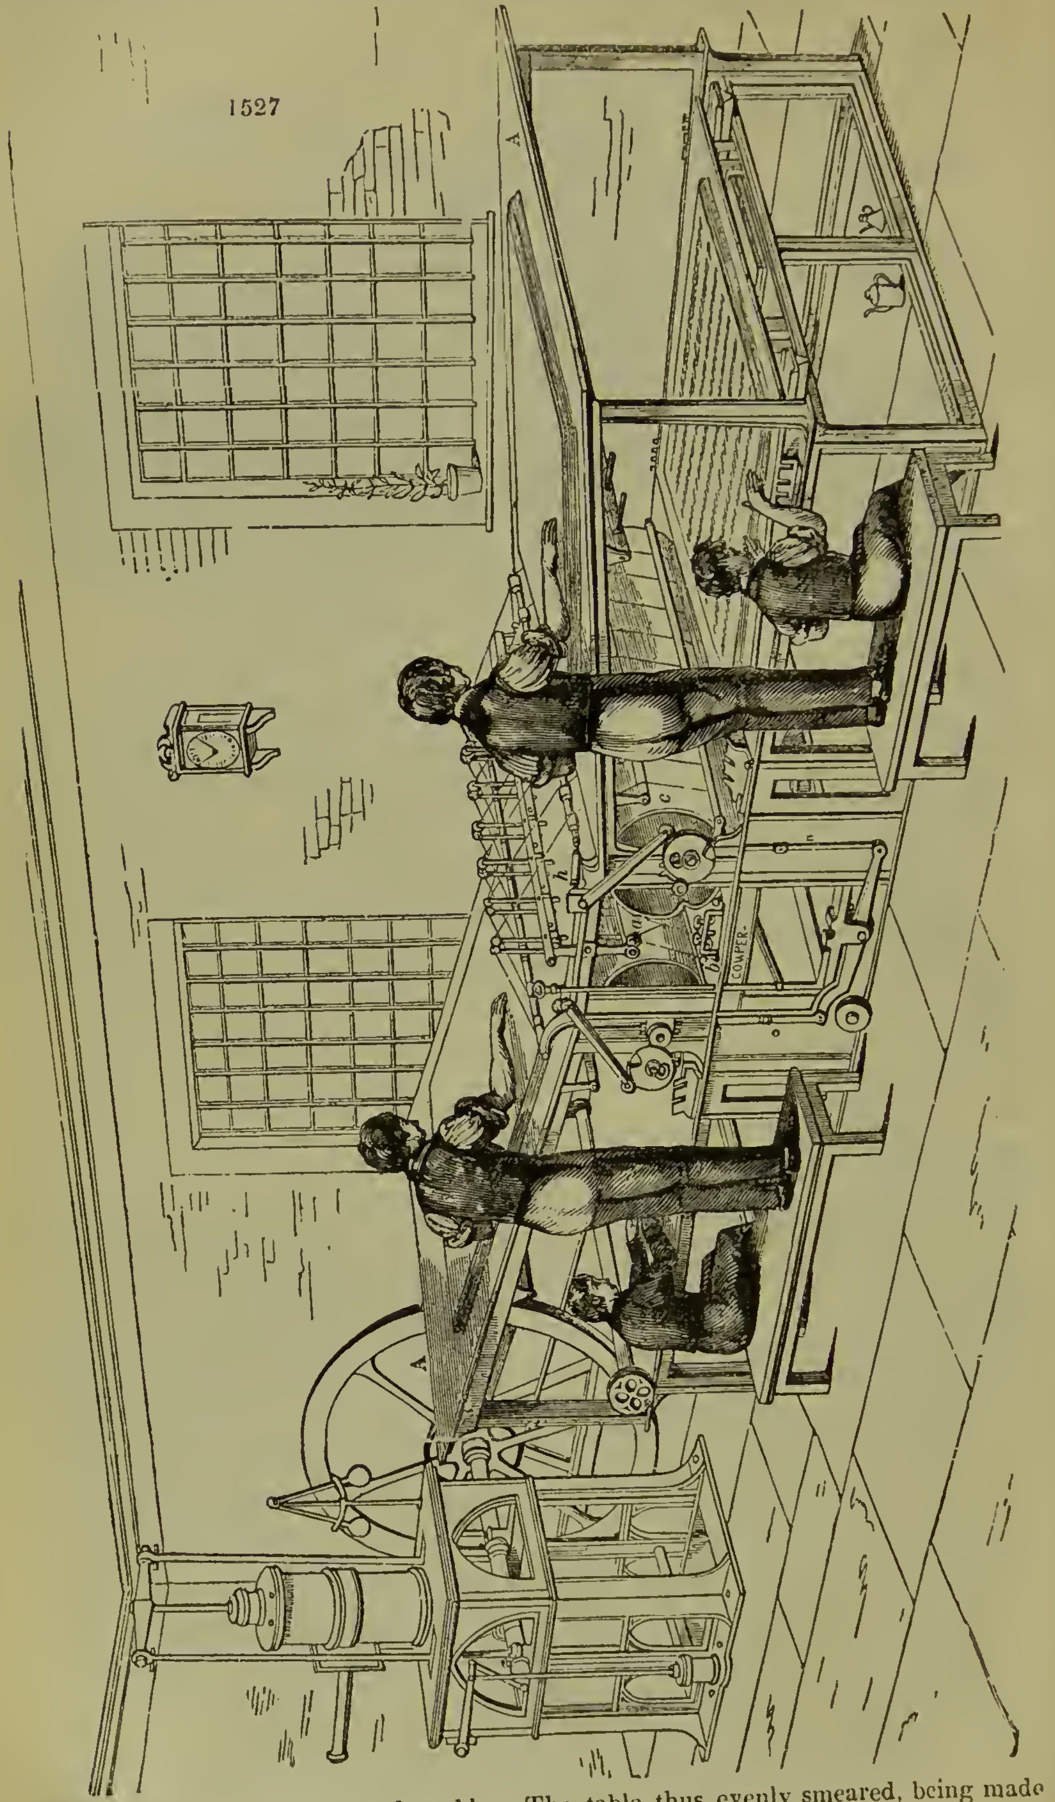


in contact with the small tension rollers *a, b, c, d, fig.* 1527, and finally arrives at the roller E, which may be called the commencement of the one series of endless tapes. The other series may be supposed to commence at the roller *h;* it has an equal number of tapes, and corresponds with the former in being placed upon the cylinders so that the sheets of paper may be held securely between them. This second series descends from the roller *h, fig.* 1527, to the entering drum E, where it meets and coincides with the first series in such a way that both sets of tapes proceed together *under* the printing cylinder F, *over* H, *under* I, and *round* G, until they arrive at the roller *i, fig.*1525, where they separate, after having continued in contact, except at the places where the sheets of paper are held between them. The tapes descend from the roller *i*, to a roller at *k*, and, after passing in contact with rollers at *l, m, n,* they finally arrive at the roller *h*, where they were supposed to commence. Hence two series of tapes act invariably in contact, without the least mutual interference.

The various cylinders and drums revolve very truly by means of a system of toothed wheels and pinions mounted at their ends. Two horizontal forms of types are laid at a certain distance apart upon the long carriage M, adjoining to each of which there is a flat metallic plate, or inking table, in the same plane. The common carriage, bearing its two forms of type and two inking tables, is moved backwards and forwards, from one end of the printing machine to the other, upon rollers attached to the frame-work, and in its traverse brings the types into contact with the sheet of paper clasped by the tapes round the surfaces of the printing cylinders. This alternate movement of the carriage is produced by a pinion working alternately into the opposite sides of a rack under the table. The pinion is driven by the bevel wheels K.

The mechanism for supplying the ink, and distributing it over the forms, is one of the most ingenious and valuable inventions belonging to this incomparable machine, and is so nicely adjusted, that a single grain of the pigment may suffice for printing one side of a sheet. Two similar sets of inking apparatus are provided; one at each end of the machine, adapted to ink its own form of type. The metal roller L, called the *ductor* roller, as it draws out the supply of ink, has a slow rotatory motion communicated to it by a catgut cord, which passes round a small pulley upon the end of the shaft of the printing cylinder G. A horizontal plate of metal, with a straight-ground edge, is adjusted by set screws, so as to stand nearly in contact with the ductor roller. This plate has an upright ledge behind, converting it into a sort of trough or magazine, ready to impart a coating of ink to the roller, as it revolves over the table. Another roller, covered with elastic composition (see *supra*), called the vibrating roller, is made to travel between the ductor roller and the inking table; the vibrating roller, as it rises, touches the ductor roller for an instant, abstracts a film of ink from it, and then descends to transfer it to the table. There are 3 or 4 small rollers of distribution, placed somewhat diagonally across the table at M (inclined only two inches from a parallel to the end of the frame), furnished with long slender axles, resting in vertical slots, whereby they are left at liberty to revolve and to traverse at the same time; by which compound movement they are enabled to efface all inequality in the surface of the varnish, or to effect a perfect

1527



distribution of the ink along the table. The table thus evenly smeared, being made to pass under the 3 or 4 proper inking rollers N, *fig.* 1526, imparts to them an uniform film of ink, to be immediately transferred by them to the types. Hence each time that the forms make a complete traverse to and fro, which is requisite for the printing of every sheet, they are touched no less than eight times by the inking rollers. Both the distributing and inking rollers turn in slots, which permit them to rise and fall so as to bear with their whole weight upon the inking table and the form, whereby they never stand in need of any adjustment by screws, but are always ready for work when dropped into their respective places.

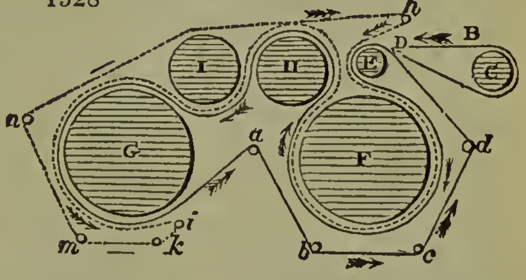
Motion is given to the whole sytem of apparatus by a strap from a steam engine going round a pulley placed at the end of the axle at the back of the frame.

The operation of printing is performed as follows :—See *fig.* 1527.

The sheets being carefully laid, one by one, upon the linen girths, at the feeder B, the rollers C and D are made to move, by means of a segment wheel, through a portion of a revolution. This movement carries on the sheet of paper sufficiently to introduce it between the two series of endless tapes at the point where they meet each other upon the entering drum E. As soon as the sheet is fairly embraced between the tapes, the rollers C and D are drawn back, by the operation of a weight, to their original position, so as to be ready to introduce another sheet into the machine. The sheet advancing between the endless tapes, applies itself to the blanket upon the printing cylinder F, and as it revolves meets the first form of types, and receives their impression; after being thus printed on one side, it is carried over H and under I, to the blanket upon the printing cylinder G, where it is placed in an inverted position; the printed side being now in contact with the blanket, and the white side being outwards, meets the second form of types at the proper instant, so as to receive the second impression, and get completely printed. The perfect sheet, on arriving at the point *i*, where the two series of tapes separate, is tossed out by centrifugal force into the hands of a boy.

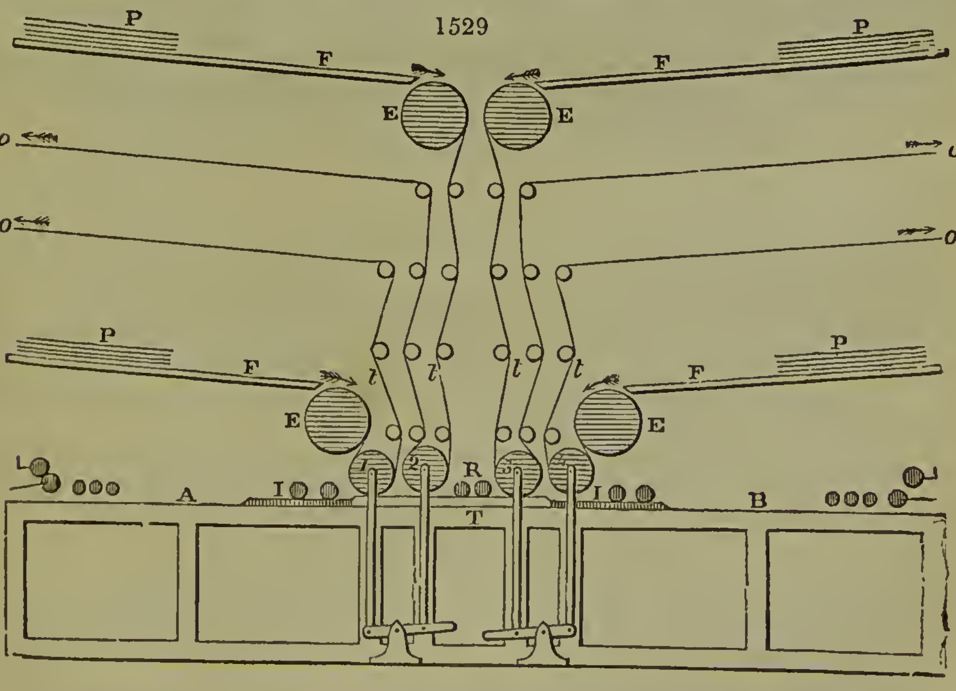
The diagram, *fig.* 1528, shows the arrangement of the tapes, agreeably to the preceding description; the feeder B, with the rollers C and D, is seen to have an independent endless girth.

1528



The diagram, *fig.* 1529, explains the structure of a machine contrived by Messrs. Applegath and Cowper for printing *The Times* newspaper; but which is now superseded by Mr. Applegath's Vertical Printing Machine. Here there are four places to lay on the sheets, and four to take them off; consequently, the assistance of eight lads is required. P, P, P, P, are the four piles of paper; F, F, F, F, are the four feeding-boards; E, E, E, E, are

1529



the four entering drums, upon which the sheets are introduced between the tapes *t*, *t*, *t t* whence they are conducted to the four printing cylinders, 1, 2, 3, 4 ; T is the form of type ; I, I, are two inking tables, of which one is placed at each end of the form. The inking apparatus is similar to that above described, with the addition of two central inking rollers R, which likewise receive their ink from the inking tables. The printing cylinders 1, 2, 3, 4, are made to rise and fall about half an inch ; the first and third simultaneously, as also the second and fourth. The form of type, in passing from A to B, prints sheets at 1 and 3; in returning from B to A, it prints sheets at 4 and 2 ; while the cylinder alternately falls to give the impression, and rises to permit the form to pass untouched.

Each of the lines marked *t*, consists of two endless tapes, which run in contact in the parts shown, but separate at the entering drums E, and at the taking-off parts *o*, *o*, *o*, *o*. The return of the tapes to the entering drum is omitted in the diagram, to avoid confusion of the lines.

The sheets of paper being laid upon their respective feeding-boards, with the fore edges just in contact with the entering drum, a small roller, called the drop-down roller, falls at proper intervals, down upon the edges of the sheets ; the drum and the roller being then removed, instantly carry on the sheet, between the tapes *t*, downwards to the printing cylinder, and thence upwards to *o*, *o*, *o*, *o*, where the tapes are parted, and the sheet falls into the hands of the attendant boy.

This invention fully answered the purpose of *The Times* until the immense demand upon its powers rendered it necessary to provide a machine which could *work off from* 12,000 *to* 15,000 *copies of the paper per hour.*

Mr. Applegath, to whom the world is indebted for the invention of the printing machine capable of doing this large duty, decided on abandoning the reciprocating motion of the type form, arranging the apparatus so as to render the motion continuous. This necessarily involved circular motion, and accordingly he resolved upon attaching the columns of type to the sides of a large drum or cylinder, placed with its axis vertical, instead of the horizontal frame which had been hitherto used. A large central drum is erected, capable of being turned round its axis. Upon the sides of this drum are placed vertically the columns of type. These columns, strictly speaking, form the sides of a polygon, the centre of which coincides with the axis of the drum, but the breadth of the columns is so small compared with the diameter of the drum, that their surfaces depart very little from the regular cylindrical form. On another part of this drum is fixed the inking table. The circumference of this drum in *The Times* printing machine measures 200 inches, and it is consequently 64 inches in diameter.

The general form and arrangement of the machine are represented *fig.* 1530, where D is the great central drum which carries the type and inking tables.

This drum is surrounded by eight cylinders, R, R, &c., also placed with their axes vertical, upon which the paper is carried by tapes in the usual manner. Each of these cylinders is connected with the drum by toothed wheels, in such a manner that their surfaces respectively must necessarily move at exactly the same velocity as the surface of the drum. And if we imagine the drum thus in contact with these eight cylinders to be put in motion, and to make a complete revolution, the type form will be pressed successively against each of the eight cylinders, and if the type were previously inked, and each of the eight cylinders supplied with paper, eight sheets of paper would be printed in one revolution of the drum.

It remains, therefore, to explain, first, how the type is eight times inked in each revolution ; and secondly, how each of the eight cylinders is supplied with paper to receive their impression.

Beside the eight paper cylinders are placed eight sets of inking rollers ; near these are placed two ductor rollers. These ductor rollers receive a coating of ink from reservoirs placed above them. As the inking table attached to the revolving drum passes each of these ductor rollers, it receives from them a coating of ink. It next encounters the inking rollers, to which it delivers this coating. The types next, by the continued revolution of the drum, encounter these inking rollers, and receive from them a coating of ink, after which they meet the paper cylinders, upon which they are impressed, and the printing is completed.

Thus in a single revolution of the great central drum the inking table receives a supply eight times successively from the ductor rollers, and delivers over that supply eight times successively to the inking rollers, which, in their turn, deliver it eight times successively to the faces of the type, from which it is conveyed finally to the eight sheets of paper held upon the eight cylinders by the tapes.

Let us now explain how the eight cylinders are supplied with paper. Over each of them is erected a sloping desk, *h*, *h*, &c., upon which a stock of unprinted paper is deposited. Beside this desk stands the "layer on," who pushes forward the paper, sheet by sheet, towards the fingers of the machine.

These fingers, seizing upon it, first draw it down in a vertical direction between tapes in the eight vertical frames until its vertical edges correspond with the position of the form of type on the printing cylinder. Arrived at this position its vertical motion is stopped by a self-acting apparatus provided in the machine, and it begins to move horizontally, and it is thus carried towards the printing cylinder by the tapes. As it passes round this cylinder it is impressed upon the type, and printed. It is then carried back horizontally by similar tapes on the other side of the frame, until it arrives at another desk, where the "taker off" awaits it. The fingers of the machine are there disengaged from it, and the "taker off" receives it, and disposes it upon the desk. This movement goes on without interruption; the moment that one sheet descends from the hands of the "layer on," and being carried vertically down-

1530

wards begins to move horizontally, space is left for another, which he immediately supplies, and in this manner he delivers to the machine at the average rate of two sheets every five seconds; and the same delivery taking place at each of the eight cylinders, there are 16 sheets delivered and printed every five seconds.

It is found that by this machine in ordinary work between 10,000 and 11,000 per hour can be printed; but with very expert men to deliver the sheets, a still greater speed can be attained. Indeed, the velocity is limited, not by any conditions affecting the machine, but by the power of the men to deliver the sheets to it.

In case of any misdelivery a sheet is spoiled, and, consequently, the effective performance of the machine is impaired. If, however, a still greater speed of printing were required, the same description of machine, without changing its principle, would be sufficient for the exigency; it would be necessary that the types should be surrounded with a greater number of printing cylinders.

It may be right to observe, that these surrounding cylinders and rollers, in the case of *The Times* machine, are not uniformly distributed round the great central drum; they are so arranged as to leave on one side of that drum an open space equal to the width of the type form. This is necessary in order to give access to the type form so as to adjust it.

One of the practical difficulties which Mr. Applegath had to encounter in the solution of the problem, which he has so successfully effected, arose from the shock produced to the machinery by reversing the motion of the horizontal frame, which in the old machine carried the type form and inking table, a moving mass which weighed a ton! This frame had a motion of 88 inches in each direction, and it was found that such a weight could not be driven through such a space with safety at a greater rate than about 45 strokes per minute, which limited its *maximum* producing power to 5000 sheets per hour.

Another difficulty in the construction of this vast piece of machinery, was so to regulate the self-acting mechanism that the impression of the type form should always be made in the centre of the page, and so that the space upon the paper occupied by the printed matter on one side may coincide exactly with that occupied by the printed matter on the other side.

The type form fixed on the central drum moves at the rate of 70 inches per second, and the paper is moved in contact with it of course at exactly the same rate. Now, if by any error in the delivery or motion of a sheet of paper, it arrive at the printing cylinder 1-70th part of a second too soon or too late, the relative position of the columns will vary by 1-70th part of 70 inches—that is to say, by one inch. In that case the edge of the printed matter on one side would be an inch nearer to the edge of the paper than on the other side. This is an incident which rarely happens, but when it does, a sheet, of course, is spoiled. The waste, however, from that cause is considerably less in the present vertical machine than in the former less powerful horizontal one.

The vertical position of the inking rollers is more conducive to the goodness of the work — for the type and engraving are only touched on their extreme surface — than the horizontal machine, where the inking rollers act by gravity; also any dust shaken out of the paper, which formerly was deposited upon the inking rollers, now falls upon the floor. With this machine 50,000 impressions have been taken without stopping to brush the form or table.

The principle of this vertical cylinder machine is capable of almost unlimited extension.

An American machine, the invention of R. Hoe and Company, of New York, has within the last two years (1860) been introduced to this country. Machines of this description have been made for *The Times*, and other newspaper offices, by Mr. Whitworth of Manchester. The following is Mr. Hoe's description of this machine.

A horizontal cylinder of about 4½ feet in diameter is mounted on a shaft, with appropriate bearings; about one-fourth of the circumference of this cylinder constitutes the bed of the press, which is adapted to receive the form of types—the remainder is used as a cylindrical distributing table. The diameter of the cylinder is less than that of the form of types, in order that the distributing portion of it may pass the impression cylinders without touching. The ink is contained in a fountain placed beneath the large cylinder, from which it is taken by a ductor roller, and transferred by a vibrating distributing roller to the cylindrical distribution table; the fountain roller receives a slow and continuous rotary motion, to carry up the ink from the fountain.

The large cylinder being put in motion, the form of types thereon is, in succession, carried to eight corresponding horizontal impression cylinders, arranged at proper distances around it, which give the impression of eight sheets, introducing one at each impression cylinder. For each impression cylinder there are two inked rollers, which vibrate on the distributing surface while taking a supply of ink, and at the proper time pass over the form, when they again fall to the distributing surface. Each page is locked up upon a detached segment of the large cylinder, called by the compositors a "turtle," and this constitutes the bed and chase. The column rules run parallel with the shafts of the cylinder, so as to bind to types near the top. These wedge-shaped column rules are held down to the bed or "turtle" by tongues, projecting at intervals along their length, and sliding in rebated grooves cut cross-wise in the face of the bed; the space in the grooves between the column rules being filled with sliding blocks of metal, accurately fitted, the outer surface level with the surface of the bed, the ends next the column rules being cut away underneath to receive a projection on the sides of the tongues and screws at the end and side of each page to lock them together, the types are as secure on this cylinder as they can be on the old flat bed.

In *The Times* office there are two of those machines, one of them being a ten-cylinder machine, which is regularly employed to print 16,000 sheets an hour, and it appears capable of printing 18,000. It is only by means of these two American machines, and two of Applegath's, all working on the different sides of the paper, that the enormous supply required every morning can be produced.

The first successful application of steam, as a motive power, to printing presses with a platen and vertical pressure, was made in the office where this book is being printed. Convinced of the superiority of the impression made by flat as compared with that of cylindrical pressure, Mr. Andrew Spottiswoode, assisted by his chief engineer, Mr. Brown, succeeded, after many experiments, in perfecting a machine which combines the excellence of the hand press with more than four times its speed, and a uniformity in colour which can never be attained by inking by hand. The main point of the invention is the endless screw or drum which takes the carriage and type under the platen, and after the impression is taken returns it to its original position.

PRINTING AND NUMBERING CARDS.—It will be remembered that in the early days of railway travelling, the ticket system then in vogue at the various stations was a positive nuisance; as every ticket before it was delivered to a passenger had to be stamped, and torn out of a book,—thus causing the loss of considerable time to travellers when many passengers were congregated. The first to remedy this was Mr. Edmondson, who constructed an ingenious apparatus for printing the tickets with consecutive numbers, and also dating the same. This gave great facilities for checking the accounts of the station clerks; but owing to the imperfect manner of inking, consequent on the construction of the apparatus, the friction to which the tickets were exposed, before they were delivered up, in a great manner obliterated the printing, and occasionally rendered them quite illegible. By Messrs. Church and Goddard's machine for printing, numbering, cutting, counting, and packing railway tickets, this difficulty is removed, and great speed is attained in manufacturing the tickets, as the several operations are simultaneously performed. Pasteboard cut into strips by means of rollers is fed into the machine, by being laid in a trough, and brought under the prongs of a fork (working with an intermitting movement), which pushes the strips successively forward between the first pair of a series of guide or carrying rollers. There are four pairs of rollers, placed so as to conduct the strip through the machine in a horizontal line; and an intermittent movement is given them for the purpose of carrying the strips forward a short distance at intervals. The standards of the machine carry, at the top, a block termed the "platten," as it acts the part of the press-head in the common printing machine,—portions of it projecting downwards between the upper rollers of the first and second, and second and third pairs of carrying rollers, nearly to the horizontal plane, in which the pasteboard lies, so as to sustain it at those points while it receives the pressure of the printing types and numbering discs, hereafter referred to. The types to designate the nature of the ticket, as "Birmingham, First Class," are secured in a "chase," upon a metal plate or table, which also carries the numbering discs for imprinting the figures upon the cards; and the table by a cam action is alternately raised, to bring the types and numbering discs in contact with the pasteboard, and then lowered into a suitable position, to admit of an inking roller moving over the types and numbering discs, and applying ink thereto. The table likewise carries at one end a knife, which acts in conjunction with a knife-edge, projecting downwards from the fixed head of the machine, and thereby gives the cross-cut to the strips between the third and fourth pairs of carrying rollers,—thus severing each into a given number of tickets. The strip of pasteboard which is fed into the machine stops on arriving at the second pair of carrying rollers; and, on the ascent of the printing table, the types print on that portion which is between the first and second pairs of rollers. The strip then passes on to the third pair of rollers, where it stops; and, on the table again ascending, the numbering discs imprint the proper number upon the pasteboard between the second and third pairs; the type, in the meanwhile, printing what is to be the next following ticket. On the next ascent of the table, the strip has advanced to the fourth pair of rollers; and the knives being now brought into contact, the printed and numbered portion of the strip is severed. The now completed ticket is lastly delivered by the fourth pair of rollers into a hollow guide piece, and conducted to a box below, provided with a piston, which, to facilitate the packing of the tickets in the box, can be adjusted to any height to receive the tickets as they fall. To avoid the necessity of having to count the tickets after they are taken from the receiving box, a counting apparatus, connected with the working parts of the machine, is made to strike a bell on the completion of every hundred or more tickets, so as to warn the attendant to remove them from the box. The inking apparatus is assimilated in character to self-acting inkers in ordinary printing presses; and the numbering discs are worked in a manner very similar to those for paging books.

A simple arrangement of apparatus for printing and numbering cards has been introduced by Messrs. Harrild and Sons. The types are fixed in a metal frame, which also carries the numbering discs. This frame is mounted on a rocking shaft, and is furnished with a handle, whereby it is rocked to bring down the types and discs upon the card, to produce the impression. When the frame is raised again, the units disc is moved forward one figure, and the types are inked by a small roller, which takes its supply of ink from an inking table, that forms the top of the frame.

M. Baranowski, of Paris, invented a machine for printing and numbering tickets, and also indicating the number printed. The types and numbering discs are carried by a horizontal rotating shaft, upon which, near each end thereof, is a metal disc; and upon the periphery of these discs a metal frame is affixed, which carries the types and numbering discs, and corresponds in curvature with the edge of the discs. The types for printing the inscription upon the ticket are arranged at right angles to the length of the shaft, which position admits of some lines of the inscription being printed in one colour, and the remainder in another colour. In the type frame a slot or opening is formed lengthwise of the shaft; and behind this opening are three numbering discs, and three discs for indicating the quantity of tickets numbered,—all standing in the same row. The numbering discs are made with raised figures, which project through the slot, in order to print the number upon the ticket; and on the peripheries of the registering discs (which move simultaneously with their corresponding numbering discs), the figures are engraved. The tickets to be printed and numbered are placed in a rectangular box or receiver, having at the bottom a flat sliding piece, which has a reciprocating motion for the purpose of pushing the lowest ticket out of the box, through an opening in the front side thereof, beneath an elastic pressing-roller of India-rubber; the type-frame (with the types and figures properly inked), is at the same time brought, by the rotation of its shaft, into contact with the ticket beneath the pressing roller, and as it continues its motion, it causes the ticket to move forward beneath the pressing roller, and to be properly printed and numbered. The ticket then falls from the machine; and the type-frame, carried on by the revolution of the shaft, brings that number on the registering discs which corresponds with the number printed on the ticket, under a small opening in the case, covered with glass; whereby the number of tickets printed will be indicated.

PRINTING, NATURE. See NATURE PRINTING.

PRINTING ROLLERS. Elastic inking rollers were introduced by Messrs. Donkin and Bacon. They are made of a mixture of glue and treacle, or of glue and honey; the American honey, it is said, being preferred. 1 pound of good glue is softened by soaking in cold water for twelve hours, and then it is united, by means of heat, with about 2 pounds of ordinary treacle. See PRINTING.

Messrs. Hoe and Co. give the following directions for making and preserving composition rollers:—For *cylinder-press rollers*, Cooper's No. 1. × glue is sufficient for ordinary purposes, and will be found to make as durable rollers as higher priced glues.

Place the glue in a bucket or pan, and cover it with water; let it stand half an hour, or until about half penetrated with water (care should be used not to let it soak too long), then pour it off, and let it remain until it is soft. Put it in the kettle and cook it until it is thoroughly melted. If too thick, add a little water until it becomes of proper consistency. The molasses may then be added, and well mixed with the glue by frequent stirring. When properly prepared, the composition does not require boiling more than an hour. Too much boiling candies the molasses, and the roller consequently will be found to lose its suction much sooner. In proportioning the material, much depends upon the weather and temperature of the place in which the rollers are to be used. 8 pounds of glue to 1 gallon of sugar-house molasses, or syrup, is a very good proportion for summer, and 4 pounds of glue to 1 gallon of molasses for winter use.

Hand-press rollers may be made of Cooper's No. $1\frac{1}{4}$ (one and a quarter) glue, using more molasses, as they are not subject to so much hard usage as *cylinder-press rollers*, and do not require to be as strong; for the more molasses that can be used the better is the roller. Before pouring a roller, the mould should be perfectly clean, and well oiled with a swab, but not to excess.

Rollers should not be washed immediately after use, but should be put away with the ink on them, as it protects the surface from the action of the air. When washed and exposed to the atmosphere for any length of time, they become dry and skinny. They should be washed about half an hour before using them. In cleaning a *new* roller, a little oil rubbed over it will loosen the ink, and it should be scraped clean with the back of a case knife. It should be cleaned in this way for about one week, when *lye* may be used. New rollers are often spoiled by washing them too soon with lye. Camphene may be substituted for oil; but owing to its combustible nature it is objectionable, as accidents may arise from its use.

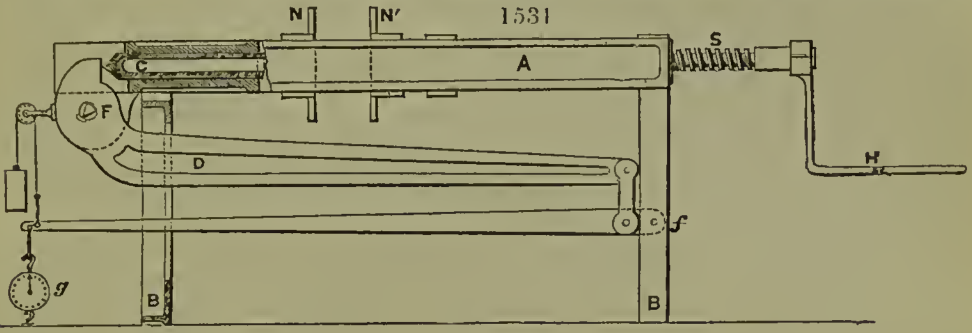
PROPYLENE. A gas obtained among the products of the decomposition of amylic alcohol. See COAL GAS.

PROTEINE. The name given to a somewhat hypothetical substance obtained by digesting albuminous matters in weak caustic potash, and precipitating by acetic acid. E. Millon (*Comptes Rendus*) proposes as a test for the so-called protein compounds, that a solution of mercury in an equal weight of concentrated nitric acid, when diluted with some water, be added to a solution of the animal matter in an alkali or sulphuric acid. When the mercurial solution is added in solutions containing only $\frac{1}{100,000}$ of nitrogenous matter, a more or less intense red colour is produced.

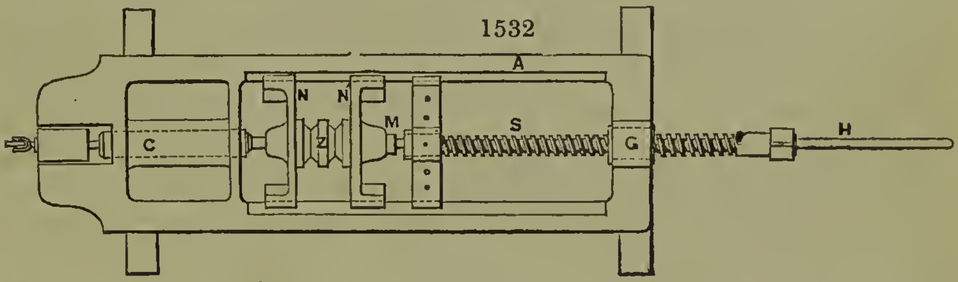
PROTOGINE (*protos*, first — *ginomai*, formed). A granite composed of felspar, quartz, and talc. This term is nearly restricted to the French geologists.

PROVING MACHINE. The drawing shows a useful machine for testing the quality and power of India-rubber springs, designed by Mr. George Spencer, of the firm of Geo. Spencer and Co., and used by them for that purpose, and referred to from CAOUTCHOUC. *Fig.* 1531 shows an elevation, partly in section, of the machine; *fig.*

1531



1532



1532 a plan of the same. A is a strong cast-iron frame, supported by two cast-iron standards, B; C is a sliding piston, working in a hole cast in the end of frame A, one end of which impinges against the short arm of a strong cast-iron lever, D, forming one of a system of compound levers as shown, having fulcrums at F and *f*, and provided with a Salter's balance, *g*, to register the power exerted by the spring.

At the other end of frame, A, a brass nut, G, is placed in a hole in the frame, through which a square-threaded screw, S, works by means of the handle, H, or by a long lever of wrought iron, according to the power of spring to be tested.

The spring to be tested is placed between the two sliding guide plates, N, N′, and a wrought-iron bolt passed through the plates, N, N′, and spring, Z, and passing into the hollow piston, C, for the purpose of keeping the spring in correct position, and receiving in its hollow head, M, the end of the screw, S. The action may be thus described:—The handle, H, being turned, the screw, S, advances and pushes on the plate, N′, by means of the bolt-head, M. The other plate, N, rests against the piston, C, and is pressed against it by the intervening spring, Z. The leverage, D, is so arranged that 1 lb. on the dial is equal to 2 cwt. on the spring, or, in other words, is 1 in 224. Springs of a force of 20 tons can be tested by this machine safely. (See CAOUTCHOUC.)

PROVISIONS, CURING OF. See MEATS, PRESERVED; PUTREFACTION.

PRUSSIAN BLUE. (*Berliner-blau*, Germ.) This is a chemical compound of iron and cyanogen. See CYANOGEN. When organic matters abounding in nitrogen, such as dried blood, horns, hair, skins, or hoofs of animals, are triturated along with potash in a strongly ignited iron pot, a dark grey mass is obtained, that affords to water the liquor originally called *lixivium sanguinis*, or blood lye. This solution yields crystals, known in commerce as the prussiate of potash. (See POTASH, PRUSSIATE.) If to this salt solutions of iron be added, prussian blue is formed. If the iron be but partially oxidised in the salt employed, it will afford a precipitate, at first pale blue, which turns dark blue in the air. If, however, the salt employed contains fully oxidised iron (peroxide of iron) the precipitate is at once a dark blue. The white cyanide of iron (the prussiate of the pure protoxide) when exposed to the air in a moist condition, becomes, as above stated, dark blue; yet the new combination formed in this case through absorption of oxygen, is essentially different from that resulting from the precipitation by the peroxide of iron, since it contains an excess of the peroxide in addition to the usual two cyanides of iron. It has been therefore called *basic* prussian blue, and, from its dissolving in pure water, *soluble* prussian blue.

Both kinds of prussian blue agree in being void of taste and smell, in attracting humidity from the air when they are artificially dried, and being decomposed at a heat above 348° F. The neutral or insoluble prussian blue is not affected by alcohol; the basic, when dissolved in water, is not precipitated by that liquid. Neither is acted upon by dilute acids; but they form with concentrated sulphuric acid a white pasty mass, from which they are again reproduced by the action of cold water. They are decomposed by strong sulphuric acid at a boiling heat, and by strong nitric acid at common temperatures; but they are hardly affected by the muriatic. They become green with chlorine, but resume their blue colour when treated with disoxidising reagents. When prussian blue is digested in warm water along with potash, soda, or lime, peroxide of iron is separated, and a ferroprussiate of potash, soda, or lime remains in solution. If the prussian blue has been previously purified by boiling in dilute muriatic acid, and washing with water, it will afford by this treatment a solution of ferrocyanodide of potassium, from which by evaporation this salt may be obtained in its purest crystalline state. When the powdered prussian blue is diffused in boiling water, and digested with red oxide of mercury, it parts with all its oxide of iron, and forms a solution of bi-cyanodide, improperly called prussiate of mercury; consisting of 79·33 mercury, and 20·67 cyanogen; or upon the hydrogen equivalent scale, of 200 mercury, and $52 = (26 \times 2)$.

The precipitation of prussian blue.— Green sulphate of iron is always employed by the manufacturer, on account of its cheapness, for mixing with solution of the ferroprussiate, in forming prussian blue, though the red sulphate, nitrate, or muriate of iron would afford a much richer blue pigment. Whatever salt of iron be preferred should be carefully freed from any cupreous impregnation, as this would give the pure blue a dirty brownish cast. The green sulphate of iron is the most advantageous precipitant, on account of its affording protoxide, to convert into ferrocyanide any cyanide of potassium that may happen to be present in the uncrystallised lixivium. The carbonate of potash in that lixivium might be saturated with sulphuric acid before adding the solution of sulphate of iron; but it is more commonly done by adding a certain portion of alum, in which case alumina falls along with the prussian blue; and though it renders it somewhat paler, yet it proportionally increases its weight; whilst the acid of the alum saturates the carbonate of potash, and prevents its throwing down iron-oxide, to degrade by its brown-red tint the tone of the blue. For every pound of pearlash used in the calcination, from two to three pounds of alum are employed in the precipitation. When a rich blue is wished for, the free alkali in the prussian lye may be partly saturated with sulphuric acid, before adding the mingled solutions of copperas and alum. One part of the sulphate of iron is generally allowed for 15 or 20 parts of dried blood, and 2 or 3 of horn-shavings or hoofs. But the proportion will depend very much upon the manipulations; which, if skilfully conducted, will produce more of the cyanides of iron, and require more copperas to neutralise them. The mixed solutions of alum and copperas should be progressively added to the lye as long as they produce any precipitate. This is not at first a fine blue, but a greenish grey, in consequence of the admixture of some white cyanide of iron; it becomes gradually blue by the absorption of oxygen from the air, which is favoured by agitation of the liquor. Whenever the colour seems to be as beautiful as it is likely to become, the liqour is to be run off by a spigot or cock from the bottom of the precipitation vats, into flat cisterns, to settle. The clear supernatant fluid, which is chiefly a solution of sulphate of potash, is then drawn off by a siphon; more water is run on with agitation to wash it, which after settling is again drawn of; and whenever the washings become tasteless, the sediment is thrown upon filter sieves, and exposed to dry, first in the air of a stove, but finally upon slabs of chalk or Paris plaster. But for several purposes, prussian blue may be best employed in the fresh pasty state, as it then spreads more evenly over paper and other surfaces.

A good article is known by the following tests: it feels light in the hand, adheres to the tongue, has a dark lively blue colour, and gives a smooth deep trace; it should not effervesce with acids, as when adulterated with chalk; nor become pasty with boiling water, as when adulterated with starch. The Paris blue, prepared without alum, with a peroxide salt of iron, displays, when rubbed, a copper-red lustre, like indigo. Prussian blue, degraded in its colour by an admixture of free oxide of iron, may be improved by digestion in dilute sulphuric or muriatic acid, washing, and drying. Its relative richness in the real ferroprussiate of iron may be estimated by the quantity of potash or soda which a given quantity of it requires to destroy its blue colour.

Sulphuretted hydrogen passed through prussian blue diffused in water, whitens it; while prussic acid is eliminated, sulphur is thrown down, and the sesquicyanide of iron is converted into the single cyanide. Iron and tin operate in the same way. When prussian blue is made with two atoms of ferrocyanide of potassium instead of one, it becomes soluble in water.

For the mode of applying this pigment in dyeing, see Calico-printing.

A process for prussian blue, which deserves notice, as the first in which that interesting compound has been made to any extent independently of animal matter, was introduced by Mr. Lewis Thompson, who received a medal from the Society of Arts, in 1837, for this invention. He observed that in the common way of manufacturing prussiate of potash, the quantity of nitrogen furnished by a given weight of animal matter is not large, and seldom exceeds 8 per cent.; and of this small quantity, at least one half appears to be dissipated during the ignition. It occurred to him that the atmosphere might be economically made to supply the requisite nitrogen, if caused to act in favourable circumstances upon a mixture of carbou and potash. He found the following to answer. Take of pearlash and coke, each 2 parts; iron turnings, 1 part; grind them together into a coarse powder; place this in an open crucible, and expose the whole for half au hour to a full red heat in an open fire, with occasional stirring of the mixture. During this process, little jets of purple flame will be observed to rise from the surface of the materials. When these cease, the crucible must be removed and allowed to cool. The mass is to be lixiviated; the lixivium, which is a solution of ferrocyanide of potassium, with excess of potash, is to be treated in the nsual way, and the black matter set aside for a fresh operation, with a fresh dose of pearlash. Mr. Thompson states that one pound of pearlash, containing 45 per cent. of alkali, yielded 1355 grains of pure prussian blue, or ferrocyanide of iron; or about 3 ounces avoirdupois.

PRUSSIAN BROWN. A fine deep brown colour obtained by adding the yellow prussiate of potash (*ferroprussiate*) to a solution of sulphate of copper.

PRUSSIATE OF POTASH. See Potash, Prussiate of.

PRUSSIC ACID. See Hydrocyanic Acid.

PSILOMELANE. An ore of Manganese, which see.

PUDDLING OF IRON. The process of converting cast iron into bar or malleable iron. See Iron.

PUMICE-STONE (*Pierre-ponce*, Fr.; *Bimstein*, Germ.) is a spongy, vitreous-looking mineral, consisting of fibres of a silky lustre, interlaced with each other in all directions. It floats upon water, is harsh to the touch, having in mass a mean sp. grav. of 0·914; though brittle, it is hard enough to scratch glass aud most metals. Its colour is usually greyish white; but it is sometimes bluish, greenish, reddish, or brownish. It fuses without addition at the blowpipe into a white enamel. According to Klaproth, it is composed of silica, 77·5; alumina, 17·5; oxide of iron, 2; potassa and soda, 3; in 100 parts. The acids have hardly any action upon pumice-stone. It is used for polishing ivory, wood, marble, metals, glass, &c.; as also skius and parchment. Pumice-stone is usually reckoned to be a volcanic product, resulting, probably, from the action of fire upon obsidians. The chief localities of this mineral are, the Islands of Lipari, Ponza, Ischia, and Vulcano. It is also found in the neighbourhood of Andernach, upon the banks of the Rhine, in Teneriffe, Iceland, Auvergne, &c. It is sometimes so spongy as to be of specific gravity 0·37.

PUMPING MACHINERY. See Water Pressure Engines.

PUOZZOLANA is a volcanic gravelly product, used in making hydraulic mortar. See Cements and Mortars.

PURBECK MARBLE. A hard bluish-grey limestone, so called from its being found in the Isle of Purbeck, where it occurs in the upper beds of the formation of that name. Like the Sussex marble, it is susceptible of a fine polish, and is crowded with the remains of a species of freshwater snail (*Paludina carinifera*), and the beauty of the marble is the result of the pattern produced by the sections of the included shells. These latter are of a much smaller species than those which occur in the Sussex marble, and the difference in the size of the shells affords an easy means of distinguishing between the two marbles.

Many old sepulchral mouuments are partly composed of Purbeck marble, as are also the slender shafts and columns of many of the Gothic churches of this country, of which there are examples in the Temple Church in London, Westminster Abbey, Winchester and Salisbury Cathedrals, &c.

Fine blocks of this marble are still quarried in the Isle of Purbeck, but, except for ecclesiastical purposes, it is little used, in consequence probably of its inferiority to other marbles with regard to colour.—H. W. B.

PURPLE OF CASSIUS, *Gold purple* (*Pourpre de Cassius*, Fr.; *Gold-purpur*, Germ.), is a vitrifiable pigment, which stains glass and porcelain of a beautiful red or purple hue. Its preparation has been deemed a process of such nicety, as to be liable to fail in the most experienced hands.

The proper pigment can be obtained only by adding to a neutral chloride of gold a mixture of the protochloride and perchloride of tin. Everything depends upon this intermediate state of the tin; for the protochloride does not afford, even with a concentrated solution of gold, either a chestnut-brown, a blue, a green, a metallic precipitate, or one of a purple tone; the perchloride occasions no precipitate whatever, whether the solution of gold be strong or dilute: but a properly neutral mixture of 1 part of crystallised protochloride of tin, with 2 parts of crystallised perchloride, produces with one part of crystallised chloride of gold (all being in solution), a beautiful purple-coloured precipitate. An excess of the protosalt of tin gives a yellow, blue, or green cast; an excess of the persalt gives a red and violet cast; an excess in the gold salt occasions, with heat (but not otherwise), a change from the violet and chestnut-brown precipitate into red. According to Fuchs, a solution of the sesquioxide of tin in muriatic acid, or of the sesquichloride in water, serves the same purpose, when dropped into a very dilute solution of gold.

Buisson prepares gold-purple in the following way. He dissolves, first, 1 gramme of the best tin in a sufficient quantity of muriatic acid, taking care that the solution is neutral; next, 2 grammes of tin in aqua regia, composed of three parts of nitric acid, and 1 part of muriatic, so that the solution can contain no protoxide; lastly, 7 grammes of fine gold in a mixture of 1 part of nitric acid, and 6 of muriatic, observing to make the solution neutral. This solution of gold being diluted with 3½ litres of water (about 3 quarts), the solution of the perchloride of tin is to be added at once, and afterwards that of the protochloride, drop by drop, till the precipitate thereby formed acquires the wished-for tone; after which it should be edulcorated by washing as quickly as possible.

Frick gives the following prescription: — Let tin be set to dissolve in very dilute aqua regia without heat, till the fluid becomes faintly opalescent, when the metal must be taken out, and weighed. The liquor is to be diluted largely with water, and a definite weight of a dilute solution of gold and dilute sulphuric acid is to be simultaneously stirred into the nitro-muriate of tin. The quantity of solution of gold to be poured into the tin liquor must be such, that the gold in the one is to the tin in the other in the ratio of 36 to 10.

Gold-purple becomes brighter when it is dry, but appears still as a dirty-brown powder. Hydrochloric acid takes the tin out of the fresh-made precipitate, and leaves the gold either in the state of metal or of a blue powder. At a temperature between 212° and 300° Fahr., mercury dissolves out all the gold from the ordinary purple of Cassius.

Relative to the constitution of gold purple, two views are entertained: according to the first, the gold is associated in the metallic state along with the oxide of tin; according to the second, the gold exists as a purple oxide along with the sesquioxide or peroxide of tin. Its composition is differently reported by different chemists. The constituents, according to —

Gay-Lussac - - - - - - -	30·89	69·11
Fuchs - - - - - - - - -	17·87	82·13

If to a mixture of protochloride of tin, and perchloride of iron, a properly diluted solution of gold be added, a very beautiful purple precipitate of Cassius will immediately fall, while the iron will be left in the liquid in the state of a protochloride. The purple thus prepared keeps in the air for a long time without alteration. Mercury does not take from it the smallest trace of gold. — *Fuchs' Journal für Chemie*, t. xv.

Purple of Cassius is best made according to the French Pharmacopœia, by dissolving 10 parts of acid chloride of gold in 2000 parts of distilled water; preparing in another vessel a solution of 10 parts of pure tin in 20 of muriatic acid, which is diluted with 1000 of water, and adding this by degrees to the gold solution as long as a precipitate is formed. The precipitate is allowed to subside, and is to be washed by means of decantation: it is then filtered and dried at a very gentle heat.

PURPLE OF MOLLUSCA. A viscid fluid, secreted by the *Buccinum lappillus*, and some other shell-fish. The Tyrian dye of the Greeks, and Imperial Purple of the Romans, was in all probability obtained from the same source, — the mollusca of the Mediterranean Sea. See MUREXIDE.

PURPLE DYES. The purple dyes now obtained by more or less complex processes from coal tar, are so incomparably superior to any others, both in brilliancy and permanence, that their production has opened up a new era in dyeing and calico-printing. The process of Mr. Perkin, the discoverer of aniline purple, is simple in principle, but the operations, from the production of the coal tar to the formation of the pure purple, are so numerous, and require to be conducted on such a large scale, that the successful manufacture involves the necessity for large capital and considerable chemical skill. Mr. Perkin's process involves the following operations:—

1. Production of benzole from coal tar by fractional distillation.
2. Conversion of benzole into nitro-benzole by the action of nitric acid.

3. Conversion of nitro-benzole into aniline.
4. Production of neutral sulphate of aniline.
5. Decomposition of sulphate of aniline by bichromate of potash.
6. Washing with water of the precipitate by bichromate of potash.
7. Drying of the washed precipitate.
8. Extraction of the brown impurity contained in the precipitate.
9. Extraction of the purple colouring matter.

An outline of the process contained in Mr. Perkin's specification will be found in the article ANILINE.

Numerous patents have been taken out for the production of colours more or less resembling Perkin's purple. J. T. Beale and J. N. Kirkham employ bleaching powder as the oxidising medium. They take a saturated solution of aniline in water, and add to it acetic acid and bleaching powder until the desired tint is acquired. They then use the fluid so procured for dyeing. It is obvious that some process of concentration must be employed to enable so weak a fluid to be employed in calico-printing. Upon the latter point the patent process does not enter at sufficient length to enable us to judge of the practicability of producing colours of the great strength required for printing on with albumen. Messrs. Beale and Kirkham, by modifying the nature of the salt and the state of concentration of the fluids employed, obtain various shades of colour from blue to lilac.

Mr. R. D. Kay, in his patent of the 7th May, 1859, treats acetate, sulphate, or hydrochlorate of aniline, with peroxide of manganese, peroxide of lead, or chloride of lime.

Mr. David S. Price, in his patent of the 25th of May, 1859, claims the use of peroxide or sesquioxide of manganese, and also peroxide of lead, as his agent of oxidation. By varying the quantities of his ingredients he obtains three colours, viz., violine, purpurine, and roseine.

C. H. G. Williams patents the green manganate of potash as the oxidising agent. By this means a part of the aniline is converted into a brilliant red dye of great beauty, and another part into an equally brilliant purple. The two colours are separated by taking advantage of the fact that the purple is precipitated by a solution of the reagent, whereas the red colour remains in solution, and can be concentrated by evaporation.

In dyeing and printing with these colours it is necessary with vegetable fabrics to use mordants, but animal fabrics absorb the colours with great avidity without the use of any mordant.

For cottons, perchloride of tin, followed by sumach, or stannate of soda and sumach, are the best mordants. Mr. Perkin recommends tartaric acid to be added to the bath in dyeing; but in practice this recommendation is not generally followed.

For printing, the purple is mixed with albumen; and after printing with the mixture the colour is fixed by steaming. Sometimes a mordant is printed on, and the pattern is obtained by passing the mordanted cloth through a bath of the colour. The purple may be rendered of a bluer and very lovely tint by adding to the mixture of dye and albumen a little carmine of indigo; Prussian blue is also sometimes used for the same purpose. In selecting patterns to be printed in purple, it must not be forgotten that the beauty of the tint is greatly enhanced by the proximity of blacks properly arranged.

Very fine purples, but decidedly inferior to Mr. Perkin's colour, are now prepared from litmus; they are also tolerably permanent. They are, nevertheless, liable to the drawback of becoming red in contact with strong acids. Strange to say, however, the orchil purples when properly made resist very well the action of weak acids. The colour-producing acids are obtained by treating the lichens with an alkaline base, which forms a soluble salt. The filtered liquid on treatment with an acid gives an abundant precipitate. It is this latter which, by proper treatment, yields the "French purple." The following is an outline of the process contained in a patent granted to William Spence (being a French communication), dated 1st May, 1858.

The precipitate obtained as above is moistened with sufficient ammonia to dissolve it. On boiling, the solution becomes orange yellow; it is then exposed to the air at ordinary temperatures, until it becomes red. The fluid is then heated in very shallow vessels to a temperature between 100° and 140° Fahr., until it becomes of a violet colour, which is unalterable by weak acids, and which will dye permanent colours on silk or wool, without the aid of mordants.

This purple colour can be thrown down from the liquid by saturation with an acid. The precipitate, after being filtered off and properly dried, is in a fit condition for dyeing or printing.

Like Perkin's purple, various shades may be obtained by using the orchil purple in combination with carmine of indigo for violets, and carthamus, or cochineal, for reds.—C. G. W.

PURPURIC ACID is an acid obtained by treating uric or lithic acid with dilute nitric acid. It has a fine purple colour. See MUREXIDE.

PURPURINE is the name of a colouring principle, supposed by Robiquet and Colin to exist in madder.

PUTREFACTION, *and its Prevention.* (*Faülniss*, Germ.) Putrefaction is the spontaneous decomposition of albumenoid or protein and gelatine compounds, when exposed to a limited amount of air. It is the decomposition of bodies containing nitrogen, called by some persons azotised bodies, although they are produced only by life, are the principal means of producing life, and more fitly called *zoogens.*

These bodies decompose at any temperature between 32° and 140° Fahrenheit (0°—60° C.). Their decomposition begins by the action of the oxygen of the air, so that a partial oxidation and a gradual disruption are simultaneous. The result of this is a number of liquid and gaseous compounds; carbonic acid, hydrogen, nitrogen, ammonia, sulphuretted hydrogen, phosphuretted hydrogen, carburetted hydrogen, acetic acid and lactic, also butyric and valeric acids are formed. But these are not all, as there are compounds arising from putrefaction which have, even in small quantities, a destructive action on animal life far beyond any of the substances mentioned.

Some of these are extremely offensive, and produce nausea as the first symptom; the further symptoms are those of general prostration, or of fevers in great variety, and eruptions equally varied, with a frequently fatal termination. In the case of a diseased person or animal, all contact is most dangerous within four or five hours after death, the disease still ruling the peculiar action of the tissues and fluids. But the result of putrefaction is most shown after a few days, and after ten to fourteen days it seems less violent. If pent up, the poisons may retain their virulence for months or years; nor do we know how many diseases may be imprisoned in graves very closely fitted. If air be absolutely excluded, putrefaction ceases, and the result is a preservation of the substance in some circumstances,—perhaps in all. If air be excluded for a time and the substance dried, a return to the light, air, and moisture is not known to reproduce the same state of decomposition that would have taken place at first. The act of drying has caused chemical union to take place more according to that of unorganised substances, and the peculiar organic and complicated molecules that produce the poisons are destroyed. If the slow decomposition takes place undisturbed for many years, the entrance of oxygen being extremely difficult, as in coffins carefully closed or deeply buried, then the organic matter is removed so completely and carefully that the ashes which remain are undisturbed, and keep the position in which they remained during life. It is in this way that men have been able to see the faces of the ancient kings of France, as well as of many other personages, and may yet see some of the undisturbed and complete bodies of the Chaldees. It is most probable that in these the air has oxidised them, as oxygen must have had access to remove so much matter. Only a light dust remains, and the slightest motion either of removal or of the atmosphere would cause it to fall. As oxidation began the process of putrefaction, so when it is finished oxidation completes the destruction of the material. It is probable that the ashes are mixed with a little humus or humate of ammonia. The result differs little from complete combustion with fire.

All organised substances are decomposed in the atmosphere. When they do not contain nitrogen, they are converted, like wood, sugar, starch, &c., into humus, or a lower compound of carbon and hydrogen, or into humic or ulmic acids. Ulmic acid, obtained from sugar by action of acids, contains (according to Mulder) carbon, 40; hydrogen. 14; oxygen, 12. From turf, carbon, 40; hydrogen, 14; oxygen, 12 + 4 aq. Humin contains, *carbon*, 40; *hydrogen*, 14; oxygen, 12. Humic acid, carbon, 40; hydrogen, 14; oxygen, 12 + 3 aq. Here the decomposition is signalised by a great diminution of hydrogen and oxygen,—a nearer approach to mere carbon. When nitrogenous bodies decompose, part of their nitrogen remains as ammonia, and a humate of ammonia is formed. Mulder traces it in the following manner. It is to be remarked that there is no proof of the existence of protein as a substance, but allowing it to represent the part of the albumenoids containing carbon, hydrogen, nitrogen, and oxygen, we have,

	C.	H.	N.	O.
1 equiv. protein + O_4 =	40	31	5	16
= 1 equiv. humic acid =	40	16	0	15
1 „ water =	0	1		1
5 „ ammonia =	0	15	5	0
	40	32	5	16

Before arriving at this stage of decomposition, the various forms of volatile substances already mentioned are given off. It has been frequently asked why such decompositions go forward; why does not the substance remain undecomposed? The very complex molecules of highly organised bodies readily lose their vital condition, and become simply chemical compounds, such as we may be able to form according to laws comparatively well understood. But compounds such as albumen seem to contain many compounds united together; or, in other words, there are many axes through which the affinity acts. These may bear an analogy to the several axes of crystals. When the force of one predominates, and the elements combine in a simple form, say of two molecules or atoms, then the breaking up of the compound as a whole must begin. In order to begin this motion, the substances must be in a condition in which the particles and atoms can move readily. This condition appears to be found when there is water present of a moderate warmth. If the temperature be below 60° Fahr. the decomposition is hindered by the cold, but it is not quite prevented at any temperature above freezing. If the temperature be above 100° Fahr. it is not certain that true putrefaction goes forward, and a much higher temperature entirely prevents it. If substances of the class which putrefy are much heated, they lose their peculiar constitution and readily yield to the ordinary chemical affinities, the action of heat rapidly destroying the balance of their forces. Cold, on the other hand, does not destroy, but preserves the relation of the substances unaltered. If left to themselves, organised substances in moderate temperature with moisture would even without air lose their peculiar condition. Some change of temperature or in the electric state of the atmosphere would in time cause a want of perfect balance of power; nay, it is even possible that some force existing in the substances themselves is capable of gaining the upper hand by the aid of time. In ordinary cases, however, the balance is disturbed by oxygen, as we know from very early times, by the action of air on organic substances. But Gay-Lussac made this remarkably clear by a beautiful and unexpected experiment, wherein he showed that the juice of grapes remained without fermentation until he allowed a single bubble of air to enter, when the fermentation, once begun, continued. Liebig explained this by saying, with La Place and Berthollet, that "a molecule set in motion by any power can impart its own motion to another molecule with which it may be in contact." This is an analogy drawn from mechanics, but only an analogy. The molecule will not, in the conditions found in Gay-Lussac's experiment, set in motion the molecules of silica or lime. Chemical action is not the same as mechanical, although, somewhere, the borders of the two touch. The use of a chemical form of explanation makes the matter much clearer. Suppose a particle of oxygen to touch the matter ready to ferment or putrefy, an oxide is formed. The oxygen has taken the place of another atom, which is now left to follow its affinities, and the whole relations of the mass are gradually changed. If the mass were neutral, having no sign of + or — before it, oxygen at once by its action changes one sign to +. The sign changed to plus, or the atom containing it, converts the one next it to minus, and so the chemical action is continued through the mass. Berzelius used the word *catalysis* for the breaking up of a substance without any strong chemical affinities. The word means simply *loosening out*, or *breaking up*, and is well adapted for the purpose, although much misapplied. Putrefaction may be said then to be an albumenoid in a state of catalysis. This catalys is is begun by the air disturbing the equilibrium of the compound. A change of electric condition will disturb the equilibrium in the air, and it will assist the first attacks of the oxygen. This action of electricity is popularly known by the changes so common in milk and beer during thunderstorms. As oxygen begins the action, so does it bring it to a conclusion, and completely destroy all decomposing matter. The same thing must no doubt be said of Ozone in a still higher degree. Now, many things may destroy this equilibrium. We see then the reason why so many substances and so many conditions act so as to alter the putrefiable substance. This equilibrium may be destroyed by the use of a strong acid, causing strong chemical affinities to upset all the delicately balanced forces in the organic substance; the same thing may be done by alkalies and by many salts that act in an antiseptic manner. But if a condition or a substance be found merely to keep the putrefactive mass in a state in which it will not putrefy, the agent is exactly opposed to catalysis. It is a *colytic* or restraining agent. See DISINFECTANT.

When resin and fat are present, they are not readily oxidised. The first may be retained for an unknown time; the second remains long in bodies when all the rest has been removed. It has been found in catacombs in Paris in large quantities, and been called *adipocere*, meaning *wax of fat* (*adeps*, fat; and *cera*, wax).

If the explanation given be correct, it is at once seen why a body in a state of putrefaction communicates its own condition to another. The loss of equilibrium has already taken place, and cannot stop till the material is consumed, unless more powerful forces arrive. Liebig says that "no other explanation can be given than that a body in the act of combination or decomposition enables another body with which it is in contact to enter the same state." It is not intended here to oppose, but rather to take another step in this theory. On the same principles both the disorganised and the organised matters carried about by the air will promote decomposition: both will break up the structure, but by different methods. The disorganised will act as shown; the organised will act by growing and by eliminating compounds, such as funguses, which will break down the equilibrium of the mass. If air be passed into the juice of grapes through red-hot tubes, it does not ferment for a long time, nor does it produce mould or infusoria. The animal and vegetable assistance to decomposition is removed. Flesh under these conditions keeps some weeks. Ozone is also destroyed by heat, and would leave only ordinary oxygen to act. Schrœder and V. Dusch even found that flesh would keep in air filtered through cotton, and in similar air no infusoria or mould occurred. Milk recently boiled and flesh warmed on a sand-bath without being steeped in water decayed equally in filtered and unfiltered air, still without vegetable or animal life.

In the case of the grape juice, one bubble of air begins fermentation which continues, but we are not sure that putrefaction can be so continued; it seems to require a more frequent stimulus. Certain products of putrefaction have been mentioned, but in reality the word putrefaction includes many modes of decomposition. There are compounds formed that destroy life more rapidly than any substance whose constitution is known, and these seem to be the more destructive according as the matter from which they are derived is from animals in a higher scale of being,—from man, for example. This idea is in accordance with all we know of the compounds of organised life. For effects, see Sanitary Economy. Sometimes a peculiar ferment is formed, which produces a similar condition in living bodies, constituting a great variety of diseases, according to its special nature and the condition of the body attacked. As we have seen, some fermentations and putrefactions begin entirely by the action of air, and some by the assistance of liquids or solids, such as yeast; so we find some diseases propagated by infection conveyed through the air, and some only by contact. In cases where air acts, it is to be understood that the organic substances are conveyed in it. We find by this means that both the contagionists and noncontagionists are correct; but it is to decide, as men are now endeavouring to do, in what diseases one or the other prevails.

As in the decomposition of flesh into humate of ammonia and ashes many deadly exhalations are given off, so in the decomposition of analogous substances in the earth putrefaction causes the rise of miasma. When there is an abundant supply of air, the ammonia is converted into nitric acid; when there is an abundant supply of vegetation, the nitric acid is reconverted into ammonia, as Kuhlman has shown, and as agriculture, by its love of nitrates, has long demonstrated. The humus and humate of ammonia spoken of form the chief portion of what we call vegetable mould. Acetic acid and other acids are also found in one if not in every layer of the soil; and the acids and ammonia are in a constant struggle for the mastery. The soil is slightly acid. A *sour* soil is not uncommon.

1. Conditions of the Prevention of Putrefaction.

The circumstances by which putrefaction is counteracted, are 1, the chemical change of the azotised juices; 2, the abstraction of water; 3, the lowering of the temperature; and 4, the exclusion of oxygen. The methods actually in use may be called salting, smoking, drying, exclusion of air, and parboiling.

1. *The chemical change of the azotised juices.*—The substance which in dead animal matter is first attacked with putridity, and which serves to communicate it to the solid fibrous parts, is albumen, as it exists combined with more or less water in all the animal fluids and soft parts. In those vegetables also which putrefy, it is the albumen probably which first suffers decomposition; and hence those plants which contain most of that proximate principle are most apt to become putrid, and most resemble in this respect animal substances. The albumen, when dissolved in water, very readily putrefies in a moderately warm air; but when coagulated, it seems as little liable to putridity as fibrin itself. By this change it throws off the superfluous water, becomes solid, and may then be easily dried. Hence those means which by coagulation make the albumen insoluble, or form with it a new compound, which does not dissolve in water, but which resists putrefaction, are powerful antiseptics. Whenever the albumen is coagulated, the uncombined water may be easily evaporated, and the residuary solid matter may be readily dried in the air, so as to be rendered unsusceptible of decomposition.

Some acids combine with the albumen, without separating it from its solution; such is the effect of vinegar, citric acid, tartaric acid, &c.

Tannin combines with the albuminous and gelatinous parts of animals, and forms insoluble compounds, which resist putrefaction; on which fact the art of tanning is founded.

Alcohol, oil of turpentine, and some other volatile oils, likewise coagulate albumen, and thereby protect it from putrescence. The most remarkable operation of this kind is exhibited by wood vinegar, chiefly in consequence of the *kreasote* contained in it, according to the discovery of Reichenbach. This peculiar substance has so decided a power of coagulating albumen, that even the minute portion of it present in pyroligneous vinegar assists in preserving animal parts from putrefaction, when they are simply soaked in it. Thus, also, flesh is cured by wood smoke. Distilled wood tar likewise protects animal matter from change, by the kreasote it contains. The ordinary pyroligneous acid sometimes contains 5 per cent. of kreasote.

The metallic salts operate still more effectually as antiseptics, because they form with albumen still more intimate combinations. Under this head we class the green and red sulphates of iron, chloride of zinc, the acetate of lead, and corrosive sublimate; the latter, however, from its poisonous qualities, can be employed only on special occasions. Nitrate of silver, though equally noxious to life, is so antiseptic that a solution containing only $\frac{1}{500}$ of the salt is capable of preserving animal matters from corruption.

2. *Abstraction of water.* — Even in those cases where no separation of the albumen takes place in a coagulated form, or as a solid precipitate, by the operation of a substance foreign to the animal juices, putrefaction cannot go on, any more than other kinds of fermentation, in bodies wholly or in a great measure deprived of their water, as the albumen itself runs much more slowly into putrefaction, when less water is contained in it; and in the desiccated state, it is as little susceptible of alteration as any other dry vegetable or animal matter. Hence, the proper drying of an animal substance becomes a universal preventive of putrescence. In this way fruits, herbs, cabbages, fish, and flesh may be preserved from corruption. If the air be not cold and dry enough to cause the evaporation of the fluids before putrescence begins, the organic substance must be dried by artificial means, such as by being exposed in thin slices in properly constructed air-stoves. At a temperature under 140° F., the albumen dries up without coagulation, and may then be redissolved in cold water, with its valuable properties unaltered. Mere desiccation, indeed, can hardly ever be employed upon flesh. Culinary salt is generally had recourse to, either alone or with the addition of saltpetre or sugar. These alkaline salts abstract water in their solution, and, consequently, concentrate the aqueous solution of the albumen; whence, by converting the simple watery fluid into salt water, which is in general less favourable to the fermentation of animal matter than pure water, and by expelling the air, and probably by chemical combinations, they counteract putridity. On this account, salted meat may be dried in the air much more speedily and safely than fresh meat. The drying is promoted by heating the meat merely to such a degree as to consolidate the albumen, and eliminate the superfluous water.

Alcohol operates similarly, in abstracting the water essential to the putrefaction of animal substances, taking it not only from the liquid albumen, but counteracting its decomposition, when mixed among the animal solids. Sugar acts in the same way, fixing in an unchangeable syrup the water which would otherwise be accessory to the fermentation of the organic bodies. The preserves of fruit and vegetable juices are made upon this principle. When animal substances are rubbed with charcoal powder or sand, perfectly dry, and are afterwards freely exposed to the air, they become deprived of their moisture, and will keep for a long time.

3. *Defect of warmth.*—As a certain degree of heat is requisite for the vinous fermentation, so is it for the putrefactive. If in a damp atmosphere, or in one saturated with moisture, if the temperature stand at from 70° to 80° F., the putrefaction goes on most rapidly; but it proceeds languidly at a few degrees above freezing, and is suspended altogether at that point. The elephants found in the polar ices are proofs of the preservative influence of low temperature. In temperate climates, ice-houses serve the purpose of keeping meat fresh and sweet for any length of time.

4. *Abstraction of oxygen gas.*—As the putrefactive decomposition of a body first commences with the absorption of oxygen from the atmosphere, so it may be retarded by the exclusion of this gas. It is not, however, enough to remove the aerial oxygen from the surface of the body, but we must expel all the oxygen that may be diffused among the vessels and other solids, as this portion suffices in general to excite putrefaction, if other circumstances be favourable. The expulsion is most readily accomplished by a boiling or lower heat, which, by expanding the air, evolves it in a great measure. Milk, soup, solution of gelatine, &c., may be kept

long in a fresh state, if they be subjected in an air-tight vessel every other day to a boiling heat. Oxygenation may be prevented in several ways: by burning sulphur or phosphorus in the air of the meat receiver; by filling this with compressed carbonic acid; or with oils, fats, syrups, &c., and then sealing it hermetically. Charcoal powder recently calcined is efficacious in preserving meat, as it not only excludes air from the bodies surrounded by it, but intercepts the oxygen by condensing it, and causing it to combine with putrefying substances. When butcher-meat is enclosed in a vessel filled with sulphurous acid, it absorbs the gas, and remains for a considerable time proof against corruption. The same result is obtained if the vessel be filled with ammoniacal gas. At the end of 76 days such meat has still a fresh look, and may be safely dried in the atmosphere.

2. Peculiar Antiseptic Processes.

Upon the preceding principles and experiments depend the several processes employed for protecting substances from putrescence and corruption. Here we must distinguish between those bodies which may be preserved by any media suitable to the purpose, as anatomical preparations or objects of natural history, and those bodies which, being intended for food, can be cured only by wholesome and agreeable means.

Preservation of specimens of animals. — Many methods have been planned to preserve animals: all of them dependent on substances mentioned under Disinfectants. Charles Waterton uses corrosive sublimate dissolved in alcohol. The skin of the animal being separated, is dipped into the solution and dried. The inside of the animal is always removed, the bones scraped clean and dipped, the feathers or hairs touched by the solution or the whole immersed in it. Sometimes alcohol of 60 to 70 per cent. is used, or alcohol of 30 per cent. with kreasote dissolved in it. Sulphurous acid will not suit when there are colours, but sulphites of the alkalies have been injected into the veins and arteries with good result; as also sulphurous acid and kreasote. Peron preserved fishes for specimens on shipboard by floating them in an alcoholic liquor by corks, thus preventing them from being pressed. He first washed them in sea-water, vinegar, and camphor spirits: he corked the vessels with tallowed corks. Dufresne wrapped each in a cloth with tow between the specimens, and all in alcoholic liquids. Louis Vernet used arsenic, 1 lb. in 40 gallons of water. Sulphate of zinc was proposed for embalming by Comte de Fontainemoreau, sometimes adding alcohol. Wood is preserved by Kyan's process, corrosive sublimate being used; also by Bethel's process, the use of heavy oil of tar; and manures are preserved by carbonites by McDougall. Injection of the arteries and veins by chloride of zinc, chloride of arsenic, and chloride of aluminum, sulphate of zinc, and sulphates, corrosive sublimate, &c., have all been tried, and are more or less satisfactory. Peppers and spices of all kinds have been used in stuffing and embalming, and may all be made to act when care is employed and abundance used. Girolamo Segato dried bodies so hard that he made a table of 214 pieces of human flesh from different parts of the body. He is said also to have made members preserve their elasticity for an indefinite time. Some remarkable specimens of this kind are said to exist, and have received the honour of sanctity. Waterton made skins preserve their flexibility for some days by the use of corrosive sublimate and slow drying. Dr. Ure says, "for preserving animal bodies in an embalmed form, mummy-like, a solution of chloride of mercury and wood vinegar are most efficacious. As there is danger in manipulating with that mercurial salt, and as in the present state of our knowledge of kreasote, we have it in our power to make a suitable strong solution of this substance in vinegar or spirit of wine, I am led to suppose that it will become the basis of most antiseptic preparations for the future."

Curing of Provisions.

Flesh, &c.—The ordinary means employed for preserving butcher meat are, drying, smoking, salting, and pickling or souring.

Drying.—The best mode of operating is as follows:— The flesh must be cut into slices from 2 to 6 ounces in weight, immersed in boiling water for 5 or 6 minutes, and then laid on open trellis-work in a drying-stove, at a temperature kept steadily about 122° F., with a constant stream of warm dry air. That the boiling water may not dissipate the soluble animal matters, very little of it should be used, just enough for the meat to be immersed by portions in succession, whereby it will speedily become a rich soup, fresh water being added only as evaporation takes place. It is advantageous to add a little salt, and some spices, especially coriander seed, to the water. After the parboiling of the flesh has been completed, the soup should be evaporated to a gelatinous consistence, in order to fit it for forming a varnish to the meat after it is dried, which may be completely effected within two days in the oven. By this process two-thirds of the weight is lost. The perfectly dry flesh must be plunged, piece by piece, in the fatty gelatinous matter liquefied by a gentle heat; then placed once more in the stove, to dry the layer of varnish. This operation may be repeated two or three times, in order to render the coat sufficiently uniform and thick. Butcher's meat dried in this way keeps for a year, affords, when cooked, a dish similar to that of fresh meat, and is therefore much preferable to salted provisions. The drying may be facilitated, so that larger lumps of flesh may be used, if they be imbued with some common salt immediately after the parboiling process, by stratifying them with salt, and leaving them in a proper pickling-tub for 12 hours before they are transferred to the stove. The first method, however, affords the more agreeable article.

Baron Cha. Wetterstedt encloses meat in corn or potato flour, then dries it on shelves at 120° F. Graefer, in 1780, parboiled and then dried. Some have proposed to hang the substances up and to allow no air to approach without passing it first through chloride of calcium to dry it. Milk is often preserved by drying to a powder.

Smoking.— This process consists in exposing meat previously salted, or merely rubbed over with salt, to wood smoke in an apartment so distant from the fire as not to be unduly heated by it, and into which the smoke is admitted by flues at the bottom of the side walls. Here the meat combines with the empyreumatic acid of the smoke, and gets dried at the same time. The quality of the wood has an influence upon the smell and taste of the smoke-dried meat; smoke from beech wood and oak being preferable to that from fir and larch. Smoke from the twigs and berries of juniper, from rosemary, peppermint, &c., imparts somewhat of the aromatic flavour of these plants. A slow smoking with a slender fire is preferable to a rapid and powerful one, as it allows the empyreumatic principles time to penetrate into the interior substance, without drying the outside too much. To prevent soot from attaching itself to the provisions, they may be wrapped in cloth, or rubbed over with bran, which may be easily removed at the end of the operation.

The process of smoking depends upon the action of the wood acid, or the kreasote volatilised with it, which operates upon the flesh. The same change may be produced in a much shorter time by immersing the meat for a few hours in pyroligneous acid, then hanging it out in a dry air, which, though moderately warm, makes it fit for keeping, without any taint of putrescence. After a few days' exposure, it loses the empyreumatic smell, and then resembles thoroughly smoked provisions. The meat dried in this way is in general somewhat harder than by the application of smoke, and therefore softens less when cooked, a difference to be ascribed to the more sudden and concentrated operation of the wood vinegar, which effects in a few hours what would require smoking for several weeks. By the judicious employment of pyroligneous acid or kreasote alone diluted to successive degrees, we might probably succeed in imitating perfectly the effect of smoke in curing provisions.

Salting.—The meat should be rubbed well with common salt, containing about one-sixteenth of saltpetre, and one thirty-secondth of sugar, till every crevice has been impregnated with it; then sprinkled over with salt, laid down for 24 or 48 hours, and, lastly, subjected to pressure. It must next be sprinkled anew with salt, packed into proper vessels, and covered with the brine obtained in the act of pressing, rendered stronger by boiling down. For household purposes it is sufficient to rub the meat well with good salt, to put it into vessels, and load it with heavy weights, in order to squeeze out as much pickle as will cover its surface. If this cannot be had, a pickle must be poured on it, composed of 4 pounds of salt, 1 pound of sugar, and 2 oz. of saltpetre dissolved in 2 gallons of water.

M. Fitch patented the use of a liquid containing 2 cwt. of common salt to the product of distillation of 2 cwt. of wood, adding sugar, treacle, and saltpetre. Some people drive the salt in by force of pressure, some by centrifugal motion.

Milk has been preserved by the use of carbonate of soda, preventing acidity. Alum has been patented, for shellfish especially.

E. Masson injects the veins and arteries of carcases with a solution containing $10\frac{1}{2}$ oz. of common salt and $3\frac{1}{2}$ of nitre in $2\frac{1}{2}$ pints of water. D. R. Long injects anti-putrescent and flavouring substances, such as salt, saltpetre, spices, and vinegar. J. Murdoch injected cloride of aluminum, a very powerful agent, common salt, and nitre. Brooman communicates a proposal to use, first, sulphurous gas, and then coat thick with a substance keeping out the air. Chloride of lime has also been used in chambers holding meat, and sulphur has been burnt and nitrous gas has been evolved in similar places.

Preserving with vinegar, sugar, &c.—Vinegar dissolves or coagulates the albumen of flesh, and thereby counteracts its putrescence. The meat should be washed, dried, and then laid in strong vinegar. Or it may be boiled in the vinegar, allowed to cool in it, and then set aside with it in a cold cellar, where it will keep sound for several months.

Fresh meat may be kept for some months in water deprived of its air. If we strew on the bottom of a vessel a mixture of iron filings and flowers of sulphur, and pour over them some water which has been boiled, so as to expel its air, meat immersed in it will keep a long time, if the water be covered with a layer of oil, from half an inch to an inch thick. Meat will also keep fresh for a considerable period when surrounded with oil, or fat of any kind, so purified as not to turn rancid of itself especially if the meat be previously boiled. This process is called potting, and is applied successfully to fish, fowls, &c.

Prechtl says that living fish may be preserved 14 days without water, by stopping their mouths with crumbs of bread steeped in brandy, pouring a little brandy into them, and packing them in this torpid state in straw. When put into fresh water, they come alive again after a few hours! —*Prechtl, Encyclop. Technologische, art. Faülniss Abhaltung.*

Meat may also be preserved by boiling in its own gravy, or embedding in fat (Plowden's patent, 1807), or in animal jelly.

Eggs.—These ought to be taken new laid. The essential point towards their preservation is the exclusion of the atmospheric oxygen, as their shells are porous, and permit the external air to pass inwards, and to excite putrefaction in the albumen. There is also some oxygen always in the air cell of the eggs, which ought to be expelled or rendered inoperative, which may be done by plunging them for 5 minutes in water heated to 140° F. The eggs must be then taken out, wiped dry, besmeared with some oil (not apt to turn rancid) or other unctuous matter, packed into a vessel with their narrow ends uppermost, and covered with sawdust, fine sand, or powdered charcoal. Eggs coated with gum arabic, and packed in charcoal, will keep fresh for a year. Lime water, or rather milk of lime, is an excellent vehicle for keeping eggs in, as Dr. Ure verified by long experience. Some persons coagulate the albumen partially, and also expel the air by boiling the eggs for two minutes, and find the method successful. S. Carson's patent says, that after this 1 minute in hot water cooks the egg. When eggs are intended for hatching, they should be kept in a cool cellar; for example, in a chamber adjoining an ice-house. Eggs exposed, in the holes of perforated shelves, to a constant current of air lose about $\frac{3}{4}$ of a grain of their weight daily, and become concentrated in their albuminous part, so as to be little liable to putrefy. This is an extremely simple and clean method, but requires a good deal of space. Each egg requires a hole in the shelf for itself. For long sea voyages, the surest means of preserving eggs is to dry up the albumen and yolk, by first triturating them into a homogeneous paste, then evaporating this in an air-stove or a water-bath heated to 125°, and putting up the dried mass in vessels which may be made air-tight. When used, it should be dissolved in three parts of cold or tepid water.

Mixed modes, &c.—The excellent process for preserving all kinds of butcher meat, fish, and poultry, first contrived by M. Appert in France, and afterwards successfully practised upon the great commercial scale by Messrs. Donkin and Gamble, for keeping beef, salmon, soups, &c., perfectly fresh and sweet for exportation from this country, as also turtle for importation hither from the West Indies, deserves a brief description.

Let the substance to be preserved be first parboiled, or rather somewhat more, the bones of the meat being previously removed. Put the meat into a tin cylinder, fill up the vessel with seasoned rich soup, and then solder on the lid, pierced with a small hole. When this has been done, let the tin vessel thus prepared be placed in brine and heated to the boiling point, to complete the remainder of the cooking of the meat. The hole of the lid is now to be closed perfectly by soldering, whilst the air is rarefied. The vessel is then allowed to cool, and from the diminution of the volume, in consequence of the reduction of temperature, both ends of the cylinder are pressed inwards, and become concave. The tin cases, thus hermetically sealed, are exposed in a test-chamber, for at least a month to a temperature above what they are ever likely to encounter; from 90° to 110° of Fahrenheit. If the process has failed, putrefaction takes place, and gas is evolved, which, in process of time, will cause both ends of the case to bulge, so as to render them convex, instead of concave. But the contents of those cases which stand the test will infallibly keep perfectly sweet and good in any climate, and for any number of years. If there be any taint about the meat when put up, it inevitably ferments, and is detected in the proving process.

This preservative process is founded upon the fact, that the small quantity of oxygen contained within the vessel gets into a state of combination, in consequence of the high temperature to which the animal substances are exposed, and upon the chemical principle, that free oxygen is necessary as a ferment to commence or give birth to the process of putrefaction.

Gunter effects the plan more rapidly by sealing the tin case whilst steam is blowing off, letting the solder fall upon the open hole, and at once closing it.

Alexander Cockburn, in 1763, cured salmon with spices — vinegar, salt, cloves, mace, and pepper. The use of a vacuum in preserving meat is old — before 1810, when two patents were taken for a mode of doing it.

A layer of oil is also used for preserving milk from the air.

Mr. R. Warrington uses oils not subject to oxidation and glycerine or treacle, also gypsum; he stops the vessels with gutta percha or caoutchouc.

Fat is preserved by melting gently and putting in bladders (*Palmer*). Charcoal powder has also been used to preserve it. A coating of collodion to keep out the air has been patented.

Grain, fruit, &c.—Grain of all kinds, as wheat, barley, rye, &c., and their flour, may be preserved for an indefinite length of time, if they be kiln-dried, put up in vessels or chambers free from damp, and excluded from the air. Well dried grain is not liable to the depredations of insects. Granaries are sometimes heated with warm air.

To preserve fruits in a fresh state, various plans are adopted. Pears, apples, plums, &c., should be gathered in a sound state, altogether exempt from bruises, and plucked in dry weather before they are fully ripe. One mode of preservation is to expose them in an airy place to dry a little for eight or ten days, and then lay them in dry sawdust or chopped straw, spead upon shelves in a cool apartment, so as not to touch each other. Another method consists in surrounding them with fine dry sand in a vessel which should be made air-tight, and kept in a cool place. Some persons coat the fruit, including the stalks, with melted wax; others lay the apples, &c., upon wicker-work shelves in a vaulted chamber, and smoke them daily during four or five days with vine branches or juniper wood. Apples thus treated and afterwards stratified with dry sawdust, without touching each other, will keep fresh for a whole year.

The drying of garden fruits in the air, or by a kiln, is a well-known method of preservation. Apples and pears of large size should be cut into thin slices. From five to six measures of fresh apples, and from six to seven of pears, afford in general one measure of dry fruit (biffins). Dried plums, grapes, and currants are a common article of commerce, coming from Greece, Spain, and the Mediterranean.

Herbs, cabbages, &c., may be kept a long time in a cool cellar, provided they are covered with dry sand. Such vegetables are in general preserved for the purposes of food by means of drying, salting, pickling with vinegar, or beating up with sugar. Cabbages should be scalded in hot water previously to drying; and all such plants, when dried, should be compactly pressed together, and kept in air-tight vessels. Tuberous and other roots are better kept in an airy place, where they may dry a little without being exposed to the winter's frost.

A partial drying is given to various vegetable juices by evaporating them to the consistence of a syrup, called a rob, in which so much of the water is dissipated as to prevent them from running into fermentation. The fruits must be crushed and squeezed in bags to expel the juices, which must then be inspissated either over the naked fire, or on a water or steam bath, in the air or in vacuo. Sometimes a small proportion of spice is added, which tends to prevent mouldiness. Such extracts may be conveniently mixed with sugar into what are called conserves, preserves, and jelly.

Salting is employed for certain fruits, as small cucumbers or gherkins, capers, olives, &c. Even for peas such a method is had recourse to for preserving them a certain time. They must be scalded in hot water, put up in bottles, and covered with saturated brine having a film of oil on its surface, to exclude the agency of the atmospheric air. Before being used they must be soaked for a short time in warm water, to extract the salt. The most important article of diet of this class is the *saur kraut*, sour herb or cabbage, of the northern nations of Europe, which is prepared simply by salting; a little vinegar being formed spontaneously by fermentation. The cabbage must be cut into small pieees, stratified in a cask along with salt, to which juniper berries and caraway seeds may be added, and packed as hard as possible by means of a wooden rammer. The cabbage is then covered with a lid, on which a heavy weight is laid. A fermentation commences, while a quantity of juice exudes and floats on the surface, which causes the cabbage to become more compact, and a sour smell is perceived towards the end of the fermentation. In this condition the cask is transported into a cool cellar, where it is allowed to stand for use during the year; and indeed, where, if well made and packed, it may be kept for several years.

Potatoes and other vegetables, as carrots and turnips, are preserved by cutting out the eyes or germinating parts (Roberts's patent, 1825). Grain and vegetables are also preserved in air-tight vessels. Potatoes have been much used dried; they are driven through small holes and thus broken, and then dried. They do not seem to retain a good flavour. The seeds of plants have been preserved by covering them with a solution of sulphate of zinc, copper, &c. E. Acres cools the air passing into air-tight reservoirs containing grain, and into the space between the mill-stones when in action.

This article may be concluded with some observations upon the means of preserving water fresh on sea voyages. Some waters kept in wooden casks, undergo a kind of putrefaction, contract a disagreeable sulphurous smell, and become undrinkable. The origin of this impurity lies in the animal and vegetable juices which the water originally contained in the source from which it was drawn, or from the cask, or insects, &c. These matters easily occasion, with a sufficient warmth, fermentation in the stagnant water, and thereby cause the evolution of offensive gases. It would appear that the gypsum of hard waters is decomposed, and gives up its sulphur, which aggravates the disagreeable odour; for waters containing sulphate of lime, are more apt to take this putrid taint, than those which contain merely carbonate of lime.

As the corrupted water has become unfit for use merely in consequence of the admixture of these foreign matters—for water in itself is not liable to corruption—so it may be purified again by their separation. This purification may be accomplished most easily by passing the water through charcoal powder, or through the powder of calcined bone-black. The carbon takes away not only the finely diffused corrupt particles, but also the gaseous impurities. By adding to the water a very little sulphuric acid, about 30 drops to 4 pounds, Lowitz says that two-thirds of the charcoal may be saved. An occasionally useful agent for the purification of foul water is to be found in alum. A dram of pounded alum should be dissolved with agitation in a gallon of water, and then left to operate quietly for 24 hours. A sediment falls to the bottom, while the water becomes clear above, and may be poured off. The alum combines here with the substances dissolved in the water, as it does with the stuffs in the dyeing copper. In order to decompose any alum which may remain in solution, the equivalent quantity of crystals of carbonate of soda may be added to it.

The red sulphate of iron acts in the same way as alum. A few drops of its solution are sufficient to purge a pound of foul water. Foul water may be purified by driving atmospheric air through it with bellows, or by agitating it in contact with fresh air, so that all its particles are exposed to oxygen. Thus we can explain the influence of streams and winds in counteracting the corruption of water exposed to them. Chlorine acts still more energetically than the air in purifying water. A little aqueous chlorine added to foul water, or the transmission of a little gaseous chlorine through it, cleanses it immediately, but chlorine and chlorides should be avoided in water, the chlorides of the earths formed, being unpleasant to the taste and hurtful to metals.

Water-casks ought to be charred inside, whereby no fermentable stuff will be extracted from the wood. British ships, however, are now commonly provided with iron tanks. Iron itself has been proposed as a purifier of water. Sea water can be purified only by distillation first and animal charcoal afterwards. The addition of chemical agents should be resorted to only when unavoidable.—R. A. S.

PUTTY POWDER. Oxide of tin, or more frequently oxide of tin and lead, in various proportions. The usual process is to oxidise the metal in a rectangular box. This is surrounded by the fire and kept at a red heat; the contents are constantly stirred, so that fresh portions of the metal are exposed to the heated air. The process is complete when all the metal has disappeared, and the oxide glows with incandescence. It is then removed with ladles and spread over the bottom of large iron pans to cool. The hard lumps of oxide are selected from the mass, ground dry, and carefully sifted through fine lawn sieves.

For the use of the optician the tin is precipitated from its solution in nitro-muriatic acid, by liquid ammonia, both the solutions being very largely diluted. The oxide of tin is then well washed, and dried by pressure in a screw-press; when dry the mass is finely powdered, and afterwards exposed in a crucible to a tolerably high temperature, 1600 Fahr. See Tin.

PYRITES. A term formerly applied to the yellow sulphide of iron, because it struck fire with steel. It is in strictness still confined to this mineral; but where sulphur is in combination with copper, cobalt, nickel, and some other metals, they, provided they assume an especial colour, are called pyrites.

Pyrites, *Iron pyrites*, *mundic*, is found in almost every formation. Its composition is, iron, 45·75; sulphur, 54·25.

Pyrrhotine, *Magnetic iron pyrites*, is found in many of the Cornish mines. Its composition is, iron, 59·72; sulphur, 40·22.

Marcasite, *White iron pyrites*. This is but a variety in form of the first named; they are identical in composition.

Copper Pyrites (*Chalcopyrite* of Dana), *Yellow copper pyrites*. The common copper ore of Cornwall. It appears to be a double sulphide of copper and iron. Its composition being, sulphur, 34·9; copper, 34·6; iron, 30·5.

Tin Pyrites, *Sulphide of tin; Bell-metal ore.* This mineral is found in many of the Cornish mines. Its composition is usually, sulphur, 30·0; tin, 27·2; copper, 29·7; iron, 13·1.

The term is occasionally applied to the other minerals named above. Combinations with arsenic are sometimes termed *Arsenical Pyrites*—as the

Leucopyrite (Dana), which is an arsenical iron composed of arsenic, 78·2; iron, 27·2.

Mispickel is a compound of arsenic, 46·0; sulphur, 19·6; iron, 34.

These ores are used largely in the manufacture of oil of vitriol. See SULPHURIC ACID.

The production of iron pyrites in the United Kingdon in 1858 was as follows:—

	Tons.	Cwts.	Qrs.	Value. £	s.	d.
Cornwall - - - - -	10,549	1	0	9,923	14	9
Devonshire - - - - -	274	10	0	97	11	9

Enormous quantities of iron pyrites exist in Spain, and are now being brought to this country. These sulphur ores contain a small quantity of copper, which increases their value.

Iron pyrites, mundic, is a mineral which is largely employed in the manufacture of copperas and of sulphuric acid. The pyrites ("brasses") of the coal measures are used in the preparation of copperas. Mr. Kirwan iu his "Antiquated Mineralogy," which is, however, very full of information, gives us the following passage, which shows that the changes which take place in the sulphur ores (*Martial pyrites*), had been well studied by him.

"Vitriol is formed in these stones by exposing them a long time to the action of the air and moisture, or by torrefaction in open air, and subsequent exposure to its action, which operation in some cases must be often repeated, according to the proportion of sulphur, and the nature of the earth; the calcareous pyrites are those in which it is most easily formed, and they effloresce the soonest. Good pyrites, properly treated, yield about two-thirds of their weight of vitriol." See SULPHURIC ACID.

In the chemical works of Yorkshire the "*coal brasses*" are exposed in thin beds, which are often turned over to the action of the air. The sulphur is converted by the oxygen of the air into sulphuric acid, which combines with the iron, forming sulphate of iron, *copperas*, which is dissolved out and crystallised. The same result may be obtained more quickly by roasting the sulphur ores.

PYRIDINE, $C^{10}H^5N$. A volatile base homologous with picoline, latidine, collidine, and parvoline. It was discovered by Anderson in bone oil. It is also contained in Dorset shale, naphtha, coal naphtha, and in crude chinoline.—C. G. W.

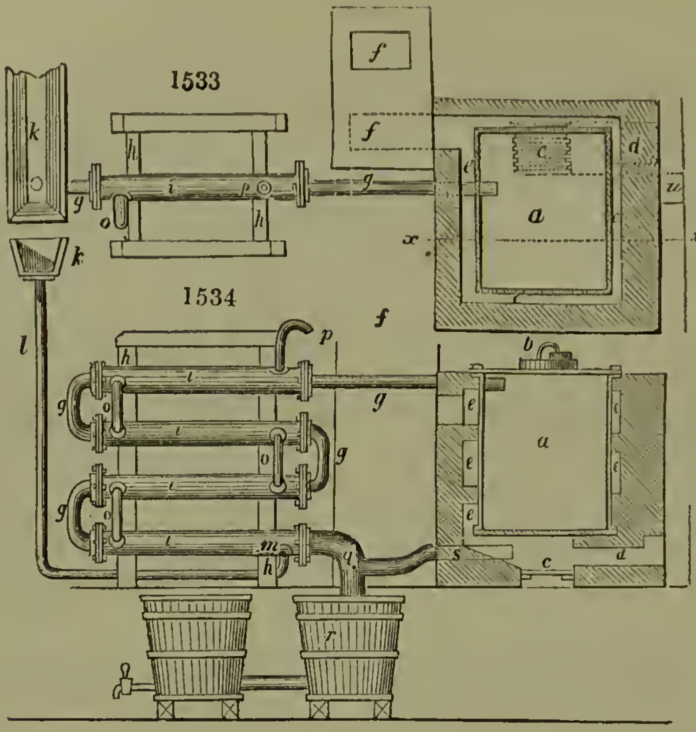
PYROACETIC SPIRIT. See ACETIC ACID.

PYROGALLIC ACID. If gallic acid is carefully heated to about 400°, it is totally decomposed into carbonic acid and pyrogallic acid ($C^7H^3O^5 = C^6H^3O^3 + C^2O$), which sublimes in brilliant white plates; it is easily soluble in ether, alcohol, and water; it reacts feebly acid; it fuses at 240°, and sublimes at 400°. If a solution containing peroxide of iron be added to a solution of pyrogallic acid, a black colour is struck, but the iron is rapidly reduced to a state of protoxide, and the liquor assumes a rich red tint.—*Kane.*

Dr. Stenhouse has fully investigated the formation of gallic and of pyrogallic acid; to his papers on this subject those interested are referred. Pyrogallic acid has of late years been largely employed in PHOTOGRAPHY, which see. See GALL NUTS.

PYROLIGNEOUS ACID. See ACETIC ACID.

The apparatus represented in *figs.* 1533 and 1534 is a convenient modification of that exhibited under acetic acid, for producing pyroligneous acid. *Fig.* 1533 shows the furnace in a horizontal section drawn through the middle of the flue which leads to the chimney. *Fig.* 1534 is a vertical section taken in the dotted line *x*, *x*, of *fig.* 1533. The chest *a* is constructed with cast-iron plates bolted together, and has a capacity of 100 cubic feet. The wood is introduced into it through the opening *b*, in the cover, for which purpose it is cleft into billets of moderate length. The chest is



heated from the subjacent grate *c*, upon which the fuel is laid, through the fire-door *d*. The flame ascends spirally through the flues *e e*, round the chest, which terminate in the chimney *f*. An iron pipe *g* conveys the vapours and gaseous products from the iron chest to the condenser. This consists of a series of pipes laid zigzag over each other, which rests upon a framework of wood. The condensing tubes are enclosed in larger pipes *i i*; a stream of cold water being caused to circulate in the interstitial spaces between them. The water passes down from a trough *k*, through a conducting tube *l*, enters the lowest cylindrical case at *m*, flows thence along the series of jackets *i*, *i*, *i*, being transmitted from the one row to the next above it, by the junction tubes *o*, *o*, *o*, till at *p* it runs off in a boiling-hot state. The vapours proceeding downwards in an opposite direction to the cooling stream of water, get condensed into the liquid state, and pass off at *q*, through a discharge pipe, into the first close receiver *r*, while the combustible gases flow off through the tube *s*, which is provided with a stopcock to regulate the magnitude of their flame under the chest. As soon as the distillation is fully set agoing, the stopcock upon the gas-pipe is opened; and after it is finished, it must be shut. The fire should be supplied with fuel at first, but after some time the gas generated keeps up the distilling heat. The charcoal is allowed to cool during 5 or 6 hours, and is then taken out through an aperture in the back of the chest, which corresponds to the opening *u*, *fig.* 1533, in the brickwork of the furnace. About 60 per cent. of charcoal may be obtained from 1000 feet of fir-wood, with a consumption of as much brush-wood for fuel.

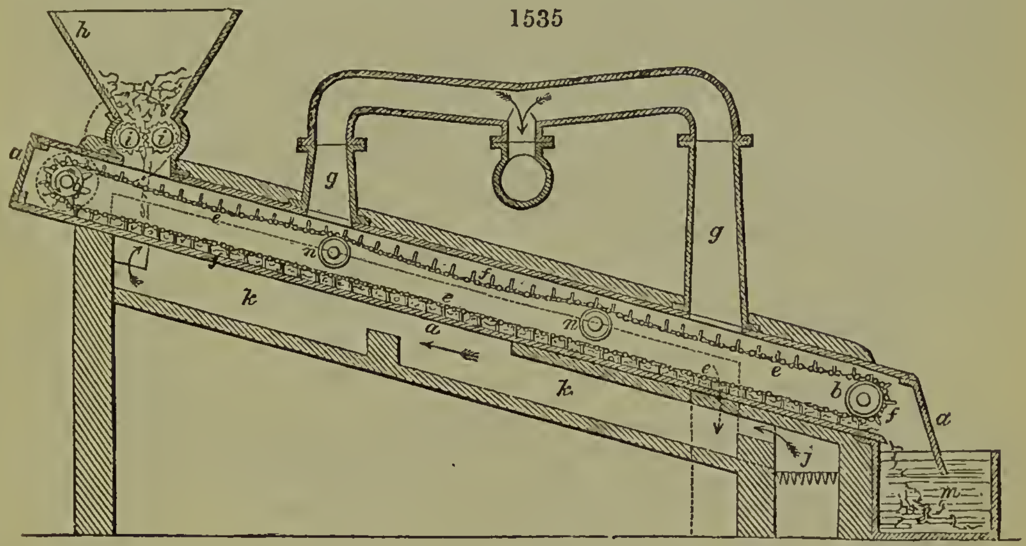
A new mode of distilling wood and producing this acid has been introduced by Mr. W. H. Bowers, of Manchester. In the rectangular retort which is used there are two revolving drums, one at each end. On these drums are endless chains; on these chains there is formed a flat surface by means of bars laid across. A hopper supplies this surface with the sawdust or other material to be heated. The surface is somewhat inclined. A very small engine is used to set the endless chain in motion. The sawdust is carried from the upper end of the retort to the lower, during which time it is exposed to heat and becomes distilled. At the lower end, as it is turning over the drum, it falls in a carbonised state into water. The vapours are carried away by pipes, as in the usual method, and the water joint at the lower part of the retort prevents any escape in that direction, whilst the thickness of the mass of sawdust passing into the retort readily prevents any from passing out there. It is said that one retort can do the work of five of those made on Halliday's plan with the screw. Two of them produce with slow motion 2500 gallons of acid in six days. The motion may be increased at will, and heat regulated accordingly. There are scrapers to prevent charcoal clogging the bars forming the inclined plane, and the apparatus does not require to be stopped for any purpose of cleansing. It feeds and discharges continuously, from month to month.

Sawdust, wood turnings, small chips, spent dye wood, and tanners' bark, peat, and such like ligneous, and carbonaceous substances, are distilled, and the carbon discharged as shown.

It is believed also that the distillation is effected more rapidly, and the gases more directly removed by this method, than by any other.

Fig. 1535 is a longitudinal section taken through the middle of the retort or

1535



rectangular vessel a, a, a; b, b are the revolving drums on which the endless chain e, e, e, revolves; f, f are cross-bars or scrapers; g, g, are tubes to convey the gases, one from the lower and one from the higher point of the moving plane; h is a hopper filled with sawdust and other material to be distilled; the supply is regulated by two small cog-wheels i, i; j, the fire-place; k, k, the flues; m is a cistern showing the level of the water and the carbon falling into it, the lower part of the retort dipping into it.

PYROTECHNY. (*Feux d'artifice*, Fr.; *Feurwerke*, Germ.) The composition of luminous devices with explosive combustibles is a modern art resulting from the discovery of gunpowder. The finest inventions of this kind are due to the celebrated Ruggieri, father and son, who executed in Rome and Paris, and the principal capitals of Europe, the most beautiful and brilliant fire-works that were ever seen. The following description of some of their processes will probably prove interesting:—

The three prime materials of this art are, nitre, sulphur, and charcoal, with filings of iron, steel, copper, zinc, and resin, camphor, lycopodium, &c. Gunpowder is used either in grain, half crushed, or finely ground, for different purposes. The longer the iron filings, the brighter red and white sparks they give; those being preferred which are made with a very coarse file, and quite free from rust. Steel filings and cast-iron borings contain carbon, and afford a more brilliant fire, with wavy radiations. Copper filings give a greenish tint to flame; those of zinc a fine blue colour; the sulphuret of antimony gives a less greenish blue than zinc, but with much smoke; amber affords a yellow fire, as well as colophony, and common salt; but the last must be very dry. Lampblack produces a very red colour with gunpowder, and a pink with nitre in excess.

Golden showers are formed with lampblack and nitre; yellow micaceous sand is also employed for the same purpose. All the copper salts tinge the flame green; those of strontian a red colour; and barytes and its salts also impart a peculiar green. Lycopodium burns with a rose colour and a magnificent flame; but it is principally employed in theatres to represent lightning, or to charge the torch of a fury.

Fire-works are divided into three classes: 1, those to be set off upon the ground; 2, those which are shot up into the air; and 3, those which act upon or under water.

Composition for *jets of fire*; gunpowder, 16 parts; charcoal, 3 parts.

Brilliant revolving-wheel; for a tube less than $\frac{3}{4}$ of an inch: gunpowder, 16; steel filings, 3. When more than $\frac{3}{4}$: gunpowder, 16; filings, 4.

Chinese or jasmine fire; when less than $\frac{3}{4}$ of an inch: gunpowder, 16; nitre, 8;

charcoal (fine), 3; sulphur, 3; pounded cast-iron borings (small), 10. When wider than $\frac{3}{4}$: gunpowder, 16; nitre, 12; charcoal, 3; sulphur, 3; coarse borings, 12.

A fixed brilliant; less than $\frac{3}{4}$ in diameter: gunpowder, 16; steel filings, 4; or gunpowder, 16, and finely-pounded borings, 6.

Fixed suns are composed of a certain number of jets of fire distributed circularly, like the spokes of a wheel. All the fusees take fire at once through channels charged with quick matches. *Glories* are large suns with several rows of fusees. *Fans* are portions of a sun, being sectors of a circle. *Patte d'oie* is a fan with only three jets.

The *mosaic* represents a surface covered with diamond-shaped compartments, formed by two series of parallel lines crossing each other. This effect is produced by placing at each point of intersection, four jets of fire, which run into the adjoining ones. The intervals between the jets must be associated with the discharge of others, so as to keep up a succession of fire in the spaces.

Cascades imitate sheets or jets of water. The Chinese fire is best adapted to such decorations.

Fixed stars. The bottom of a rocket is to be stuffed with clay, the vacant space is to be filled with the following composition, and the mouth covered with pasteboard, which must be pierced into the preparation, with five holes, for the escape of the luminous rays, which represent a star.

	Ordinary.	Brighter.	Coloured.
Nitre - - - - -	16	12	0
Sulphur - - - -	4	6	6
Gunpowder meal - -	4	12	16
Antimony - - -	2	1	2

Lances are long rockets of small diameter, made with cartridge paper. Those which burn quickest should be the longest. They are composed as follows:—

White lances: nitre, 16; sulphur, 8; gunpowder, 4 parts.

Bluest white lances: nitre, 16; sulphur, 8; antimony, 4 parts.

Blue lances: nitre, 16; antimony, 8 parts.

Yellow lances: nitre, 16; sulphur, 8; gunpowder, 16; amber, 8 parts.

Yellower lances: nitre, 16; sulphur, 4; gunpowder, 16; colophony, 3; amber, 4 parts.

Greenish lances: nitre, 16; sulphur, 6; antimony, 6; verdigris, 6 parts.

Pink lances: nitre, 16; gunpowder, 3; lampblack, 1.

Cordage is represented by imbuing soft ropes with a mixture of nitre, 2; sulphur, 16; antimony, 1; resin of juniper, 1 part.

The Bengal flames consist of nitre, 7; sulphur, 2; antimony, 1. This mixture is pressed strongly into earthen porringers, with some bits of quick match strewed over the surface.

Revolving suns are wheels upon whose circumference rockets of different styles are fixed, and which communicate by *conduits*, so that one is lighted up in succession after another. The composition of their common fire is, for sizes below $\frac{3}{4}$ of an inch: gunpowder meal, 16: charcoal, not too fine, 3. For larger sizes: gunpowder, 20; charcoal, not too fine, 4. For *fiery radiations:* gunpowder, 16; yellow micaceous sand, 2 or 3. For *mixed radiations:* gunpowder, 16; pitcoal, 1; yellow sand, 1 or 2.

The *waving or double Catherine wheels*, are two suns turning upon the same axis in opposite directions. The fusees are fixed obliquely and not tangentially to their peripheries. The wheel spokes are charged with a great number of fusees; two of the four wings revolve in one direction, and the other two in the opposite; but always in a vertical plane.

The *girandoles, caprices, spirals*, and some others have on the contrary a horizontal rotation. The fire-worker may diversify their effects greatly by the arrangement and colour of the jets of flame. Let us take for an example the *globe of light.* Imagine a large sphere turning freely upon its axis, along with a hollow hemisphere, which revolves also upon a vertical axis passing through its under pole. If the two pieces be covered with coloured lances or cordage, a fixed luminous globe will be formed, but if horizontal fusees be added upon the hemisphere, and vertical fusees upon the sphere, the first will have a relative horizontal movement, the second a vertical movement, which, being combined with the first, will cause it to describe a species of curve, whose effect will be an agreeable contrast with the regular movement of the hemisphere. Upon the surface of a revolving sun, smaller suns might be placed, to revolve like satellites round their primaries.

Ruggieri exhibited a luminous serpent pursuing with a rapid winding pace a butterfly which flew continually before it. This extraordinary effect was produced in the following way. Upon the summits of an octagon he fixed eight equal wheels turning freely upon their axles, in the vertical plane of the octagon. An endless chain passed round their circumference, going from the interior to the exterior, covering the outside semi-circumference of the first, the inside of the second, and so in succession; whence arose the appearance of a great festooned circular line. The chain, like that of a watch, carried upon a portion of its length, a sort of scales pierced with holes for receiving coloured lances, in order to represent a fiery serpent. At a little distance there was a butterfly constructed with white lances. The piece was kindled commonly by other fire-works, which seemed to end their play, by projecting the serpent from the bosom of the flames. The motion was communicated to the chain by one of the wheels, which received it like a clock from the action of a weight. This remarkable curious mechanism was called by the artists a *salamander*.

The rockets which rise into the air with a prodigious velocity, are among the most common, but not least interesting fire-works. When employed profusely they form those rich volleys of fire which are the crowning ornaments of a public fête. The cartridge is similar to that of the other jets, except in regard to its length, and the necessity of pasting it strongly, and planing it well; but it is charged in a different manner. As the sky-rockets must fly off with rapidity, their composition should be such as to kindle instantly throughout their length, and extricate a vast volume of elastic fluids. To effect this purpose, a small cylindric space is left vacant round the axis; that is, the central line is tubular. The fire-workers call this space the soul of the rocket (*âme de la fusée*). On account of its somewhat conical form, hollow rods, adjustable to different sizes of broaches or skewers, are required in packing the charge; which must be done while the cartridge is sustained by its outside mould, or copper cylinder. The composition of sky-rockets is as follows:—

When the bore is - -	$\frac{3}{4}$ of an inch;	$\frac{3}{4}$ to 1;	$1\frac{2}{3}$.
Nitre - - - -	16	16	16
Charcoal - - -	7	8	2
Sulphur - - -	4	4	4
Brilliant Fire.			
Nitre - - - -	16	16	16
Charcoal - - -	6	7	8
Sulphur - - -	4	4	4
Fine steel filings - -	3	4	5
Chinese Fire.			
Nitre - - - -	16	16	16
Charcoal - - -	4	5	6
Sulphur - - -	3	3	4
Fine borings of cast iron	3 coarser	4 mixed	5

The cartridge being charged as above described, the *pot* must be adjusted to it, with the *garniture;* that is, the serpents, the crackers, the stars, the showers of fire, &c. The pot is a tube of pasteboard wider than the body of the rocket, and about one-third of its length. After being strangled at the bottom like the mouth of a phial, it is attached to the end of the fusee by means of twine and paste. These are afterwards covered with paper. The garniture is introduced by the neck, and a paper plug is laid over it. The whole is enclosed within a tube of pasteboard terminating in a cone, which is firmly pasted to the pot. The quick-match is now finally inserted into the *soul* of the rocket. The rod attached to the end of the sky-rockets to direct their flight, is made of willow or any other light wood. M. Ruggieri replaced the rod by conical wings containing explosive materials, and thereby made them fly further and straighter.

The *garnitures* of the sky-rocket pots are the following:—

1. *Stars* are small, round, or cubic solids, made with one of the following compositions, and soaked in spirits. *White stars:* nitre, 16; sulphur, 8; gunpowder, 3. Others more vivid consist of nitre, 16; sulphur, 7; gunpowder, 4.

Stars for golden showers: nitre, 16; sulphur, 10; charcoal, 4; gunpowder, 16; lampblack, 2. Others yellower are made with nitre, 16; sulphur, 8; charcoal, 2; lampblack, 2; gunpowder, 8.

The serpents are small fusees made with one or two cards; their bore being less than half an inch. The *lardons* are a little larger, and have three cards; the *vetilles* are smaller. Their composition is, nitre, 16; charcoal, not too fine, 2; gunpowder, 4; sulphur, 4; fine steel filings, 6.

The *petards* are cartridges filled with gunpowder and strangled.

The *saxons* are cartridges clayed at each end, charged with the brilliant turning fire, and perforated with one or two holes at the extremity of the same diameter.

The *cracker* is a round or square box of pasteboard, filled with granulated gunpowder, and hooped all round with twine.

Roman candles are fusees which throw out very bright stars in succession. With the composition (as under) imbued with spirits and gum-water, small cylindric masses are made, pierced with a hole in their centre. These bodies, when kindled and projected into the air, form the stars. There is first put into the cartridge a charge of fine gunpowder of the size of the star; above this charge a star is placed; then a charge of composition for the Roman candles.

The *stars*, when less than $\frac{3}{4}$ of an inch, consist of nitre, 16; sulphur, 7; gunpowder, 5. When larger, of nitre, 16; sulphur, 8; gunpowder, 8.

Roman candles, nitre, 16; charcoal 6; sulphur, 3. When above $\frac{3}{4}$ of an inch, nitre, 16; charcoal, 8; sulphur, 6.

The *girandes*, or bouquets, are those beautiful pieces which usually conclude a firework exhibition; when a multitude of jets seem to emblazon the sky in every direction, and then fall in golden showers. This effect is produced by distributing a number of cases open at top, each containing 140 sky-rockets, communicating with one another by quick-match strings planted among them. The several cases communicate with each other by *conduits*, whereby they take fire simultaneously, and produce a volcanic display.

The *water fire-works* are prepared like the rest; but they must be floated either by wooden bowls, or by discs and hollow cartridges fitted to them.

Blue fire for lances may be made with nitre, 16; antimony, 8; very fine zinc filings, 4; Chinese paste for the stars of Roman candles, bombs, &c.:—Sulphur, 16; nitre, 4; gunpowder meal, 12; camphor, 1; linseed oil, 1; the mixture being moistened with spirits.

The *feu grégois* of Ruggieri, the son:—Nitre, 4, sulphur, 2; naphtha, 1.

The red fire composition is made by fixing 40 parts of nitrate of strontia, 13 of flowers of sulphur, 5 of chlorate of potash, and 4 of sulphuret of antimony.

White fire is produced by igniting a mixture of 48 parts of nitre; $13\frac{1}{4}$ sulphur; $7\frac{1}{4}$ sulphuret of antimony; or, 24 nitre, 7 sulphur, 2 realgar; or, 75 nitre, 24 sulphur, 1 charcoal; or, finally, 100 of gunpowder meal; and 25 of cast-iron fine borings.

The blue fire composition is, 4 parts of gunpowder meal; 2 of nitre; sulphur and zinc, each 3 parts.

Mr. A. H. Church has published the following very interesting process for the production of coloured flames:—Bibulous paper soaked for ten minutes in a mixture of 4 parts by measure of oil of vitriol with 5 parts of strong fuming nitric acid, and then wash out thoroughly with warm distilled water, is to be dried at a gentle heat. The gun-paper thus prepared is then saturated with chlorate of strontium, with chlorate of barium, or with nitrate of potassium, by immersion in a warm solution of these salts; a solution of chlorate of copper also may be used. If, after complete drying, a small pellet of any of these papers be made, lighted at one point at a flame, and then thrown into the air, a flash of intensely-coloured light is produced, while the combustion is so perfect that there is no perceptible ash. The barium salt gives a beautiful green light, the strontium salt a crimson, the potassium salt a violet, and the copper salt a fine blue. The chlorate may be prepared sufficiently pure for these experiments by mixing warm solutions of the chlorides of barium, strontium, or copper, with an equivalent quantity of a warm solution of chlorate of potassium. The clear liquid is to be poured off the precipitated chloride of potassium, and employed for the saturation of different portions of the gun-paper. The foregoing makes an admirable lecture-experiment, for illustrating the colours imparted to flame by barium, strontium, and other salts.

PYROMETER. An instrument employed to measure temperatures which are too high to be determined by any thermometer. Some pyrometers have been constructed of bars of metal; the rates of expansion of which are known, and by which, therefore, any high degree of heat could be, with some precision, determined. The pyrometer of Wedgwood has been much employed; but it is still a defective instrument. It consists of two slightly convergent pieces of copper, between which a small cylinder of clay is set; the latter contracts by the heat, and the convergence is therefore increased. Its amount being measured, the heat to which the cylinder has been exposed can be calculated.

A good pyrometer is an instrument much wanted.

PYROPE, *Bohemian Garnet.* From the mountain on the south side of Bohemia, imbedded in trap tufa. It occurs also at Toblitz, in Saxony, in serpentine.

PYROPHORUS. The generic name of any chemical preparation which inflames spontaneously on exposure to the air. The sulphide of potassium is a good example of this when it is prepared with lampblack, in the place of charcoal.

PYROXANTHINE. A substance detected in pyroxylic spirit by Mr. Scanlan. He thus describes this compound:—

If potash water be added to raw wood-spirit (*pyroligneous*), as long as it throws down anything, a precipitate is produced, which is *pyroxanthine*, mixed with tarry matter. The precipitate is to be collected on a filter cloth, and submitted to a strong pressure between folds of blotting-paper; it is next to be washed with cold alcohol, spec. grav. 0·840, in order to free it from any adhering tarry matter; when the pyroxyline is left nearly pure. If it be dissolved in boiling alcohol, or hot oil of turpentine, it crystallises regularly on cooling, in right square prisms, of a fine yellow colour, that look opaque to the naked eye, but when examined under the microscope, have the transparency and colour of ferroprussiate of potash. Its turpentine solution affords crystals of a splendid orange-red colour, having the appearance of minute plates, whose form is not discernible by the naked eye, but when examined by the microscope, they are seen to be thin right rectangular prisms. The orange-red colour is only the effect of aggregation; for when ground to powder, these crystals become yellow; and under the microscope, the difference in colour between the two is very slight. Its melting-point is 318° F. It sublimes at 300° in free air; heated in a close tube in a bath of mercury, it emits vapour at 400°; it then begins to decompose, and is totally decomposed at 500°. Sulphuric acid decomposes it, producing a beautiful blue colour, which passes into crimson, as the the acid attracts water from the atmosphere, and it totally disappears on plentiful dilution with water, leaving carbon of a dirty brown colour. Its alcoholic or turpentine solution imparts a permanent yellow dye to vegetable or animal matter.

Pyroxanthine consists, according to the analysis of Drs. Apjohn and Gregory, of carbon, 75·275; hydrogen, 5·609; oxygen, 19·116, in 100 parts.

PYROXILIC SPIRIT. *Syn. Pyroligneous spirit, Pyroligneous ether, Wood-spirit, Wood-naphtha, Methylic alcohol, Hydrate of methyle, Hydrated oxide of methyle.* $C^2H^4O^2 = C^2H^3O,HO$. Density of strongest wood-spirit at 32°, 0·8179. Density at 68°, 0·798. Density of vapour, 1·12 = 4 volumes. Boiling-point, 150° F.

Wood-spirit was first recognised as a distinct substance by Taylor, in 1812. Its true nature, however, was unknown until the appearance of the important research of MM. Dumas and Peligot, in 1835.

Pyroxilic spirit is obtained from the liquid products of the distillation of wood by taking advantage of its superior volatility. The crude wood-vinegar, if distilled *per se*, yields up to a certain point highly impure and weak spirit. It is, however, free from ammonia and alkaloids. If, on the other hand, the vinegar is first neutralised by lime or soda previous to the distillation of the spirit, it is rendered more free from acetate of methyle and some other impurities, but it then contains alkaloids and ammonia. At times the quantity of the latter substance present is so large that the spirit smokes strongly on the approach of a rod dipped in hydrochloric or acetic acid. In order to apply this test it is obvious that the hydrochloric acid must be diluted until it does not fume by itself. By repeated rectifications over lime or chalk, rejecting the latter portions, the wood-spirit may be obtained colourless, and of a strength varying from 80 to 90 per cent. of pure spirit, the specific gravity being from 0·870 to 0·830.

Inasmuch as wood-spirit boils at a temperature far less than the point of ebullition of the impurities ordinarily found in it, it may always be greatly improved in solvent power, appearance, and odour, by mere rectification on the water bath or in a rectifying still. But, nevertheless, a certain quantity of the more volatile impurities always accompany the methylic alcohol, being carried over with its vapour. Among the foreign bodies may be mentioned the hydrocarbons of the benzole series. These may be entirely removed by mixing the crude spirit with three or four times its volume of water; the hydrocarbons are thus rendered insoluble and rise to the surface of the fluid. By means of a separator the lower layer may be removed, and after two or three rectifications, at as low a temperature as possible, the spirit may be procured quite clean.

To obtain wood-spirit quite pure it is generally recommended to mix it with chloride of calcium, and again rectify on a steam or water bath. By operating in this manner, the methylic alcohol combines with the chloride of calcium, forming a compound not decomposable at the temperature of the water bath. The impurities present therefore distil away, leaving in the still a compound of pure methylic alcohol with chloride of calcium. But this latter compound possesses little stability, and may be decomposed by the mere addition of water, which liberates the spirit. It is then to be distilled away from the salt, and after one or two rectifications over quicklime will be quite pure.

It is highly important that wood-spirit should be of considerable purity if required for the purpose of dissolving the gums. It is true, that as far as its use for dissolving shellac is concerned, there is no need for extreme purity, as shellac will dissolve in most specimens of wood-spirit. But it is not in this case the mere solvent power that is required; for if a solution of shellac in impure wood-spirit be employed by hatters, the vapour evolved is so irritating to the eyes that the workmen are unable to proceed. If the spirit has the property of fuming on the approach of a rod dipped in acetic or hydrochloric acids, it may be taken for granted that it will be incapable of dissolving gum sandarach. This arises from the fact that such spirit has been distilled from an alkaline base, such as lime or soda, and contains alkaloids, ammonia, and various other impurities which destroy its solvent power. The alkaline reaction may be destroyed and the spirit rendered fit for use by adding 2 or 3 per cent. of sulphuric acid and tnen distilling. The alkaloids and many other impurities will then be retained, and the spirit may either be used at once or still further purified by dilution with water and subsequent rectification. It is possible to combine the two processes at one operation, by diluting the spirit with four times its bulk of water, and adding just enough oil of vitriol to the diluted liquid to give it a faint acid reaction to litmus paper. It is absolutely essential to the success of this process that the mixture of spirit water and acid be perfectly well mixed.

A wood-spirit which refuses to dissolve sandarach may often be rendered a good solvent by adding from 5 to 7 per cent. of acetone. See ACETONE.

When wood-spirit is required in a state of extreme purity for the purpose of research, it may be obtained by distilling oxalate of methyle with water. Oxalate of methyle, or methyle oxalic ether may be obtained by distilling equal parts of sulphuric acid, oxalic acid, and wood-spirit. The distillate when evaporated very gently yields crystals of the compound in question. As it does not volatilise below 322° F., the retort containing the materials for its preparation requires to be pretty strongly heated to bring the ether over. It may be purified by sublimation from oxide of lead.

Pure methylic alcohol is a colourless transparent liquid, neutral, very inflammable, burning with a blue flame like common alcohol. It has a very nauseous flavour, and is fiery in the mouth. It dissolves in any proportion in water, alcohol, or ether, and is a good solvent for fatty bodies and certain resins. It is miscible with essential oils.

Wood-spirit may be detected, according to Dr. Ure, even when greatly diluted with alcohol, by the brown colour which it assumes in presence of solid caustic potash. Even when alcohol contains only 2 per cent. of wood-spirit, it acquires a yellow tint in 10 minutes on addition of powdered caustic potash. In half an hour the colour becomes brown.

According to Mr. Maurice Scanlan, wood-spirit may be distinguished from acetone (with which it appears to have sometimes been confounded in medicine), by the action of a saturated solution of chloride of calcium, which readily mixes with the former, but separates immediately from the latter.

Wood-spirit is but seldom employed now in the arts, as it is generally cheaper and more convenient to use the mixture of 90 parts of spirit of wine with 10 parts of purified wood-spirit, which is now permitted by Government to be employed free of duty under the title of "methylated spirit." See METHYLATED SPIRIT.

The theoretical constitution of methylic alcohol is of course represented differently by various chemists. The radical theory regards it as the hydrated oxide of methyle. The formula being C^2H^3O,HO. Another theory assumes it to be methylene (or the olefiant gas of the methyle series), plus two equivalents of water: thus, $C^2H^2,2HO$. But the most convenient method of viewing it is, perhaps, by using the water type, and considering it as two equivalents of water in which one atom of hydrogen is replaced by methyle, thus:—

$$\left.\begin{matrix} C^2H^3 \\ H \end{matrix}\right\} O^2$$

This method of regarding it has the advantage of enabling us to give a direct and simple definition of alcohols and ethers. Thus, an alcohol may in this manner be defined as two atoms of water in which one atom of hydrogen is replaced by an electro-positive radical, while an ether is to be looked upon as two atoms of water in which both atoms of hydrogen are replaced by the electro-positive radical.

Methylic alcohol, treated with solution of bleaching powder, yields chloroform, but the resulting product is not so fine as that prepared from the vinic alcohol. In fact, methylic alcohol is seldom or never found in commerce of such purity as to enable good chloroform to be prepared by the action of chloride of lime. Moreover it should be mentioned that so acrid and pungent are the products of the action of chlorine on the bodies accompanying crude wood-spirit, that great danger would be incurred in using a chloroform containing even minute traces of them. The following equation represents the action of the chlorine of the bleaching powder on wood-spirit:—

$$\underbrace{C^2H^4O^2}_{\text{Wood spirit.}} + 4Cl = \underbrace{C^2HCl^3}_{\text{Chloroform.}} + 2HO + HCl.$$

Specific Gravity.	Real Spirit per cent.	Over Excise proof.	Specific Gravity.	Real Spirit per cent.	Over or under proof.

0·9429	40
0·9576	30
0·9709	20
0·9751	10
0·9857	5

Wood-spirit unites with chloride of calcium with such energy that the liquid enters into ebullition. The product of the union is sufficiently stable to endure a heat considerably above the boiling-point of water, without giving off the alcohol. Water, however, destroys the compound, and enables the spirit to be distilled away on the water bath. — C. G. W.

PYROXYLINE is one of the names given to gun-cotton.

PYRROL. C^8H^5N. A volatile organic base, discovered in coal naphtha by Rungé. It has been chiefly studied by Dr. Anderson. Its vapour possesses the singular property of dyeing fir-wood moistened with hydrochloric acid, a deep red. It appears to be formed whenever animal or vegetable matters containing nitrogen are distilled.—C. G. W.

Q.

QUANNET, THE. A kind of file. It is especially used for scraping zinc plates for the process denominated anastatic printing.

QUARTATION is the alloying of one part of gold that is to be refined along with three parts of silver, so that the gold shall constitute one *quarter* of the whole, and thereby have its particles too far separated to be able to protect the other metals originally associated with it, such as silver, copper, lead, tin, palladium, &c., from the action of the nitric or sulphuric acid employed in the subsequent parting process. See REFINING.

QUARTZ. Flint, Silex. Pure silica in the insoluble state. Quartz includes as sub-species, *Amethyst*, *Rock-crystal*, *Rose-quartz*, *Prase* or *Chrysoprase*, and several varieties of chalcedony, as *Cat's-eye*, *Plasma*, *Chrysoprase*, *Onyx*, *Sardonyx*, *&c.* Lustre vitreous, inclining sometimes to resinous; colours, very various; fracture conchoidal; hardness, 7; specific gravity, 2·69.

QUASSIA is the wood of the root of the *Quassia excelsa*, a tree which grows in Surinam, the East Indies, &c. It affords to water an intensely bitter decoction, which is occasionally used in medicine, and was formerly substituted by some brewers for hops, but is now prohibited under severe penalties. It affords a safe and efficacious fly-water, or poison for flies.

QUEEN'S WARE. See POTTERY.

QUEEN'S YELLOW. Turbith's mineral; the yellow subsulphate of mercury.

QUERCITRON is the bark of the *Quercus nigra*, or yellow oak, a tree which grows in North America. The colouring principle of this yellow dye-stuff has been called *Quercitrin*, by its discoverer Chevreul. It forms small pale yellow spangles, like those of *Aurum musivum;* has a faint acid reaction, is pretty soluble in alcohol, hardly in ether, and little in water. Solution of alum developes from it, by degrees, a beautiful yellow dye. See CALICO-PRINTING and YELLOW DYE.

QUICKLIME. See LIME.

QUICKSILVER. See MERCURY.

QUILL. See FEATHERS.

QUINIDINE is one of the alkaloids obtained from the cinchona barks, and is found in most of them. The quantity, however, varies with the quality of the bark; *Cinchona calisaya*, or *yellow bark*, which is the most prized, containing *quinine*, with but little, if any, *quinidine*, while some of the Loxa barks contain *quinidine*, and some *cinchonine*, and little or no *quinine;* such are the H.O. Crown barks.

Quinidine was discovered in 1833 by MM.Henry and Delandre. It has the same composition as quinine, $C^{40}H^{24}N^{2}O^{4}$, but is nevertheless a distinct alkaloid.

It is obtained from the barks containing it in the same manner as quinine from the quinine-yielding barks; and owing to the employment of the inferior barks in the manufacture of this latter alkaloid or its sulphate, some quinidine is always present in it, but from the greater solubility of the salts of quinidine, they principally remain in the mother liquors, from which the sulphate of quinine has crystallised.

Van Heijningen (*Gerhardt's Chemie Organique*), gives the following description of quinidine:—" When crystallised from its ethereal solution, it yields crystals, which are oblique rhombic prisms, perfectly transparent, but which effloresce in the air, becoming opaque. They contain 4 atoms = 10·8 per cent. of water of crystallisation. It fuses at 320° F., and, on cooling, becomes a resinoid mass. It requires for solution 1,500 parts of cold water, 750 parts of boiling-water, 45 parts of cold absolute alcohol, 3·7 parts of hot ordinary alcohol, and 90 parts of cold ether." Gerhardt states also that its solution yields with chlorine and ammonia the same green colour as quinine. The alcoholic solution of quinidine turns the plane of polarisation strongly to the right, while quinine turns it powerfully to the left.

Finding that Pereira did not agree in any point with Van Heijningen, I determined to make some experiments on quinidine myself, in which I was greatly assisted by the kindness of Messrs. Howard and Sons, who placed at my disposal some of the purest quinidine they had ever prepared. The results are as follows, and will be found to agree closely with those of Van Heijningen.

I found that the sample I experimented on required for solution 3,500 parts of water at 60° F., 750 parts of boiling-water, 30 parts of ordinary alcohol at 60° F., and 60 parts of cold ether. By the spontaneous evaporation of its alcoholic solution it yielded clear crystals, possessing a brilliant lustre, but became opaque by exposure to the air. They contained 4 atoms of water of crystallisation. When treated with chlorine and then ammonia, it yielded the same green colour as quinine does under the same circumstances. It crystallises readily from water, alcohol, or ether, when the hot saturated solutions are allowed to cool. By the application of heat it first fuses, and, by raising the heat, decomposes, yielding an odour of bitter almonds.

Quinidine, like quinine and cinchonine, forms two kinds of salts; the one neutral, the other acid.

The neutral sulphate, $C^{40}H^{24}N^2O^4HSO^4 + 10$ aq., very much resembles sulphate of quinine. It crystallises in long, silky, shining, acicular crystals, but which are somewhat more downy than the sulphate of quinine. It requires for solution 350 parts of water at 50° F., and 32 parts of absolute alcohol. At 266° F. it loses 15·6 per cent. of water of crystallisation = 6 atoms. Its solution is fluorescent, like that of quinine.

The acid or bisulphate, $C^{40}H^{24}N^2O^4,2HSO^4 + 12$ aq. This salt is obtained by adding sulphuric acid to the neutral sulphate, and crystallising. It consists of an asbestos-like mass of fine acicular crystals, which are very soluble in water.

Quinidine may in some degree be distinguished from quinine by the difference of solubility of the neutral oxalates; that of quinine being but little soluble in water, while that of quinidine is very soluble.—H. K. B.

QUININE. This alkaloid is found, together with four other alkaloids, in the cinchona barks, of which there are numerous varieties, some containing principally *quinine*, as the *Calisaya* or yellow bark, which is the most valuable of all the barks on that account; others containing principally *quinidine* and *cinchonine*, with but little *quinine*.

Quinine is the principal of these alkaloids, and is now manufactured on a very large scale for medicinal purposes, it being a valuable tonic and febrifuge.

It was usually prepared from the *C. calisaya*, but, owing to the scarcity and high price of this bark, several of the inferior barks have been employed in its manufacture, and on that account the quinine of commerce frequently contains some of the other alkaloids. The sulphate is the only salt of quinine which is manufactured for commercial purposes, and is generally known, though improperly, as "Disulphate of quinine."

The following is the process most generally followed in the manufacture of this salt. The coarsely-powdered bark is digested with hot dilute sulphuric or hydrochloric acid for one or two hours; the liquor is strained off, and the bark treated with a fresh portion of still more dilute acid for the same time. This process may be repeated a third time, but the liquor then obtained, containing so little quinine, is used for a fresh portion of bark. The liquors from the first and second digestion are strained and mixed, and are then mixed with lime, magnesia, or carbonate of soda, until the liquid acquires a slight alkaline reaction, which may be known by its turning red litmus paper blue. Owing to the solubility of quinine, to a certain extent, in milk of lime and chloride of calcium, carbonate of soda is the best to be used for this purpose. A precipitate is formed, which is separated from the supernatant liquid by straining through a cloth. This dark-coloured mass, which contains the alkaloids, colouring matter, some lime, and some sulphate of lime,—these latter, of course, only when both lime and sulphuric acid have been used in the process,—is treated with boiling ordinary alcohol, which dissolves the alkaloids and colouring matter. This solution is filtered, and the greater part of the alcohol removed by distillation, when a brown viscid mass remains; this is treated with dilute sulphuric acid, till the solution remains slightly acid; this solution is then digested with animal charcoal, filtered, evaporated, and allowed to cool, when the sulphate of quinine crystallises out, together with some sulphate of quinidine or cinchonine, according to the barks which have been employed; but, owing to the greater solubility of these latter salts than the sulphate of quinine, they principally remain in the mother liquors. When *pure* animal charcoal has not been used, the sulphate of quinine is likely to be contaminated with some sulphate of lime, formed by the action of the sulphuric acid on the lime in the animal charcoal; and in this process also some quinine is likely to be precipitated by the lime and lost in the animal charcoal.

In order to separate the sulphate of quinine thus obtained from the sulphates of quinidine and cinchonine, advantage is taken of the greater solubility of the two latter salts, as above mentioned, and by several crystallisations the sulphate of quinine may be obtained nearly free from these salts. The quantity of sulphate of quinine obtained from each pound of bark of course varies with the bark used. Some of the best calisaya bark will yield half an ounce of the sulphate from every pound of bark, while many other barks which are used in the manufacture of sulphate of quinine do not yield a quarter of an ounce.

A process has been patented by Mr. Edward Herring for the manufacture of sulphate of quinine without the use of alcohol, and it yields the article known as hospital sulphate of quinine at the first crystallisation and without the use of animal charcoal. The following is the outline of the process:—

The powdered bark is boiled in solution of caustic alkali (soda preferred), which removes the useless extractive gummy matters and colouring matter. After being well boiled, the bark is washed and pressed. This process of boiling with alkali, &c., may be repeated, if necessary, and the bark, after being well washed and pressed, having become decolourised, is boiled with dilute sulphuric acid, being kept constantly stirred whilst boiling. After the separation of the liquid, the bark is boiled with a second portion of dilute acid, and sometimes with a third; but the liquid from the last boiling is kept to be used for a fresh portion of bark. The first and second portions are mixed, strained, and treated with soda, which precipitates the alkaloids; the precipitate is washed and pressed, and then digested with dilute sulphuric acid, which dissolves the alkaloids; this solution is evaporated and allowed to cool, when the sulphate of quinine crystallises out, accompanied with some sulphates of quinidine and cinchonine, if the bark employed contained these latter alkaloids in any quantity. The sulphate of quinine thus obtained is dried, and forms the unbleached or hospital quinine. When the sulphate of quinine is required quite pure, this is treated with *pure* animal charcoal, and subjected to two or three further crystallisations.

It will be seen that the principal points in this process are the extraction of the colouring matter by the caustic alkali and the use of *pure* animal charcoal in producing the perfectly white sulphate, which prevents completely the admixture of sulphate of lime with the sulphate of quinine.

This process yields from 80 to 90 per cent. of the quinine contained in the bark employed; and to obtain the remaining 10 or 20 per cent. the blood-red solutions formed by boiling the bark with the caustic alkali are treated with dilute hydrochloric acid in excess, which retains in solution any alkaloids that are present. This solution is strained and mixed with lime. The precipitate thus formed is collected, pressed, dried, and powdered.

It is then digested with *benzol*, or any solvent which is not a solvent of lime. These various tinctures or preparations are well agitated with dilute sulphuric acid, which extracts the quinine, &c.; when allowed to settle, the *benzol*, *oil of turpentine*, or *lard*, whichever has been used, rises to the surface. The acid liquid is then siphoned off and evaporated, and the sulphate of quinine obtained from it is purified by two or three crystallisations, when it yields a salt equal to that obtained by the first process, viz. the unbleached or hospital sulphate of quinine.

The sulphate of quinine of commerce is the neutral sulphate, and has the following composition:

$$2C^{40}H^{24}N^{2}O^{4},2HSO^{4} + 14\ aq.$$

When pure it occurs as white spangles, or slender needles, which are slightly flexible, and possess a pearly lustre and an intensely bitter taste. It effloresces in the air, and loses about 12 atoms of water (*Baup*). It requires for solution, 740 parts of cold water and 30 parts of boiling water, 60 parts of alcohol at ordinary temperatures, and much less of boiling alcohol.

Its solution in acidulated water turns the plane of polarisation strongly to the left, and presents a blue tint, which is due to a peculiar refraction of the rays of light on the first surface of the solution, and is termed *fluorescence* by Professor Stokes, who, as well as Sir John Herschel, has examined the cause of it, the latter referring it to epipolic dispersion.

Heated to 212° F., sulphate of quinine becomes luminous, which is augmented by friction, and the rubbed body is found to be charged with vitreous electricity, sensible to the electroscope. It fuses easily, and in that state resembles fused wax; at a higher temperature it assumes a red colour, and at length becomes charred. When a solution of quinine is treated with chlorine and ammonia, it yields a bright green solution, very characteristic of quinine.

Besides the neutral sulphate, there exists an acid sulphate, or *bisulphate*, of the following composition:

$$C^{40}H^{24}N^{2}O^{4},2HSO^{4} + 16HO.$$

It is formed by dissolving the neutral sulphate in dilute sulphuric acid, evaporating and crystallising. It crystallises in rectangular prisms, or silky needles. It is much more soluble in water than the neutral sulphate, requiring only 11 parts of water at ordinary temperatures to dissolve it. The solution reddens blue litmus paper.

It fuses in its water of crystallisation, and at 212° F. loses 24·6 per cent. of water (*Liebig* and *Baup*). With sulphate of sesquioxide of iron, it forms a double salt, which crystallises in octahedra resembling those of alum.

An interesting compound of iodine and bisulphate of quinine has been discovered by Dr. Herapath, which crystallises in large plates, and by reflected light presents an emerald green colour and a metallic lustre, but by transmitted light appears almost colourless. The point of interest in this compound is, that its crystals have the same effect upon a ray of light as plates of *tourmaline*, and have even been used instead of this latter substance.

Its composition is: $C^{40}H^{24}N^2O^4,I^2,2HSO^4 + 10$ aq.

It may be obtained by dissolving the bisulphate of quinine in concentrated acetic acid, and adding to the heated liquid an alcoholic solution of iodine, drop by drop. After standing a few hours, the salt is deposited in large flat rectangular plates.

Adulteration of sulphate of quinine.—Owing to the high price of sulphate of quinine, it is often adulterated with various substances, as alkaline and earthy salts, boracic acid, sugar, starch, mannite margaric acid, salicine, sulphates of cinchonine and quinidine; the two latter substances will be found in most of the commercial sulphate of quinine, and are not looked upon as fraudulent mixtures when present only in small quantities, arising then from the imperfect purification of the sulphate of quinine. Sometimes, however, sulphate of cinchonine is present in large quantities, and this is effected by briskly stirring the solution from which the sulphate of quinine is crystallising, when, although under other circumstances the sulphate of cinchonine would remain in solution, it will by this agitation be deposited in a pulverulent form, together with the sulphate of quinine. No doubt this fraud has been practised to a considerable extent.

The inorganic substances may be easily detected by incinerating some of the suspected salt, when they will be left as ash. When some of the suspected sample is dissolved in dilute sulphuric acid, the margaric acid would remain undissolved; if we then add to the solution a slight excess of baryta water, the sulphuric acid and quinine will be precipitated; the excess of baryta is preciptated by carbonic acid, the solution is then boiled and filtered, when the sugar, mannite, and salicine remain in solution, and may be detected afterwards. The presence of salicine may be detected directly in sulphate of quinine by the addition of sulphuric acid, when it becomes red if salicine be present. Starch is detected by solution of iodine, with which it forms a deep blue compound. Boracic acid is dissolved by alcohol, and is recognised by the green tinge given to the flame of the ignited alcohol. For the discovery of cinchonine, several processes have been proposed. The one most generally adopted, and perhaps the best, is that known as Liebig's process, which depends on the difference of solubility, in ether, of quinine and cinchonine. It consists in putting into a test tube 10 grains of the sulphate of quinine with 120 grains of ether, then adding 10 or 20 drops of caustic ammonia; it is then briskly shaken. If the sulphate of quinine under examination contains no cinchonine, we obtain two layers of liquids, the one of water containing sulphate of ammonia, and the other ether holding the quinine in solution; if the salt contained cinchonine, this would remain suspended at the surface of the watery layer. The same process will detect quinidine also when present in quantities exceeding 10 per cent. of the sulphate of quinine; but the great distinction between quinine and quinidine is their deportment with oxalate of ammonia, this re-agent causing in a solution of sulphate of quinine, a precipitate of oxalate of quinine, whereas the oxalate of quinidine, being very soluble in water, no precipitate is formed by the addition of oxalate of ammonia to a solution of its salt.

Determination of the quantity of quinine in samples of cinchona barks.

In commerce the value of a cinchona bark depends on the quantity of *crystallisable quinine* which it will yield; it is therefore not sufficient to determine the amount of quinine which it contains, as the whole of this may not be convertible into crystallisable sulphates. In order to be accurate not less than a pound of bark should be used, and even then the result is often from ⅛th to ¼th less than can be obtained on the large scale, where the loss in the process is much less in proportion (*Pereira*).

Several processes have been employed for determining the quantities of alkaloids in cinchona barks.

Perhaps as good a process as any is, to exhaust a known quantity of bark by boiling with dilute acid; the solution is filtered, and the residue washed, the washings being added to the other liquid; it is then digested with *pure* animal charcoal, the solution again filtered, and the alkaloids precipitated by carbonate of soda; they are then collected, dried, and digested with ether to separate the quinine; after the evaporation of the ethereal solution, the quinine is dissolved in dilute sulphuric acid, the solution is evaporated, *exactly* neutralised by ammonia, and allowed to cool, when the sulphate of quinine crystallises, which is collected, dried, and weighed; the quantity of the mother liquor being, of course, a cold saturated solution of sulphate of quinine, and knowing the solubility of sulphate of quinine in water, the quantity remaining in the solution may be determined and added to the former weight.—H. K. B.

R.

RAFFAELLE WARE. A fine kind of Majolica ware. This pottery was made in the city of Urbino, and the designs for many of the pieces were "furnished by the scholars of Raffaelle from the original drawings of their great master," and hence the name. (*Marryatt.*) See POTTERY.

RAGS. The fragments and shreds of linen, cotton, or woollen fabrics. Linen and cotton rags are collected from all quarters for the purpose of making paper pulp. The quantity imported annually is seldom less than 11,000 tons. Woollen rags of every kind are worked up into *mungo* and *shoddy*. (See these terms.) Coarse cloths and druggets are made of them; and the fine dust of woollen rags is used in preparing the beautiful flock papers with which our rooms are decorated. They are also used largely for manure. All the early broccoli which are brought to the London market from the western part of Cornwall, are dressed with woollen rags in preference to any other manure.

Rags and other materials for making paper and other purposes, imported in 1858.

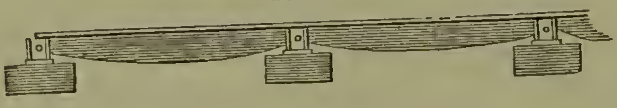
RAG-STONE. A variety of hone slate used for sharpening steel instruments upon. The Norway rag-stone is well known.

RAILS. The manufacture of iron rails has, with the extension of our railway system, increased in a remarkable manner. This is, however, rather a subject for a treatise on mechanical engineering, than for a Dictionary of Manufactures. A short notice only will therefore be given.

In 1820, Mr. Birkinshaw patented an improvement in the form of hammered iron rail. The malleable iron rails previously used were bars from two to three feet long, and one to two inches square; but either the narrowness of the surface produced such injury to the wheels, or by increasing the breadth their cost became so great, as to exceed that of cast iron, which consequently was preferred.

It was to remedy these defects in the malleable form, and at the same time to secure the same strength as the cast iron, that Mr. Birkinshaw made his rails in the form of prisms, or similar in shape to the cast-iron ones of the most approved character.

1536



1538

1537

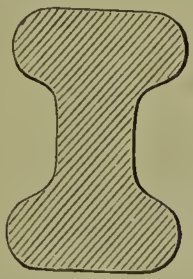
Fig. 1536 shows a side view of this kind of rail; *fig.* 1537, a plan, and *fig.* 1538, a section of the same rail cut through the middle.

These rails are made by passing bars of iron, when red hot, through rollers with indentations or grooves in their peripheries, corresponding to the intended shape of the rails; the rails thus formed present the same surface to the bearing of the wheels, and their depths being regulated according to the distance from the point of bearing, they also present the strongest form of section with the least material. See ROLLING MILLS.

Malleable iron rails are now always employed. An objection has been urged against these rails on the ground that the weight on the wheels rolling on them expanded their upper surface, and caused it to separate in thin laminæ. In many of our large stations rails may be frequently seen in this state; layer after layer breaking off, but this may be regarded rather as an example of defective manufacture than anything else. It is true, Professor Tyndal has referred to those laminating rails, as examples in proof of his hypothesis, that lamination is always due to, and is always produced by, mechanical pressure upon a body which has freedom to move laterally. Careful examination, however, convinces the writer that whenever lamination of the rail becomes evident, it can be traced to the imperfect welding together of the bars of which the rail is formed.

The weight of railway bars varies according to section and length. There are some of 40 pounds per yard, and some of 80 pounds, almost every railway company employing bars of different weight. Beside flat rails, which are occasionally still used, we have bridge rails employed, which have the form of a reversed U. These have sometimes parallel sides, or, as in dovetail rails, the sides are contracted. The ∩-rails are more easily manufactured than the I-rails, the difficulty of filing the flanges not being so great as in the latter rail.

1539



1540

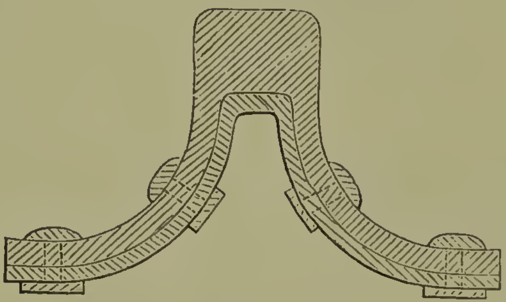


Fig. 1539 represents the old rail, and *fig.* 1540, Mr. W. H. Barlow's patent rail, which is made to form its own continuous bearing. In section this rail somewhat resembles an inverted V, with its ends considerably turned outwards. This portion forms the surface by which the rail bears upon the ballasting, the apex of the Λ being formed with flanges in the ordinary form of rails; and the rail, therefore, beds throughout on the ballast. It can be very easily packed up and adjusted when out of place, and all the fittings of sleepers, chairs, and keys, are done away with, nothing being required besides the rails themselves, except a cross or tie-rod at the joints, to hold them at the proper distance asunder, so as to keep the gauge of the line.

RAKE VEIN, *in Mining*. A vein cutting indifferently through all the strata; under some circumstances they are known as *gash veins* and *slip veins*.

RAISINS are grapes allowed to ripen and dry upon the vine. The best come from the south of Europe, as from Roqueviare, in Provence, Calabria, Spain, and Portugal. Fine raisins are also imported from Smyrna, Damascus, and Egypt. Sweet fleshy grapes are selected for maturing into raisins, and such as grow upon the sunny slopes of hills sheltered from the north winds. The bunches are pruned, and the vine is stripped of its leaves, when the fruit has become ripe; the sun then beaming full upon the grapes completes their saccharification, and expels the superfluous water. These are *muscatels* or *blooms*. The raisins called *lexias*, are plucked, cleansed, and dipped for a few seconds in a boiling lye of woodashes and quicklime, at 12° or 13° of Beaumé's areometer. The wrinkled fruit is lastly drained, dried and exposed in the sun upon hurdles of basket-work during 14 or 15 days.

The finest raisins are those of the sun, so called; being the plumpest bunches, which are left to ripen fully upon the vine, after their stalks have been half cut through.

Valentia raisins are prepared by steeping them in boiling water, to which a lye of vine stems has been added.

Corinthian raisins or *currants* are obtained from a remarkably small variety of grape, called the *black corinth.* They are now grown in Zante, Cephalonia, and Patras.

Our *imports*, in 1858, were as follows:—

Imports of Raisins and Currants, 1858.

Raisins.	Cwts.	Computed real value. £
Spain	287,725	393,064

RAM, HYDRAULIC. Originally invented by Montgolfier, in France, and patented by him in 1797.

This machine, which is self-acting, is composed of an air-vessel and 3 valves, 2 for the water and 1 for keeping up the supply of air. Upon pressing down the valve in the conducting tube, which opens downwards, the water escapes from it, until this momentum is sufficient to overcome the weight, when the valve immediately rises and closes the aperture. The water, having then no other outlet than the inner valve, rushes through it by its general force, compressing the air in the air vessel until equilibrium takes place, when the air reacts by its expansive force, closing the inner valve, which retains the water above it, and driving it up the ascending tube. By this reaction the water is forced back along the conducting pipe, producing a partial vacuum beneath the outer valve, which immediately falls by its own weight. The water thus escapes until it has acquired sufficient force to close this, when the action proceeds as before. It is best adapted for raising moderate quantities of water, as for household or farming purposes.

RAPE SEED. *Brassica campestris oleifera.* Summer Rape, Wild, Navew, or Colza. This and the winter rape (*B. napus*) are the only sorts cultivated to any extent in Britain for the manufacture of oil, and growers generally agree that the former of these is to be preferred from its yielding a greater quantity of seed, in the proportion of 955 to 700. (*Lawson.*) See Colza.

RAPE SEED OIL. See Oils.

RASPS AND FILES. File-making is a manufacture which is still in a great measure confined to Sheffield. It is remarkable that hitherto no machine has been constructed capable of producing files which rival those cut by the human hand. Machine-made files have not the "bite" which hand-cut files have: this is accounted for by the peculiar facilities of the human wrist to accommodate itself to the particular angle suitable to produce the proper "cut." Small files are made out of the best cast steel; those of a larger size from ordinary steel; flat files are forged on an ordinary study; other forms on bolsters, with the indentature corresponding to the shape required being thereon impressed, a chisel wider than the blank to be cut is used as the only instrument to form the teeth; it is moved by the hand with the greatest nicety. After cutting, and previous to hardening, the file is immersed in some adhesive substance, such as ale-grounds, in which salt has been dissolved; this protects the teeth from the direct action of the fire; it is then immersed perpendicularly in water; cleaned and finished.

The manufacture of rasps and files does not belong to this work. Those interested in it will find an elaborate description of all the varieties of files, and of their manufacture, in *Turning and Mechanical Manipulation*, by Holtzapffel; and in *Manufactures in Metal*, vol. i., *Iron and Steel*, revised by Robert Hunt.

RASP, MECHANICAL, is the name given by the French to an important machine much used for mashing beet-roots. See SUGAR.

RATAFIA is the generic name, in France, of *liqueurs* compounded with alcohol, sugar, and the odoriferous or flavouring principles of vegetables. Bruised cherries with their stones are infused in spirit of wine to make the ratafia of Grenoble *de Teyssère*. The liquor being boiled and filtered, is flavoured, when cold with spirit of *noyeau*, made by distilling water off the bruised bitter kernels of apricots, and mixing it with alcohol. Syrup of bay laurel and galango are also added. See LIQUEURS.

RATTANS. The stems of the *Calamus rotang*, of *C. rudentum*, and various species of palms. They are used for caning chairs, as a substitute for whalebone, for walking-sticks, and many other purposes. We *imported* in 1858, 18,625,368 Rattan Canes, valued at 38,960*l.*

RAZORS. The manufacture of razors differs from the manufacture of the finer varieties of cutting instruments, only in the degree of care which is required to produce a perfect instrument.

Two workmen are always engaged in razor-making. The rod of steel of which they are made is about half an inch in breadth, and of sufficient thickness to form the back. The stake upon which they are forged is rounded on both sides of the tops, which is instrumental in thinning the edge, and much facilitates the operation of grinding. The blades are then hardened and tempered in the ordinary way, with the exception that they are placed on their back on an iron plate, and the moment they assume a straw colour of a deep shade they are removed.

The grinding follows, on a stone revolving in water; then glazing on a wooden disc. The fine polish is given by a wooden wheel, having its circumference covered with buff leather, which is covered with crocus. The ornamentation of the blade by etching with acid and gilding, if such is required, is the last process. See *Manufactures in Metal*, as revised by Robert Hunt, and *Mechanical Manipulation* by Holtzapffel.

RAZOR HONE. In the manufacturing of the razor, for the first process of setting, the Charnley Forest stone is used, but the principal part of the setting is accomplished almost invariably on the German hone. Various kinds of hones are, however, sold under this name, and they are of course of very various qualities. See HONES.

RAZOR-STROP. "Perhaps for the razor-strop a fine smooth surface of calf-skin, with the grained or hair side outwards, is best. It should be pasted or glued down flat on a slip of wood, and for the dressing almost any extremely fine powder may be used — such as impalpably fine emery, crocus, natural and artificial specular iron, black lead, or the charcoal of wheat straw; * * * combinations of these and other fine powders, mixed with a little grease and wax, have been with more or less mystery applied to the razor-strop. The choice appears nearly immaterial, provided the powders are exceedingly fine, and they are but sparingly used.

"One side of the strop is generally charged with composition; on the other side the leather is left in the natural state, and the finishing stroke is in general given on the plain side." (*Holtzapffel.*) The razor-strop requires to be kept very clean, and it should be very sparingly used.

REALGAR, *Red sulphide of arsenic.* (*Arsenic rouge sulfure*, Fr.; *Rothes Schwefelarsenik*, Germ.) This ore occurs in primitive mountains, associated sometimes with native arsenic, under the form of veins, efflorescences, very rarely crystalline; as also in volcanic districts; for example, Solfaterra near Naples; or sublimed in the shape of stalactites, in the rents and craters of Etna, Vesuvius, and other volcanoes. Specific gravity varies from 3·3 to 3·6. It has a fine scarlet colour in mass, but orange red in powder, whereby it is distinguishable from cinnabar. It is soft, sectile, readily scratched by the nail; its fracture is vitreous and conchoidal. It volatilises easily before the blow-pipe, emitting the garlic smell of arsenic, along with that of sulphurous acid. It consists of 70 parts of arsenic and 30 parts of sulphur. It is employed sometimes as a pigment

Nearly all the commercial realgar is an artificial product, prepared by submitting arsenical pyrites to distillation, or arsenious acid and sulphur in due proportions. It is an energetic poison, more so than the native realgar, from the fact of its containing free arsenious acid. The principal use of realgar is for fireworks, white Indian fire; often used as a signal light; contains 7 parts sulphur, 2 parts realgar, and 24 parts nitre. — H. K. B.

RECTIFICATION is a second distillation of alcoholic liquors, to free them from whatever impurities may have passed over in the first. See ALCOHOL and DISTILLATION.

REDDLE, or RED CHALK. One of the ores of iron having an earthy texture and conchoidal fracture. It is found more or less mixed with earthy matter, and is used for marking sheep in some of the western counties. A fine variety occurs not far from Rotherham, and is employed in grinding spectacle lenses in Sheffield, and Mr. Greg informs us that it is found at Wastwater in Cumberland.

RED LEAD, a pigment formed by exposing litharge to the action of the air at a temperature of about 560°, by which it absorbs oxygen, and is converted into red lead. See Lead.

RED LIQUOR, when prepared by the dyer or printer, is a liquid compound of acetate of alumina, having in it a little sulphate of alumina and potash, and is prepared by dissolving 8 pounds of alum in boiling water, and adding to this a solution of 6 pounds of acetate of lead, and stirring the whole well together. Sulphate of lead is formed and deposited as a heavy mass at the bottom of the liquid. The clear supernatant liquid is red liquor.

Red liquor of commerce is a crude acetate of alumina, prepared from pyroligneous acid (which see, and Calico Printing). Looking upon the composition of this commercial article, and supposing that alumina was the only intermediate fixing agent, the pyrolignite of alumina, by its easy decomposition into acetic acid and alumina, would be the one preferred; but practice has shown that a sulpho-acetate of alumina gives the best results, and which is composed as follows:—

$$Al^2O^3 \begin{cases} +SO^3 \\ +2C^4H^3O^3 \end{cases}$$

and prepared by mixing together

453 lbs. of ammoniacal alum.
379 lbs. of acetate of lead, or 315 lbs. of pyrolignite of lead.
1132 lbs. of water.

or,

383 lbs. of sulphate of alumina.
379 lbs. of acetate of lead, or 315 lbs. of pyrolignite of lead.
1132 lbs. of water.

or,

453 lbs. of alum, and a quantity of solution of pyrolignite of lime, amounting to 158 lbs.

or,

333 lbs. of sulphate of alumina, with the same amount of pyrolignite of lime.

These substances are well stirred together for several hours, complete double decomposition ensues, sulphate of lead is deposited, and sulpho-acetate of alumina remains in solution with one equivalent of sulphate of ammonia, proceeding from the ammoniacal alum employed, as only two equivalents of sulphuric acid are removed from the four which alum contains.

But as sulphate of ammonia is of no use in the process of mordanting cloth, and as it may be considered as increasing the price of the articles to the manufacturer, a very intelligent firm had the good idea of replacing ammoniacal alum by sulphate of alumina, thus not only rendering the liquor cheaper, but their liquor marks the same strength as that of other manufacturers,—namely, sp. gr. 1·085, or 17 Twaddle. The red mordant D of this firm contains a larger amount of useful agents under the same bulk of fluid.

The following analyses clearly show this point:—

Composition of Four Mordants per Gallon.

Substances.	Formula. $Al^2O^3SO^3,2C^4H^3O^3+NH^3SO^3,HO$.						Formula. $Al^2O^32SO^3,C^4H^3O^3+NH^3SO^3,HO$.			Formula. $Al^2O^3+SO^3,2C^4H^3O^3$.		
	Mordant A.			Mordant B.			Mordant C.			Mordant D.		
	grains.	oz.	grs.	grains.	oz.	grs.	grains.	oz.	grs.	grains.	oz.	grs.
Alumina	1680·0	3	18	1830·0	4	19	1239·0	2	365	2164·4	4	416
Sulphuric acid	1642·5	6	20	2800·0	6	178	3017·0	6	395	1664·6	3	323
Acetic acid	3369·8	7	307	3570 0	8	70	1281·7	2	406	3679·2	8	179
Ammonia and water	·674·1	1	236	·910·0	2	35	·653·1	1	215			

Nevertheless where sulphate of alumina is used, a little ammonia, soda, or potash may be added advantageously for certain colours, giving greater power to the mordant.

From these results it is easy to perceive that the composition of red liquors varies a great deal, and that it is of importance to our extensive calico-printing firms to inquire more than they at present do into the composition of their red mordants. The use of the hydrometer should be confined to its legitimate purpose—taking the sp. gr., — and banished as being a test for quality. Let this be found by the chemist, — the calico printer should always know it — and by doing so we have no doubt they will arrive at two ends, — viz. account better than they do for the superiority of some prints over others, and attribute failures to the proper source, as a slight variation in the composition of a mordant will make a great difference in the production of a colour.

RED MARL. *A geological term*, designating the upper members of the new red sandstone formation.

RED OCHRE. An earthy oxide of iron.

REDRUTHITE. A name given, very absurdly, by Brooke and Miller to the vitreous copper of Phillips, from the circumstance that some fine varieties have been found in the mines near Redruth, although much finer are produced by the St. Just mines. The *chalcosine* of Greg and Lettsom, *cuivre sulfure* of Hauy, and the *Kupferglanz* of Haidinger and Naumann. Thomson gives the analysis of a specimen from the united mines in Groennass.

RED SANDERS WOOD. A hard and heavy wood, which is imported from Calcutta in logs. It is much used as a dyewood, and occasionally for turning.

RED WOOD. A wood used by dyers, which is obtained from the Siberian buckthorn, *Rhamnus arythroxylon.*

REED is the well-known implement of the weaver, made of parallel slips of metal or reeds, called dents. A thorough knowledge of the adaptation of yarn of a proper degree of fineness to any given measure of reed, constitutes one of the principal objects of the manufacturer of cloths; as upon this depends entirely the appearance, and in a great degree the durability, of the cloth when finished. The art of performing this properly is known by the names of *examining*, *setting*, or *sleying*, which are used indiscriminately, and mean exactly the same thing. The reed consists of two parallel pieces of wood, set a few inches apart, and they are of any given length, as a yard, a yard and a quarter, &c. The division of the yard being into halves, quarters, eighths, and sixteenths; the breadth of a web is generally expressed by a vulgar fraction, as $\frac{1}{4}$, $\frac{4}{4}$, $\frac{5}{5}$, $\frac{6}{5}$; and the subdivisions by the eighths or sixteenths, or *nails*, as they are usually called, as $\frac{7}{8}$, $\frac{9}{8}$, $\frac{11}{8}$, &c., or $\frac{13}{16}$, $\frac{15}{16}$, $\frac{19}{16}$, &c. In Scotland, the splits of cane which pass between the longitudinal pieces or ribs of the reed are expressed by hundreds, porters, and splits. The porter is 20 splits, or, $\frac{1}{5}$th of an hundred.

In Lancashire and Cheshire a different mode is adopted, both as to the measure and divisions of the reed. The Manchester and Bolton reeds are counted by the number of splits, or, as they are there called, dents, contained in 24¼ inches of the reed. These dents, instead of being arranged in hundreds, porters, and splits, as in Scotland, are calculated by what is there termed *hares* or *bears*, each containing 20 dents, or the same number as the porter in the Scotch reeds. The Cheshire or Stockport reeds, again, receive their designation from the number of ends or threads contained in one inch, two ends being allowed for every *dent*, that being the almost universal number in every species and description of plain cloth, according to the modern practice of weaving, and also for a great proportiou of fanciful articles.

The number of threads in the warp of a web is geuerally ascertained with considerable precision by means of a small magnifying glass, fitted into a socket of brass, under which is drilled a small round hole in the bottom plate of the standard. The number of threads visible in this perforation ascertains the number of threads in the standard measure of the reed. Those used in Scotland have sometimes four perforations, over any one of which the glass may be shifted. The first perforation is ¼ of an inch in diameter, and is therefore well adapted to the Stockport mode of counting; that is to say, for ascertaining the number of ends or threads per inch; the second is adapted for the Holland reed, being $\frac{1}{200}$th part of 40 inches; the third is $\frac{1}{700}$th of 37 inches, and is adapted for the now almost universal construction of Scotch reeds; and the fourth, being $\frac{1}{200}$th of 34 inches, is intended for the French cambrics. Every thread appearing in these respective measures, of course, represents 200 threads, or 100 splits, in the standard breadth; aud thus the quality of the fabric may be ascertained with considerable precision, even after the cloth has undergone repeated wettings, either at the bleaching ground or dye-work. By counting the other way, the proportion which the woof bears to the warp is also known, and this forms the chief use of the glass to the manufacturer and operative weaver, both of whom are previously acquainted with the exact measure of the reed.

Comparative table of 37-inch reeds, being the standard used throughout Europe, for linens, with the Lancashire and Cheshire reeds, and the foreign reeds used for holland and cambric.

Scotch.	Lancashire.	Cheshire.	Dutch holland.	French cambric.
600	20	34	550	653
700	24	38	650	761
800	26	44	740	870
900	30	50	832	979
1000	34	54	925	1089
1100	36	60	1014	1197
1200	40	64	1110	1300
1300	42	70	1202	1414
1400	46	76	1295	1464
1500	50	80	1387	1602
1600	52	86	1480	1752
1700	56	92	1571	1820
1800	58	96	1665	1958
1900	62	104	1757	2067
2000	66	110	1850	2176

In the above table, the 37-inch is placed first. It is called Scotch, not because it either originated or is exclusively used in that country; it is the general linen reed of all Europe; but in Scotland it has been adopted as the regulator of her cotton manufactures.

REFINING GOLD AND SILVER. Since the object of this book is to treat more especially of the application of scientific processes to commercial undertakings, it would be out of place to give a detailed account of the processes by which gold and silver are refined, or rendered free from other metals. In the laboratory, where chemical manipulation has reached a great way to perfection, the precious metals are separated by nitric acid and other agents, but the processes are far too expensive and tedious to admit of being used upon a large scale.

For the purposes of rendering gold containing foreign metals sufficiently pure for the operations of coining, Mr. Warrington has recently described a process by which fused gold is treated with black oxide of copper, with a view to oxidising those metals which render gold too brittle for manufacture into coin. Mr. Warrington proposes to add to fused gold, which is found to be alloyed with tin, antimony, and arsenic, 10 per cent. of its weight of the black oxide of copper, which, not being fusible, is capable of being stirred up with the fused mass of gold, just as sand may be stirred up with mercury, but with this great advantage, that the oxide of copper contains oxygen, with which it parts readily to oxidise any metal having a greater affinity for oxygen than itself. The metals, once oxidised, become lighter than the fused metal, and mixing mechanically, or combining chemically with the black oxide of copper, float to the surface and are removed. In the execution of Mr. Warrington's proposition, it is imperative to use crucibles free from reducing agents, such as carbon, and it is found that half an hour is sufficient time to allow the contact of the oxide of copper with the fused gold.

It has been generally stated by those supposed to be acquainted with the subject, that gold containing tin, antimony, and arsenic is so brittle as to render it wholly unfit for coining. This requires modification, for although these metals, as well as lead, render gold so brittle that it will readily break between the fingers, yet it is not true to say that it renders gold so brittle as to be incapable of being coined. In June and July, 1859, some brittle gold, to the extent of about 64,000 ounces, passed through the Mint. The bars were so brittle that they broke with the slightest blow from a hammer, but by special treatment the gold was coined into the toughest coins ever produced. It may now be stated that if the system of manufacture be changed to suit the requirements of the case, gold cannot be found too brittle for the purpose of coining. This is simply a matter of fact, but the expense of coining brittle gold is undoubtedly very great; it is therefore wise that Mr. Warrington's plan should be adopted for all gold containing the volatile metals or tin. Osmium-iridium does not render gold brittle. Dr. Percy and Mr. Smith have demonstrated that all metallic substances found in commerce contain traces of gold, which can be separated by carefully conducted chemical processes, and it is found that silver is peculiarly liable to be in alloy with gold, and gold with silver; hence a process of refining which shall effect the separation of as little as one five-hundredth part of gold from its mass of silver, is a matter of the utmost commercial importance.

It is with regret that it is stated that the refineries of London are conducted with such secrecy as to render a full description of any one of them impossible, while the ignorance which will induce the proprietors of these establishments to attempt such quietude is much to be pitied, for, except so far as regards details of interior arrangement, their processes are as well known and understood as it is possible for any manufacture to be.

In Paris (the London refiners are known to use the "French process"), the plan adopted is founded on the fact, that at a high temperature sulphuric acid parts with one equivalent of its oxygen to oxidise an atom of a metal, while the atom of oxide so formed at once combines with another atom of sulphuric acid to form a sulphate. The atom of sulphuric acid which has parted with its atom of oxygen passes off as gaseous sulphurous acid.

If mercury be boiled with sulphuric acid (commonly called oil of vitriol), it is found that it entirely loses its metallic existence, and assumes the form of a dense white salt. This change takes place at the expense of the sulphuric acid, and is shown by the following equation. For explanation sake, call mercury Hg, and sulphuric acid SO^3; if now it is assumed that one part or atom of Hg be boiled with two parts or atoms of SO^3, we have $Hg + SO^3 + SO^3$, and for elucidation we may write SO^3 as equal to $SO^2 + O$; then we have $Hg + O + SO^3 + SO^2$, which, under the influence of heat, become $\underbrace{HgOSO^3}_{\text{a white salt.}} + \underbrace{SO^2}_{\text{gas.}}$

If now the mind substitutes silver for mercury, and so writes Ag instead of Hg, the whole matter will be understood. The silver is dissolved in sulphuric acid just as sugar would be in water, and in this fact we have a valuable means of separating it from gold. If for a moment one imagines a mass of silver alloyed with gold to be represented by a piece of sponge filled with water and frozen, it is well known that if the mass be warmed the ice is melted, and in the form of water filters from the sponge, just so, if a mass of the alloy of the precious metals be boiled in sulphuric acid, the silver is dissolved or washed away, leaving the gold in the form of a sponge, which, as it becomes exposed to the bubbling of the acid, is detached and falls to the bottom of the vessel in which it is boiled.

If by assay the silver to be refined is found to be very rich in gold, it is better to fuse the mass with more silver, so as to produce a mass containing at least 3 of silver to 1 of gold, and this alloy, in its fluid state, should be poured into cold water, by which the falling stream is suddenly chilled, and the particles become what is technically called "granulated." The stream should fall some distance (not less than 2 feet) through the air before it reaches the water, that the copper (if any be present) may be as much as possible oxidised, with a view to saving sulphuric acid.

In all cases the alloyed metals should be granulated, because the extended surface of metal presented to the hot acid saves much time.

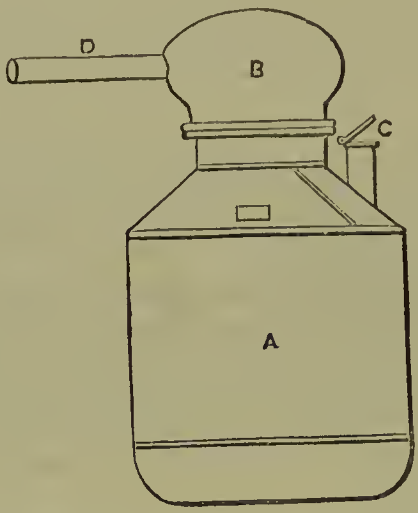
Silver containing less than $\frac{1}{500}$ part of its weight of gold is found not to pay for separation, but any which contains this amount or more is treated as follows:—

Vessels of platinum were formerly used and were deemed indispensable, but experiment has proved that these may be safely replaced by cast-iron vessels; in both cases the boilers or retorts are provided with tubes passing from the top into chambers which receive the acid gases and vapours.

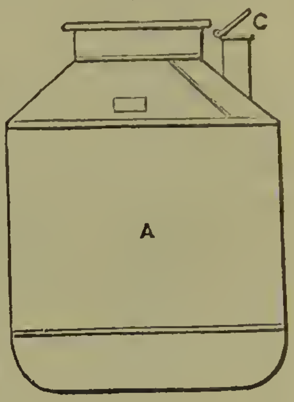
The platinum vessels used by Mr. Mathison and subsequently by Messrs. Rothschild for many years are now out off use, but as sketches of the vessels actually used cannot be obtained, it is deemed wise to give a sketch of the platinum vessels, which weigh 323·40 troy ounces, and contain, if filled to the neck, 8 gallons of water. A, the retort or boiler; B, the head, provided with a tube of platinum, D, to which is joined at the time of use a long tube of lead. C is a tube terminating on the shoulder of the boiler, and provided with a lid, and is of service to allow of the occasional stirring of the silver during solution, and of the addition of the small quantity of acid at the termination of the chemical action. The vessels became much coated with gold, which was removed with difficulty and at great risk of attacking the platinum. The sketches (*figs.* 1541, 1542, and 1543) are 1 in. to a foot.

According to convenience and requirements, the retort or boilers may be multiplied as to number, but about 5 or 6 would seem to be a convenient set for operations. Independently of the smaller prime cost of cast-iron retorts or boilers (now used in place of platinum), there is the advantage of being able to use acid which is not free from impurities, because the cost of the retorts is practically not worth consideration, if taken in relation to the extra price which must be paid for pure acid. Beside these facts, it is found that owing to some influence (is it chemical or catalytic?) which the iron exerts, less acid is required to be used in proportion to the precious metals than was used when platinum vessels were believed to be necessary.

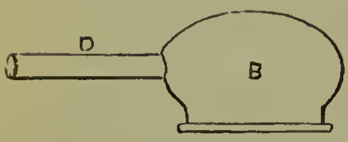
1541



1542



1543



A charge for one boiler varies from 1130 to 1300 troy ounces of the granulated mixed precious metals, and is heated with about twice or twice and a half times its weight of sulphuric acid of sp. gr. 1·7047. The heat is gradually raised until effervescence takes place, and it is then regulated with care, while at last, the temperature is raised nearly to the boiling point. As in the case of mercury so in the case of silver, it is better not to rise quite to the boiling point, else sulphuric acid distils off with the escaping sulphurous acid. According to the care with which the granulating has been effected, each charge is heated from 3 to 4 hours. When the elimination of sulphurous acid ceases the operation is known to be terminated, and chemical examination shows that exactly equivalent quantities of sulphate of silver and sulphate of copper are formed to account for the sulphuric acid. In practice the sulphurous acid is frequently lost, although in all refineries it should be used for the re-composition of sulphuric acid.

Leading from the top of the boiler or retort is an horizontal leaden tube from 8 to 10 yards long, terminating in a leaden chamber, in which sulphuric acid and sulphurous acids accumulate with some sulphate of silver, mechanically carried over by the violence of the chemical action. It is found that the acid which accumulates in this leaden chamber has a sp. gr. of from 1·3804 to 1·4493. The reduced strength of the acid from 1·7047 to this point is readily understood if the fact be remembered that sulphuric acid is really a compound of anhydrous sulphuric acid and water, and that only the anhydrous sulphuric acid is concerned, although the water performs the friendly part of leading it into action on the silver; the action having commenced, the water is done with, and passes off with the sulphurous acid as it is eliminated; but independently of this cause, it is found that sulphuric acid, by boiling, parts with water, and concentrates itself, until by and by the anhydrous acid itself distils off, and when this is seen, it is at once known that the operation is carried rather too far. When the action has quite terminated, it is customary to add to each boiler or retort from 60 to 80 Troy ounces of sulphuric acid of sp. gr. 1·6656, procured from the liquor which has deposited sulphate of copper (presently described), then to pour the whole into a leaden boiler, and boil it for a few minutes, then withdraw the fire, and allow to stand for half an hour, during which time the gold is precipitated. The object in adding this amount of sulphuric acid is to form a clear solution, that the gold may be enabled to settle to the bottom; water could not be added, because it would probably cause an explosion by the heat evolved in its combination, and because sulphate of silver is not very soluble in water, while it is soluble to a very large extent in hot sulphuric acid. At the end of half an hour the clear liquor, containing in solution the silver and copper as sulphates, is decanted and mixed with so much water as shall reduce it to a sp. gr. of from 1·2080 to 1·2605, and well stirred. Copper plates are then introduced, while the solution is kept hot or boiling by a jet of steam.

The silver salt is decomposed by the copper plates, and the copper passes into solution as sulphate of copper, so that at the end of the precipitation the solution contains the copper of the original alloy, as well as the copper which has been used to precipitate the silver. The silver precipitates or falls to the bottom in a finely divided or spongy form, and it is commonly thought that the whole of the silver is thrown down when a portion of the solution is not rendered turbid by a solution of chloride of sodium; but in the presence of a strongly acid solution this test is not to be relied on for minute quantities; therefore, in some refineries, the solution is allowed to rest for days together in leaden cisterns in which copper plates are placed, so that by these means the last traces of silver are obtained.

If the amount of gold be very minute, the original solution is well stirred and then allowed to settle for some time; when finely divided gold, mechanically mixed with crystals of sulphate of silver and crystals of sulphate of copper, is found at the bottom. This deposit is boiled with water, and is then transferred to a vessel in which it is kept hot, and is brought into contact with suspended copper-plates, by which the silver is rendered metallic, and falling to the bottom of the vessel, mixes with the gold. The mixed precipitate of silver and gold is then dried, melted, and granulated, and treated with sulphuric acid, as in the process already described. By this extra process the gold becomes concentrated by the removal of the silver, and is then thrown down in larger and more easily collected particles. When the gold is finely divided and precipitates slowly, the following plan is sometimes adopted:—The whole precipitate containing finely divided gold mixed with sulphate of silver, is washed well with warm water, and left to rest. The sulphate of silver is dissolved, but the gold settles to the bottom of the vessel, but is still mixed with a minute quantity of sulphate of silver. It is drained and placed in the retort or boiler of cast-iron, and boiled with sulphuric acid; this boiling is twice repeated, and at last a very diluted solution of sulphate of silver is obtained; but by the boiling the gold has assumed a form which enables it to precipitate rapidly; in fact, the flocculent sponge becomes a mass of dense particles, which fall readily to the bottom, are collected and well washed, to free them from silver, and are then dried ready for melting.

The solution of sulphate of silver is evaporated in leaden vessels by the agency of steam, until it becomes saturated, and is then allowed to stand for an hour that all the gold may separate, and is then drawn off either by a tap placed about half an inch from the bottom of the vessel, or by a siphon, and is then treated with copper-plates as already detailed.

In all cases the precipitated spongy silver is carefully washed to free it from sulphate of copper, and dried by heat or by hydraulic pressure; but if dried by pressure the masses obtained are found to contain from 8 to 10 per cent. of water, and are therefore dried by a gentle heat to avoid the breaking up of the masses, from the sudden formation of steam, as well as to save the chance of destroying the pot of Picardy clay in which the silver is melted when it has been dried.

After melting the silver is found to retain traces of gold, which are so minute as to be overlooked, since the cost of recovery would exceed the value of the gold to be recovered; but the silver is found to be alloyed with from 5 to 6 thousandths of its weight of copper, which appears to be left in the form of sulphate, notwithstanding the washings to which the silver has been subjected. It is practically impossible to wash away the last traces of sulphate of copper. This small amount of copper is of little importance, since it amounts to but 5 parts of copper alloyed with 995 parts of silver, yet this may be removed by fusion and treatment with nitrate of potassa.

During the whole process, even if copper be not present in the original mass of metal to be refined, it is to be observed that copper plates are used for precipitating the silver; therefore sulphate of copper is found in considerable quantities, and as this salt has a high commercial value as giving the base for many colours used in painting and paper-hangings, as well as for agricultural purposes, it becomes desirable to obtain this salt in a saleable form. The solution is therefore evaporated to a sp. gr. of 1·3804, and allowed to cool, when crystals deposit; but since sulphate of copper deposited from strongly acid solutions is mixed with the anhydrous salt, the whole mass of crystals is redissolved in warm water, and allowed to stand in leaden vessels about 6 ft. long, 3 ft. deep, and 3 ft. wide, that the crystals may deposit slowly, as slow formation produces large crystals, which are more easily collected. The sulphate of copper is represented by $CuO,SO^3,5HO$. The mother liquors are evaporated and returned to the works, being in fact free sulphuric acid, with a small amount of sulphate of copper in solution. The parts of the hydraulic presses which come in contact with the silver at the time of pressing, are coated with a compound of tin and lead, hardened by mixture with antimony. Cast-iron is very little attacked by concentrated sulphuric acid, but it is necessary to avoid wrought iron in any shape, and copper vessels would of course be rapidly destroyed.

The floors should be covered with lead of tolerable thickness. The melting pots used in France are made of Picardy clay, and hold from 2200 to 2600 Troy ounces of silver. The pots cost from 4*d.* to 6*d.* each, and if dried and used with care, very seldom crack or break.

The total cost of refining silver in Paris, inclusive of the loss by melting, is stated to be 15 centimes for 32 Troy ounces; but it must be understood that the loss of silver by melting is absolutely very minute, because the flues are swept, and the sweepings so obtained are made to yield the silver which has been volatilised, while the pots, &c., are ground and made to yield their absorbed silver.

In the event of the mass containing much copper and little silver, it is usual to granulate the mass and roast the granulated particles to oxidise the copper; the oxide of copper is then dissolved out by diluted sulphuric acid, and the remaining mass of silver, with a smaller amount of copper, is treated in the ordinary way.

If the gold contains platinum, it is found that it is apt to retain from 4 to 5 per cent. of silver, which must be separated by mixing the precipitated gold with about a fourth of its weight of anhydrous sulphate of soda (which is preferred to sulphate of potassa, on account of its greater solubility in water), and to moisten this mass with concentrated sulphuric acid, using about 6 or 7 parts of acid to every 10 parts of sulphate of soda. The moistened mass is then heated till sulphuric acid ceases to distil off, and the heat is then raised till the whole mass melts; and by extracting the sulphate of silver and sulphate of soda the gold will be found to contain 99·40 parts of gold in 100·00 parts; but if the process be repeated, the gold is obtained of a purity of 99·90.

When the silver has been removed, the gold is fused with nitre, which oxidises and removes the platinum; but the potash salt formed is found to contain gold, so that the gold and platinum are obtained from the potash salt mixed with fused nitre by the process of cupellation, for which see Assay.—G. F. A.

REFRIGERATION OF WORTS, &c. The simplest mode of refrigeration is by exposing the hot liquor or wort in shallow vessels, called coolers, to the action of the atmosphere or a current of air, sometimes accelerated by fans rotating horizontally just above the surface of the liquor; but sometimes utensils called refrigerators are employed, and so constructed that a quantity of cold water should be brought into contact with the heated fluid.

A simple form of refrigerator is that of the worm used by distillers; and the reverse process is commonly used by brewers, viz. a stream of cold water passing through pipes in a zigzag form, laid horizontally in the shallow cooler. But in every construction of refrigerator heretofore used, the quantity of cold water necessarily employed in the operation, greatly exceeded the quantity of the fluid cooled, which, in some situations, where water cannot be readily obtained, was a serious impediment and objection to the use of such apparatus.

In August, 1826, Mr. Yandall obtained a patent for an apparatus designed for cooling worts and other hot fluids, without exposing them to evaporation; and contrived a mode of constructing a refrigerator so that any quantity of wort or other hot fluid may be cooled by an equal quantity of cool water; the process being performed with great expedition, simply by passing the two fluids through very narrow passages, in opposite directions, so that a thin stratum of hot wort is brought into contact over a large surface with an equally thin stratum of cold water, in such manner that the heated water, when about to be discharged, still absorbs heat from the hottest portion of the wort, which as it flows through the apparatus is continually parting with its heat to water of a lower temperature flowing in the contrary direction; and however varied may be the form, the same principle should be observed.

Figs. 1544, 1545, 1546 represent different forms in which the apparatus is proposed to be made. The two first have zigzag passages; the third, channels running in convolute curves. These channels or passages are of very small capacity in thickness, but of great length, and of any breadth that may be required, according to the quantity of fluid intended to be cooled or heated.

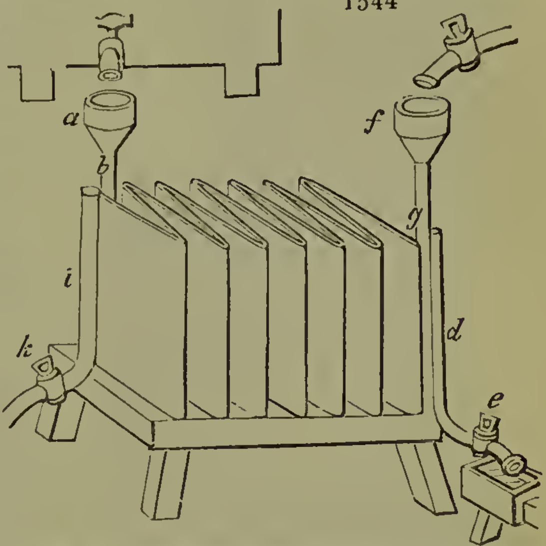
Fig. 1547 is the section of a portion of the apparatus shown at *figs.* 1544 and 1545 upon an enlarged scale; it is made by connecting three sheets of copper or any other thin metallic plates together, leaving parallel spaces between each plate for the passage of the fluids, represented by the black lines.

These spaces are formed by introducing between the plates thin straps, ribs, or portions of metal, to keep them asunder, by which means very thin channels are produced, and through these channels the fluids are intended to be passed, the cold liquor running in one direction, and the hot in the reverse direction.

Supposing that the passages for the fluids are each one-eighth of an inch thick, then the entire length for the run of the fluid should be about 80 feet, the breadth of the apparatus being made according to the quantity of fluid intended to be passed through it in a given time. If the channels are made a quarter of an inch thick, then their length should be extended to 160 feet; and any other dimensions in similar proportions; but a larger channel than a quarter of an inch, the patentee considers would be objectionable. It is, however, to be observed, that the length here recommended is under the consideration that the fluids are driven through the apparatus by some degree of hydrostatic pressure from a head in the delivery-vats above; but if the fluids flow without pressure, then the lengths of the passages need not be quite so great.

In the apparatus constructed as shown in perspective at *fig.* 1544, and further developed by the section, *fig.* 1547, cold water is to be introduced at the funnel *a*, whence it passes down the pipe *b*, and through a long slit or opening in the side of the pipe, into the passage *c, c* (see *fig.* 1547), between the plates, where it flows in a horizontal direction through the channel towards the discharge-pipe *d*. When such a quantity of cold water has passed through the funnel *a*, as shall have filled the channel *c, c*, up to the level of the top of the apparatus, the cock *e* being shut, then the hot wort or liquor intended to be cooled, may be introduced at the funnel *f*, and which, descending in the pipe *g*, passes in a similar manner to the former, through a long slit or opening in the side of the pipe *g*, into the extended passage *h, h* (*fig.* 1547), and from thence proceeds horizontally into the discharge-pipe *i*.

1544



The two cocks *e* and *k*, being now opened, the wort or other liquor is drawn off, or otherwise conducted away through the cock *k*, and the water through *e*. If the apertures of the two cocks *e* and *k*, are equal, and the channels equal also, it follows that the same quantity of wort, &c., will flow through the channel *h, h, h*, in a given time, as of water through the channel *c, c*; and by the hot fluid passing through the apertures in contact with the side of the channel which contains the cold fluid, the heat becomes abstracted from the former, and communicated to the latter; and as the hot fluid enters the apparatus at that part which is in immediate contact with the part where the cooling fluid is discharged, and the cold fluid enters the apparatus at that part where the wort is discharged, the consequence is, that the wort or other hot liquor becomes cooled down towards its exit-pipe nearly to the temperature of cold water; and the temperature of the water, at the reverse end of the apparatus, becomes raised nearly to that of the boiling wort.

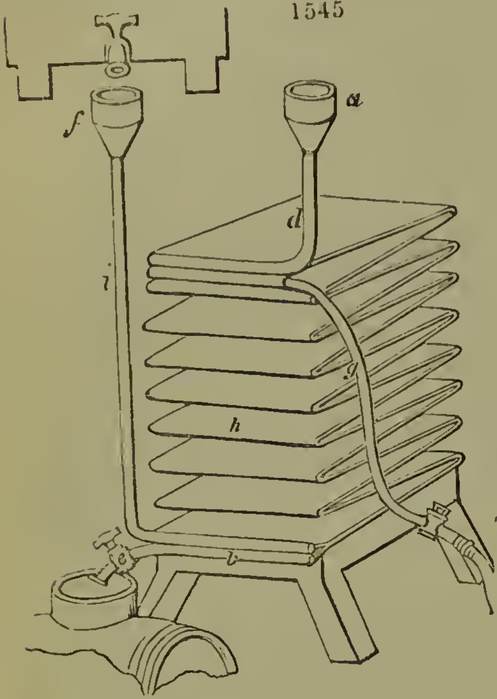
It only remains to observe, that by partially closing either of the exit-cocks, the quantity of heat abstracted from one fluid, and communicated to the other, may be regulated; for instance, if the cock *e* of the water-passage be partially closed, so as to diminish the quantity of cold water passed through the apparatus, the wort or other hot fluid conducted through the other passages will be discharged at a higher temperature, which in some cases will be desirable, when the refrigerated liquor is to be fermented.

Fig. 1545 exhibits an apparatus precisely similar to the foregoing, but different in its position; for instance, the zigzag channels are made in obliquely descending planes. *a* is the funnel for the hot liquor, whence it descends through the pipe *d* into the channel *c, c* (see *fig.* 1547), and ultimately is discharged through the pipe *b*, at the cock *e*. The cold water being introduced into the funnel *f*, and passing down the pipe *i*, enters the zigzag channel *h, h*, and, rising through the apparatus, runs off by the pipe *g*, and is discharged at the cock below.

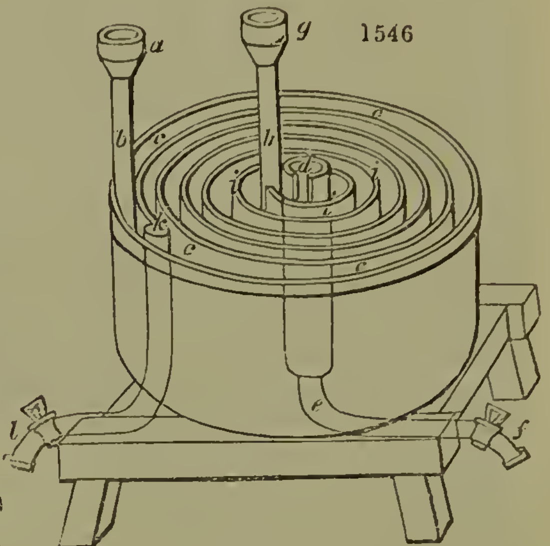
The passages of this apparatus for heating and cooling fluids, may be bent into various contorted figures; and one of the most convenient forms, being very compact and easily cleaned, is that represented at *fig.* 1546, which consists of only two sheets of thin copper, soldered together at their edges, forming a continuous spiral chamber for the passage of a thin stratum of water, and contained in a cylindrical case. The passages here run in convolute curves, the one winding in a spiral to the centre, the other receding from the centre.

The wort or other hot liquor intended to be cooled, is to be introduced at the funnel *a*, and passing down the pipe *b*, is delivered into the open passage *c*, which winds round to the central chamber *d*, and is thence discharged through the pipe *e*, at the cock *f*. The cold water enters the apparatus at the funnel *g*, and proceeding down the pipe *h*, enters the closed channel *i*, and after traversing round through the apparatus, is in like manner discharged through the pipe *k*, at the cock *l*. Or the hot liquor may be passed through the closed channel, and the cold through the open one; or these chambers may be both of them open at top, and the apparatus covered by a lid when at work, the principal design of which is to afford the convenience of cleaning them more readily than could be done if they were closed; or they may be both closed.

1545



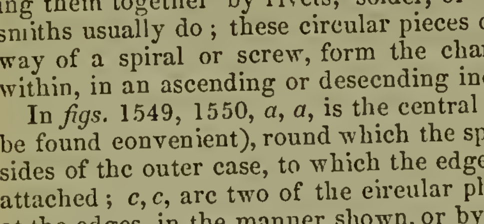
1546



A similar ingenious apparatus for cooling brewers' worts, or wash for distillers, and also for condensing spirits in place of the ordinary worm tub, is called by the inventor, Mr. Wheeler, an Archimedes condenser, or refrigerator, the peculiar novelty of which consists in forming the chambers for the passage of the fluids in spiral channels, winding round a central tube, through which spiral channels the hot and cold fluids are to be passed in opposite directions.

Fig. 1548 represents the external appearance of the refrigerator, enclosed in a cylindrical case; *fig.* 1549, the same, one-half of the case being removed to show the form of the apparatus within; and *fig.* 1550, a section cut through the middle of the apparatus perpendicularly, for the purpose of displaying the internal figure of the spiral channels.

1547

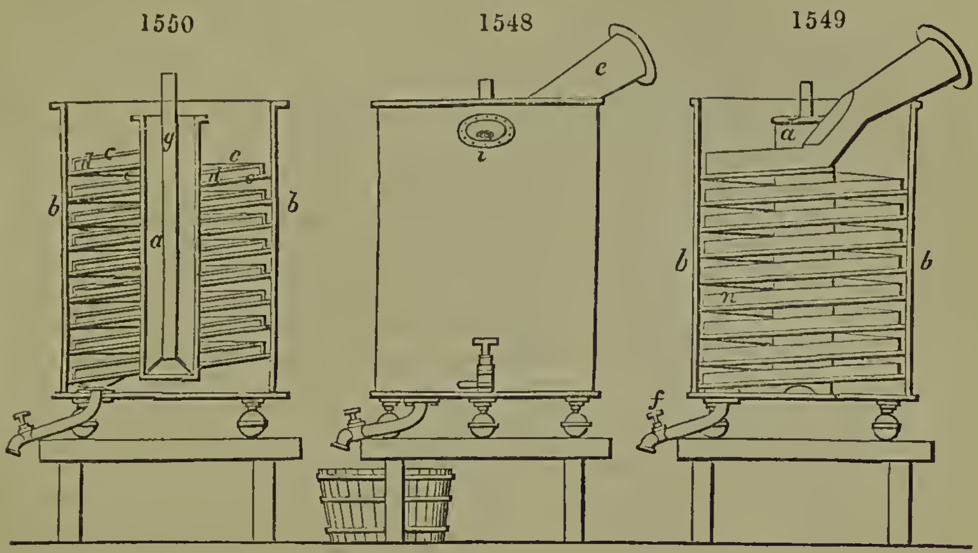


The apparatus is proposed to be made of sheet copper, tinned on its surface, and is formed by cutting circular pieces of thin copper, or segments of circles, and connecting them together by rivets, solder, or by any other convenient means, as coppersmiths usually do; these circular pieces of copper being united to one another, in the way of a spiral or screw, form the chambers through which the fluids are to pass within, in an ascending or descending inclined plane.

In *figs.* 1549, 1550, *a*, *a*, is the central tube or standard (of any diameter that may be found convenient), round which the spiral chambers are to be formed; *b*, *b*, are the sides of the outer case, to which the edges of the spiral fit closely, but need not be attached; *c*, *c*, are two of the circular plates of copper, connected together by rivets at the edges, in the manner shown, or by any other suitable means; *d*, is the chamber, formed by the two sheets of copper, and which is carried round from top to bottom in a spiral or circular inclined plane, by a succession of circular plates connected to each other.

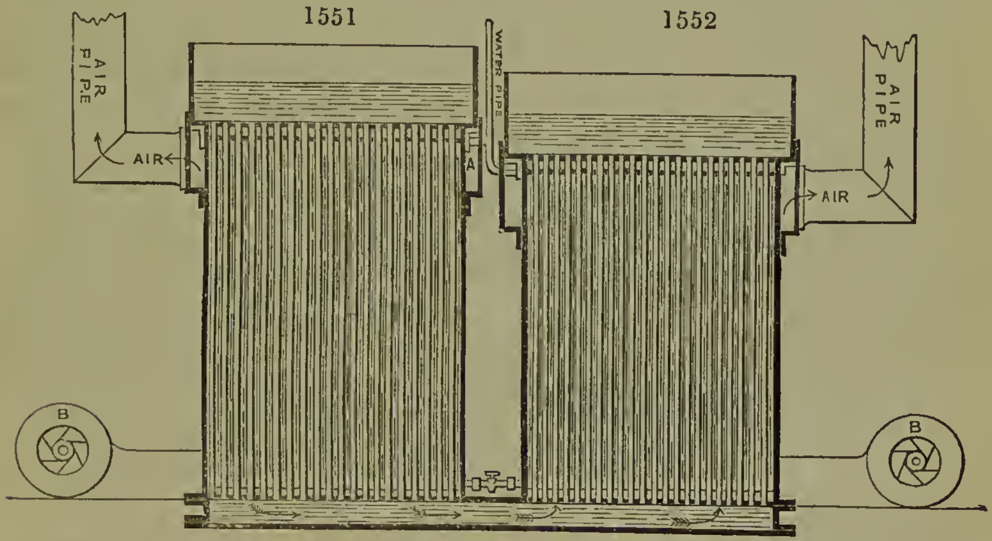
The hot fluid is admitted into the spiral chamber *d*, through a trumpet or wide-mouthed tube *e*, at top, and is discharged at bottom by an aperture and cock *f*. The cold water which is to be employed as the cooling material is to be introduced through the pipe *g*, in the centre, from whence, discharging itself by a hole at bottom, the cold water occupies the interior of the cylindrical case *b*, and rises in the spiral passage *n*, between the coils of the chamber, until it ascends to the top of the vessel, and then it flows away by a spout *i*, seen in *fig.* 1548.

It will be perceived that the hot fluid enters the apparatus at top, and the cold fluid at bottom, passing each other, by means of which an interchange of temperature takes place through the plates of copper, the cooling fluid passing off at top in a heated state, by means of the caloric which it has abstracted from the hot fluid; and the hot



fluid passing off through the pipe and cock at bottom, in a very reduced state of temperature, by reason of the caloric which it held having been given out to the cooling fluid.

Hodge's Patent Refrigerator for reducing the temperature of liquids.—This refrigerator is stated to be more effectual than anything yet offered to the public for cooling brewers' worts. The worts are passed down through the tubes in *fig.* 1551, and ascend through the tubes in *fig.* 1552. These tubes are of copper, and are encased in



a chamber; water is let on under a head through the pipes A, sprinkling the outer surface of the tube with a jet, keeping them moist; at the same time a blast of cold air is blown into the chambers by the fans B B impinging on the surface, carrying away the caloric as fast as it is transmitted. Worts can be brought down from 212° to the desired temperature by this process cheaper and quicker than any other refrigerator; in fact, worts may be brought down to freezing temperature.

REGULUS. A name introduced by the alchemists, and applied by them in the first instance to antimony; it signifies *the little king;* and from the facility with which antimony alloyed with gold, these empirical philosophers had great hopes that this metal *antimony* would lead them to the discovery of the philosopher's stone. The name is now applied to other metals in an impure state.

RENNET. The gastric juice of the stomach of the sucking calf, which, being extracted by infusion immediately after the death of the animal, serves to curdle milk. As the juice passes rapidly into putrefaction, the stomach must be salted after the outer skin has been scraped off, and all the fat and useless membranes carefully removed. It is only the inner coat which is to be preserved after it is freed from any curd or other extraneous matter in the stomach. The serum left in it should be pressed out with a cloth, and is then to be replaced in the stomach with a large quantity of the best salt. The skins, or vells as they are called, are next put into a pan and covered with a saturated solution of salt, and soaked for some hours; but there should be no more brine than covers the vells. They are afterwards hung up to dry, a piece of wood being put crosswise into each to stretch them out. They should be perfectly dried, and look like parchment. In this state they may be kept in a dry place for any length of time, and are always ready for use.

Pieces of vell are cut off and soaked for some hours in whey or water, and the whole is added to the warm milk for curdling it, its strength having been first tested on a small quantity. By the rapidity with which it curdles and the form of the flakes, a judgment is formed of its strength and the quantity required for the whole milk.

RESIN KAURI, OR COWDEE, is a new and peculiar substance, imported from New Zealand. It oozes from the trunk of a noble tree called *Dammara Australis*, or *Pinus kauri*, which rises sometimes to the height of 90 feet without a branch, with a diameter of 12 feet, and furnishes a log of heart of timber of 11 feet. The resin, which is called Cowdee gum by the importers, is brought to us in pieces varying in size from that of a nutmeg to a block of 2 or 3 cwts. The colour varies from milk-white to amber, or even deep brown; some pieces are transparent and colourless. In hardness it is intermediate between copal and resin. The white milky pieces are somewhat fragrant, like elemi. Specific gravity, 1·04 to 1·06. It is very inflammable, burns all away with a clear bright flame, but does not drop. When cautiously fused, it concretes into a transparent hard tough mass, like shellac.

RESINS (*Resines*, Fr.; *Harze*, Germ.) are principles found in most vegetables, and in almost every part of them; but the only resins which merit a particular description, are those which occur naturally in such quantities as to be easily collected or extracted. They are obtained chiefly in two ways, either by spontaneous exudation from the plants, or by extraction by heat and alcohol. In the first case, the discharge of resin in the liquid state is sometimes promoted by artificial incisions made through the bark into the wood of the tree.

Resins possess the following general properties: — They are soluble in alcohol, in ether and the volatile oils, and with the aid of heat, combine with the unctuous oils. They may be combined by fusion with sulphur, and with a little phosphorus. They are insoluble in water, and melt by the application of heat, but do not volatilise without partial decomposition. They are almost all translucid, not often colourless, but generally brown, occasionally red or green. Any remarkable taste or smell, which they sometimes possess, may be ascribed to some foreign matter, commonly an essential oil. Their specific gravity varies from 0·92 to 1·2. Their consistence is also very variable. The greater part are hard, with a vitreous fracture, and so brittle as to be readily pulverised in the cold. Some of them are soft, a circumstance probably dependent upon the presence of a heterogeneous substance. The hard resins do not conduct electricity, and they become negatively electrical by friction. When heated they melt more or less easily into a thick viscid liquid, and concrete, on cooling, into a smooth shining mass, of a vitreous fracture, which occasionally flies off into pieces, like Prince Rupert's drops; especially after being quickly cooled, and scratched with a sharp point. They take fire by contact of an ignited body, and burn with a bright flame, and the diffusion of much sooty smoke. When distilled by themselves in close vessels, they afford carbonic acid and carburetted gases, empyreumatic oil of a less disagreeable smell than that emitted by other such oils, a little acidulous water, and a very little shining charcoal. See COAL GAS.

Resins are little acted upon by acids, except by the nitric, which converts them into artificial tan. They combine readily with the alkalies and alkaline earths, and form what were formerly reckoned soaps; but the resins are not truly saponified; they rather represent the acid constitution themselves, and, as such, saturate the salifiable bases.

Every resin is a natural mixture of several other resins, as is the case also with oils; one principle being soluble in cold alcohol, another in hot, a third in ether, a fourth in oil of turpentine, a fifth in naphtha, &c. The soft resins, which retain a certain portion of volatile oil, constitute what are called balsams. Certain other balsams contain benzoic acid. The solid resins are, *amber*, *animé*, *benzoin*, *colophony* (common rosin), *copal*, *dammara*, *dragon's blood*, *elemi*, *guaiac*, *lac*, resin of *jalap*, *labdanum*, *mastic*, *sandarach*, *storax*, *takamahac*.

A memoir upon the resins has been published by M. Guibourt, from which the following extracts may be found interesting.

1. *The hard copal* of India and Africa, especially Madagascar, is the product of the *Hymenæa verrucosa*; it is transparent and vitreous within, whatever may be its appearance outside; nearly colourless, or of a tawny yellow; without taste or smell

in the cold, and almost as hard as amber, which it much resembles, but from which it may be distinguished, 1st, by its melting and kindling at a candle-flame, and running down in drops, while amber burns and swells up without flowing; 2ndly, this hard copal when blown out and still hot, exhales a smell like balsam copaiva or capivi; while amber exhales an unpleasant bituminous odour; 3rdly, when moistened by alcohol of 85 per cent., copal becomes sticky, and shows after drying a glazed opaque surface, while amber is not affected by alcohol; 4thly, the copal affords no succinic acid, as amber does, on distillation.

Ether, boiling hot, dissolves 39·17 per cent. of copal.

Essence (spirits) of turpentine does not dissolve any of the copal, but it penetrates and combines with it at a heat of 212° Fahr.

2. *Resin of courbaril* of Rio Janeiro, the English gum-animé, and the semi-hard copal of the French. It is characterised by forming, in alcohol, a bulky, tenacious, elastic mass. It occurs in rounded tears, has a very pale glassy aspect, transparent within, covered with a thin white powder, which becomes glutinous with alcohol. Another variety is soft, and dissolves, for the most part, in alcohol; and a third resembles the oriental copal so much as to indicate that they may both be produced from the same tree. 100 parts of the oriental and the occidental animé yield respectively the following residua:—

	With alcohol.	With ether.	With essence.
Oriental - - -	65·71	60·83	71
Occidental - -	43·53	27·50	75·76

The hard and soft copals possess the remarkable property in common of becoming soluble in alcohol, after being oxygenated in the air.

3. *Dammar puti, or dammar batu.*—This resin, soft at first, becomes eventually like amber, and as hard. It is little soluble in alcohol and ether, but more so in essence of turpentine.

4. *Aromatic dammar.*—This resin occurs in large orbicular masses. It is pretty soluble in alcohol. Only small samples have hitherto been obtained. Of 100 parts, 3 are insoluble in alcohol, none in ether, and 93 in essence of turpentine. M. Guibourt thinks that this resin comes from the Molucca isles. Its ready solubility in alcohol, and great hardness, render it valuable for varnish-making.

5. *Slightly aromatic dammar* leaves, after alcohol, 37 per cent.; and after ether 17 per cent.; and after essence, 87 per cent.

6. *Tender and friable dammar selan.*—This resin occurs in considerable quantity in commerce (at Paris). It is in round or oblong tears, vitreous, nearly colourless, and transparent within, dull whitish on the surfaces. It exhales an agreeable odour of olibanum, or mastic, when it is heated. It crackles with the heat of the hand, like roll sulphur. It becomes fluid in boiling water, but brittle when cooled again. It sparkles and burns at the flame of a candle; but this being the effect of a volatile oil, the combustion soon ceases.

RESINS, MINERAL. Petroleum, bitumen, asphalte, amber, and other mineral hydrocarbons are so called.

RETORT. Retorts may be of various shapes, and made of very different materials, according to the requirements. Some are of glass; others of clay. They may be made of any of the metals. Retorts are employed to effect the decomposition of compound bodies by the action of heat; sometimes alone, and sometimes aided by the action of other substances. They vary in shape; but generally may be regarded as consisting of a bulb and a beak. For producing coal gas, there are many modifications, varying in dimension and shape with the caprice of the constructor.

They may be divided into three general classes:

1st. The circular retort, from 12 to 20 inches in diameter, and from 6 to 9 feet in length.

2nd. The small or London D retort, so called in consequence of its having first been used by the Chartered Company in London.

3rd. The York D retort, (so called in consequence of its having been introduced by Mr. Outhit, of York). See Coal Gas.

REVERBERATORY FURNACE. See Metallurgy, Copper, Iron, and Soda, &c.

REVOLVERS. See Rifles and Revolvers.

RHINE WINES. See Wine.

RHODIUM. A metal discovered by Dr. Wollaston in 1803, in the ore of platinum. It is contained to the amount of three per cent. in the platinum ore of Antioquia in Columbia, near Barbacoas; it occurs in the Ural ore, and alloyed with gold in Mexico. The palladium having been precipitated from the muriatic solution of the platinum ore previously saturated with soda by the cyanide of mercury, muriatic acid is to be poured into the residuary liquid, and the mixture is to be evaporated to dryness, to expel the hydrocyanic acid, and convert the metallic salts into chlorides. The dry mass is to be reduced to a very fine powder, and washed with alcohol of specific gravity 0·837. This solvent takes possession of the double chlorides which the sodium forms with the platinum, iridium, copper, and mercury, and does not dissolve the double chloride of rhodium and sodium, but leaves it in the form of a powder of a fine dark-red colour. This salt being washed with alcohol, and then exposed to a very strong heat, affords the rhodium. But a better mode of reducing the metal upon the small scale consists in heating the double chloride gently in a glass tube, while a stream of hydrogen passes over it, and then to wash away the chloride of sodium with water.

Rhodium resembles platinum in appearance. According to Wollaston, the specific gravity of rhodium is 11. It is insoluble by itself in any acid; but when an alloy of it with certain metals, as platinum, copper, bismuth, or lead, is treated with aqua regia, the rhodium dissolves with the other metals; but when alloyed with gold or silver, it will not dissolve along with them. It may, however, be rendered very soluble by mixing it in the state of a fine powder with chloride of potassium or sodium, and heating the mixture to a dull red-heat, in a stream of chlorine gas. It thus forms a triple salt, very soluble in water. The solutions of rhodium are of a beautiful rose colour, whence its name. Its chief use at present is for making the unalterable nibs of the so-named rhodium pens.

The following remarks from a recent paper by Deville and Debray, "*On some properties of the so-called platinum metals*," are full of interest. These chemists prepare rhodium by fusing platinum residues with an equal weight of lead and twice its weight of litharge. When the crucible has attained a bright red heat, and the litharge is thoroughly liquid, the crucible is shaken once or twice, and is then allowed to cool slowly. The button of lead, which contains all the metals in the residue less oxidisable than lead, is treated with nitric acid, diluted with an equal volume of water, which removes besides the lead the copper and the palladium. The insoluble powder which remains is mixed with five times its weight of binoxide of barium, weighed exactly, and is heated to redness in a clay crucible for one or two hours. After this it is first treated with water, and then with aqua regia to remove the osmic acid. When the liquor has lost all smell, sufficient sulphuric acid is added to exactly precipitate the baryta. It is then boiled, filtered, and evaporated, first adding to it a little nitric acid and then a great excess of sal ammoniac. The evaporation is carried to dryness at 212°, and the residuum is washed with a concentrated solution of sal-ammoniac, which removes all the rhodium. When the washings are no longer coloured, the liquor is evaporated with a great excess of nitric acid, which destroys the sal-ammoniac, and when only the salt of rhodium is left, the evaporation is finished in a porcelain crucible. The rhodium salt is now moistened with hydro-sulphide of ammonia, mixed with three or four times its weight of sulphur, and the crucible is heated to bright redness, after which metallic rhodium is left in the crucible. So obtained rhodium may be considered almost pure, after it has been boiled for some time, first in aqua regia, and then in concentrated sulphuric acid. To obtain it perfectly pure it must be melted with four times its weight of zinc. The alloy is treated with concentrated hydrochloric acid, which dissolves most of the zinc, but leaves a crystalline matter which is really an alloy of rhodium and zinc in definite proportions. This is dissolved in aqua regia, and the solution is treated with ammonia until the precipitate first formed is redissolved. The solution is boiled and evaporated, by which is obtained the yellow salt, or chloride of rhodium. This is purified by repeated crystallisation, and then calcined with a little sulphur, by which means rhodium is procured absolutely pure.

Rhodium melts less easily than platinum, so much so that the same fire which will liquefy 300 grammes of platinum will only melt 40 or 50 grammes of rhodium. It is not volatilised, but it oxidises on the surface like palladium. Less white and lustrous than silver, it has about the same appearance as aluminum. When perfectly pure it is ductile and malleable, at least after fusion. Its density is 12·1.

The alloys of rhodium, those at least which have been examined, are true chemical combinations, as is shown by the high temperature developed at the moment of their formation. The alloy with zinc already described resists the action of muriatic acid, but in contact with *air* and the *acid* there is soon a well marked rose coloration which reveals an oxidation of the two metals under the double influence of the air and acid. The alloy with tin is crystallised, black, brilliant and fusible at a very high temperature.

RHUBARB (*Rheum*). Thirteen species of plants have been named as yielding the medicinal rhubarb; it is, however, generally thought that the *Rheum palmatum* is the true rhubarb plant. The best rhubarb is called Turkey rhubarb, and is only procured by the Russians, at Kiachta, from the Chinese. Several species of rhubarb are cultivated in this country, for the agreeable acidity of their stems.

RHUS. The SUMACH, which see.

RIBBON MANUFACTURE. This differs in no particular respect from the manufacture of woven fabrics in similar materials. See SILK, and WEAVING.

RICE. (*Oryza sativa*, Linn.) This plant, originally a native of Asia, is now extensively cultivated in India, China, the islands of the Eastern Archipelago, in the West Indies, Central America, and the southern of the United States. Roxburgh informs us that there are above forty different varities. Carolina and Patna rice are the kinds most esteemed in this country. Braconnot (*Ann. Chim. Phys.*) has given the following analyses of two varieties of rice:—

	Carolina Rice.	Piedmont Rice.
Starch	85·07	83·80
Woody fibre	4·80	4·80
Gluten	3·60	3·60
Tallowy oil	0·13	0·25
Sugar (uncrystallisable)	0·29	0·25
Gum	0·71	0·10

The inorganic constituents being, as estimated from the ash of the grain, as follows:—

Potash	18·48
Soda	10·67
Lime	1·27
Magnesia	11·69
Oxide of iron	0·45
Phosphoric acid	53·36
Chlorine	0·27
Silica	3·35

Rice is used as food by a hundred millions of the inhabitants of the earth, and it is employed as an agreeable and nutritive diet in various forms by ourselves.

Our *imports* of rice were, in 1858, as follow:—

			Computed real value.
Not rough or in the husks	cwts.	3,665,765	£1,652,505
Rough and in the husks	quarters	25,877	23,727
Meal	cwts.	14,298	7,277
Dust for feeding cattle	"	11,960	3,737

RICE CLEANING. Various machines have been contrived for effecting this purpose, of which that invented by Mr. Melvil Wilson, may be regarded as a good example. It consists of an oblong hollow cylinder, laid in an inclined position, having a great many teeth stuck in its internal surface, and a central shaft also furnished with teeth. By the rapid revolution of the shaft, its teeth are carried across the intervals of those of the cylinder with the effect of parting the grains of rice, and detaching whatever husks or impurities may adhere to them. A hopper is set above to receive the rice, and conduct it down into the cleansing cylinder.

About 80 teeth are supposed to be set in the cylinder, projecting so as to reach very nearly the central shaft; in which there is a corresponding number of teeth, that pass freely between the former.

RICE PAPER. A name given to the membrane of the bread-fruit tree, on which the Hindoos paint flowers, &c.

RICE STARCH. See STARCH.

RIFLES. RIFLED ORDNANCE and REVOLVERS.—Under the head of FIRE-ARMS, in addition to the general description of the manufacture of the ordinary musket barrel and the twisted barrel, with that of gun-locks of various kinds, there is an account of the mode adopted for rifling barrels, and of the methods in use at the Royal Manufactory at Enfield. Beyond this, the *carabine à tige*, the minie rifle, with the needle musket, or zundnadelgewher of the Prussians, were severally noticed; and some information given respecting the more recent Enfield rifle. So many and so important have been the improvements which have been introduced that it is necessary to return, somewhat more fully, to the consideration of this subject. Fire-arms are rifled to give rotation to the projectile round its axis of progression, in order to insure a regular and steady flight. The only practical method of doing this, hitherto adopted, has been to make the barrel of a fire-arm of such a shape in its interior, that the projectile, while being propelled from the breach to the muzzle, may receive a rotatory, combined with a forward, motion.

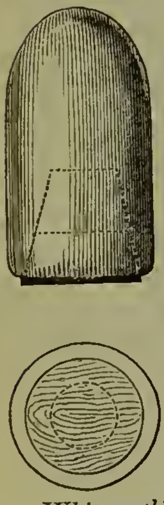
Enfield Rifle.— The dimensions, &c., of the long Enfield is given in the article already referred to. The barrel of the short Enfield is only 2 ft. 9 in. in length.

The material for the barrels of the arms made at the Government works is brought to the factory in slabs, half an inch thick, and 12 in. long, by 4 in. broad. These slabs of iron are carefully forged, to ensure the crossing of the fibres of the iron. They are heated, and first bent into a tubular form ; the yare then heated again, and, while white hot, passed between iron rollers, which weld the joining down the middle, and at the same time lengthen the tube nearly three inches. This heating is several times repeated, and the processes of rolling continued until the barrel assumes the form of a rod, about 4 ft. long, having a bore down the centre, about a $\frac{1}{4}$ of an inch in diameter.

The muzzles are then cut off, the "butts" made up, and the process of welding on the nipple lump is begun. This operation requires much care, and it is executed with great quickness and skill by the trained workmen. The barrels pass from the smithy to the boring department. The barrels are arranged horizontally, and the first-sized borer is drawn upwards from the breech to the muzzle. The second boring is effected with rapidity ; but the third slowly ; and after the fourth boring the barrel is finished to within the $\frac{3}{1000}$ of an inch of its proper diameter. The outside is ground down to its service size, and the barrel is straightened ; it is then tested by a proof-charge of 1 oz. of powder and 1 ball. The next step is to fit the nipple-screw, nipple, and breech-pin. The barrel is then bored for the fifth time, and it passes to the finishing shop. In rifling the Enfield, each groove is cut separately, the bit being drawn from the muzzle to the breech. The depth of the rifling is 0·5 at the muzzle, and 0·13 at the breech, and the width of each grove is $\frac{3}{16}$ of an inch. After rifling the barrel is again proved, with half an ounce of powder and a single ball. It is then sighted, trimmed off, milled, levelled, browned, gauged, and, at last, finished so perfectly, that the steel gauge of ·577 of an inch passes freely through, while that of ·580 will not enter the muzzle.

The system of rifling by grooves is the plan which has been generally employed, and many experiments with different numbers of groves, some of varying depths, being deeper at the breech, and with different turns ; some increasing towards the muzzle, have been tried, and thought advantageous, at various times. The Enfield rifle has three grooves, with a pitch of 6 ft. 6 in, so that the bullet receives half a turn round its axis while moving through the barrel, the length of which is 3 ft. 3 in. The bullet is cylindro-conchoidal ; it is wrapped in paper, and made of such a diameter as to pass easily down the barrel. It requires very pure lead, to allow of its being properly expanded, or "upset," by the explosion and is driven partly against the original portions of the bore, called the *lands*, and partly in the form of raised ribs, is forced into the grooves, whose spiral shape gives the required rotation. The Enfield bullet is shown in the annexed figure. It is conical in shape, and has its back end recessed for the insertion of a box-wood plug. This plug, driven forward at the first shock of the explosion of gunpowder, expands the lead until it fills the grooves at the breech. (*Fig.* 1553.)

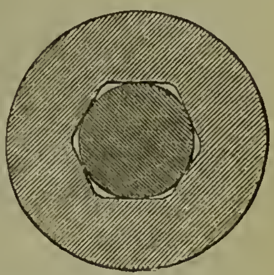
1553



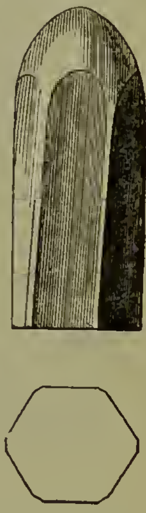
The prime cost of a finished Enfield rifle is stated to be about £2 5*s.*; and from 1,500 to 1,800 rifles per week are at present made at the Enfield rifle factory.

Whitworth's Rifle.—This fire-arm, and the principles on which it is constructed, cannot be better described than by adopting, to a great extent, the words of the inventor : In the system of rifling which I have adopted, the interior of the barrel is hexagonal, and instead of consisting partly of non-effective *lands*, and partly of grooves, consists of effective rifling surfaces. The angular corners of the hexagon are always rounded, as shown in section, *fig.* 1554, which shows a cylindrical bullet in a hexagonal barrel. The hexagonal bullet, which is preferred to the cylindrical one,— although either may be used, is shown in *fig.* 1555. Supposing, however, that a bullet of a cylindrical shape is fired, when it begins to expand it is driven into the recesses of the hexagon, as shown in *fig.* 1554. It thus adapts itself to the curves of the spiral, and the inclined sides of the hexagon offering no direct resistance expansion is easily effected. With all expanding bullets proper powder must be used. In many cases this kind of bullet has failed, owing to the use of a slowly-igniting powder, which is desirable for a hard metal projectile, as it causes less strain upon the piece; but is unsuitable with a soft metal expanding projectile, for which a quickly igniting powder is absolutely requisite to ensure a complete expansion, which will fill the bore: unless this is done the gases rush past the bullet, between it and the barrel, and the latter becomes foul, the bullet is distorted, and the shooting must be bad. If the projectile be made of the same hexagonal shape externally, as the bore of the barrel internally, that is with a mechanical fit, metals of all degrees of hardness, from lead, or lead and tin, up to hardened steel, may be employed, and slowly-igniting powder, like that of the service, may be used. As we have already stated, the Enfield rifle has one turn in 6 ft. 6 in.; that is, the bullet rotates once on its axis, in passing over this space. This moderate degree of rotation, according to Mr. Whitworth, only admits of short projectiles being used, as long ones turn over on issuing from the barrel; and, at long ranges, the short ones become unsteady. With the hexagonal barrel much quicker turns are used; and "I can fire projectiles of any required length, as, with the quickest that may be desirable, they do not 'strip.' I made a short barrel, with one turn in the inch (simply to try the effect of an extreme velocity of rotation) and found that I could fire from it mechanically-fitting projectiles, made of an alloy of lead and tin; and with a charge of 35 grains of powder they penetrated through 7 inches of elm planks."

1554



1555



"For an ordinary military barrel 39 inches long, I proposed a ·45-inch bore, with one turn in 20 inches, which is, in my opinion, the best for this length. The rotation is sufficient, with a bullet of the requisite specific gravity, for a range of 2,000 yards. The gun responds to every increase of charge, by giving better elevation, from the service charge of 70 grains up to 120 grains; this latter charge is the largest that can be effectually consumed, and the recoil then becomes more than the shoulder can conveniently bear with the weight of the service musket."

The advocates of the slow turn of one in 6 ft. 6 in., consider that a quick turn causes so much friction as to impede the progress of the ball to an injurious, and sometimes dangerous, degree, and to produce loss of elevation and range; but Mr. Whitworth's experiments show the contrary to be the case. The effect of too quick a turn, as to friction, is felt in the greatest degree when the projectile has attained its highest velocity in the barrel, that is at the muzzle, and is felt in the least degree when the projectile is beginning to move, at the breech. The great strain put upon a gun at the instant of explosion is due, not to the resistance of friction, but to the *vis inertiæ* of the projectile which has to be overcome. In a long barrel with an extremely quick turn, the resistance offered to the progress of the projectile as it is urged forward becomes very great at the muzzle, and although moderate charges give good results, the rifle will not respond to increased charges by giving better elevation. If the barrel be cut shorter, an increase of charge then improves the elevation.

Rifled Ordnance. See ARTILLERY. Whitworth's system of rifling is equally applicable to ordnance of all sizes, the principle of construction is simple, and the extent of bearing afforded by the rifling surfaces provides amply for the wear of the interior of the gun; any requisite allowance for windage may be made at the same time that the projectile is kept concentric with the bore. We have not space to enter on any examination of the rifled ordnance manufactured by Mr. Whitworth, which is in principle the same as the rifle which we have briefly described. The extraordinary results obtained in the trials of Whitworth's guns have been so remarkable, that as a matter of curious history it appears important to preserve a statement of these trials, as made at Southport, which were witnessed by many of the most eminent authorities.

Our space will not admit of our giving tables of all the experiments made; we have, therefore, chosen those which give the best and most interesting results. We have in each table given the distance of every shot fired in the series or group forming the particular experiment. In some cases average distances are calculated from the ascertained centre of the group of shots fired, and are taken longitudinally and laterally. This is, in fact, applying to the horizontal area in which the shots fell the same principles on which the "figure of merit" is determined on the vertical targets at the Hythe School of Musketry. This method of calculation is the most accurate, for, as the gun was always laid for the line of fire, and no alteration was made in its direction during the firing of a particular group, a certain amount of deviation would be given to all the shots by the wind. Therefore, the closer the shots lay, the better was the shooting, without regard to the general deviation from the line of fire, which might be greater or less according to the direction and force of the wind.

Table of Experiments.

3-POUNDER GUN, 9 shots fired at an elevation of 3°, charge $7\frac{1}{2}$ oz., Feb. 22.

Range in yards.	Deviation from line of fire in yards.

3107	$1\frac{1}{3}$ right	
3107	0	

80-POUNDER GUN, 4 shots, at 7° elevation, charge 14 lb.

3482	$6\frac{1}{3}$ right	Greatest difference in range, 21 yards; greatest difference in width, $1\frac{2}{3}$ yard.
3487	$6\frac{1}{8}$,,	
3498	6 ,,	
3503	$4\frac{2}{3}$,,	

After this digression we return again to the Rifles. A professional writer, well qualified to judge of the matter on which he wrote, has made some striking remarks on the Whitworth rifle in the *Mechanics' Magazine*. After pointing out the small importance of a high prime cost in the case of so durable a weapon as the rifle in question, he refers to the strength of the metal used.

In illustration of its great strength, this fact is quoted. Mr. Whitworth put into a rifle barrel, one inch in diameter at the breach, with a bore of 0·49 inch, a leaden plug 18 inches long, as tightly as it could be driven home upon the charge. It was fired with an ordinary charge of powder, and the leaden plug being expanded by the explosion remained in the barrel, the gases generated by the gunpowder all passing out through the touch-hole. With such strength great durability must of necessity co-exist, unless the quick turn of the rifling should tend to its rapid deterioration. But this is not the case, Mr. Longridge's elaborate investigations having proved that the amount of the force expended upon the rifling of the Whitworth rifle scarcely exceeds two per cent. of the total force of the powder.

Perhaps the most remarkable testimony which has been borne to the merits of this rifle is that of General Hay, the director of musketry instruction at Hythe. After admitting the superiority of the Whitworth to the Enfield in point of accuracy, General Hay said there was a peculiarity about the Whitworth small-bore rifles which no other similar arms had yet produced,—they not only gave greater accuracy of firing, but treble power of penetration. For special purposes, any description of bullet could be used, from lead to steel. The Whitworth rifle, with a bullet one-tenth of tin, penetrated 35 planks, whereas the Enfield rifle, with which a soft bullet was necessary, only penetrated 12 planks. He had found that at a range of 800 yards, the velocity added to the hardened bullet gave a power of penetration in the proportion of 17 to 4 in favour of the Whitworth rifle. This enormous penetration is of the highest importance in a military weapon, in firing through gabions, sandbags, and other artificial defences. Mr. Bidder, President of the Institution of Civil Engineers, says, the Whitworth small-bore rifle, fired with common sporting powder, would never foul so as to render loading difficult. He had himself fired 100 rounds one day, 60 rounds the next, then 40 rounds, and so on, and left the gun without being cleaned for ten days, when it fired as well as it did on the first day. The words of Mr. Whitworth as to the application of his principle to the Enfield weapon must be quoted in answer to the objections of cost, &c., urged against it. "With regard to the cost of my rifled musket, which has been stated to be an impediment in the way of its adoption for the service, I may state that there would be no difficulty in adapting the machinery and plant already in operation at Enfield, or any requisite portion of it, for making rifles on my system. The change would not cause an increase in the manufacturing expenses; and, supposing the quality of the workmanship and the materials to remain the same, the advantages arising from the use of my bore and turn, and hard metal projectiles, would double the efficiency of the rifle without increasing the cost."

Amongst arms requiring some notice from us, the more remarkable, as involving some excellence in construction, or peculiarity in principle, are the following:—

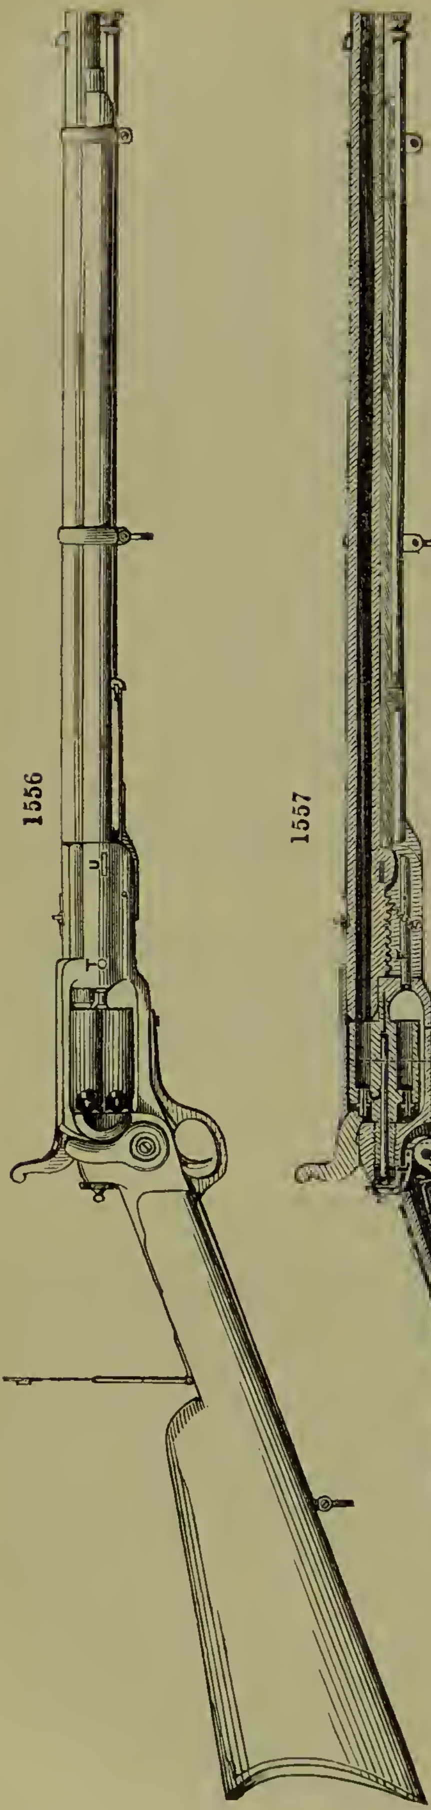
Colt's Repeating Rifle.—This weapon is constructed mainly on the principle which was introduced by Colonel Colt, in his "revolvers," to be noticed presently. The Secretary of War of the United States reports as follows on this arm, which is shown in *fig.* 1556, and in section *fig.* 1557. *Fig.* 1558 is a vertical section of the revolving barrels, and *fig.* 1559 the wiping rod.

"The only conclusive test of the excellence of the arms for army purposes is to be found in the trial of them by troops in actual service. Colonel Colt's arms have undergone this test, and the result will be found, in some measure, by reports of General Harney and Captain Marcy, who used them in Florida, against the Indians. These reports relate only to the *rifle*, but are clear and satisfactory. * * * * A board of officers recently assembled to consider the best mode of arming our cavalry, made a report, showing the present appreciation of the arm by officers of the army standing deservedly high for their services, experience, and intelligence."

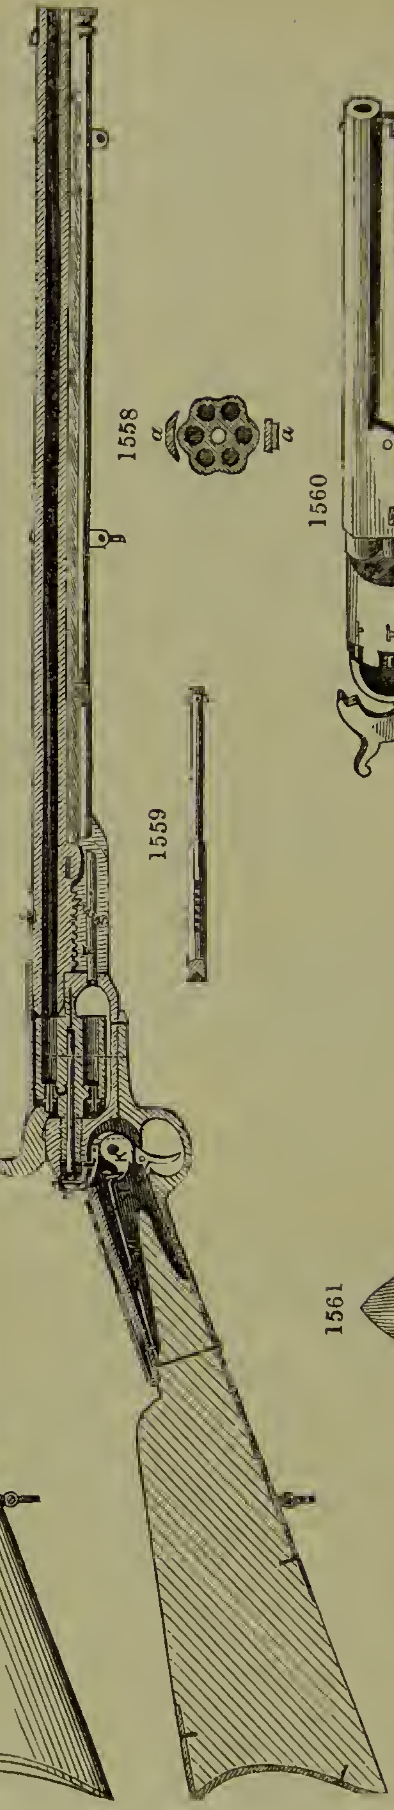
In its internal construction this rifle differs in some respects from the pistols and early revolving rifles. The catch which causes the breech cylinder to revolve, instead of acting against ratchet teeth, and on the cylinder itself, works in teeth cut on the circumference of the cylinder end of the base-pin, in such a manner, that the base-pin rotates with the cylinder itself, being locked by a small mortise in the cylinder; and the stop-bolt gears into corresponding notches, also cut in the end of the base-pin, and thus locks it when required. This is an improvement in the arrangement of these weapons, and by a simple arrangement, the small spring catch, which, by means of a circular grove in the front end of the base-pin, keeps it in place, is immediately released by pressing on a small stud, and the cylinder can be instantaneously removed or replaced. Instead of the pin, which, in the pistol, is used to let the hammer down on, when carrying it, a small recess is cut between each nipple, in the cylinder itself, into which the hammer fits when let down, and makes security doubly secure.

The rifle is provided with two sights; the ordinary leaf-sight usually employed is also provided. The hinder sight is adjustable to suit long or varying ranges, and the front sight is that known as the bead sight, which consists of a small steel needle, with a little head upon it, like the head of an ordinary pin inclosed in a steel tube. In aiming with this sight, the eye is directed through a minute hole in the sliding piece of the hinder sight, to the small bead in the tube, which bead should

1556



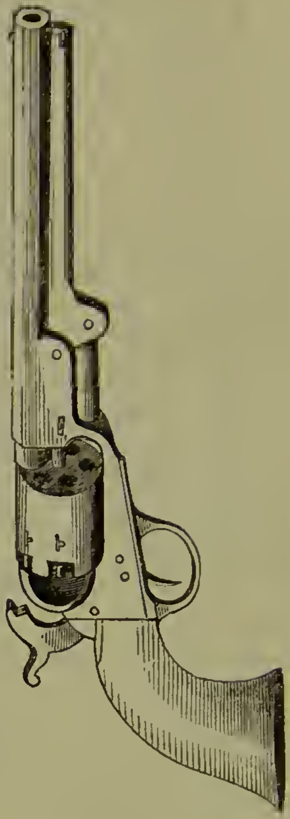
1557



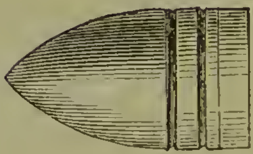
1558

1559

1560



1561



1562

cover the mark aimed at; and this sight affords great accuracy in shooting. The wiping rod, which occupies the position usually allotted to the ramrod, in muzzle loaders, is ingeniously constructed so as to admit of being lengthened. In its interior, which is hollow, slides a slight steel rod, in the end of which a screw thread is cut; on drawing out the rod, a turn or so of the hand in one direction, enables this steel rod to be drawn out to a length, as nearly as possible that of the outer case, and a few turns in the contrary direction, fastens it firmly in its place; thus enabling it to be used with as much facility as if it were solid. When done with, the reversal of the former motions enable the rod to be returned to its original dimensions, and it can then be returned to its place. This weapon has a real business-like serviceable appearance, and its weight varies, according to the length of the barrel, from 8 lb. to 10 lb. each, with five and six shots.

Colonel Colt has introduced a new shot gun, which is adapted for being loaded alternately with shot and ball. This is adapted for colonists, enabling him to use the gun as an ordinary sporting weapon for birds, &c., or for more deadly purposes. The ball for Colt's rifle is shown by *figs.* 1561, 1562.

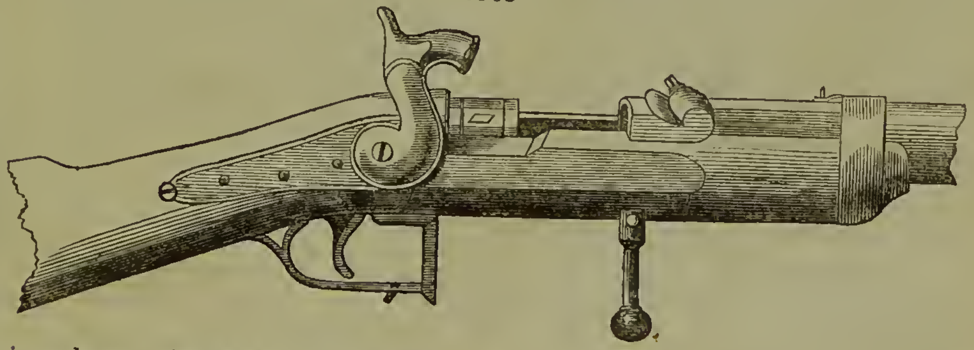
Lancaster's Elliptic Rifle. — So called, although the Elliptical rifle is very old. The bore in this rifle is slightly oblate; the twist found, by experience, to be most advantageous is one turn in 52 inches, the approved diameter of the bore ·498 inches, the length of the barrel being 32 inches. An eccentricity of ·01 inch in half an inch is found sufficient to make the bullet spin on its axis to the extreme verge of its flight. The length of the bullet found to answer best with these rifles is $2\frac{1}{4}$ diameters in length, with a windage of four or five thousandths of an inch.

Major Nuthall's Rifle.—In the ordinary mode of grooving rifles, sharp angles are left between the groove and "land" (those parts of the smooth bore left in their original state after the process of grooving has been completed). These create great friction with the projectile, both in loading and discharging. Major Nuthall removes these objections by rounding off the "lands" into the grooves, that is, making them a series of convex and concave curves, the bore assuming a beautiful appearance to the eye, for the smoothness and evenness with which the lands and grooves blend into each other.

There are also General Boileau's rifle, and some others, which our space will not admit of our noticing.

Breech-loading Rifles have been introduced, and they prove so satisfactory that the principle of breech-loading is applied to ordinary fowling pieces. Prince's breech-loader has been highly recommended. In this rifle, *fig.* 1563, the barrel has attached

1563



to it a lever with a knob at its end, kept in its place and locked by a little bolt attached to the bow of the guard. In order to load, the stock being firmly grasped under the right arm, the catch is released, and the knob attached to the lever is drawn to the right, and almost simultaneously pushed forward. The lever being firmly connected with the breech end of the barrel, the whole of the barrel is thus slipped forward in the stock, to the extent of about three inches, disclosing a steel cone, provided on either side with inclined planes, forming a segment of a screw, and locking tightly into slots at the breech end of the barrel. The cartridge is dropped into the open space at the extremity of the cone, the lever is depressed, pulled backward, and then pushed into its place. The barrel and cone are thus tightly locked together, and until they are in this position the gun cannot possibly be fired. It is, therefore, obvious, that in strength and security this rifle is not inferior to any. At a trial at Hythe, Mr. Prince fired 120 rounds in less than eighteen minutes, showing the rapidity of loading which this weapon admits of. The rifling preferred by the inventor is a five-grooved bore rather deeply cut, the twist being three quarters of a turn in three feet. The London gunmakers have certified to the great merits of Prince's breech-loading rifle.

Prince's cartridge is an ingenious invention; it can be used either with a muzzle or with a breech-loader. The cartridge is made of gun-paper, produced in the manner described for making gun-cotton. The spark fires this with the powder, and if the paper is pure there is no ash left from its combustion. Mr. Prince is bringing out a new breech-loading rifle which is simpler than any yet produced. His practical experience in such matters, extending over more than a quarter of a century, combined with the success he has already attained, causes any fresh arm emanating from him to be regarded with considerable attention. The breech is opened by a half turn of a lever, and closed by a corresponding movement. Either common ammunition or a flask can be used in loading. The barrel is a fixture; a chamber being attached to the breach end, so that existing muzzle loaders may be readily converted. For cavalry a simple addition is made to the arm, so that the caps are placed on the nipple in the act of loading.

Terry's Breech-loading Rifle differs from Prince's in having the barrel fixed. There is an opening at the base of the breech, which being lifted by a lever discloses a receptacle for the cartridge.

Mr. Westley Richards, Mr. James Leetch, and some others have introduced breech-loading rifles. Of the former, Colonel Wilford says: "The weapon manufactured by Mr. Westley Richards is a perfect wonder. I saw a small carbine, weighing only 5½ lbs., fire better at 800 yards than the long Enfield."

In the rifle by Leetch the opening for the admission of the charge is in front of the chamber; consequently the shooter has all the security that the solidity of the breech can import.

Revolvers or *Repeating Pistols.*—The fame attached to Colt's revolvers, *fig.* 1560, renders them so well known as to require but little introduction necessary. Although the invention of revolvers of course cannot be ascribed to Colonel Colt, their adaptation to modern requirements, and their general use, are undoubtedly due to his extreme energy, perseverance, and skill, and to him, therefore, every credit ought to be given. This make is now extensively used in the United States, and indeed in almost every corner of the world, and seem not to lose favour anywhere. In Turkey, Egypt, Brazil, Peru, Spain, Holland, Prussia, Russia, Italy, and Chili, as well as the United States, and our own country, they have been and are extensively used and approved; and we are given to understand that 40,000 of them have been supplied to our authorities, and have been served out and used in the Baltic, in the Crimea, in China, and in India, with the utmost effect. The shooting with Colt's arms is highly satisfactory. With Colt's revolver you can make first-rate shooting, and be perfectly satisfied with its action. As a proof that it is not liable to get out of repair, we need only state that the American Board of Ordnance had a holster pistol fired 1200 times, and a belt pistol 1500 times, without the slightest derangement. The penetration of the first named was through 7 inches of board, and of the second through 6 inches.

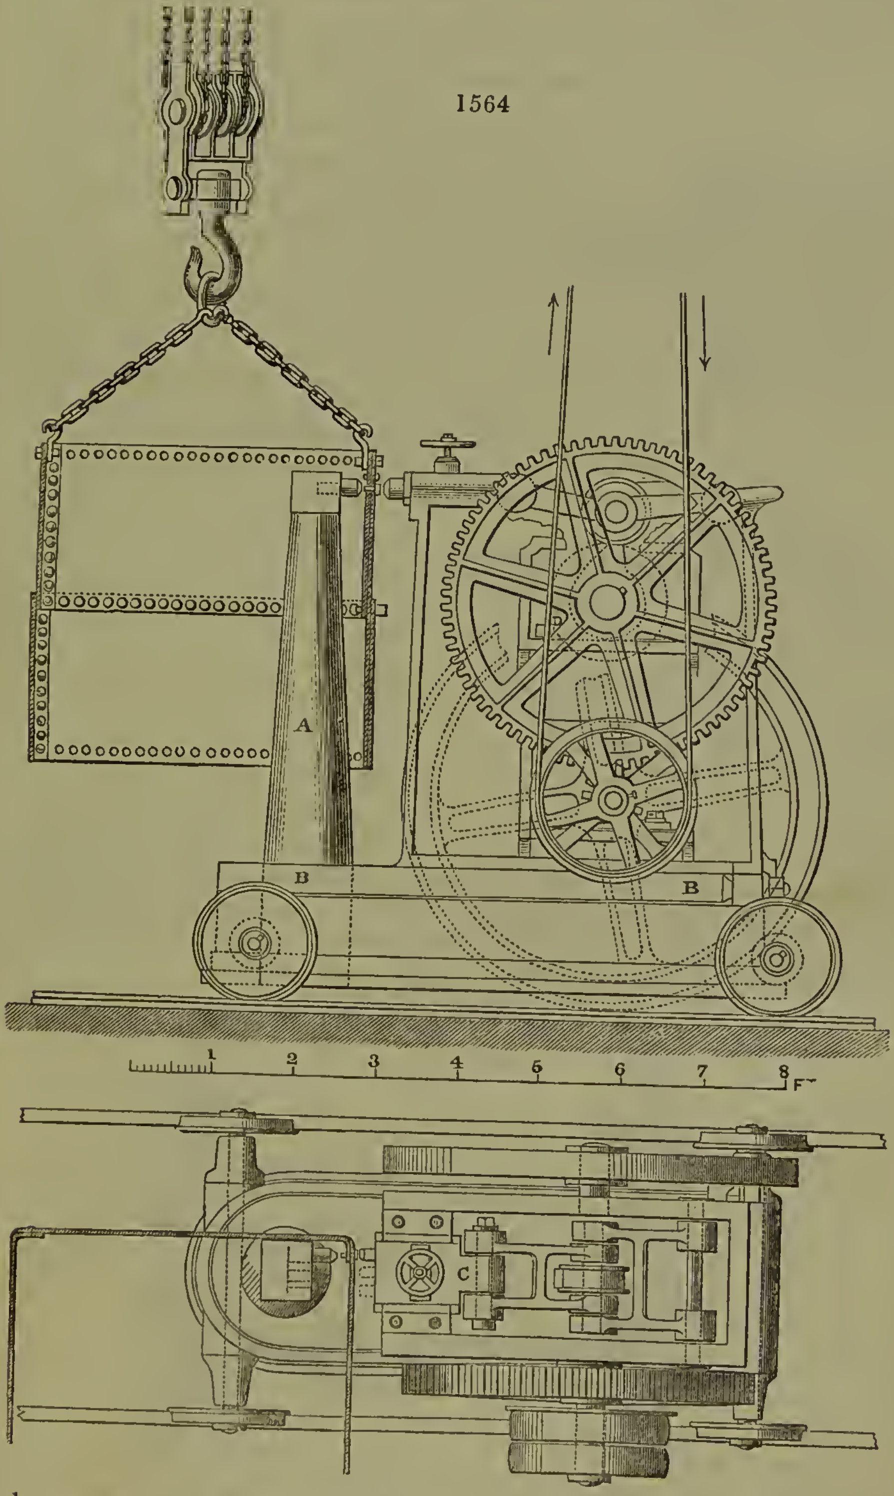
The barrel is rifle-bored. The lever ramrod renders wadding or patch unnecessary, and secures the charge against moisture, or becoming loose by rough handling or hard riding. The hammer, when at full cock, forms the sight by which to take aim, and is readily raised at full cock by the thumb, with one hand. It has been tested by long and actual experience, that Colt's arrangement is superior to those weapons in which the hammer is raised by pulling the trigger, which, in addition to the great danger from accidental discharge, the strength of the pull necessary for cocking, interferes with the correctness of aim, which is of so much importance. A very effectual provision is made to prevent the accidental discharge of this pistol whilst being carried in the holster, pocket, or belt. Between each nipple (the position of which secures the caps in their places) is a small pin, and the point of the hammer has a corresponding notch; so that if the hammer be lowered on the pin, the cylinder is prevented from revolving, and the hammer is not in contact with the percussion cap, so that, even if the hammer be struck violently by accident, it cannot explode the cap.

The movements of the revolving chamber and hammer are ingeniously arranged and combined. The breech, containing six cylindrical cells for holding the powder and ball, moves one sixth of a revolution at a time; it can only be fixed when the chamber and the barrel are in a direct line. The base of the cylinder being cut externally into a circular ratchet of six teeth (the lever which moves the ratchet being attached to the hammer); as the hammer is raised in the act of cocking, the cylinder is made to revolve, and to revolve in one direction only; while the hammer is falling the chamber is firmly held in position by a lever fitted for the purpose; when the hammer is raised the lever is removed, and the chamber is released. So long as the hammer remains at half cock, the chamber is free and can be loaded at pleasure. Revolvers by Daw, by Adams and Dean, and others, have been introduced. They are all so similar in principle that they need not be described.

RINMAN'S GREEN. Oxide of cobalt and oxide of zinc.

RIVETING MACHINE *of Fairbairn.* The invention of the riveting machine originated in a turn-out of the boiler-makers in the employ of that engineer about fifteen years ago. On that occasion, the attempt was made to rivet two plates together by compressing the red-hot rivet in the ordinary punching-press. The success of this experiment immediately led to the construction of the original machine, in which the movable die was forced upon the rivet by a powerful lever acted upon by a cam. A short experience proved the original machine inadequate to the numerous requirements of the boiler-maker's trade, and the present form was therefore adopted about twelve years since.

1564



The large stem A, is made of malleable iron, and, having an iron strap B B, screwed round the base, it renders the whole perfectly safe in case of the dies coming in contact with a cold rivet, or any other hard substance during the process. Its construction also allows the workmen to rivet angle iron along the edges, and to finish the corners of boilers, tanks, and cisterns; and the stem being now made 4 feet 6 inches high, it renders the machine more extensive in its application, and allows of its riveting the fire-box of a locomotive boiler or any other work within the given depth.

In addition to these parts, it has a broad moving slide, c, in which are three dies corresponding with others in the wrought iron stem. By using the centre die, every description of flat and circular work can be riveted, and by selecting those on the sides, it will rivet the corners, and thus complete vessels of almost every shape. This machine is in a portable form, and can be moved off rails with care to suit the article suspended from the shears.

The introduction of the knee-joint gives to the dies a variable motion and causes the greatest force to be exerted at a proper time, viz. at the closing of the joint and finishing of the head of the rivet.

In other respects the machine operates as before, effecting by an almost instantaneous pressure what is performed in the ordinary mode by a long series of impacts. The machine fixes in the firmest manner and completes eight rivets of $\frac{3}{4}$ inch diameter in a minute, with the attendance of two men and boys to the plates and rivets; whereas the average work that can be done by two riveters, with one "holder on" and a boy, is 40 $\frac{3}{4}$-inch rivets per hour; the quantity done in the two cases being in the proportion of 40 to 480, or as 1 to 12, exclusive of the saving of one man's labour. The cylinder of an ordinary locomotive engine boiler 8 feet 6 inches long and 3 feet diameter can be riveted and the plates fitted completely by the machine in 4 hours; whilst to execute the same work by hand would require with an extra man twenty hours. The work produced by the machine is likewise of a superior kind to that made in the ordinary manner; the rivets being found stronger, and the boilers more free from leakage, and more perfect in every respect. The riveting is done without noise, and thus is almost entirely removed the constant deafening clamour of the boiler-maker's hammer.

ROAN. The name of a common leather used for book-binding, and for slippers. It is prepared from sheep-skin by tanning with sumach. See LEATHER.

ROCCELLA, from the Italian *rocca*, a rock; a genus of lichens. See ARCHIL.

ROCK. A term used, generally, in South Staffordshire by quarrymen and miners to denote any hard sandstone.

ROCK CRYSTAL. A very fine variety of quartz.

ROCKETS. See PYROTECHNY.

ROCK SALT. See SALT.

ROE STONE. The familiar English name for *oolite*, from its being composed of rounded grains, like the roe of a fish.

ROLLERS, ELASTIC, for printing. See PRINTING ROLLERS.

ROLLING MILLS. These useful aids to many of our metallugical processes appear to have been introduced to this country in the seventeenth century; but it was not until 1784, when Mr. Cort patented "a new mode and art of shingling, welding, and manufacturing iron and steel into bars, plates, &c.," that much attention was directed to the value of the rolling mill.

1565

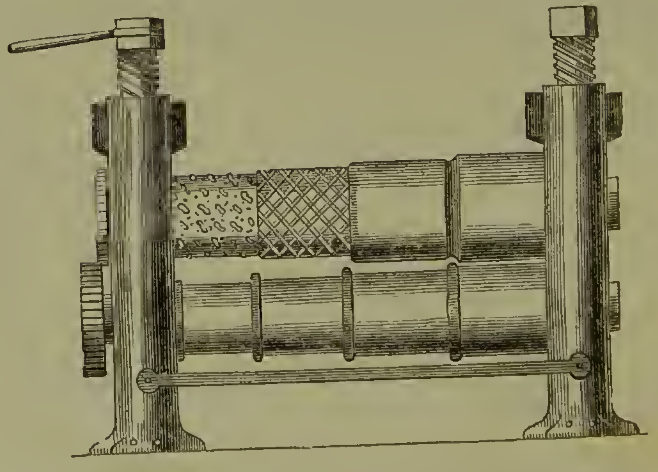


Fig. 1565 is a front view of a pair of rollers, used in the manufacture of iron in connection with the puddling furnace. They are about 4 feet long, divided into 4 parts, the largest being about 20 inches in diameter. That portion of the upper roller under which the metal is first passed, is cut in a deep and irregular manner, resembling that chiselling in stone called moveque work, that it may the more easily get hold of and compress the metal when almost in a fluid state. The plate is next passed under the cross-cut portion of the roller, and successively through the flat sections. The lower roller, it will be observed, is formed with raised collars at intervals, to keep the metal in its proper course. The rollers are connected by cog-wheels placed upon their axes; upon the lowermost of these, works also the wheel by means of which the revolution is communicated. The cheeks are of cast-iron, very massive, that they may bear the violent usage to which they are subjected.

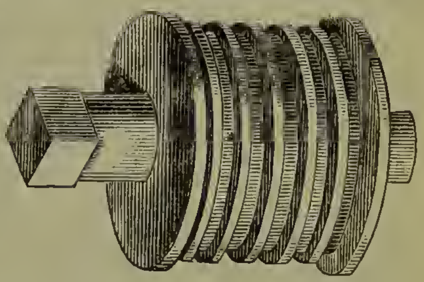
We cannot go into the numerous purposes to which rolling mills of this kind are applied; a few may however be mentioned.

The practice of "slitting" sheets of metal into light rods, either for the use of the wire-drawers or of nail-makers, is carried out by means of two large steel rollers, channelled circularly, as in *fig.* 1566. These are so placed that the cutters or raised parts of one roller, which are exactly turned for that purpose, shall work in corresponding channels of the other roller, thus forming what may be called revolving shears, for the principle is that of clipping; so that a sheet of metal on being passed through this machinery, is separated into slips agreeing in size with the divisions of the rollers.

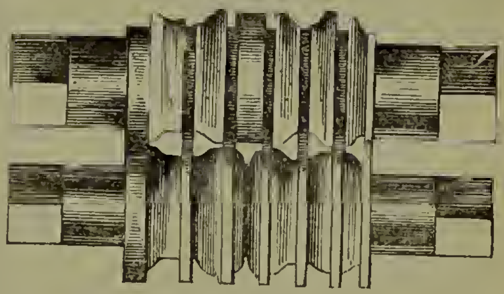
1566



Rolling mills have been patented for rolling tubes for gas and other purposes. See Tubes.

For the manufacture of rails, rolling mills are also employed, *fig.* 1567 representing a rolling mill as constructed for rolling Birkinshaw's rails. The open spaces along the middle of the figure, and which owe their figure to the moulding on the periphery of the rollers, indicate the form assumed by the iron rail as it is passed successively from the larger to the smaller apertures, till it is finished at the last.

1567



For a further description, and for the arrangement of rolling mills and slitters, see Iron, Vol. II. p. 591. Beyond these few notices the character of this Dictionary will not admit of our going; the reader is therefore referred to the works which have been published on the Metallurgy of Iron and Steel, for further information.

ROMAN CEMENTS. Under the name of Roman cement, some hydraulic mortars, varying considerably in their chemical composition, though physically possessing the same general character, are sold. Like all the hydraulic cements, it is an argillaceous lime. It is usually manufactured from a dark brown stone—a carbonate of lime with much alumina—found in the Island of Sheppy. This stone is calcined and mixed with a certain proportion of sand.

Any hydraulic limestone, that is, one containing from 15 to 20 per cent. of clay, will, when properly prepared, form this cement. Calcine any ordinary clay, and mix it with two-thirds its quantity of lime, grind to powder, and calcine again; this makes a very beautiful cement, improperly called Roman, since the preparation was entirely unknown to the Romans.

ROMAN OCHRE. A deep and powerful orange-yellow colour, transparent and durable. It is used both raw and burnt by artists. The colouring matter is oxide of iron mixed with earthy matter.

ROOFING, ASPHALTE. Patent asphalte roofing felt, particularly applicable for warm climates. It is a non-conductor. It is portable, being packed in rolls, and not being liable to damage in carriage, it effects a saving of half the timber usually required. It can be easily applied by any unpractised person. From its lightness, weighing only about 42 lbs. to the square of 100 feet, the cost of cartage is small. The felt can be laid on from gable to gable, or across the roof from eaves to eaves. It is essential that it should be stretched tight and smooth, overlapping full one inch at the joinings, and closely nailed through the overlap, with twopenny fine clout nails, (heated in a shovel and thrown when hot into grease to prevent rust,) about $1\frac{1}{2}$ inches apart, but copper nails are preferable.

The whole roof must have a good coating of coal-tar and lime, (about two gallons of the former to six pounds of the latter), well boiled together, kept constantly stirring while boiling, and put on hot with a common tar mop, and while it is soft some coarse sharp sand may be sifted over it. The coating must be renewed every fourth or fifth year, or more or less frequently according to the climate. The gutters should be made of two folds, one over the other, cemented together with the boiling mixture.

ROOFING SLATE. See SLATE.

ROPE-MAKING. The fibres of hemp which compose a rope seldom exceed in length three feet and a half, at an average. They must, therefore, be twined together so as to unite them into one; and this union is effected by the mutual circumtorsion of the two fibres. If the compression thereby produced be too great, the strength of the fibres at the points where they join will be diminished; so that it becomes a matter of great consequence to give them only such a degree of twist as is essential to their union.

The first part of the process of rope-making by hand, is that of spinning the yarns or threads, which is done in a manner analogous to that of ordinary spinning. The spinner carries a bundle of dressed hemp round his waist; the two ends of the bundle being assembled in front. Having drawn out a proper number of fibres with his hand, he twists them with his fingers, and fixing this twisted part to the hook of a whirl, which is driven by a wheel put in motion by an assistant, he walks backwards down the rope-walk, the twisted part always serving to draw out more fibres from the bundle round his waist, as in the flax spinning-wheel. The spinner takes care that these fibres are equally supplied, and that they always enter the twisted parts by their ends, and never by their middle. As soon as he has reached the termination of the walk, a second spinner takes the yarn off the whirl, and gives it to another person to put upon a reel, while he himself attaches his own hemp to the whirl hook, and proceeds down the walk. When the person at the reel begins to turn, the first spinner, who has completed his yarn, holds it firmly at the end, and advances slowly up the walk, while the reel is turning, keeping it equally tight all the way, till he reaches the reel, where he waits till the second spinner takes his yarn off the whirl hook, and joins it to the end of that of the first spinner, in order that it may follow it on the reel.

The next part of the process is that of warping the yarns, or stretching them all to one length, which is about 200 fathoms in full-length rope-grounds, and also in putting a slight turn or twist into them.

The third process in rope-making is the tarring of the yarn. Sometimes the yarns are made to wind off one reel, and, having passed through a vessel of hot tar, are wound upon another, the superfluous tar being removed by causing the yarn to pass through a hole surrounded with spongy oakum; but the ordinary method is to tar it in skeins or hanks, which are drawn by a capstan with a uniform motion through the tar-kettle. Yarn for cables requires more tar than for hawser-laid ropes; and for standing and running rigging, it requires to be merely well covered. Tarred cordage has been found to be weaker that what is untarred, when it is new; but the tarred rope is not so easily injured by immersion in water.

The last part of the process of rope-making, is to lay the cordage. For this purpose two or more yarns are attached at one end to a hook. The hook is then turned the contrary way from the twist of the individual yarn, and thus forms what is called a strand. Three strands, sometimes four, besides a central one, are then stretched at length, and attached at one end to three contiguous but separate hooks, but at the other end to a single hook; and the process of combining them together, which is effected by turning the single hook in a direction contrary to that of the other three, consists in so regulating the progress of the twists of the strands round their common axis, that the three strands receive separately at their opposite ends just as much twist as is taken out of them, by their twisting the contrary way, in the process of combination.

Large ropes are distinguished into the *cable-laid* and the *hawser-laid*. The former are composed of nine strands, namely, three great strands, each of these consisting of three smaller secondary strands, which are individually formed with an equal number of primitive yarns. A *cable-laid* rope, eight inches in circumference, is made up of 333 yarns, or threads, equally divided among the nine secondary strands. A *hawser-laid* rope consists of only three strands, each composed of a number of primitive yarns, proportioned to the size of the rope; for example, if it be eight inches in circumference, it may have 414 yarns, equally divided among three strands. Thirty fathoms of yarn are reckoned equivalent in length to eighteen fathoms of rope cable laid, and to twenty fathoms hawser-laid. Ropes of from one inch to two inches and a half in circumference are usually hawser-laid; of from three to ten inches, are either hawser or cable-laid; but when more than ten inches, they are always cable-laid.

Every hand-spinner in the dockyard is required to spin, out of the best hemp, six threads, each 160 fathoms long, for a quarter of a day's work. A hawl of yarn, in the warping process, contains 336 threads.

The following are Captain Huddart's improved principles of the rope manufacture: —

"1. To keep the yarns separate from each other, and to draw them from bobbins revolving upon skewers, so as to maintain the twist while the strand, or primary cord, is forming.

2. To pass them through a register, which divides them by circular shells of holes; the number in each concave shell being conformable to the distance from the centre of the strand, and the angle which the yarns make with a line parallel to it, and which gives them a proper position to enter.

3. To employ a tube for compressing the strand, and preserving the cylindrical figure of its surface.

4. To use a gauge for determining the angle which the yarns in the outside shell make with a line parallel to the centre of the strand, when registering; because, according to the angle made by the yarns in this shell, the relative lengths of all the yarns in the strand will be determined.

5. To harden up the strand, and thereby increase the angle in the outside shell; which compensates for the stretching of the yarns, and the compression of the strands.

All improvements in the manufacture of cordage at present in use either in her Majesty's yards or in private rope-grounds, owe their superiority over the old method of making cordage to Captain Huddart's invention of the register plate and tube.

Captain Huddart invented and took a patent for a machine, which, by registering the strand at a short length from the tube, and winding it up as made, preserved an uniformity of twist, or angle of formation, from end to end of the rope, which cannot be accomplished by the method of forming the strands down the ground, where the twist is communicated from one end to the other of an elastic body upwards of 300 yards in length. This registering-machine was constructed with such correctness, that when some were afterwards required, no alteration could be made with advantage.

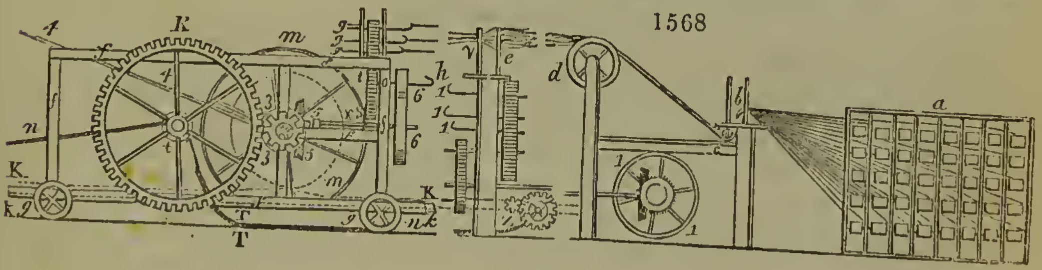
A number of yarns cannot be put together in a cold state, without considerable vacancies, into which water may gain admission; Captain Huddart, therefore, formed the yarns into a strand immediately as they came from the tar-kettle, which he was enabled to do by his registering-machine, and the result was most satisfactory. This combination of yarns was found by experiment to be 14 per cent. stronger than the cold register; it constituted a body of hemp and tar impervious to water, and had great advantage over any other cordage, particularly for shrouds, as, after they were settled on the mast-head, and properly set up, they had scarcely any tendency to stretch, effectually secured the mast, and enabled the ship to carry the greatest press of sail.

In order more effectually to obtain correctness in the formation of cables and large cordage, Captain Huddart constructed a laying machine, which has carried his inventions in rope-making to the greatest perfection, and which, founded on true mathematical principles, and the most laborious calculations, is one of the noblest monuments of mechanical ability since the improvement of the steam-engine by Mr. Watt. By this machine, the strands receive that degree of twist only which is necessary, and are laid at any angle with the greatest regularity; the pressure is regulated to give the required elasticity, and all parts of the rope are made to bear equally.

The following description of one of the best modern machines for making ropes on Captain Huddart's plan, will gratify the reader.

Fig. 1568 exhibits a side elevation of the tackle-board and bobbin-frame at the head

1568



of the ropery, and also of the carriage or rope-machine in the act of hauling out and twisting the strands.

Fig. 1569 is a front elevation of the carriage.

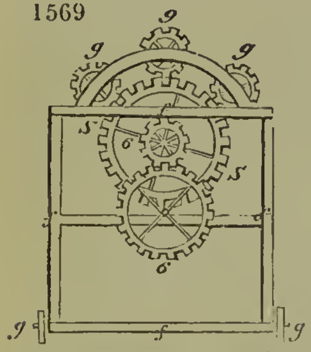
Fig. 1570 is a yarn-guide, or board, or plate, with perforated holes for the yarns to pass through before entering the nipper.

Figs. 1571 and 1572, are side and front views of the nipper for pressing the rope-yarns.

a is the frame for containing the yarn bobbins. The yarns are brought from the frame, and pass through a yarn-guide at *b*. *c* is a small roller, under which the rope-yarns pass; they are then brought over the reel *d*, and through another yarn-guide *e*, after which they enter the nippers at *v*, and are drawn out and formed into strands by the carriage. The roller and reel may be made to traverse up and down, so as to regulate the motion of the yarns.

The carriage runs on a railway. *f*, *f*, is the frame of the carriage; *g*, *g*, are the small wheels on which it is supported; *k*, *k*, is an endless rope reaching from the head to the bottom of the railway, and is driven by a steam-engine; *m*, *m*, is a wheel with gubs at the back of it, over which the endless rope passes, and gives motion to the machinery of the carriage. *n* is the ground rope for taking out the carriage, as will be afterwards described. On the shaft of *m*, *m*, are two bevel wheels, 3, 3, with a shifting catch between them; these bevel wheels are loose upon the shaft, but when the catch is put into either of them, this last then keeps motion with the shaft, while the other runs loose. One of these wheels serves to communicate the twist to the strand in drawing out; the other gives the opposite or after turn to the rope in closing. 4, 4, is a lever for shifting the catch accordingly. 5 is a third bevel wheel, which receives its motion from either of the other two, and communicates the same to the two spur wheels 6, 6, by means of the shaft *x*. These can be shifted at pleasure; so that by applying wheels of a greater or less number of teeth above and beneath, the twist given to the strands can be increased or diminished accordingly. The upper of these two communicates motion, by means of the shaft *o*, to another spur wheel 8, which working in the three pinions above, 9, 9, gives the twist to the strand hooks. The carriage is drawn out in the following manner: — On the end of the shaft of *m*, *m*, is the pinion 3, which, working in the large wheel R, gives motion to the ground-rope shaft upon its axis. In the centre of this shaft is a curved pulley or drum *t*, round which the ground-rope takes one turn. This rope is fixed at the head and foot of the ropery, so that when the machinery of the carriage is set agoing by the endless rope *k*, *k*, and gives motion to the ground-rope shaft, as above described, the carriage will necessarily move along the railway; and the speed may be regulated either by the diameter of the circle formed by the gubs on the wheel *m*, *m*, or by the number of teeth in the pinion 3. At T, is a small roller, merely for preventing the ground-rope from coming up among the machinery. At the head of the railway, and under the tackle-board, is a wheel and pinion Z, with a crank for tightening the ground-rope. The fixed machinery at the head, for hardening or tempering the strands, is similar to that on the carriage, with the exception of the ground-rope gear, which is unnecessary. The motion is communicated by another endless rope, (or short band, as it is called, to distinguish it from the other,) which passes over gubs at the back of the wheel 1, 1.

1569



1570

1572

1571

When the strands are drawn out by the carriage to the requisite length, the spur wheels 3, R, are put out of gear. The strands are cut at the tackle-board, and fixed to the hooks 1, 1, 1; after which they are hardened or tempered, being twisted at both ends. When this operation is finished, three strands are united on the large hook *h*, the top put in, and the rope finished in the usual way.

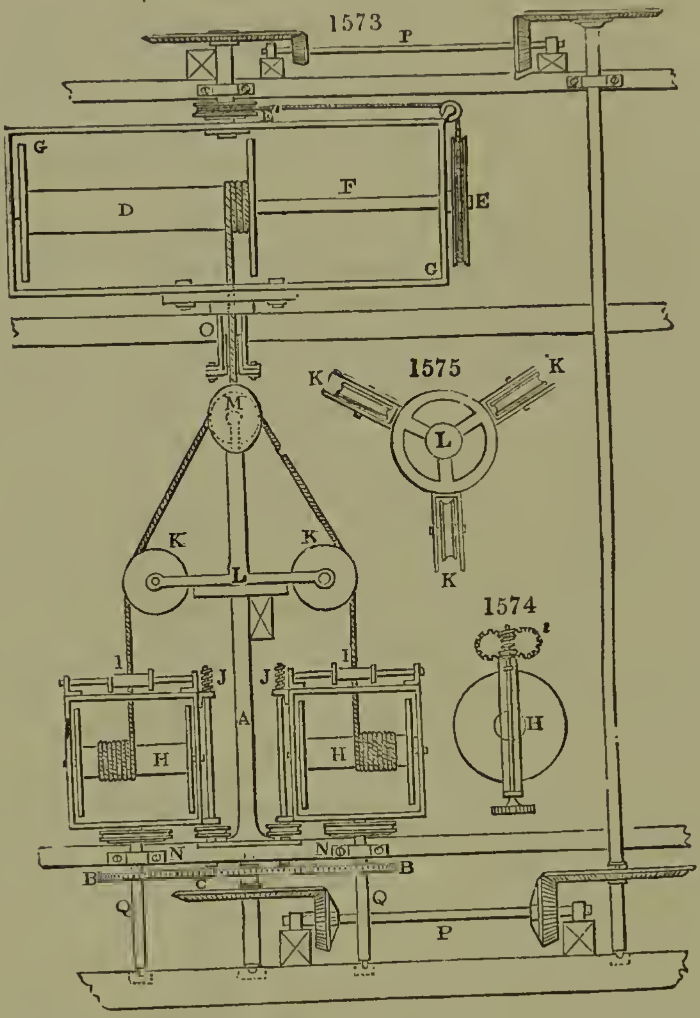
In preparing the hemp for spinning an ordinary thread or rope-yarn, it is only heckled over a large keg or clearer, until the fibres are straightened and separated, so as to run freely in the spinning. In this case the hemp is not stripped of the tow, or cropped, unless it is designed to spin beneath the usual grist, which is about 20 yarns for the strand of a 3-inch strap-laid rope. The spinning is still performed by hand, being found not only to be more economical, but also to make a smoother thread than has yet been effected by machinery. Various ways have been tried for preparing the yarns for tarring. That which seems now to be most generally in use is, to warp the yarns upon the stretch as they are spun. This is accomplished by having a wheel at the foot, as well as the head of the walk, so that the men are able to spin both up and down, and also to splice their threads at both ends. By this means they are formed into a haul, resembling the warp of a common web, and a little turn is hove into the haul, to preserve it from getting foul in the tarring. The advantages of warping from the spinners, as above, instead of winding on winches, as formerly, are, 1st, the saving of this last operation altogether; 2ndly, the complete check which the foreman has of the quantity of yarn spun in the day; 3rdly, that the quality of the work can be subjected to the minutest inspection at any time. In tarring the yarn, it is found favourable to the fairness of the strip, to allow it to pass around or under a reel or roller in the bottom of the kettle while boiling, instead of coiling the yarn in by hand. The tar is then pressed from the yarn, by means of a sliding nipper, with a lever over the upper part, and to the end of which the necessary weight is suspended. The usual proportion of tar in ordinary ropes is something less than a fifth. In large strap-laid ropes, which are necessarily subjected to a greater press in the laying of them, the quantity of tar can scarcely exceed a sixth, without injuring the appearance of the rope when laid.

For a long period the manner of laying the yarns into ropes was by stretching the haul on the rope-ground, parting the number of yarns required for each strand, and twisting the strands at both ends, by means of hand-hooks, or cranks. It will be obvious that this method, especially in ropes of any considerable size, is attended with serious disadvantages. The strand must always be very uneven; but the principal disadvantage, and that which gave rise to the many attempts at improvement, was, that the yarns being all of the same length before being twisted, it followed, when the rope was finished, that while those which occupied the circumference of the strand were perfectly tight, the centre yarns, on the other hand, as they were now greatly slackened by the operation of hardening or twisting the strands, actually would bear little or no part of the strain when the rope was stretched, until the former gave way. The method displayed in the preceding figures and description is among the latest and most improved. Every yarn is given out from the bobbin-frame as it is required in twisting the rope; and the twist communicated in the out-going of the carriage can be increased or diminished at pleasure. In order to obtain a smooth and well-filled strand, it is necessary also, in passing the yarns through the upper board, to proportion the number of centre to that of outside yarns. In ordinary sized ropes, the strand seems to have the fairest appearance, when the outside yarns form from two thirds to three fourths of the whole quantity, in the portion of twist given by the carriage in drawing out and forming the strands.

In laying cables, torsion must be given both behind and before the laying top. *Figs.* 1573 to 1575 represent the powerful patent apparatus employed for this purpose. A, is a strong upright iron pillar, supported upon the great horizontal beam N, N, and bearing at its upper end the three-grooved laying top M. H, H, are two of the three great bobbins or reels round which the three secondary strands or small hawsers are wound. These are drawn up by the rotation of the three feeding rollers I, I, I, thence proceed over the three guide pulleys K, K, K, towards the laying top M, and finally pass through the tube O, to be wound upon the cable-reel D. The frames of the three bobbins H, H, H, do not revolve about the fast pillar A, as a common axis; but each bobbin revolves round its own shaft Q, which is steadied by a bracing collet at N, and a conical step at its bottom. The three bobbins are placed at an angle of 120 degrees apart, and each receives a rotatory motion upon its axis from the toothed spur wheel B, which is driven by the common central spur wheel C. Thus each of the three secondary cords has a proper degree of twist put into it in one direction, while the cable is laid, by getting a suitable degree of twist in an opposite direction, from the revolution of the frame or cage G, G, round two pivots, the one under the pulley E, and the other over O. The reel D has thus, like the bobbins H, H, two movements; that in common with its frame, and that upon its axis, produced by the action of the endless band round the pulley E, upon one of its ends, and the pulley E′ above its centre of rotation. The pulley E is driven by the bevel mill-gearing P, P, P, as also the under spur wheel C. L, in *fig.* 1573, is the place of the ring L, *fig.* 1575, which bears the three guide pulleys K, K, K. *Fig.* 1574, is an end view of the bobbin H, to show the worm or endless screw J, of *fig.* 1573 working into the two snail-toothed wheels, upon the ends of the two feed-rollers I, I, which serve to turn them. The upright shafts of J, J, receive their motion from pulleys and cords near their bottom. Instead of these pulleys, and the others E, E′, bevel-wheel geering has been substituted with advantage, not being liable to slip, like the pulley-band mechanism. The axis of the great reel is made twice the length of the bobbin D, in order to allow of the latter moving from right to left, and back again alternately, in winding on the cable with uniformity as it is laid. The traverse mechanism of this part is, for the sake of perspicuity, suppressed in the figure.

Mr. William Norvell, of Newcastle, obtained a patent for an improvement adapted to the ordinary machines employed for twisting hempen yarns into strands, affording, it is said, a simpler and more eligible mode of accomplishing that object, and also of laying the strands together, than has been hitherto effected by machinery.

His improvements consist, first, in the application of three or more tubes, two of which are shown in *fig.* 1576, placed in inclined positions, so as to receive the strands immediately above the press-block *a*, *a*, and nearly in a line with A, the point of closing or laying the rope. B[1], and B[3], are opposite side views; B[2], an edge view;



and B, a side section of the same. He does not claim any exclusive right of patent for the tubes themselves, but only for their form and angular position.

Secondly, in attaching two common flat sheaves, or pulleys, C, C, *fig.* 1576, to each of the said tubes, nearly round which each strand is lapped or coiled, to prevent it from slipping, as shown in the section B[1]. The said sheaves or pulleys are connected by a crown or centre wheel D, loose upon *b*, *b*, the main or upright axle; E, E, is a smaller wheel upon each tube, working into the said crown or centre wheel, and fixed upon the loose box I, on each of the tubes.

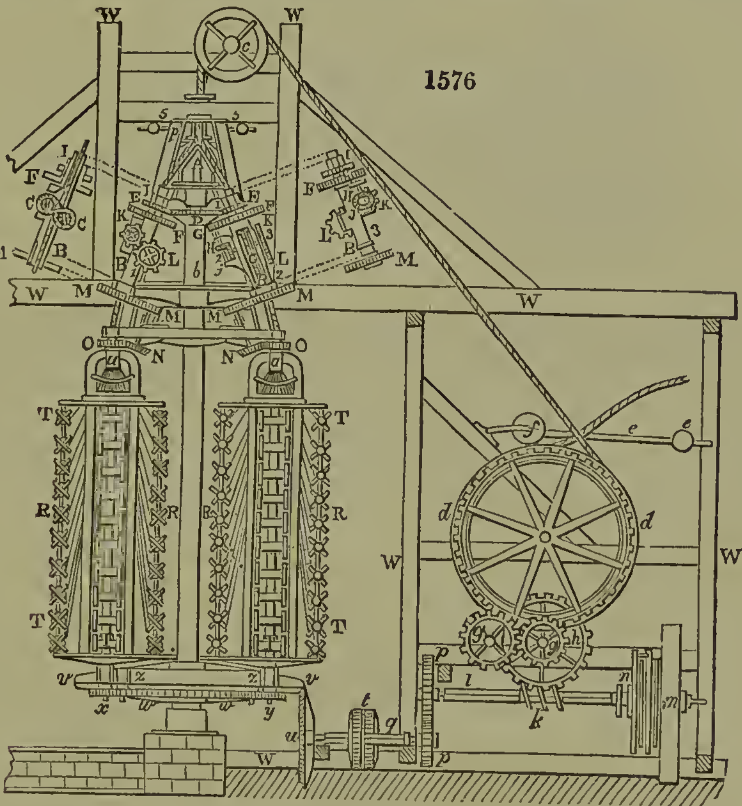
F, F, is a toothed or spur wheel, fixed also upon each of the loose boxes I, and working into a smaller wheel G, upon the axis 2, of each tube; H, is a bevel wheel fixed upon the same axis with G, and working into another bevel wheel *j*, fixed upon the cross axle 3 of each tube; K, is a spur wheel attached to the same axis with *j*, at the opposite end, and working into L, another spur wheel of the same size upon each of the tubes. By wheels thus arranged and connected with the sheaves or pulleys, as above described, a perfectly equal strain or tension is put upon each strand as drawn forward over the pulley C.

Thirdly, the invention consists in the introduction of change wheels M, M, M, M, *fig.* 1576, for putting the forehard or proper twist into each strand before the rope is laid; this is effected by small spindles on axles 4, 4, placed parallel with the line of each tube B.

Upon the lower end of each spindle the bevel wheels N, N, are attached, and driven by other bevel wheels O, O, fixed immediately above each press-block *a*, *a*. On the top end of each spindle or axle 4, 4, is attached one of the change wheels, working into the other change wheel fixed upon the bottom end of each of the tubes, whereby the forehard or proper twist in the strands for all sizes of ropes, is at once attained, by simply changing the sizes of those two last described wheels, which can be very readily effected, from the manner in which they are attached to the tubes B, B, and 4, 4.

From the angular position of the tubes towards the centre, the strands are nearly in contact at their upper ends, where the rope is laid, immediately below which the forehard or proper twist is given to the strands.

1576

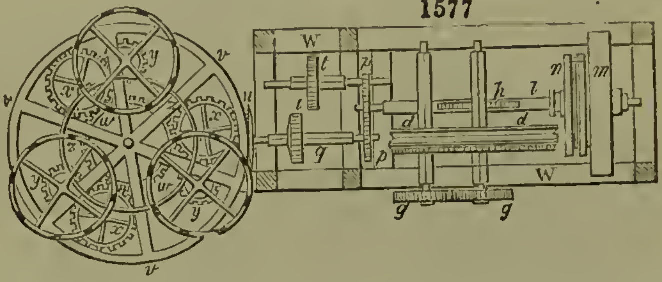


Fourthly, in the application of a press-block, P, of metal, in two parts, placed directly above and close down to where the rope is laid at A, the inside of which is polished, and the under end is bell-mouthed; to prevent the rope from being chafed in entering it, a sufficient grip or pressure is put upon the rope by one or two levers and weights 5, 5, acting upon the press-block, so as to adjust any trifling irregularity in the strand or in the laying; the inside of which being polished, gives smoothness, and by the said levers and weights, a proper tension to the rope, as it is drawn forward through the press-block. By the application of this block, ropes may be made at once properly stretched, rendering them decidedly preferable and extremely advantageous, particularly for shipping, inclined planes, mines, &c.

The preceding description includes the whole of Mr. Norvell's improvements; the remaining parts of the machine may be briefly described as follows: — A wheel or pulley *c*, is fixed independently of the machine, over which the rope passes to the drawing motion represented at the side; *d*, *d*, is a grooved wheel, round which the rope is passed, and pressed into the groove by means of the lever and weight *e*, *e*, acting upon the binding sheaf *f*, to prevent the rope from slipping. After the rope leaves the said sheaf, it is coiled away at pleasure. *g*, *g*, are two change wheels, for varying the speed of the grooved wheel *d*, *d*, to answer the various sizes of ropes; *h*, is a spiral wheel, driven by the screw *k*, fixed upon the axle *l*; *m*, is a band-wheel, which is driven by a belt from the shaft of the engine, or any other communicating power; *n*, *n*, is a friction strap and striking clutch. The axle *q* is driven by two change wheels *p*, *p*; by changing the sizes of those wheels, the different speeds of the drum R, R, for any sizes of ropes, are at once effected.

The additional axle *s*, and wheels *t*, *t*, shown in *fig.* 1577 are applied occasionally for reversing the motion of the said drums, and making what is usually termed left-hand ropes; *u*, *figs.* 1576, 1577, show a bevelled pinion, driving the main crown wheel *v*, *v*, which wheel carries and gives motion to the drums R, R; *w*, *w*, is a fixed or sun wheel, which gives a reverse motion to the drums, as they revolve round the same, by means of the intervening wheels *x*, *x*, *x*, whereby the reverse or retrograding motion is produced, and which gives to the strands the right twist. The various retrograding motion or right twist for all sizes and descriptions of ropes, may be obtained by changing the diameters of the pinions *y*, *y*, *y*, on the under ends of the drum spindles; the carriages of the intervening wheels *x*, *x*, *x*, being made to slide round the ring *z*, *z*: W, W, is the framework of the machine and drawing motion; T, T, T, are the bobbins containing the yarns; their number is varied to correspond with the different sizes of the machines.

1577



Messrs. Chapman of Newcastle, having observed that rope yarn is weakened by passing through the tar-kettle, that tarred cordage loses its strength progressively in cold climates, and so rapidly in hot climates as to be scarcely fit for use in three years, discovered that the deterioration was due to the reaction of the mucilage and acid of the tar. They accordingly proposed the following means of amelioration. 1. Boiling the tar with water, in order to remove these two soluble constituents. 2. Concentrating the washed tar by heat, till it becomes pitchy, and then restoring the plasticity which it thereby loses, by the addition of tallow, or animal or expressed oils.

The same engineers patented a method of making a belt or flat band, of two, three, or more strands of shroud or hawser-laid rope, placed side by side, so as to form a band of any desired breadth, which may be used for hoisting the kibbles and corves in mine-shafts, without any risk of its losing twist by rotation. The ropes should be laid with the twist of the one strand directed to the right hand, that of the other to the left, and that of the yarns the opposite way to the strands, whereby perfect flatness is secured to the band. This parallel assemblage of strands has been found also to be stronger than when they are all twisted into one cylinder. The patentees at the same time contrived a mechanism for piercing the strands transversely, in order to brace them firmly together with twine. Flat ropes are usually formed of hawsers with three strands, softly laid, each containing 33 yarns, which with four ropes compose a cordage four and a half inches broad, and an inch and a quarter thick, being the ordinary dimensions of the grooves in the whim-pulleys round which they pass.

Relative Strength of Cordage, shroud-laid.

The above statement is the result of several hundred experiments.

ROPE, WIRE. See WIRE ROPE.

ROSALIC ACID, discovered by Rungé, more fully examined by Hugo Müller; obtained by exhausting the crude carbonate of lime with a dilute boiling solution of carbonate of ammonia: evaporating to dryness, ammonia is evolved and a dark resinous body separates, which is the crude rosalic acid. The crude acid thus obtained was purified by conversion into a lime salt, and liberation of the acid again by acetic acid.

It is a dark green amorphous substance, possessing in a high degree the greenish lustre of cantharides. It is transparent with a fine red tint; very thin films appear of a deep orange colour in reflected light, and of a golden metallic lustre.—H. M. W.

ROSETTA WOOD. An East Indian wood of a lively red orange colour, and handsomely veined with darker marks. It is occasionally used in fine cabinet work.

ROSEWOOD. This well-known wood, which has long been fashionable for drawing-room and library furniture, is a native of the Brazils, the East Indies, the Canary Islands, and some parts of Africa. The best rosewood comes from Rio de Janeiro.

"Rosewood is a term as generally applied as iron wood, and to as great a variety of plants in different countries, sometimes from the colour, and sometimes from the smell of the woods. The rosewood of Bahia and Rio Janeiro, called also Jacaranda, is so named, according to Prince Maximilian as quoted by Dr. Lindley, because when fresh it has a faint but agreeable smell of roses, and is produced by a mimosa in the forests of Brazil. Mr. G. Loddiges informs me it is the *Mimosa jacaranda*"—*Holtzapffel.*

Rosewood is imported in large slabs, or the halves of trees, some of these logs producing as much as £150 when cut into veneers. We *imported* in 1858, 1529 tons; computed real value of which was £21,222.

ROSIN, or *common resin*. The residue of the process for obtaining oil of turpentine. While liquid it is run into metallic receivers coated with whiting to prevent adhesion, and from these laded into casks. See TURPENTINE.

When the distillation is not carried too far, the product is called *yellow rosin;* it then contains a little water. The heat being continued the water is expelled and *transparent rosin* is the result.

If the process be continued up to a point short of producing the decomposition of the rosin, it acquires a deep colour, and becomes *brown* or *black rosin*, sometimes cal ed *colophony.*

Rosin is insoluble in water, but soluble in alcohol, ether, and the volatile oils. It unites with wax and the fixed oils by heat, forming the *emplastrum resinæ* of the London Pharmacopœia.

Rosin is employed in common varnishes; it is united with tallow in the preparation of common candles. It has been proposed to employ rosin as a source from which gas might be obtained. The experiments made were not, however, of so successful a kind as to warrant the general adoption of the process.

Rosin *imported* in 1858:—

	Cwts.	Computed real value. £
Hamburgh	7,041	3,168

	701,430	£314,715

ROSIN OIL. By distillation rosin separates into rosin oil and tar. (See TAR.) This oil is a mixture of four carbides of hydrogen:

$$C^{14}H^{8};\ C^{10}H^{12};\ C^{32}H^{16};\ \text{and}\ C^{20}H^{8}.$$

The rosin oil, which distils over at about 300 F., is sometimes used in the arts as a substitute for the oil of turpentine. The part which boils at 464° F., called *retinole*, $C^{32}H^{16}$, enters into the composition of some printing inks.

ROTCH, or ROCHE. A local term, used by quarrymen and miners in South Staffordshire for a soft and friable sandstone. — H. W. B.

ROTTEN-STONE. A polishing powder which is much used for giving lustre to brass, silver, and even to glass surfaces. According to the analysis of Richard

Philips, the rotten-stone of Ashford in Derbyshire consists of carbon, 10; alumina, 86·0; silica, 4·0. Rotten-stone is nearly peculiar to this country, being found principally in Derbyshire, near Bakewell, and in Carmarthenshire and Breconshire, South Wales.

It is thought by geologists to be derived in Derbyshire from the siliceous limestone, "the lime being decomposed, and the silex remaining as a light earthy mass." This does not, however, agree with the above analysis, in which alumina occupies so large a proportion. The total annual produce of the country is under 300 tons.

ROUGE. (*Fard*, Fr.) A cosmetic employed to brighten a lady's complexion. See CARMINE.

ROUGE, JEWELLERS'. An oxide of iron prepared with much care. See OXIDES FOR POLISHING.

ROYAL BLUE. (*Bleu du Roi*, Fr.) A fine deep blue prepared from cobalt, and used for enamel and porcelain painting.

RUBBLE. A local term used by quarrymen and miners for loose angular gravel, or a slightly compacted brecciated sandstone.—H. W. B.

RUBIACINE. See MADDER.

RUBIAN. See MADDER.

RUBICELLE. The name given to yellow or orange-red varieties of spinel.—H. W. B.

RUBIRETINE. See MADDER.

RUBY. A beautiful and favourite gem; it is known, according to its various colours, as the

Ruby spinel, or *Spinel ruby*, which is of a light or dark red, and, if held near the eye, a rose-red colour. Its hardness is 8; specific gravity, 3·523. Its fundamental form is the hexahedron, but it occurs crystallised in many secondary forms: octahedrons, tetrahedrons, and rhombohedrons. Fracture conchoidal; lustre vitreous; colour red, passing into blue and green, yellow, brown, and black; and sometimes it is nearly white. Red spinel consists of alumina, 74·5; silica, 15·5; magnesia, 8·25; oxide of iron, 1·5; lime, 0·75. Vauquelin discovered 6·18 per cent. of chromic acid in the red spinelle. The red varieties exposed to heat become black and opaque; on cooling they appear first green, then almost colourless, but at last resume their red colour. *Pleonaste* is a variety which yields a deep green globule with borax.

Crystals of spinelle from Ceylon have been observed embedded in limestone, mixed with mica, or in rocks containing adularia, which seem to have belonged to a primitive district. Other varieties, like the pleonaste, occur in the drusy cavities of rocks ejected by Vesuvius. Crystals of it are often found in diluvial and alluvial sand and gravel, along with true sapphires, pyramidal zircon, and other gems, as also with octahedral iron ore, in Ceylon. Blue and pearl-grey varieties occur in Südermannland in Sweden, embedded in granular limestone. Pleonaste is met with also in the diluvial sands of Ceylon. Clear and finely coloured specimens of spinel are highly prized as ornamental stones. When the weight of a good spinel exceeds 4 carats, it is said to be valued at half the price of a diamond of the same weight. M. Brard has seen one at Paris which weighed 215 grains.

Balas ruby. Pale red or rose red, with sometimes a tinge of brown or violet.

Almandine ruby, which is of a violet red colour. Spinel occurs embedded in granular limestone, and with calcareous spar in gneiss and serpentine. It also occupies the cavities of volcanic rocks.—*Dana*.

It is also found in clay and in the sand of rivers. Spinel scratches quartz; but the sapphire is harder than the ruby. As gems, the ruby is cut in the same form as the diamond, and is set with a foil of copper or gold. Pure spinel is a compound of alumina and magnesia, usually in the proportions of about 28 magnesia and 72 alumina, although we sometimes find the magnesia partially replaced by lime, and the alumina by oxide of iron.

Ruby, oriental, the red sapphire, containing 97 or 98 of alumina.

RUE (*Ruta graviolens*) produces a yellow colouring matter, similar to that obtained from BUCKWHEAT, which see.

RUM is a variety of ardent spirits, distilled in the West Indies from the fermented skimmings of the sugar teaches, mixed with molasses, and diluted with water to the proper degree. A sugar plantation in Jamaica or Antigua, which makes 200 hogsheads of sugar, of about 16 cwt. each, requires for the manufacture of its rum two copper stills; one of 1000 gallons for the wash, and one of 600 gallons for the low wines, with corresponding worm refrigeratories. It also requires two cisterns, one of 3000 gallons for the lees or spent wash of former distillations, called dunder (*quasi redundar*, Span.), another for the skimmings of the clarifiers and teaches of the sugar-house; along with twelve, or more, fermenting cisterns or tuns.

Lees that have been used more than three or four times are not considered to be equally fit for exciting fermentation, when mixed with the sweets, as fresher lees. The wort is made, in Jamaica, by adding to 1000 gallons of dunder, 120 gallons of molasses, 720 gallons of skimmings (=120 of molasses in sweetness), and 160 gallons of water; so that there may be in the liquid nearly 12 per cent. of solid sugar. Another proportion, often used, is 100 gallons of molasses, 200 gallons of lees, 300 gallons of skimmings, and 400 of water; the mixture containing, therefore, 15 per cent. of sweets. These two formulæ prescribe so much spent wash, according to Dr. Ure's opinion, as would be apt to communicate an unpleasant flavour to the spirits. Both the fermenting and flavouring principles reside chiefly in the fresh cane juice, and in the skimmings of the clarifier; because, after the syrup has been boiled, they are in a great measure dissipated. Dr. Ure has made many experiments upon fermentation and distillation from West India molasses, and always found the spirits to be perfectly exempt from any rum flavour.

The fermentation goes on most uniformly in very large masses, and requires from 9 to 15 days to complete; the difference of time depending upon the strength of the wort, the condition of its fermentable stuff, and the state of the weather. The progress of the attenuation of the wash should be examined from day to day with a hydrometer. When it has reached nearly to its *maximum*, the wash should be as soon as possible transferred by pumps into the still, and worked off by a properly regulated heat; for if allowed to stand over, it will deteriorate by acetification. Dr. Higgin's plan, of suspending a basket full of limestone in the wash-tuns, to counteract the acidity, has not been found to be of much use. It would be better to cover up the wash from the contact of atmospheric air, and to add perhaps a very little *sulphite* of lime to it, both of which means would tend to arrest the acetous fermentation. But one of the best precautions against the wash becoming sour, is to preserve the utmost cleanliness among all the vessels in the distillery. They should be scalded at the end of every round with boiling water and quicklime.

About 115 gallons of proof rum are usually obtained from 1200 gallons of wash. The proportion which the product of rum bears to that of sugar, in very rich moist plantations, is rated, by Edwards, at 82 gallons of the former to 16 cwt. of the latter; but the more usual ratio is 200 gallons of rum to 3 hogsheads of sugar. But this proportion will necessarily vary with the value of rum and molasses in the market, since whichever fetches the most remunerating price, will be brought forward in the greatest quantity. In one considerable estate in the island of Grenada, 92 gallons of rum were made for every hogshead (16 cwts.) of sugar.

Rum is largely used in the navy. Its general consumption will, however, be shown by the quantities imported.

Rum imported during the 10 *years form* 1848.

Rum Shrub is imported at the same rate of duties.

RUSH. A common plant, extensively employed in the manufacture of mats, baskets, &c. The pith of the rush is used in making *rushlights*. Bulrushes are a different plant. These are used for polishing wood, and also by coopers. The Dutch rush is also much used for polishing metals and stone.

RUSSIAN LEATHER. See LEATHER, RUSSIAN.

RUST is the orange-yellow coat of peroxide which forms upon the surface of iron exposed to moist air. Oil, paint, varnish, plumbago, grease, or indeed any body which will shield the metal from the moist air, may be employed, according to circumstances, to prevent the rusting of iron utensils.

Iron under all ordinary circumstances effects the decomposition of water, abstracting the oxygen, and combining with it. The rusting of iron is one of the many instructive examples of chemical affinity which are constantly occurring around us.

RUTHENIUM. After osmium, ruthenium is the most refractory metal we are acquainted with. It requires a very extreme heat to melt the smallest quantity. When melting there is formed the oxide of ruthenium (RuO^2) which is volatilised, and which smells something like osmic acid. When removed from the flame ruthenium is blackish-brown on the surface, and is brittle and hard like iridium. It is only distinctly separated from this last metal by its density, which is obviously half that of iridium. The purest ruthenium obtained weighs from 11 to 11·4.

To prepare the metal mix the osmide in fine powder with 3 parts of binoxide of barium and 1 part of nitrate of baryta, and heat them to redness in a clay crucible for an hour. The black friable mass which remains is powdered with great care and introduced into a flask in which has been previously mixed 20 parts of water and 10 parts of ordinary muriatic acid. The flask must be placed in cold water to avoid the elevation of temperature which would ensue from the violent reaction which takes place. This operation should be conducted under a good chimney to avoid the escape of the osmic acid vapour into the laboratory.

When this reaction is finished 1 part nitric acid is added, and then 2 parts ordinary strong sulphuric acid. The flask is now well shaken, and the sulphate of baryta is allowed to deposit. The supernatant liquid is then poured off, the precipitate is washed by decantation, and the liquid and the washings are distilled together in a tubulated retort, until about a fourth of their volume of a liquid very rich in osmic acid has passed over. The red liquor which is left in the retort is evaporated to a small volume, 2 or 3 parts of sal-ammoniac in small pieces are added, and a small quantity of nitric acid. The whole is now evaporated to dryness at the temperature of boiling water. A crystalline violet-black precipitate remains in the capsule, which is treated with a small quantity of water partly saturated with sal-ammoniac, and wash with the same solution until it is no longer coloured. The insoluble salt left (chloro-iridiate of ammonia containing ruthenium) is heated by degrees to redness in a porcelain crucible. The mixture of iridium and ruthenium thus obtained is fused in a silver crucible with an equal weight of hydrated potash and twice its weight of nitre, and when cold the rutheniate of potash is dissolved out with cold water; the solution, which is yellow, is decomposed by means of carbonic or nitric acid, and the precipitated oxide of ruthenium is strongly calcined in a charcoal crucible. The ruthenium is then reduced in the apparatus before described. Iridium and ruthenium present many analogies; their coloured reactions are the same, and the oxide of iridium dissolves in a mixture of nitre and potash.

Ruthenium forms with zinc an alloy which will burn in the air; it crystallises in hexagonal prisms. With tin there is formed an alloy $RuSn^2$, which crystallises in cubes as beautiful in their form and lustre as crystallised bismuth.—*Deville and Debray on the platinum metals.*

RUTILE. Native oxide of titanium, coloured by iron. It is used in porcelain painting to produce a yellow colour.

RYE (*Seigle*, Fr.; *Roggen*, Germ.) is a cereal grain, supposed to be a native of Crete. It appears to have been used at a very early period by man. The culture of rye is confined to the temperate zones. Rye consists, according to the analysis of Einhof, of 24·2 of husk, 65·6 of flour, and 10·2 of water, in 100 parts. This chemist found in 100 parts of the flour, 61·07 of starch, 9·48 of gluten, 3·28 of vegetable albumen, 3·28 of uncrystallisable sugar, 11·09 of gum, 6·38 of vegetable fibre, and the loss was 5·62, including a vegetable acid not yet investigated. Some phosphate of lime and magnesia are also present.

Rye is sometimes used as a source, when fermented, of obtaining spirituous liquors. The straw has been long used and celebrated for the manufacture of straw plait.

RYE, ERGOT OF. (*Secale cornutum.*) The grain rye is subject to a disease (*spermedia clavis*) commonly known as *ergot*, which causes the grain to turn black. It is used medicinally. See Pereira's *Materia Medica*.

S.

SABOTIERE. The apparatus for making ices, called "sabotière," is composed of two principal parts—a pail which is indented towards the top and covered; and the sabotière, or inner vessel, slightly conical, which is inserted in a pail, on which it rests by a projecting border or rim; this vessel is closed at the bottom like a cup, and open at the top to admit the creams to be iced. It is closed at the top by a cover furnished with a handle and a hook, which fastens it to the rim of the vessel. This apparatus works as follows:—The freezing mixture is turned into the pail, and the creams to be iced into the inner vessel; its cover is then fastened by the hook, and the vessel is set into the pail among the freezing liquid; then taking the whole by the handle of the sabotière, an alternate motion of rotation is given to it for about a quarter of an hour, when the cream is sufficiently frozen. The cover is opened from time to time, and the mixture well stirred with a spoon adapted for the purpose. The freezing mixture must be renewed every 15 or 20 minutes. See FREEZING MIXTURE.

SACCHAROMETER is the name of a hydrometer, adapted by its scale to point out the proportion of sugar, or the saccharine matter of malt, contained in a solution of any specific gravity. Brewers, distillers, and the Excise, sometimes denote by the term gravity the excess of weight of 1000 parts of a liquid by volume above the weight of a like volume of distilled water, so that if the specific gravity be 1045, 1070, 1090, &c.; the gravity is said to be 45, 70, or 90; at others, they thereby denote the weight of saccharine matter in a barrel (36 gallons) of worts; and again, they denote the excess in weight of a barrel of worts over a barrel of water, equal to 36 gallons, or 360 pounds. This and the first statement are identical, only 1000 is the standard in the first case, and 360 in the second.

The saccharometer used by the Excise, and by the trade, is that constructed by the late Mr. R. B. Bate, well known for the accuracy of his philosophical and mathematical instruments. The tables published by him for ascertaining the value of wort or wash, and low wines, are preceded by explicit directions for their use. "The instrument is composed of brass; the ball or float being a circular spindle, in the opposite ends of which are fixed a stem and a loop. The stem bears a scale of divisions numbered downwards from the first to 30; these divisions, which are laid down in an original manner, observing a diminishing progression according to true principles; therefore each division correctly indicates the one-thousandth part of the specific gravity of water; and further, by the alteration made in the bulk of the saccharometer at every change of poise, each of the same divisions continues to indicate correctly the said one-thousandth part throughout."

The following table shows the quantities of sugar contained in syrups of the annexed specific gravities. It was the result of experiments carefully made by Dr. Ure.

Experimental Spec. Gravity of Solution at 60° F.	Sugar in 100· by Weight.	Experimental Spec. Gravity of Solution at 60° F.	Sugar in 100· by Weight.
1·3260	66·666	1·1045	25·000
1·2310	50·000	1·0905	21·740
1·1777	40·000	1·0820	20·000
1·4400	33·333	1·0635	16·666
1·1340	31·250	1·0500	12·500
1·1250	29·412	1·0395	10·000
1·1110	26·316		

N.B. The column in the next table, marked *extract by weight*, is Mr. Bate's; it may be compared with this short table, and also with the table of malt infusions in the Dictionary. See BEER; MALT; FERMENTATION.

If the decimal part of the number denoting the specific gravity of syrup be multiplied by 26, the product will denote very nearly the quantity of sugar per gallon in pounds at the given specific gravity.

Table exhibiting the Quantity of Sugar, in Pounds Avoirdupois, which is contained in One Gallon of Syrup, at successive Degrees of Density, at 60° F.

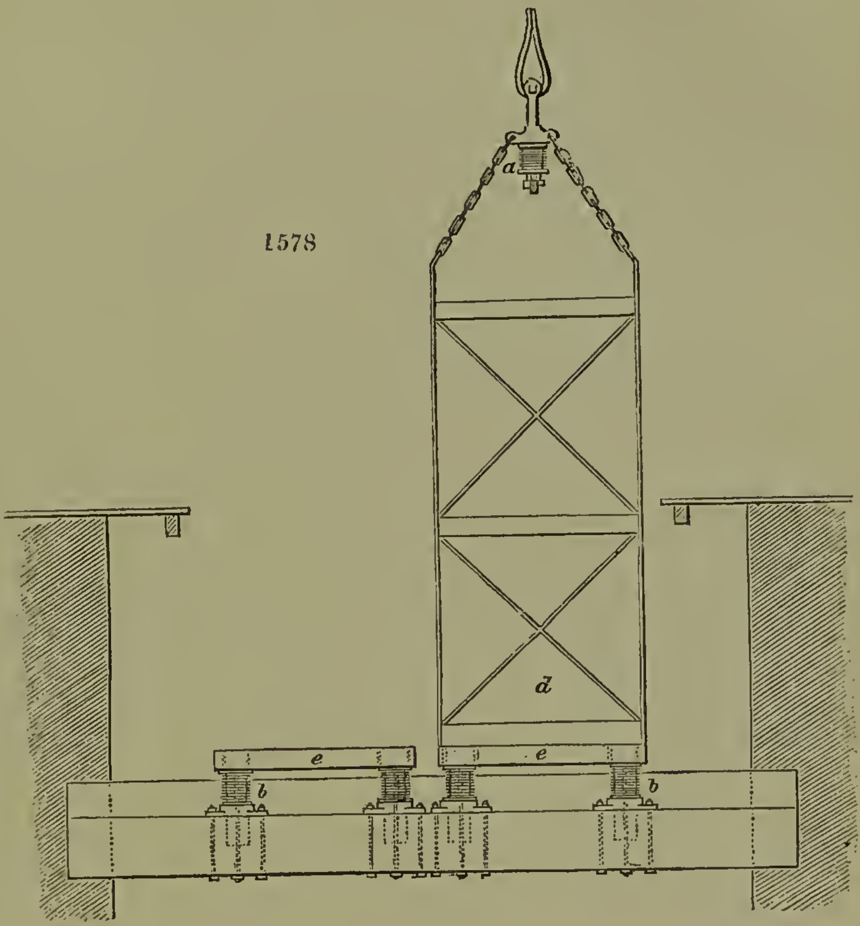
SAFETY CAGE. In all our collieries the men descend to their labour and are raised from the depth of the mine by the winding machinery. This may be described in general terms as a stage travelling in guides fixed to the sides of the shafts. The rapidity with which these stages are moved up or down is very great, and consequently, if anything occurs to engage the attention of the man in charge of the

1578



winding-engine, the stage with its living load is either landed with injurious violence at the bottom of the pit, or it is carried over the pulley, and thus the lives of the men are sacrificed. The above drawing, *fig.* 1578, shows an ingenious contrivance for obviating the blow which arises from reaching the bottom at too great a speed. *e e*, are platforms placed on Indian-rubber springs (see Caoutchouc) *b b*, on the landing at the bottom of the pit; *d*, is one of the cages which has descended, the other being supposed to be at the surface. The elasticity of these springs certainly serves to protect the men from the violence of the concussion in the event of the rope breaking, or if from any other cause they suddenly reach the bottom.

Many safety cages, so called, have been invented, the principles of which are to allow them to travel freely on their guides, so long as the rope by which they are suspended remains entire; but, in the event of its breaking, the arms, levers, or catches seize the guide-rods, and thus suddenly stop the cage. Experience has not satisfactorily confirmed the value of these arrangements.

A simple arrangement for a safety cage was published by Mr. Andrew Smith, in 1852. According to Mr. Smith's invention, the drawing rope is connected with the chain-work supporting the cage by a strong elastic tube, which gives the cage an easy motion until an accident takes place. Immediately the rope breaks, the weight of the cage forces the end of a lever against the guide-rods, which extend from top to bottom of the shaft. The following description may render the invention more intelligible:—A horizontal bar is provided with a slot at each end, through which the guide rods pass; at the inner end of each slot is a pin, which forms the fulcrum of a lever, the shorter arm of which is towards the guide-rod. While the machinery is working properly, each lever forms as it were a link of the chain by which the cage is suspended; the bar and the connecting levers forming about an equilateral triangle. To the extremity of the longer arm of the lever are connected the rods by which the cage itself is suspended; these rods cross each other, and the cage is hooked upon the end. It will readily be understood that, while all is in order, the short arms of the lever are held back from the guide-rods, and the slot of the cross-bar is sufficiently large to admit the rise and fall of the cage without impediment; but upon the breakage of the rope the long arms of the levers are depressed, and the short arms forced, as stated, against the guide-rods, preventing the further fall of the cage. The cost of the contrivance is comparatively trifling, which is another recommendation to its use. Among the more prominent patented inventions are those of Mr. F. Emery, of Cobridge, Staffordshire, of Messrs. White and Grant of Glasgow, and of Mr. Foudriner. Messrs. White and Grant's cage is simple and inexpensive, no rack-work being required upon the guide-rods, and the suspending power depending upon the simple turning of an eccentric, which is only kept from revolving by the tension of the suspending rope or chain. An eccentric is placed on each side of each guide-rod, and while the tension is sufficient, the narrow parts of the eccentrics being towards the rods, there is just room for the guide-rod to pass between them. The breakage of the rope, however, releases the eccentrics, and in their attempt to revolve they grip the guide-rods and prevent the descent of the cage.

Again, a variety of contrivances have been introduced to release the cage from the rope or chain in the event of its being drawn up to the pulley: some of these have been adopted with apparent advantage. Humane care, however, whatever may be the mechanical appliances adopted, is necessary to ensure safety.

SAFETY FUSE. A woven cylinder containing gunpowder, employed in blasting rocks, especially in our mines. The safety fuse is also prepared for blasting under water.

SAFETY LAMP. The dangerous nature of the accumulation of fire-damp renders it necessary that some means should be employed to produce light, under such circumstances that the risks of explosion are greatly reduced.

The contrivance of *a steel mill* was long known, and it afforded a tolerable gleam, with which the miners were obliged to content themselves in hazardous atmospheres.

The steel mill consisted of a small frame of iron, mounted with a wheel and pinion, which gave rapid rotation to a disk of hard steel placed upright, to whose edge a piece of flint is applied. The use of this machine entailed on the miner the expense of an attendant, called the miller, who gave him light. Nor was the light altogether safe, for occasionally the ignited shower of steel particles attained to a sufficient heat to inflame the fire-damp.

At length the attention of the scientific world was powerfully attracted to the means of lighting the miner with safety, by an awful catastrophe which happened at Felling Colliery, near Newcastle, on the 25th May, 1812. This mine was working with great vigour, under a well-regulated system of ventilation, set in action by a furnace and air-tube, placed over a rise-pit in elevated ground. The depth of winning was above 100 fathoms; 25 acres of coal had been excavated, and one pit was yielding at the rate of 1700 tons per week. At 11 o'clock in the forenoon the night shift of miners was relieved by the day shift; 121 persons were in the mine, at their several stations, when, at half-past 11, the gas fired, with a most awful explosion, which alarmed all the neighbouring villages. The subterraneous fire broke forth with two heavy discharges from the dip-pit, and these were instantly followed by one from the rise-pit. A slight trembling, as from an earthquake, was felt for about half a mile round the colliery, and the noise of the explosion, though dull, was heard at from 3 to 4 miles' distance. Immense quantities of dust and small coal accompanied these blasts, and rose high into the air, in the form of an inverted cone. The heaviest part of the ejected matter, such as corves, wood, and small coal, fell near the pits; but the dust borne away by a strong west wind fell in a continuous shower a mile and a half from the pit. In the adjoining village of Heworth it caused a darkness like that of early twilight, covering the roads where it fell so thickly that the footsteps of passengers were imprinted in it. The heads of both shaft-frames were blown off, their sides set on fire, and their pulleys shattered to pieces. The coal-dust ejected from the rise-pit into the horizontal part of the ventilating tube, was about 3 inches thick, and speedily burnt to a cinder; pieces of burning coal, driven off the solid stratum of the mine, were also blown out of this shaft. Of the 121 persons in the mine at the time of the explosion, only 32 were drawn up the pit alive, 3 of whom died a few hours after the accident. Thus no less than 92 valuable lives were instantaneously destroyed by this pestilential fire-damp. The scene of distress among the relatives at the pit mouth was indescribably sorrowful.

Dr. W. Reid Clanny, of Sunderland, was the first to contrive a lamp which might burn in explosive air without communicating flame to the gas in which it was plunged. This he effected, in 1813, by means of an air-tight lamp, with a glass front, the flame of which was supported by blowing fresh air from a small pair of bellows through a stratum of water in the bottom of the lamp, while the heated air passed out through water by a recurved tube at top. By this means the air within the lamp was completely insulated from the surrounding atmosphere. This lamp was the first ever taken into a body of inflammable air in a coal-mine, at the exploding point, without setting fire to the gas around it. Dr. Clanny made another lamp upon an improved plan, by introducing into it the steam of water generated in a small vessel at the top of the lamp, heated by the flame. The chief objection to these lamps is their inconvenience in use.

Various other schemes of safe-lamps were offered to the miner by ingenious mechanicians, but they have been all superseded by the admirable invention of Sir H. Davy, founded on his fine researches upon flame. The lamp of Davy was instantly tried and approved of by Mr. Buddle and the principal mining engineers of the Newcastle district. A perfect security of accident is therefore afforded to the miner in the use of a lamp which transmits its light, and is fed with air, through a cylinder of wire gauze; and this invention has the advantage of requiring no machinery, no philosophical knowledge to direct its use, and is made at a very cheap rate.

In the course of a long and laborious investigation on the properties of the fire-damp, and the nature and communication of flame, Sir H. Davy ascertained that the explosions of inflammable gases were incapable of being passed through long narrow metallic tubes; and that this principle of security was still obtained by diminishing their length and diameter at the same time, and likewise diminishing their length, and increasing their number, so that a great number of small apertures would not pass an explosion, when their depth was equal to their diameter. This fact led him to trials upon sieves made of wire-gauze, or metallic plates perforated with numerous small holes; and he found it was impossible to pass explosions through them.

The apertures in the gauze should never be more than 1-20th of an inch square. In the working models sent by Sir H. to the mines, there were 748 apertures in the square inch, and the wire was about the 40th of an inch diameter. The cage or cylinder of wire gauze should be made by double joinings, the gauze being folded over in such a manner as to leave no apertures. It should not be more than two inches in diameter; or in large cylinders the combustion of the fire-damp renders the top inconveniently hot; and a double top is always a proper precaution, fixed at a distance of about half an inch above the first top.

The principles upon which these lamps are constructed, dependent as they are upon some of the most refined researches of science, must be briefly described. Flame is gaseous matter in a state of combustion, that is, it is under all the ordinary circumstances carburetted hydrogen gas in active combination with oxygen. During the intense chemical action there is a great increase of volume, carbonic acid and water vapour escaping. Fire-damp is light carburetted hydrogen or marsh gas. This is formed by the changes which are going on in the carbonaceous compounds of which our fossil fuel is constituted, and is condensed in the coal.

A few of the analyses which have been published by different chemists will show the composition of the fire-damp of our coal mines.

	Carburetted Hydrogen.	Light Air.	Nitrogen.	Oxygen.	Carbonic Acid.	Name of Chemist.
Wallsend, Bensham seam	77·50	- -	21·10	- -	1·30	Playfair.

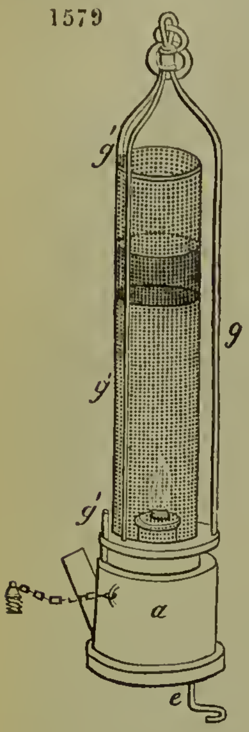
The theories which have been devised by chemists to explain the formation of fire-damp have not been consistent with themselves, nor have they satisfied the conditions under which the gas is found in "fiery seams."

Mr. Tennant, in his *Researches on Flame*, first noticed that burning gases would not pass through tubes of a certain diameter. Dr. Paris says, Davy was not aware of Tennant's researches. Be this as it may, he greatly extended the inquiry.

The first full account of Davy's beautiful researches was published in the *Philosophical Transactions* for 1816, his memoir being entitled "An account of an invention for giving light in explosive mixtures of fire-damp in coal mines, by consuming the fire-damp." In January 1817, the principle was announced in a paper on "Some new experiments and observations on the combustion of gaseous mixtures, with an account of a method of preserving a continued light in mixtures of inflammable gases and air without flame."

The lamp of Davy, *fig.* 1579, consists therefore of a common oil lamp, surmounted with a covered cylinder of wire gauze, for transmitting light to the miner without endangering the kindling of the atmosphere of fire-damp which may surround him.

1579



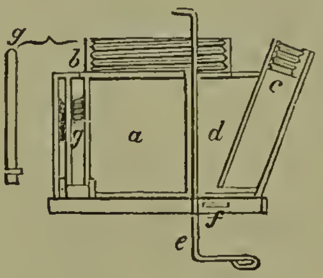
The gauze cylinder should be fastened to the lamp by a screw, *b*, *fig.* 1580, of four or five turns, and fitted to the screw by a tight ring. All joinings in the lamp should be made with hard solder; as the security depends upon the circumstance, that no aperture exists in the apparatus larger than in the wire-gauze.

The parts of the lamp are,

1. The brass cistern *a*, *d*, *fig.* 1580, which contains the oil. It is pierced at one side of the centre with a vertical narrow tube, nearly filled with a wire which is recurved above, at the level of the burner, to trim the wick, by acting on the lower end of the wire *e* with the fingers. It is called the safety-trimmer.

2. The rim *b* is the screw neck for fixing on the gauze cylinder, in which the wire-gauze cover is fixed, and which is fastened to the cistern by a screw fitted to *b*.

1580



3. An aperture *c* for supplying oil. It is fitted with a screw or a cork, and communicates with the bottom of the cistern by a tube at *f*. A central aperture for the wick.

4. The wire-gauze cylinder, *fig.* 1579, which should not have less than 625 apertures to the square inch.

5. The second top, ¾ of an inch above the first, surmounted by a brass or copper plate, to which the ring of su pension may be fixed. It is covered with a wire cap in the figure.

6. Four or six thick vertical wires, g' g' g' g', joining the cistern below with the top plate, and serving as protecting pillars round the cage. g is a screw-pin to fix the cover, so that it shall not become loosened by accident or carelessness. The oil-cistern *fig.* 1580 is drawn upon a larger scale than *fig.* 1579, to show its minuter parts.

When the wire-gauze safety-lamp is lighted and introduced into an atmosphere gradually mixed with fire-damp, the first effect of the fire-damp is to increase the length and size of the flame. When the inflammable gas forms so much as 1-12th of the volume of the air, the cylinder becomes filled with a feeble blue flame, while the flame of the wick appears burning brightly within the blue flame. The light of the wick augments till the fire-damp increases to 1-6th or 1-5th, when it is lost in the flame of the fire-damp, which in this case fills the cylinder with a pretty strong light. As long as any *explosive* mixture of gas exists in contact with the lamp, so long it will give light; and when it is extinguished, which happens whenever the foul air constitutes so much as 1-3rd of the volume of the atmosphere, the air is no longer proper for respiration; for though animal life will continue where flame is extinguished, yet it is always with suffering. By fixing a coil of platinum wire above the wick, ignition may be maintained in the metal when the lamp itself is extinguished; and from this ignited wire the wick may be again rekindled, on carrying it into a less inflammable atmosphere. This, however, is rarely employed.

The late Mr. John Buddle, one of the most experienced of coal miners, writes as follows, in the *Journal of Science*, on the general use of the safety lamp: "We have frequently used the lamps where the explosive mixture was so high as to heat the wire-gauze red-hot; but on examining a lamp which has been in constant use for three months, and occasionally subjected to this degree of heat, I cannot perceive that the gauze cylinder of iron wire is at all impaired. I have not, however, thought it prudent, in our present state of experience, to persist in using the lamps under such circumstances, because I have observed, that in such situations the particles of coal dust floating in the air, fire at the gas burning within the cylinder, and fly off in small luminous sparks. This appearance, I must confess, alarmed me in the first instance, but experience soon proved that it was not dangerous.

"Besides the facilities afforded by this invention to the working of coal-mines abounding in fire-damp, it has enabled the directors and superintendents to ascertain, with the utmost precision and expedition, both the presence, the quantity, and correct situation of the gas. Instead of creeping inch by inch with a candle, as is usual, along the galleries of a mine suspected to contain fire-damp, in order to ascertain its presence, we walk firmly on with the safety-lamps, and, with the utmost confidence, prove the actual state of the mine. By observing attentively the several appearances upon the flame of the lamp, in an examination of this kind, the cause of accidents which happened to the most experienced and cautious miners is completely developed; and this has hitherto been in a great measure matter of mere conjecture.

"It is not necessary that I should enlarge upon the national advantages which must necessarily result from an invention calculated to prolong our supply of mineral coal, because I think them obvious to every reflecting mind; but I cannot conclude without expressing my highest sentiments of admiration for those talents which have developed the properties, and controlled the power, of one of the most dangerous elements which human enterprise has hitherto had to encounter." The two first safety lamps used in a colliery are preserved in the Museum of Practical Geology.

The action of the wire-gauze has been supposed to depend upon a cooling process, but many experiments tried by the editor of the present work tends to convince him that the cooling hypothesis will not explain the phenomenon. He conceives the impermeability of wire-gauze to flame to be due to a repulsive power established between the hot metal and the ignited gas, similar in character, although differing in condition, to that which prevails between water and a white-hot metal. The gas undergoing combustion and the metal appear to repel each other in a similar manner. Frequently, from the intensity of the explosion going on within the lamp, the iron wires of the gauze will become red-hot,—so hot, indeed, that, as Mr. Buddle says, coal dust would be ignited by it, and yet the flame would not pass through.

Previously to the introduction of the "Davy," as it is commonly called, Dr. Clanny in 1813 proposed a lamp, the flame of which was carefully guarded from the external atmosphere, air being supplied by means of a bellows, and made to pass through a vessel containing oil. George Stephenson, proceeding not improbably upon the data furnished by Mr. Tennant, as Davy, notwithstanding Dr. Paris's statement, may have done, with that peculiar aptitude in mechanical design which ever characterised that remarkable man, at once, and without any knowledge of the researches of the chemist, devised a lamp by which air was admitted to the flame through "apertures of wire-gauze." This lamp is said by Mr. Brandling to have been tried in "the Killingworth pits on Saturday, October 21st, 1815." The result, however, of a very careful examination of the question as between George Stephenson and Humphry Davy by a meeting of coal-owners was, on the 11th October, 1816, a decision that the merits of discovering a real safety lamp belonged to Davy; and on the 13th of September, 1817, a service of plate was presented by the coal-owners at Newcastle, "as a testimony of their gratitude for the services you have rendered to them and to humanity." It is to be regretted that the repose which is ever so necessary to the progress of science, and the discovery of truth, should be invaded by the influences of jealousy and assailed by the shafts of malevolence. Two mighty minds, gifted beyond their brethren, discover a principle. One of these minds, as a mechanic, gives his idea a visible expression in a mechanical manner, and he is not completely successful; the other, trained as an analyst, seeks out the laws of action involved; dives further into the mysteries of nature; and when he develops his idea to the world, it is a success. These two giants in intellect should have been friends at heart; they were both equally discoverers, and their names shine as "beacons to the abodes where the Eternals are."

Numerous modifications of the Davy safety lamp have been from time to time introduced. A few of the more important must be named:—

1. George Stephenson modified his original plan. His modified lamp consisted of a wire gauze cylinder about $2\frac{1}{4}$ inches diameter, and about 6 inches high, with a glass shield inside. The air for combustion was admitted through a series of perforations in the bottom, and a metal chimney, full of small holes, is fixed inside on the top of the glass cylinder.

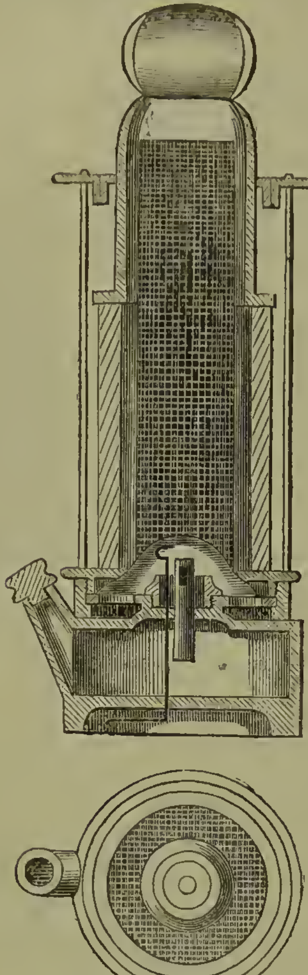
2. Mr. Smith, of Newcastle, improved this by covering all the perforations in the metal with wire gauze.

3. Newman, to meet the objection that strong currents of air, or of gas, could be forced through the gauze, made a lamp with a double wire gauze, commencing from nearly the top of the flame of the lamp, leaving the lower portion with one gauze only; there was no obstruction to the light, and it has not been found possible to light a gas flame by the Newman double gauze lamp, whereas this may be done by suddenly driving the flame through the single gauze of the Davy.

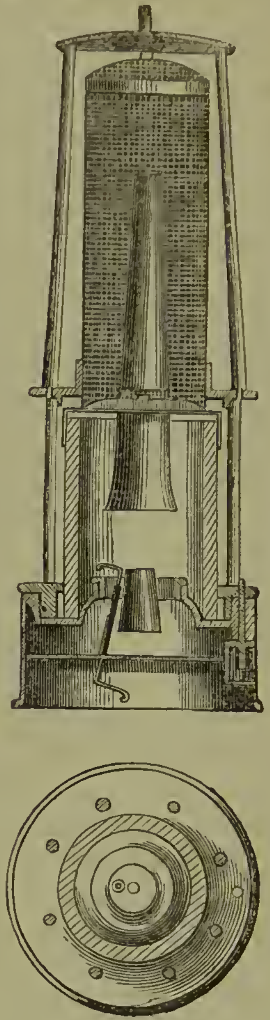
4. Upton and Roberts, *fig.* 1581. Their lamp consists of a wire gauze-cylinder $5\frac{1}{2}$ inches long and $1\frac{1}{2}$ inch in diameter, which is attached to the cylinder in the

usual manner. The lower half is protected by a thick glass cylinder, and the remaining portion by one of copper, screwed to the upper ring of the frame. The air for combustion passes through a range of small openings in the upper part of the cistern

1581



1582



into a space protected by a double shield of closely compressed wire-gauze. A cone of sheet metal stands above this shield and conducts the air directly upon the wick.

5. Martin's lamp was, in many respects, similar to Upton and Roberts's, but so constructed that the flame was extinguished as soon as an explosive mixture was within the glass cylinder.

6. Dumesnil sought to increase the quantity of light, at the same time as he protected the flame against any rapid current. The glass shield surrounding the flame is of carefully annealed glass, and is protected from mechanical injury by curved metal bars; a chimney of sheet metal being above the glass, and all the air being compelled to pass through apertures rendered safe by the use of wire gauze.

7. Dr. Clanny, who had for so many years directed his attention to safety-lamps, introduced a new lamp, with an impervious metal shield, having glass and lenses in its sides, only open at the highest part of the gauze cylinder for about 1½ inches. Thus there is no admission of air to the lamp, or of the products of combustion from the lamp, except over the top of the shield. This in many respects resembles Mueseler's lamp, to be next described.

8. Muesler's lamp is shown in section, *fig.* 1582. The cistern opening for the wick, &c., are precisely the same as we find them in the "Davy." A glass shield occupies about two-fifths of the entire height, the lower edge resting in an annular recess on the upper surface of the cistern. A conical tube of metal carries off the products of combustion. Upon the bars which protect the glass rests the gauze cylinder above it. When this lamp is brought into an explosive mixture the flame is first lengthened and then extinguished. It unfortunately happens that by turning the lamp on one side the flame is often put out, and in the mines of Liège boys are employed to relight the extinguished lamps. It is, however, stated that not less than 12,000 of these lamps are in daily use in Belgium.

9. Combe's and Boty's are modifications of the preceding.

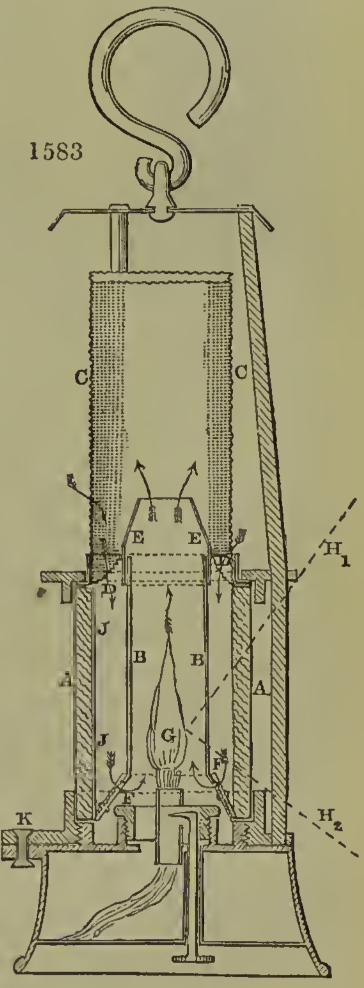
10. Parish's lamp, one by Dr. Fyfe, and some others by Mr. Hewitson and by Mr. Biram, involve the use of talc in the place of gas.

11. Eloin's lamp consists of a cylinder fixed upon the upper surface of the cistern and the glass shield, which is pierced with several holes covered with wire gauze, through which the air enters. As in Upton and Roberts's lamp, a cone assists the combustion. A copper chimney is connected with the base, pierced in the upper end with small holes, through which the products of combustion escape. The light is improved by means of a reflector, which slides upon the bars, by which the glass is protected.

12. Dr. Glover, Mr. Cail, and Mr. T. Y. Hall have recently introduced lamps which are so similar to those already named that they need not be described.

13. Mackworth's safety lamp. This safety lamp was contrived by one of the Government Inspectors of coal mines, to meet the objections raised in resisting the general introduction of the Davy lamp into fire-damp mines. The objections were the small light given by the Davy, which is an inconvenience in working high seams of coal, or in picking out the shale and pyrites from the small coal of dirty seams. 2ndly, that the Davy was not safe in a rapid current of air and gas, and that glass lamps were not safe in places where the glass might become cracked, besides being heavy to carry; and, 3rdly, that the ordinary locks of Davy lamps could be easily picked and opened by the workmen to obtain more light, and light their pipes. The lamp differs from other glass lamps in having a thick outer glass, A A, *fig.* 1583, and a thin inner chimney, B B. The air enters to the flame, as shown by the arrows, through three wire gauzes; 1st, the cylindrical gauze, C; then through the gauze D, which supports the brass cover E, of the glass chimney B; and, 3rdly, through the conical wire gauze F, which, with its frame, acts as a support to the glass chimney B. This conical frame throws the air on to the flame G, so as to produce a more perfect combustion and a whiter light. A wire gauze may be placed on the top of the cover E, but it is unnecessary, as the products of combustion passing through the contracted aperture, prevent any explosion passing up into the cylindrical gauze C.

1583



The objects sought to be obtained in this lamp are, the production of from twice to three times the light of the Davy, by a more perfect combustion of oil, throwing the light more up and down, as shown by the lines H_1 H_2. The reflector, J, placed between the glasses, where it is untarnished by smoke, adds to the light. This lamp burns with a steady flame, in currents of air which extinguish other lamps. It is $1\frac{1}{4}$ lb. heavier than a Davy, and $1\frac{1}{2}$ lb. lighter than a Mueseler or a Clanny lamp. The outside glass does not get so hot as in the two latter lamps, which renders the glass liable to be cracked by cold water; and if the outside glass is broken by a blow or otherwise, there is still a perfect safety lamp inside. The mode of locking or riveting the lamp detects any attempt of the workman to tamper with it. The lead rivet K, is clinched by nippers, leaving a die-mark on the lead. This lamp can be locked and unlocked in a shorter time than other locks, which is an object when several hundred lamps have to be given out every morning to workmen.

Some other lamps have been brought forward, the chief object being to prevent the lamp being opened by the miner, one of the most ingenious being the *miners' safety lamp*, invented by Mr. W. P. Struve, of Swansea.

The sketch on next page will convey a better notion of it than any written description, and it is only needful to add, that although the diameter of the gauze cylinder at its base is considerably more than that of the Davy, yet owing to the oil-box being placed within the gauze cylinder, instead of below it, and thus occupying a considerable portion of the internal space, the cubical contents of the cylinder does not exceed that of an ordinary Davy. The greater amount of cooling surface near the flame, and the less obstructed admission of air thus obtained, renders it practicable and perfectly safe to use a larger wick than in the Davy, whilst the combustion of the oil is much more perfect, and the smoke very considerably diminished. The light emitted from this lamp has been carefully ascertained to be equal to that from three Davys, and owing to the conical form of the cylinder and the shape of the oil-box, it diffuses the light both upwards and downwards, as well as in every other direction, with less shadow than any other lamp that has been offered to the miner. From the more perfect combustion, the consumption of oil in this lamp but slightly exceeds that of the Davy, whilst its simplicity of construction gives great facilities for keeping it in order and for repairs. It barely weighs 1½ lb. We learn that this lamp has been extensively introduced into many of the fiery collieries in South Wales.

SAFFLOWER. This dye-stuff has been fully described under CARTHAMUS.

SAFFLOWER DYEING. See CALICO PRINTING.

SAFFRON. (*Saffran*, Fr. and Germ.) The leaves of the saffron crocus. *Hay saffron* is the only kind now found in the shops—*cake saffron* rarely containing any of that flower. *Hay saffron* consists of the stigmas with part of the style of the flowers, which have been very carefully dried. Spanish saffron is the best which is imported. It is stated that 4,320 flowers are required to produce an ounce of saffron. True cake saffron, no longer to be found, was a filamentous cake, composed of the stigmata of the flowers of the *Crocus sativus*. It is now, however, generally the leaves of the safflower (*carthamus tinctorius*). True saffron contains a yellow matter called *polychroïte*, because of its being susceptible of numerous changes of colour. This is obtained by evaporating the watery infusion of saffron to the consistence of an extract, digesting the extract with alcohol, and concentrating the alcoholic solution. The polychroïte remains in the form of a brilliant mass, of a scarlet red colour, transparent, and of the consistence of honey. It has no smell, with the bitter pungent taste of saffron. It is slightly soluble in water; and if it be stove-dried it deliquesces speedily in the air. According to M. Henry *père*, polychroïte consists of 80 parts of colouring matter, combined with 20 parts of a volatile oil, which cannot be separated by distillation till the colouring matter has been combined with an alkali. Light blanches the reddish-yellow of saffron, even when it is contained in a full phial well corked. Polychroïte, when combined with fat oils, and subjected to dry distillation, affords ammonia, which shows that azote is one of its constituents. Sulphuric acid colours the solution of polychroïte, indigo blue, with a lilac cast; nitric acid turns it green, of various shades, according to the state of dilution. Protochloride (muriate) of tin produces a reddish precipitate.

Saffron is employed in cookery. It is also used to colour confectionery articles, liqueurs, varnishes, and especially cakes in the west of England. It was formerly used to such an extent in Cornwall, that that one county consumed more saffron than all the rest of England.

SAGO (*sagou*, Fr. and Germ.) is a species of starch, extracted from the pith of the sago palm, a tree which grows to the height of 30 feet in the Moluccas and the Philippines. The tree is cut down, cleft lengthways, and deprived of its pith, which being washed with water upon a sieve, the starchy matter comes out, and soon forms a deposit. This is dried to the consistence of dough, pressed through a metal sieve to corn it (which is called *pearling*), and then dried over a fire with agitation in a shallow copper pan. Sago is sometimes imported in the pulverulent state, in which it can be distinguished from arrow-root only by microscopic examination of its particles. These are uniform and spherical, not unequal and ovoid, like those of arrow-root. In this state it is known as *sago meal*. A factitious sago is prepared in France and Germany with potash starch.

SAL AMMONIAC. See AMMONIUM CHLORIDE.

SALANGANA. See SWALLOW and ALGÆ.

SALAMSTONE. A variety of corundum of little value.

SALEP, or SALOUP, is the name of the dried tuberous roots of the *Orchis*, imported from Persia and Asia Minor, which are the product of a great many species of the plant, but especially of the *Orchis mascula.* Salep occurs in commerce in small oval grains, of a whitish-yellow colour, at times semi-transparent, of a horny aspect very hard, with a faint peculiar smell, and a taste like that of gum tragacanth, but slightly saline. These are composed almost entirely of starchy matter, well adapted for making a thick pap with water or milk, and are hence in great repute in the Levant, as restorers of the animal forces. Semolina is sometimes sold under this name.

SALICINE is a substance, which may be obtained in white pearly crystals from the bark of the white willow (*Salix alba*), of the aspen tree (*Salix helix*), as also of some other willows. It has a very bitter taste. It has been employed for the purpose of adulterating the sulphate of quinine. Its composition is $C^{26}H^{18}O^{14}$, quinine being $C^{38}H^{22}N^{2}O^{4}$. The presence of nitrogen in the latter renders the salicine essentially different in its chemical as in its medicinal relations.

SAL MARINE. Common salt (chloride of sodium).

SAL MARTIS. Protosulphate of iron.

SAL MIRABILE. Sulphate of soda.

SAL PRUNELLA is fused nitre cast into cakes or balls.

SAL VOLATILE is carbonate of ammonia.

SALT, EPSOM, is sulphate of magnesia.

SALT, FUSIBLE. Phosphate of ammonia.

SALT, GLAUBER'S. Sulphate of soda.

SALT, GLAZER'S. Sulphate of potash.

SALT, MICROCOSMIC, is the triple phosphate of soda and ammonia.

SALT OF AMBER is succinic acid.

SALT OF LEMERY. Sulphate of potash.

SALT OF LEMONS is citric acid and binoxalate of potash.

SALT OF SATURN is acetate of lead.

SALT OF SODA is carbonate of soda.

SALT OF SORREL is binoxalate of potassa.

SALT OF TARTAR is carbonate of potassa.

SALT OF TIN. Protochloride of tin.

SALT OF VITRIOL is sulphate of zinc.

SALT PERLATE is phosphate of soda.

SALTPETRE is nitre, or nitrate of potassa, which see.

SALT, ROCK, SEA, or CULINARY. These terms are used to designate different forms of a substance which is composed, chemically speaking, of single equivalents of sodium and chlorine, or of 39·4 parts of sodium and 60·6 of chlorine in 100 parts by weight: it is known also by the names of chloride of sodium and muriate of soda. (*Chlorure de sodium; Hydrochlorate de Soude*, Fr.; *Chlornatrium*, Germ.)

Chloride of sodium generally occurs crystallised in the cube, and occasionally in other forms belonging to the regular system; among these varieties, the octahedron, the cubo-octahedron, the dodecahedron, have been observed; but there is another which at first sight appears singular, and deserves notice on account of its frequent occurrence. It is called the funnel or hopper-shaped crystal; and is a hollow, rectangular pyramid, forming on the surface of a saline solution in the course of its evaporation: it appears to commence with the formation of a small floating cube, to the edges of the upper face of which lines of other little cubes attach themselves by the edges of their lower faces. By a repetition of this proceeding, the sides of a hollow pyramid are formed, the apex of which, the single cubical crystal, is downward: the crystal sinks by degrees as the aggregation goes on above, until a pyramidal boat of considerable size is constructed.

The crystals of chloride of sodium are anhydrous, but generally contain a little water entangled in their interstices, the expansion of which causes them to decrepitate when heated. This salt is fusible at a red heat, and at a white heat volatilises. Its crystals are white, frequently perfectly transparent, of a specific gravity of 2·13, and a hardness of 2·5. A remarkable feature in this salt is, that its solubility in water increases but slightly as the temperature of the latter is raised, for, according to the experiments of M. Gay-Lussac, 100 parts of water dissolve

35·81	parts of the salt, at a	temperature of	57·0°	Fahr.
35·88	,,	,,	62·5°	,,
37·14	,,	,,	140·0°	,,
40·38	,,	,,	229·5°	,,

This must be understood to apply only to the pure substance, for the presence of other salts frequently increases its solubility.

Chloride of sodium, when perfectly colourless and transparent, is also perfectly diathermanous, i.e., it allows the rays of heat to pass through its substance almost without perceptible interception. It stands first among solid bodies in this respect, all others absorbing a very considerable portion of the heat which passes through them, and some almost the whole:

Of 100 rays of heat	Clear rock salt transmits - -	92
"	Muddy ditto - - - -	65
"	Plate glass - - - -	24
"	Clear ice - - - - -	0

The source of heat in these experiments was red-hot platinum.

Chloride of sodium occurs in nature chiefly in two forms, either as rock-salt, forming extensive deposits, or disseminated in minute quantity through the mass of the strata which form the earth's crust. Water penetrating the layers of rock-salt, and exerting there a solvent action, gives rise to the brine springs which are found in various countries; whilst streams and rivers dissolving the same substance out of the strata through which they flow, carry it down to the sea, where, from its great solubility, it has gone on gradually increasing, and now constitutes the principal saline ingredient in the waters of the ocean.

Even in mass, i.e., as Rock-salt (*Sal gemme*, F.; *Steinsaltz*, Germ.), this substance possesses a crystalline structure derived from the cube, which is its primitive form. It has generally a foliated texture, and a distinct cleavage, but it has also sometimes a fibrous structure. Its lustre is vitreous, and its streak white. It is not so brittle as nitre; its hardness =2·5, which is nearly that of alum; a little harder than gypsum, but softer than calcareous spar. Its specific gravity varies between 2·1 and 2·257. It is white, occasionally colourless, and perfectly transparent, but usually of a yellow or red, and more rarely of a blue or purple tinge. A few analyses will show the general purity of this substance.

The principal impurities occurring in rock salt are sulphate of lime, oxide of iron and clay, but the chlorides of potassium, calcium, and magnesium, the sulphates of soda and magnesia, and bituminous matters, are sometimes found in it; and occasionally shells, and insect and infusorial remains, exist enclosed in the mass. To the presence of infusoria, indeed, is attributed the red or green colour with which some varieties are tinted, which, upon analysis, are found to be absolutely pure chloride of sodium, as in the case of the second specimen quoted in the above table. Carburetted hydrogen gas in a state of strong compression is met with in some varieties, and these when dissolved in water emit a peculiar crackling sound, caused by the expansion and escape of the confined gas.

The geological position of rock salt is very variable; it is found in all sedimentary formations, from the transition to the tertiary, and is generally interstratified with gypsum, and associated with beds of clay. When the latter is present in large quantity, the term "saliferous clay" is applied to the deposit. The great British deposits of this substance in Cheshire and Worcestershire are found in the new red sandstone. At Northwich, in the Vale of the Weaver, the rock salt consists of two beds, which are not less than 100 feet thick, and are supposed to constitute large insulated masses, about a mile and a half long, and nearly 1300 yards broad. There are other deposits of rock salt in the same valley, but of inferior importance. The uppermost bed occurs at 75 feet beneath the surface, and is covered with many layers of indurated red, blue, and brown clay, interstratified more or less with gypsum, and interspersed with argillaceous marl. The second bed of rock-salt lies 31½ feet below the first, being separated from it by layers of indurated clay, with veins of rock-salt running between them. The lowest bed of salt was excavated to a depth of 110 feet, several years ago. Many of the German deposits of rock-salt occur in their *bunter sandstein*, which is the representative of our new red sandstone, and is so called because its colours vary from red to salmon and chocolatic. In the Austrian Alps salt is found in oolitic limestone; at Cardonna, in Spain, in the greensand; and the famous mines of Wieliczka, in Galicia (excavated at a depth of 860 feet, in a layer 500 miles long, 20 broad, and 1200 feet deep), occur in tertiary strata. But in addition to these concealed deposits, this substance presents itself in vast masses upon many parts of the earth's surface: in the high lands of Asia and Africa are often extensive wastes, the soil of which is covered and impregnated with salt, which has never been enclosed by superimposed deposits; near Lake Oroomiah, in the N.W. of Persia, it forms hills and extended plains; it abounds in the neighbourhood of the Caspian Sea, and penetrates the entire soil of the steppes of the south of Russia.

The beds of rock salt are sometimes so thick, as at Wieliczka and Northwich, that they have not yet been bored through, although mined for many centuries; but in ordinary cases the thickness of the layers varies from an inch or two to ten or fifteen yards. When the strata are thin, they are usually numerous, and throughout a certain extent parallel, but when explored at several points such enlargements and diminutions are observed, as to destroy this appearance of parallelism.

It has been remarked that the plants which generally grow on the sea-shore, such as the *Triglochinum maritimum*, the *Salicornia*, the *Salsola kali*, the *Aster trifolium*, or farewell to summer, the *Glaux maritima*, &c., occur also in the neighbourhood of salt mines and salt springs, even of those which are most deeply buried beneath the surface. It is also generally found that the interior of salt mines is extremely dry, so that the dust produced in the workings becomes an annoyance to the miners, though in other respects the excavations are not insalubrious.

Much discussion has been raised concerning the origin of these rock-salt deposits; some asserting that they were the result of igneous agency, and others that they have been in every case deposited from solution in water. The great argument in favour of the former view appears to rest upon the fact that chloride of sodium and hydrochloric acid gas are among the substances erupted by volcanoes; whilst on the other hand it is urged that the specimens of erupted chloride of sodium which have been analysed always differ much from rock salt, since they contain a large amount of chloride of potassium; and in addition to this, the frequent occurrence of bodies such as bitumen and organic remains, and of cavities containing liquids, and in some cases gases, in almost all varieties of rock salt, are held to furnish indisputable proof of the deposition of this substance from its aqueous solution. The occurrence of sandstone pseudomorphs in the cubical form of rock salt, also favours this opinion; and so also does the general character of these deposits; they are usually lenticular, or irregularly shaped beds, having a great horizontal extension, and but rarely occur in the form of dikes, or masses filling vertical fissures, which is the usual form assumed by a molten mass projected upwards from the interior of the earth. The method of its formation was, according to those who hold the aqueous theory, somewhat as follows:—A sea, such as the Mediterranean, is, by an elevation of the land at Gibraltar, cut off from communication with the ocean,—the rate of evaporation from its surface is greater than the supply of water by rain and rivers, consequently the amount of salts which it holds dissolved, increases; now chloride of sodium is the principal saline constituent of sea water, and Bischof's experiments have shown that when a solution of this salt is allowed to be at rest, the particles of salt sink, so that the lower layers soon become more saturated than the upper; concentration is then supposed to go on until at the undisturbed bottom of this inland sea a saturated solution of chloride of sodium exists, from which masses of rock salt are slowly deposited. Its great purity is accounted for by the fact, that the other salts existing in sea water are either far less or far more soluble than chloride of sodium; thus the carbonate and sulphate of lime would be almost wholly precipitated before the solution became sufficiently concentrated to deposit rock salt, whilst at that degree of concentration the sulphate and chloride of magnesium would still remain for the most part in solution.

The principal European mines of rock salt are those of Wieliczka, in Galicia, excavated at a depth of 860 feet below the soil; at Hall, in the Tyrol, and along the mountain range through Aussee, in Styria, Ebensee, Ischl, and Halstadt, in Upper Austria; Hallein in Salzburg, 3300 feet above the sea level, and Reichenthal in Bavaria; in Hungary, at Marmoros; in Transylvania and Wallachia; at Vic and Dieuze in France; at Bex, in Switzerland; in the Valley of Cardonna, and elsewhere, in Spain; and in the region around Northwich, in Cheshire, in our own country. Some of these deposits, as at Wieliczka and Northwich, are almost pure chloride of sodium; others, again, as many of the Austrian beds, are only saliferous clay; whilst others, as at Arbonne in Savoy, elevated 7200 feet above the level of the sea, and in the region of perpetual snow, are masses of saccharoid gypsum and anhydrite, which are imbued with chloride of sodium, and which become quite light and porous when the salt has been removed by water.

The natural transition from the consideration of these strata of rock salt is to those brine springs which generally accompany them, and which have frequently first called attention to the deposits below. It has been noticed that salt springs issue, in general, from the upper portion of the saliferous strata; cases, however, occur in which the brines are not accompanied by rock salt, and in which, therefore, their whole saline contents must be derived from the ordinary constituents of the strata. Thus, in England, besides the strong brines of the new red sandstone, we have salt springs issuing from the carboniferous rocks. The purest and most saturated brines are, however, found to be those which can be traced to rock salt beds, and in the foremost rank of these stand the English springs of the Northwich, Middlewich, and Sandbach districts in Cheshire; of Droitwich and Stoke, in Worcestershire; and of Weston and Shirleywich, in Staffordshire; and the continental brines of Würtemberg and Prussian Saxony. The following is the composition of these saturated brines.

Compared with these may be some weaker and less pure brines, which rise from other geological formations. The brines in the United States come for the most part from Silurian sandstones, but those in the Alleghany Mountains spring from the coal; and the weak salt springs of Nauheim and Homburg, which can only be called brines because chloride of sodium is their largest constituent, rise from transition strata.

These weak salt springs are supposed to have no connection with beds of rock salt, but to obtain their chloride of sodium, in common with the other salts which they contain, from the strata which they permeate. The singular brines of the Alleghany Mountains must obviously pass through strata containing little if any soluble sulphate, otherwise their chloride of barium would be separated as insoluble sulphate of baryta; and all indeed may be regarded as coming more under the head of ordinary mineral waters, which happen to contain rather a large quantity of chloride of sodium.

The next source of chloride of sodium which demands notice is found in the inland seas, salt lakes, pools, and marshes, which have their several localities obviously independent of peculiar geological formations. They appear to owe their origin to two causes, being due, firstly, to the formation of lakes upon, and the passage of rivers through, some of the surface deposits of salt already alluded to; and, secondly, by the cutting off of a portion of the ocean by the elevation of the land, and the consequent formation of an inland lake. To the former cause are probably due the existence of the Lake Oroomiah in the N.W. of Persia, the numerous brine pools of Southern Russia, and the Great Salt Lake of N. America. The Lake Oroomiah is 82 miles long by 24 wide, and elevated 4000 feet above the level of the sea; it is surrounded, especially on the east and north, by some of the most remarkable surface deposits of rock salt in the world, and through these salt streams are continually flowing into the lake. The Russian brine pools are situated in the salt-impregnated steppe between the rivers Ural and Wolga, and doubtless derive their saline constituents from thence. The Great Salt Lake is a saturated solution of almost pure chloride of sodium, but whence the salt is derived appears at present to be but a matter of conjecture. To the second cause the origin of the Dead Sea is frequently attributed; its surface is about 1300 feet below that of the Mediterranean, and it is thought to have lost a column of water of that height by evaporation. The Crimean lakes also have probably originated thus.

Bischof has shown that in proportion as chloride of magnesium increases in a solution, it renders chloride of sodium and sulphate of lime more and more insoluble; he is therefore of opinion that at the bottom of the Dead Sea, and similar lakes, an impure rock-salt deposit, interstratified also with mud, is forming, similar to the saliferous clays or clayey marls which are frequently met with on the continent.

The three following analyses exhibit the peculiarities of two classes of salt lakes: Lake Oroomiah, formed by the solution of pure rock salt, contains but little magnesia salt, whilst the Crimean Lake and the Dead Sea, produced probably by the evaporation of sea water, show how the very soluble salts of magnesia increase as the water concentrates.

Finally, to compare with the above results, the composition of the sea may be given: numerous analyses have been made of the water taken at widely distant points, and at different depths, and the difference in composition has been small. The water of some partially enclosed seas, as the Baltic and Black Seas, into which numerous rivers pour, is below the average concentration, and that of others again, as the Mediterranean, is above that point. The deep sea water is also more concentrated than that at the surface, as Von Bibra has shown that the Pacific Ocean, in 25° 11′ S. and 93° 24′ W. contains 3·47 of saline matter in 100 parts, at a depth of 11 feet, whilst at a depth of 420 feet it contains 3·52. Bischof's experiments, before alluded to, would lead to this supposition. The following analyses are by Von Bibra, except the last, which is by Laurent :—

The average specific gravity of sea water is from 1·029, to 1·030.

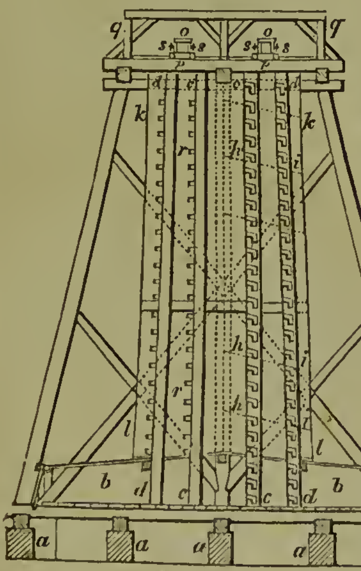
Culinary salt is prepared from each of the four sources above mentioned; it but rarely happens that rock salt is sufficiently pure for immediate use, and when employed, as in some places on the continent, and formerly in Cheshire, it is dissolved in water, the insoluble impurities allowed to subside, aud the solution treated as a concentrated brine. From its other sources, salt is obtained by evaporation, and this is effected in two ways; 1. Entirely by the application of artificial heat; 2. By natural evaporation preceding the application of artificial heat.

The first method is employed invariably in this country, and also on the continent when the brines contain more than 16 or 20 per cent. of chloride of sodium, the cost of fuel at different places of course regulating the application of this method. The manufacture of salt at Droitwich in Worcestershire, is said to have existed in the time of the Romans, and in Cheshire, the "Wiches" were very productive in the reign of Edward the Confessor; some time elapsed before the method of evaporation was devised, and the original mode of obtaining the salt was by pouring the brine upon the burning branches of oak and hazel, from the ashes of which the deposited salt was afterwards collected. The process of evaporation was first conducted in small leaden vessels, which were afterwards exchanged for iron ones, having a surface of about a square yard, and a depth of six inches; the size of these pans increased but slowly, for only a century since the largest pans at Northwich were but 20 feet long by 10 broad. The pans now in use in Cheshire, Worcestershire, and Staffordshire have a length of 60 or 70 feet, with a width of from 20 to 25, and a depth of about 18 inches; they are made of stout iron plates riveted together, are supported on brickwork, and have from one to three furnaces placed at one end, the flues of which are in immediate contact with the bottom of the pan. In the works of Messrs. Kay of Winsford, the brine is heated to its boiling point in a small iron reservoir, and from thence caused to circulate through a series of brick-lined channels until it is again, by a simple arrangement, pumped into the first iron vessel, and heated afresh. The brine is generally raised by steam power, and its supply appears inexhaustible. The shafts are lined with wooden or iron casings to prevent the admixture of fresh-water springs with the brine; the depth of the borings is in Cheshire usually from 210 to 250 feet, but at Stoke, in Worcestershire, a shaft of 225 feet was constructed, but no satisfactory supply of brine obtained until a further boring of 348 feet was made. At Droitwich the borings are only to a depth of 175 feet, and so abundant is the supply of brine, that if the pumps cease working, it speedily rises to within nine feet of the surface, and if left unremoved soon overflows. The freedom of the brine from dilution by fresh-water springs is from time to time tested by the hydrometer. From the pumps the brine is directly conveyed by means of pipes to reservoirs, from which, as the evaporation proceeds, it is admitted into the pans. As the water is vaporised, the salt is deposited and falls to the bottom of the pan; it is then drawn to the sides by the workmen, until a heap is accumulated, and from this portions are ladled out into rectangular wooden boxes with perforated bottoms, allowed to drain and solidify, removed from the boxes, and placed in the drying room; the salt of coarser grain is simply drained roughly in baskets and dried. The grain of the salt, *i.e.* its occurrence in larger or smaller crystals, is entirely the effect of temperature; the fine grained or table salt is produced by rapid heating, and is formed at that end of the pan next the fire-place; the coarse or bay-salt is formed by the slow evaporation which goes on at the other end; whilst an intermediate variety, common salt, is produced in the middle. A pan may sometimes be slowly evaporated for the express purpose of obtaining bay-salt.

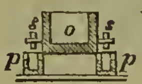
In the preparation of salt various substances have been added to the brine with a view of improving the quality of the product: these have been chiefly bodies containing albuminous matters, which, coagulating upon the application of heat, entangle all solid impurities and carry them to the surface; blood, white of egg, glue, and calves' feet have thus been extensively used. There is also another class of substances employed for a different purpose. When a concentrated solution of any saline matter is evaporated, much annoyance is caused by a layer of the solid salt forming on the surface of the liquid and impeding evaporation: this is called a "pellicle"; to obviate this, and to avoid the loss of labour entailed by constant stirring, oils, butter, or resin, have been added to the brine. The effect of the latter is said to be perfectly magical, the introduction of a very few grains being amply sufficient to clear the largest pan, and to prevent any recurrence of the "setting over."

When it is required to prepare salt from the weak brines which are of common occurrence in France and Germany, the second method is resorted to, and the brine is concentrated by natural evaporation previous to the application of artificial heat: this concentration was formerly effected by distributing the brine over flat inclined wooden surfaces, but it is now brought about by allowing the brine to trickle in a continuous stream through walls of thorns exposed to the sun and wind. This, which is called the method of graduation, is employed, among other places, at Moutiers in France, and at Nauheim, Dürrenberg, Rodenberg, and Schönebeck, in Germany. The weak brine is pumped into an immense cistern on the top of a tower, and is thence allowed to flow down the surface of bundles of thorns built up in regular walls between parallel wooden frames. At Salza, near Schönebeck, the graduation-house is 5817 feet long, the thorn walls are from 33 to 52 feet high, in different parts, and present a total surface of 25,000 square feet. Under the thorns, a great brine cistern, made of strong wooden planks, is placed to receive the perpetual shower of water. Upon the ridge of the graduation-house there is a long spout, perforated on each side with numerous holes, and furnished with spigots or stopcocks for distributing the brine either over the surface of the thorns or down through their mass; the latter method affording larger evaporation. The graduation-house should be built lengthwise in the direction of the prevailing wind, with its ends open. An experience of many years at Salza and Dürrenberg, has shown that in the former place graduation can go on 258, and in the latter 207 days, on an average in the year; the best season being from May till August. At Dürrenberg, 3,596,561 cubic feet of water are evaporated annually. According to the weakness of the brine, it must be the more frequently pumped up, and made to flow down over the thorns in different compartments of the building, called the 1st, 2nd, and 3rd graduation. A deposit of gypsum incrusts the twigs, which requires them to be renewed at the end of a certain time. *Figs.* 1585, and 1586, represent the graduation-house of the salt-works at Dürrenberg. *a*, *a*, *a*, are low stone pillars for supporting the brine-

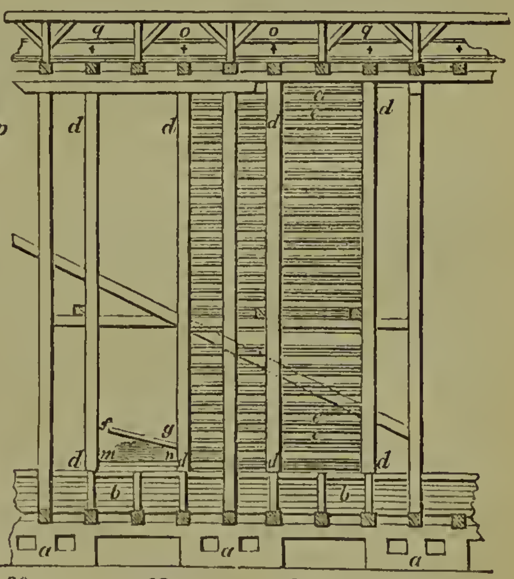
1585



1587



1586



cistern *b*, called the *soole-schiff*. *c*, *c*, are the inner, *d*, *d*, the outer walls of thorns; the first have perpendicular sides, the last sloping. The spars *e*, *e*, which support the thorns, are longer than the interval between two thorn walls from *f* to *g*, *fig.* 1586, whereby they are readily fastened by their tenons and mortises. The spars are laid at a slope of 2 inches in the foot, as shown by the line *h*, *i*. The bundles of thorns are each 1½ foot thick, from 5 to 7 feet long, and are piled up in the following way:— Guide-bars are first placed in the line *k*, *l*, to define the outer surface of the thorn wall, the undermost spars *m*, *n*, are fastened upon them, and the thorns are evenly spread after the willow-withs of the bundles have been cut. Over the top of the thorn walls are laid, through the whole length of the graduation-house, the brine spouts *o*, *o*, which are secured to the upper beams; and at both sides of these spouts are the drop-spouts *p*, *p*, for discharging the brine by the spigots *s*, *s*, as shown upon a larger scale in *fig.* 1587. The drop-spouts are 6 feet long, have on each side small notches, 5 inches apart, and are each supplied by a spigot. The space above the ridge of the graduation-house is covered with boards, supported at their ends by binding-beams, *q*. *r*, *r*, show the tenons of the thorn-spars. Over the soole-schiff *b*, inclined planes of boards are laid for conducting downwards the innumerable showers. The brine, which contains at first 7·692 per cent. of salt, indicates after the first shower, 11·473; after the second, 16·108; and after the third, 22. The brine thus concentrated to such a degree as to be fit for boiling, is kept in great reservoirs, of which the eight at Salza, near Schönebeck, have a capacity of 2,421,720 cubic feet, and are furnished with pipes leading to the sheet-iron salt-pans. The capacity of these is very different at different works. At Schönebeck there are 22, the smallest having a square surface of 400 feet, the largest of 1250, and are enclosed within walls, to prevent their being affected by the cold external air. They are covered with a funnel-formed or pyramidal trunk of deals, ending in a square chimney to carry off the steam.

The graduation range should be divided lengthwise into several sections; the first to receive the water of the spring, the lake, or the sea; the second, the water from the first shower-receiver; the third, the water from the second receiver; and so on. The pumps are usually placed in the middle of the building, and lift the brine from the several receivers below into the alternate elevated cisterns. The square wooden spouts of distribution may be conveniently furnished with a slide-board attached to each of their sides, to serve as a general valve for opening or shutting many trickling orifices at once. The rate of evaporation at Moutiers is exhibited by the following table:—

Number of Showers.	Total Surface of the Fagots.	Specific Gravity of the Brine.	Water evaporated.
		1·010	0·000
1 and 2 - - - -	5158 square feet - -	1·023	0·540
3, 4, 5, 6, 7, 8, and 9 -	2720 - - - - -	1·072	0·333
10 - - - - -	550 - - - - -	1·140	0·062
Total evaporation - - - - -			0·935
Water remaining in the brine at the density of 1·140 -			0·065
Water assigned at the density of 1·010 - - - - -			1·000

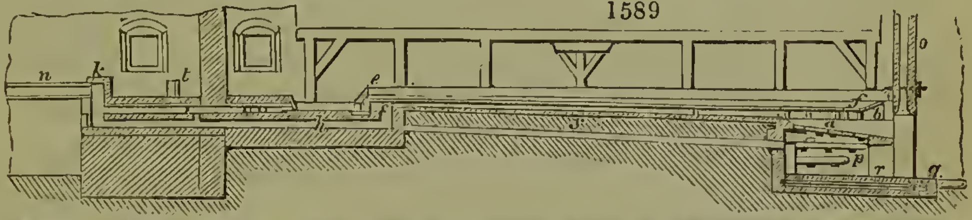
From the above table it appears that no less than 10 falls of the brine have been required to bring the water from the specific gravity 1·010 to 1·140, or 18° Beaumé. The evaporation is found to proceed at nearly the same rate with the weaker water, and with the stronger, within the above limits. When it arrives at a density of from 1·140 to 1·16, it is run off into the settling cisterns. M. Berthier calculates, that upon an average in ordinary weather, at Moutiers, 60 kilogrammes of water (13 gallons imp.) are evaporated from the fagots, in the course of 24 hours, for every square foot of their surface. Without the aid of currents of air artificially warmed, such an amount of evaporation could not be reckoned upon in this country. In the *schlotting*, or throwing down of the sediment, a little bullock's blood previously beaten up with some cold brine, promotes the clarification. When the brine acquires, by brisk ebullition, the density of 1·200, it should be run off from the preparation to the finishing or salting pans. The boilers constructed at Rosenheim, in Bavaria, evaporate 3½ pounds of water for every pound of wood burnt: this is reckoned a favourable result; but some of the boilers described under Evaporation would throw off much more.

Figs. 1588, 1589, 1590, represent the construction of a salt-pan, its furnace, and the salt store-room of the works at Dürrenberg; *fig.* 1590, being the ground plan, *fig.* 1589, the longitudinal section, and *fig.* 1588, the transverse section. *a*, is the fire-grate, which slopes upwards to the back part, and is 31½ inches distant from the bottom of the pan. The ratio of the surface of the grate to that of the bottom of the pan is as 1 to 59·5; that of the air-hole into the ash-pit, as 1 to 306. The bed under the pan is laid with bricks, smoothly plastered over from *b* to *c*, in *fig.* 1588. Upon this bed the pillars *d*, *d*, &c., are built in a radiated direction, being 6 inches broad at the bottom, and tapering to 1½-inch at top. The pan is so laid that its bottom has a fall towards the middle of 2½ inches: see *e*, *f*, *fig.* 1589. The fire diffuses itself in all directions under the pan, proceeds thence through several holes, *g*, *g*, *g*, into flues *h*, *h*, *h*, which run round three sides of the pan; the burnt air then passes through *i*, *fig.* 1590, under other pans, from which it is collected in the chimneys *k*, *k*, to be conducted into the drying-room. At *l*, *l*, there is a transverse flue, through which by means of dampers, the fire-draught may be conducted into an extra chimney *m*. From the flues *k*, *k*, four square iron pipes *n*, *n*, issue and conduct the burnt air into the main chimneys in the opposite wall.

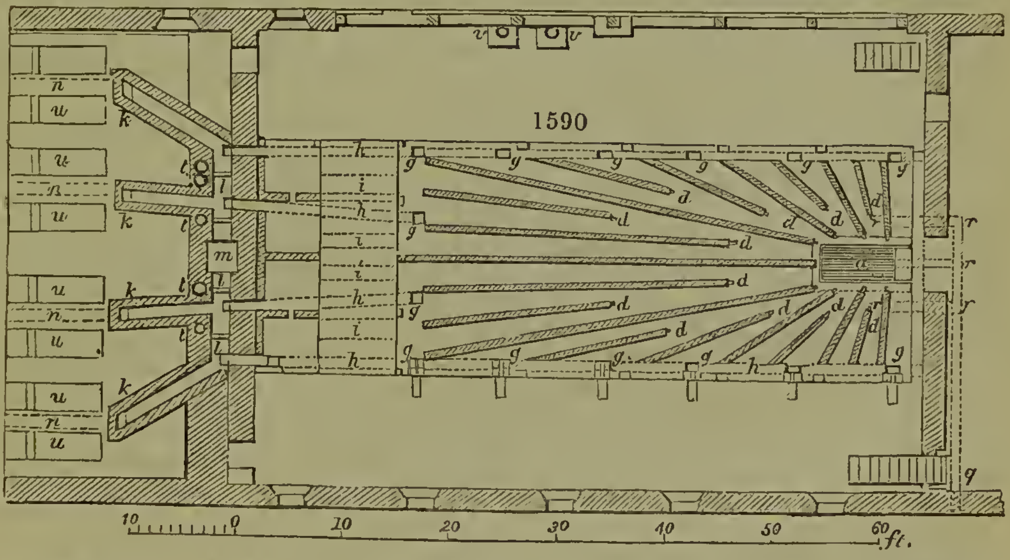
1588

The bottoms of the several flues have a gradual ascent above the level of the fire-grate. A special chimney *o*, rises above the ash-pit, to carry off the smoke which may chance to regurgitate in certain states of the wind. *p*, *p*, are iron pipes laid upon each side of the ash-pit (see *figs*. 1588, and 1589), into which cold air is admitted

1589



1590

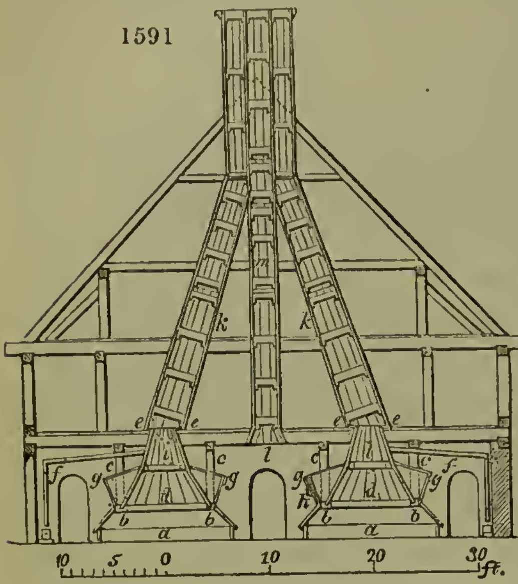


by the flue *q*, *r*, where, becoming heated, it is conducted through iron pipes *s*, and thence escapes at *t*, into the stove-room. Upon both sides of the hot flues in the stove-room, hurdle-frames *u*, *u*, are laid, each of which contains 11 baskets, and every basket, except the undermost, holds 60 pounds of salt, spread in a layer 2 inches thick. *v*, *v*, show the pipes by which the pan is supplied with graduated brine.

Description of the Steam-trunk, in fig. 1591.

In front of the pan *a*, *a*, there are two upright posts, upon which, and in holes of the back wall, two horizontal beams *b*, *b*, are supported. The pillars *c*, *c*, are sustained upon the bearers *d*, *d*. At *e e*, a deep quadrangular groove is made in the beams, for fixing down the four boards which form the bottom of the steam-way. In this groove any condensed water from the steam collects, and is carried off by a pipe *f*, to prevent it falling back into the pan. Upon the three sides of the pan not in contact with the wall, there are three rows of boards hinged upon planks *b*, *b*. Behind the upper one, a board is hung on at *g*, upon which the boiled salt is laid to drain. The two other rows of boards are hooked on so as to cover the pan, as shown at *h*. Whenever the salt is sufficiently drained, the upper shelves are placed in a horizontal position; the salt is put into small baskets and carried into the stove-room. *i*, *k*, is the steam-trunk; *l*, *m*, is a tunnel for carrying off the steam from the middle of the pan, when this is uncovered by lifting the boards.

1591



In proportion as the brine becomes concentrated by evaporation, more is added from the settling reservoir of the graduation-house, till finally small crystals appear on the surface. No more weak brine is now added, but the charge is worked off, care being taken to remove the scum as it appears. In some places the first pan is called a schlot-pan, in which the concentration is carried only so far as to cause the deposition of the sludge, from which the saline solution is run into another pan, and gently evaporated to produce the precipitation of the fine salt. This salt should be continually raked towards the cooler and more elevated sides of the pan, and then lifted out with cullender-shovels into large conical baskets, arranged in wooden frames round the border of the pan, so that the drainage may flow back into the boiling liquor. The drained salt is transferred to the hurdles or baskets in the stove-room, which ought to be kept at a temperature of from 120° to 130° Fahr. The salt is then stowed away in the warehouse.

In summer the saturated boiling brine is crystallised by passing it over vertical ropes; for which purpose 100,000 metres (110,000 yards) are mounted in an apartment 70 metres (77 yards) long. When the salt has formed a crust upon the ropes about 2½ inches thick, it is broken off, allowed to fall upon the clean floor of the apartment, and then gathered up. The salting of a charge, which would take five or six days in the pan, is completed in this way in seventeen hours, and the salt is remarkably pure, but the mother-waters are more abundant.

The mother-water contains a large quantity of chloride of magnesium, along with chloride of sodium and sulphate of magnesia. Since the last two salts mutually decompose each other at a low temperature, and are transformed into sulphate of soda, which crystallises, and chloride of magnesium, which remains dissolved, the mother-water may with this view be exposed in tanks to the frost during winter, when it affords three successive crystalline deposits, the last being nearly pure sulphate of soda.

The chloride of magnesium, or bittern, not only deteriorates the salt very much, but occasions a considerable loss of weight. It may, however, be most advantageously be removed, and converted into chloride of sodium by the following simple expedient: Let quicklime be introduced in equivalent quantity to the chloride of magnesium present; double decomposition will take place, resulting in the precipitation of magnesia, and the formation of chloride of calcium; the latter will then react upon the sulphate of soda in the mother-water, producing sulphate of lime and chloride of sodium, the former of which, being sparingly soluble, is almost entirely separated.

In those countries, as Portugal and the coasts of the Mediterranean, where sea water is used as the source of salt, a peculiar method of natural evaporation is resorted to, in what are called "Salt Gardens." Large shallow basins, the bottom of which is very smooth and is formed of clay, are excavated along the sea-shore; they consist of—

1stly. A large reservoir, of from two to six feet in depth, communicating with the sea by means of a channel provided with a sluice. Advantage is taken of the high tide to fill this basin; and the water is allowed to remain here for some time to deposit any suspended impurities; it is then drawn off into the brine-pits.

2ndly. The brine-pits are divided into a large number of compartments by means of little banks; these all have a communication with each other, but so arranged that the water has a long circuit to make in its passage from one set to another; it frequently flows 400 or 500 yards before it reaches the extremity of this sort of labyrinth. The various divisions are distinguished by a number of technical names. They should be exposed to the north, north-east, or north-west winds.

In the month of March the water of the sea is let into these reservoirs, where a vast surface is exposed to evaporation from the first or clearing reservoir; the others are refilled as their contents decrease. The salt is considered to be on the point of crystallising when the water begins to grow red; soon after this, a pellicle forms on the surface, which breaks and falls to the bottom. Sometimes the salt is allowed to subside in the first compartment; but generally, the strong brine is made to pass on to the others, where a larger surface is exposed to the air; in either case, the salt as it forms is raked out, and left upon the borders to drain and dry. To get rid of the chloride of magnesium, which is one of the principal impurities of this kind of salt, it is frequently heaped up under sheds, where it is just protected from the rain, and the chloride of magnesium being a very deliquescent salt, attracts moisture from the air and drains away. The salt thus obtained partakes of the colour of the bottom on which it is formed, and is hence white, red, or grey.

The following table shows the composition of several varieties of culinary salt:—

Analyses of several varieties of culinary salt; composition in 100 *parts.*

	Cheshire stoved.	Lymington cat. salt.	Scotch common.	Königs-born, West-phalia.	St. Malo. sea-salt.	Moutiers.

The specific gravity of a saturated solution of large-grained cubical salt, is 1·1962 at 60° F. 100 parts of this brine contain 25·5 of salt (100 Water + 34·2 Salt.)

From mutual penetration 100 volumes of the aqueous and saline constituents form rather less than 96 of the solution.

In Great Britain the rock-salt mines and principal brine springs are in Cheshire; and the chief part of the Cheshire salt, both fossil (rock) and manufactured, is sent by the river Weaver to Liverpool, a very small proportion of it being conveyed elsewhere, by canal or land carriage.

There are brine springs in Staffordshire, from which Hull is furnished with white salt, and the Worcestershire salt chiefly supplies the London Market.

According to M. Clement Desormes, engineer and chief *actionnaire* of the great salt works of Dieuze, in France, the internal consumption of that kingdom is rather more than 200,000 tons per annum, being at the rate of 6½ kilogrammes for each individual of a population estimated at 32,000,000. As the retail price of salt in France is ten sous per kilogramme (of 2½ lbs. avoirdupois), while in this country it is not more than two sous (one penny), its consumption per head will be much greater with us; and taking into account the immense quantity of salted provisions that are used, it may be reckoned at 22 lbs.—A. B. N.

The Salt produce of the United Kingdom in 1857, was as follows:—

	Tons.

Hunt's Mineral Statistics.

SALTS. It is not possible, even were it advisable, to introduce into this work any discussion on the subject of the chemical compounds which are included under the name of salts. Within the range of science there are not many terms to which more varied meanings have been given.

It may be sufficient to state here that, at present, salts are generally grouped as follows:—

1. Those formed by the union of simple bodies, as chlorine and sodium, iodine and iron, or the like.

2. Those formed by the union of substances already compound, as sulphuric acid (sulphur and oxygen), with soda (sodium and oxygen), &c., or, in the case of many of the salts formed from the organic acids exhibiting a yet more complex constitution.

Salts may be either *neutral*, or such as do not exhibit any acid or alkaline properties, or *acid*, *i.e.* those in which there is an excess of acid in its hydrated form, or those in which dry acid is in excess; and *basic salts*, in which there is present more than one equivalent of base for each equivalent of acid. For a further account of salts see EQUIVALENTS, HALOGENE, the several metals and alkalies, and consult *Ure's Chemical Dictionary.*

SALT, SEDATIVE, is boracic acid.

SALT WATER, DISTILLATION OF. See WATER.

SAND (Eng. and Germ; *Sable*, Fr.) is the name given to any mineral substance in a hard granular or pulverulent form, whether strewed upon the surface of the ground, found in strata at a certain depth, forming the beds of rivers, or the shores of the sea. The siliceous sands seem to be either original crystalline formations, like the sand of Neuilly, in 6-sided prisms, terminated by two 6-sided pyramids, or the *débris* of granitic, schistose, quartzose, or other primary crystalline rocks, and are abundantly distributed over the globe; as in the immense plains known under the names of deserts, *steppes*, *landes*, &c., which, in Africa, Asia, Europe, and America, are entirely covered with loose sterile sand. Valuable metallic ores, those of gold, platinum, tin, iron, titanium, often occur in the form of sand, or mixed with that earthy substance. Pure siliceous sands are very valuable for the manufacture of glass, for ameliorating dense clay soils, for moulding, and many other purposes.

Specimens of the finer kinds of sand, from the Isle of Wight, and the neighbourhood of Lynn, are remarkably white and beautiful. Ryegate also furnishes pure siliceous sand. By far the finest samples of sand ever seen in this country were in the American department of the Great Exhibition of 1851, and did not fail to attract the notice of those interested in such matters. This sand was totally free from iron and every other source of contamination. It was as white as snow, and so far as the making of glass is concerned, no sand is equal to it: considerable quantities have been imported since that period. The principal sources of sand for the manufacture of glass are Charlton, Hastings, Derbyshire, Alum Bay, Yarmouth. Isle of Wight, Reigate, Limerick, Cork, Landudno, and Hartwell, near Aylesbury. These sands have all more or less of the yellow topaz hue, indicating oxide of iron, and which imparts to all glass the green tinge so very perceptible in the common window variety. To remove this oxide of iron from sand, has never yet, we believe, been attempted; though if we may judge by the trouble taken to modify its influence in the manufacture of glass, an effectual process of the kind would be a lucrative discovery. When sand containing oxide of iron is mixed with a little charcoal and subjected at a red heat to the action of chlorine gas, the whole of the iron is volatilised as chloride of iron, and the silica remains pure as soon as the excess of charcoal is burnt off: this experiment seems to suggest the possibility of purifying the glass-makers' sand, by the employment of the waste muriatic acid. Even at ordinary temperatures, the solution of oxide of iron by this means might be hoped for; but there can be no practical objection to the use of a reasonable amount of heat for such a purpose, if found necessary.

The sand from Alum Bay, in the Isle of Wight, is composed of

Silica	97·
Alumina, with trace of oxide of iron and magnesia	2·
Moisture	1·
	100·

The French, or Fontainebleau sand, now used in glass-making very extensively, is—

Silica	98·8
Alumina and trace of iron	0·7
Moisture	0·5
	100·

—T. T. H.

SANDAL or RED SAUNDERS WOOD (*Santal*, Fr.; *Sandelholz*, Germ.), is the wood of the *Pterocarpus santalinus*, a tree which grows in Ceylon, and on the coast of Coromandel. The old wood is preferred by dyers. Its colouring matter is of a resinous nature; and is therefore quite soluble in alcohol, essential oils, and alkaline lyes; but sparingly in boiling water, and hardly, if at all, in cold water. The colouring matter which is obtained by evaporating the alcoholic infusion to dryness, has been called *santaline;* it is a red resin, which is fusible at 212° F. It may also be obtained by digesting the rasped sandal wood in water of ammonia, and afterwards saturating the ammonia with an acid. The *santaline* falls, and the supernatant liquor, which is yellow by transmitted, appears blue by reflected light. Its spirituous solution affords a fine purple precipitate with the protochloride of tin, and a violet one with the salts of lead. Santaline is very soluble in acetic acid, and the solution forms permanent stains upon the skin.

Sandal wood is used in India, along with one-tenth of *sapan* wood (the *Cæsalpinia sapan* of Japan, Java, Siam, Celebes, and the Philippine isles), principally for dyeing silk and cotton. Trommsdorf dyed wool, cotton, and linen a carmine hue by dipping them alternately in an alkaline solution of the sandal wood, and in an acidulous bath. Bancroft obtained a fast and brilliant reddish-yellow, by preparing wool with an alum and tartar bath, and then passing it through a boiling bath of sandal wood and sumach.

According to Togler, wool, silk, cotton, and linen mordanted with a salt of tin, and dipped in a cold alcoholic tincture of the wood, became of a superb ponceau-red colour. With alum they took a scarlet-red; with sulphate of iron a deep violet or brown-red. Unfortunately, those dyes do not resist the influence of light.

SANDERS WOOD. See SANDAL WOOD.

SANDARACH, or JUNIPER RESIN, is a peculiar resinous substance, the product of the *Thuya articulata*, a small tree of the coniferous family, which grows in the northern parts of Africa, especially round Mount Atlas. It is imported from Mogadore.

The resin comes to us in pale yellow, transparent, brittle, small tears, of a spherical or cylindrical shape. It has a faint aromatic smell, does not soften, but breaks between the teeth, fuses readily with heat, and has a specific gravity of from 1·05 to 1·09. It contains three different resins; one soluble in spirits of wine, somewhat resembling *pinic acid* (see TURPENTINE); one not soluble in that menstruum; and a third, soluble only in alcohol of 90 per cent. It is used as pounce-powder for strewing over paper erasures, as incense, and in varnishes.

Sandarach is softer and less brilliant than shell-lac, but much lighter in colour; it is therefore used for making a pale varnish for light coloured woods. See VARNISHES.

SANITARY ECONOMY. This term is used to express and to include everything which is done or can be done towards the preservation of health, but in its more restricted and usual sense it is the method of preserving the health of communities. It therefore interests the largest communities, such as nations, and the smallest, such as families, whilst of necessity the interest of the individual is not forgotten; and there is a point at which it merges into medicine or medical economy. It is sometimes called sanitary science, but it is not well to be very lavish of the word *science*, which, although originally only knowledge, is now better confined to cases in which nature herself has pointed out a definite system of laws. Now all the facts brought into prominence by sanitary economy are more or less connected with some science the laws of which are investigated in other relations; but so wonderfully does nature act, that isolated facts from all the sciences frequently come out and form a series so connected, that for a time the judgment is in favour of believing that they may be so arranged as to form a true science; and in some cases this is an open question. Many sciences, perhaps every science, assists in the art of true sanitary economy. Its necessity has arisen from that class of misfortunes to which man has been subject affecting his health; or, as some would say, from certain defects of nature which man is required to supplement. Many of these defects are told in a long series of the greatest miseries; some in a long series of more limited but constant sorrows; and others have been sufficiently small to be considered rather as annoyances. In "Bascombe's History of Epidemic Pestilences" we may read of many hundreds that have attacked man in every known country, and, we may almost add, in every age. In the East we have frequent mention of plagues.

Plagues have frequently followed the track of great, and especially of defeated armies, as well as taken refuge in beleaguered cities.

Hecker's "Epidemics of the Middle Ages" shows few years in which some part of the world has not been suffering under an epidemic. In our own times cholera has long been known to be seldom quite extinct. As an instance of the mode in which these epidemics travel, let us follow the track of cholera. It first appeared at Jessore, on the Delta of the Ganges, reached Jaulnah and Java, and the Burmese Empire in 1818; Bombay, in August of the same year, Arracan and Malacca: in 1819, Penang in Sumatra, Siam, Ceylon, Mauritius, and Bourbon; in 1820, in Tonquin, Cambogia, Cochin-China, South China, Philippines; in 1821, Java, Bantam, Madura, Borneo, &c., Muscat in Arabia, and Persian shores; in 1822–23–24, Tonquin, Pekin, Central and North China, Moluccas, Amboyna, Macassar, Assam; in 1822–23, Persia, Mesopotamia, Judæa; in 1823, Astrachan, part of Russia; in 1827, Chinese Tartary — in all these countries committing ravages hitherto unheard of. In 1830 it went back to Russia, to Poland, Moldavia, and Austria. In 1831 it appeared in Riga and Dantzic, Petersburg, Berlin, Vienna, Sunderland, Leith, and Calais; in 1832, in London; 1834, Spain, the Mediterranean, and North America. In Arabia, one-third in the chief towns died; in Persia, one-sixth; in Mesopotamia, one-fourth; in a province of Caucasus, 10,000 died out of 16,000; in a province of Russia, 31,000 out of 54,000. Plagues are, therefore, still capable of exercising a fatal influence equal to that of the most ancient times. In European towns generally the greatest number of deaths was found to be in the districts least provided with means of cleanliness. It was found among the poor and ill-fed, among the dark races, and the grades of lowest constitutional power. (*Copland's Dictionary: — Pestilence.*) It is also to be remarked, that in all the places where cholera was most violent, civilisation had not attained its European maximum. Cholera is an attack of the chemical forces on the vital forces; vital force even in the form of moral confidence repels it to a great extent, as it does other infectious diseases; but, for the same reason, fatigue and depression of mind hasten the action. The ordinary chemical forces act in the viscera instead of the chemico-vital. The lungs are gorged with blood, unable to send it away oxidised; the gall increases because carbon is not burnt, and urea is not secreted as there is no normal decomposition of the food. Vital force therefore fails, and a kind of putrefaction or fermenting action begins. This is only one instance of the many evils that have followed man. This is not the place to speak of black death, sweating sickness, and the other diseases, down to milder influenzas, which are continually infesting some of our race.

Diseases of this kind are believed to be caused by decomposing matter; they seem to rise from fœtid cities or fœtid land. Deltas have been chiefly blamed; that of the Ganges for cholera, that of the Nile for plague, that of the Mississippi for yellow fever. Although from this view diseases would be considered as under the power of mankind to suppress, their cause seems too widely diffused to place them under the direct control of limited communities, much less of individuals.

About 1350 the whole world was thrown into violent commotion. The change may be said to have begun in 1333, when floods, earthquakes, and sinking mountains are spoken of as occurring in China. Plague and parching drought covered much of the East: Cyprus was nearly destroyed. In that island the earth opened and sent out a fœtid vapour which killed many. A mist, thick and putrid, came to Italy from the East. Earthquakes occurred all along the Mediterranean. Noxious vapours and chasms seem to have extended hundreds of miles. (*Hecker.*) Diseases from these causes are of course out of our control.

Another natural source of disease is the existence of marsh land, producing malaria. Malaria may also be produced from woody land and moist land, especially if there be many impurities. Deltas, or low lands, at the mouths of rivers, land flooded either by salt or by fresh water, especially if alternately by one and the other, not forgetting the great alluvial deposits, which are kept moist in hot climates. Numerous as are the cases of malaria where it is difficult to see the cause, the connection of the marshes with some febrile diseases is beyond any question. The fevers from this source seem in their worst states to pass into yellow fever. This class of fevers is not epidemic, and does not travel far from its source. There are of course many cases of its being carried by the winds to a great distance, and the distance seems to depend on the amount of marshy land, or, in other words, on the extent of the poison produced. If little exist, it is dispersed before the wind travels far.

Conditions of the weather may cause vegetation to putrefy instead of growing. In 1690, a striking example of this occurred at Modena, although other examples might be taken much nearer if there were not such multitudes of opinions upon them. Four or five years of unusual dryness had occurred; fruit was abundant, however, and health satisfactory. A wet winter came, cloudy and calm, without cold. This state continued through summer, with much rain. The numerous and noisy grasshoppers of Italy almost ceased, and frogs, that belong to a country of marshes, took their place. The corn had ceased to grow, and its place was supplied by fishes, so abundant was the water on the land; whilst also organic matter was driven into the streams in unusual quantities. Vegetation was attacked with *rubigo*,—a rusty withered appearance,—which increased in spite of all precaution; beginning with the mulberry, it attacked the corn, and then the legumens, and especially the beans. This extended over the higher spots as well as the lower. It was melancholy to look on the fields, which, instead of being green and healthy, were everywhere black and sooty. "The very animals returned the food which they had eaten. . . . . The sheep and the silkworms perished. . . . . The bees made their honey with timidity. . . . . The waters became corrupt, and fevers attacked the inhabitants, chiefly the country people, such as lived on the wet lands. This state produced intermittent fevers." — *Bern. Ramazzini.*

Again, there are causes purely artificial arising from the state of our towns in manufacturing districts.

It has been proved that diseases may be produced artificially of a kind closely resembling the great world epidemics. When persons live closely crowded together health gradually begins to fail, and loathsome diseases rapidly grow. These diseases vary immeasurably, and the variation seems to be as great as the modes of decomposition of animal matter. After a time these diseases attain virulence sufficient to be infectious or contagious through the atmosphere.

These various conditions are not perfectly understood, but even the statement of our ascertained knowledge has been most widely misunderstood by the public, and sometimes even by professional men, many of whom, if they have conceived the matter clearly, have not expressed it well.

There are at least three principal methods by which the air is rendered impure. 1st. By noxious gases, dust, and ashes, produced by geological, atmospheric, or artificial causes, sulphurous gas, carbonic acid, sulphuretted hydrogen, and perhaps many others. 2. Epidemic or travelling causes to all appearance reproducing themselves as they advance, as in plague and cholera. Similar diseases produced by artificial or neglected accumulations of filth. 3. Malaria, or diseases caused by the disturbed or badly-regulated relation between the soil and the atmospheric conditions, whether from natural or artificial causes. It would be difficult to include all the various evils arising from too much heat, cold, &c. &c.; knowing these things, we are able to a considerable extent to guide ourselves. When the disease or nuisance is caused by processes of manufacture the law sanctions interference. The judicious management of this branch of the subject is of the greatest importance to the community.

There are also causes of disease relating more to the condition of the atmosphere; for example, from the prolongation of a current of air or wind from one particular district, without due mixture; and from conditions of moisture, and of electricity.

Sanitary economy devises a method of avoiding the diseases spoken of. As to the first, those produced by geological phenomena, our chief protection lies in the choice of place: this remark may also apply to those diseases produced by atmospheric stagnation and electrical condition. All we can do is to choose places which are known to be free from disturbances or irregularities; when such occur, we are then able only to remove or to suffer. Such diseases are but little understood. When the disease is epidemic, some trace its origin to causes which may be termed cosmic. One may be an excess of the decomposing agent, or by conditions of the atmosphere unfavourable to the continuation or tenacity of delicate chemical compounds. Take, as illustration, milk during a thunderstorm; this action is probably caused by a very rapid oxidation, which oxidation begins the phenomena of putrefaction. To bring such an analogy to explain the condition generally of organic matter, is legitimate, and we may either suppose the action to begin in living animals themselves, or on substances external to them. The belief may be said to be established by a long host of great observers, that putrefying matter produces diseases under certain not very well known conditions, and that it reacts unfavourably on the health in every condition, and as a cause of instant death in concentrated forms. In Cairo, where houses are crowded with the living, and where the dead are buried with slight covering, underneath the living, there seems to be a periodic clearing out of the population by plague, reducing the number until there be enough of air to allow of healthy life. In our own prisons at one time the same thing occurred, and in many of the prisons of the world imprisonment is death; such as in Turkey, China, and places not civilised by modern sanitary knowledge. Prisons in Europe, also, might readily be mentioned as most unwholesome; and prisons and workhouses in England itself, where the greatest care must be taken to prevent want of cleanliness, as it produces an immediate result in disease. This is merely on a small scale what takes place on a great scale in nature. It is similar to what we every day see, that man lays hold of some of the facts of nature, and under his hand they act by the same laws as they do in their cosmic manifestations. So in his diseases, man produces them by causing circumstances so to concur that the laws of nature act under his hand as they do when he has not interfered. Sanitary inquirers have ultimately been compelled to attribute many of the greatest effects on health to decomposition of organic matter. Almost all ages have referred to putrefaction or fermentation as an evil. The words have been used synonymously. For various opinions on this subject see DISINFECTION and PUTREFACTION. M. Place, in 1721, says that *in putrefaction a body works another to conformity with itself.* This is believed to be the case in many diseases. One erroneous opinion is very common. Gases which might be prepared in the chemist's laboratory have been blamed as the causes of infectious diseases. Sulphuretted hydrogen and carbonic acid are spoken of as if they were infections, and productive of fevers. Permanent chemical compounds, gaseous or otherwise, are not capable of acting as infections. The idea of infection given is that of a body in a state of activity. But any gas, the atmospheric mixture excepted, is capable sooner or later of causing death. A true gas diffuses itself in the air, and is rapidly removed from any spot; to render a place long unwholesome the gas must be continuously generated at the spot. The movements of plagues are not similar to anything we know of gases; on the contrary, we know that gases could not move in the manner that cholera and plague do. Sulphuretted hydrogen is not miasma, it is poisonous; it may destroy the constitution and produce diseases which may be deadly enough, but the sources of it are resorted to by invalids; this would never be the case were it a miasm. It has occasionally an internal beneficial action, and although in using it a little be taken into the lungs, this momentary breathing is not found prejudicial; but an amount of cholera infection, such as we could perceive by the nose as readily as sulphuretted hydrogen, would no doubt be a most deadly dose: we probably know of no such amount. The same may be said of carbonic acid and other gases. Some persons are capable of smelling the miasms of certain places—no doubt very fine senses could detect them wherever they existed; but generally bad air may injure very important organs without any effect being perceived by the senses until the evil has become very great. The chemical action is not one that the senses fully observe. Fermentation and putrefaction exhaust their powers after a short time, and cease; so do infections, but not so pure gases, which act only by combining. The fermenting substances lose their power not by combination so much as a change of condition, a transformation of their particles. All these actions, similar to fermentation, are connected with moist bodies: dried bodies cannot ferment, putrefy, or infect. Infection, like fermentation, is most violent at an early stage, gradually spending its strength, and frequently changing a portion of the substance into analogous forms. It has been argued that putrefaction cannot produce disease; but there are no facts in nature better established than the production of disease by the presence of dead animals or vegetables, especially the first. The production of fever by crowding hospitals, barracks, and ships, is as easy as the formation of many other artificial organic actions, although no exact form of fever can be produced at will; cases depending no doubt on time, place, climate, and constitution. The knowledge of these facts concerning zymotic diseases leads to this conclusion: in order to avoid the evil effects of decaying matter, it is necessary to have all our surroundings as clean as possible. Sanitary economy resolves itself at last chiefly into cleanliness. Individuals may learn personal cleanliness, but to render a town or a county clean many difficult arrangements are needed. Impurities arise from the conditions of animal life. Life is generated by the activities of certain substances which compose animals. When the activity is over the substances are dead and unpleasant, and they pass into their former condition through a number of stages. In some of these stages the substances are gaseous, some liquid, some solid; we may add, some in the state of vapour. Some of these substances are exhalations, some excretions. Exhalations come from the surface of the whole body, but from the lungs principally. The lungs give out air with about 4, 6, and even 8 per cent. of carbonic acid in it, and the amount respired is about 380 cubic feet in 24 hours, about 31 cubic inches per respiration, and 15 respirations per minute. The amount of air proposed as the supply for an individual varies greatly. Dr. Reid gave 30 cubic feet per minute = 1800 feet per hour, and even 3600. Liebig supposes 216 feet per hour. Dr. Reid gave more than was considered agreeable. Brennan supposes about 600, and calculates the following for every room per minute and per individual, the air being at 64°, and dew point at 50°.

For supply to the lungs	0·83 feet.
To carry off insensible perspiration	10·2 „
For each common-sized candle	0·25 „

If heated air is used for warming—

For each square foot of glass in the window	1·0 „
Each window to make up for leakage	8·5 „
Each door for the same	5·2 „
Each 200 square feet of wall and ceiling	1 „

Allowing this to be excessive, the advantage of pure air is still to be urged, and it is desired most by the healthiest specimens of men.

In speaking of the impure gases of the air, carbonic acid is generally referred to. This carbonic acid has been considered to be the great cause of disease in crowded localities, but the conclusion is contrary to our knowledge of the effects of carbonic acid when pure. There can be little doubt that there is a considerable amount of organic matter in the air of crowded places, and to that organic matter must be attributed most of the evil. It may be true that 1 per cent. of carbonic acid may be observed by the senses, but this is generally tried with carbonic acid given out from the lungs. In the case of a prison in Germany, 2 per cent. of carbonic acid was found in the air. Skin diseases appeared rapidly, and deaths were excessive. But we do not know the action of the pure gas; there must have been a large amount of corrupt matter in air which contained 2 per cent. of carbonic acid escaped from persons. It shows also great general filth. Amounts of organic matter, which are wonderfully less than even an hundredth of a per cent., are known to make the air unhealthy. In Manchester it seems to be the sulphurous acid which is chiefly felt, and that when it is less than one in a million, although it rises up in some places close to chimneys to 1, and even 4, in 100,000.

It is not intended here to give statistics of disease, but it will be right to refer to the enormous amount of disease amongst miners in Cornwall. The depths being great, above 1800 feet in some, and the temperature rising to about 100°, the difficulty of working is extremely great. Candles are burnt, and the air has become so deteriorated that it contained less than 18 per cent. of oxygen. The amount of carbonic acid had not risen above 0·085 per cent., which is not very high. Mr. R. Q. Couch, Sir J. Forbes, and Mr. Mackworth, have successively reported on this subject and given some interesting details. Mr. Roberton, of Manchester, remarks on the great cleanliness of the women; but they do not enter the mines, and their lives are longer. Consumption destroys the men rapidly in many of the deep mines.*

Exhalations from the skin are abundant, both acid and oleaginous.

Dr. Vogel found organic matter in the air of his class-rooms after a lecture. Dr. Angus Smith has shown that the exhalations may be traced on the walls of crowded rooms, which become coated with organic matter; and he adds that the furniture becomes coated with a similar substance, which must be continually removed. Thus furniture and walls which are never touched in time become impure, and give out noxious exhalations when these substances begin to decompose. Again, these substances are caught in our clothes and are retained there in a decided manner, on account of a peculiar faculty of retention in the fibre. This necessitates constant washing. Long custom has shown, that when retained by the cloth, a certain amount of it becomes innocent; that is, different fibres have the power of retaining matter so firmly that it is imperceptible and incapable of acting on the air. Wool has this faculty to a great extent; linen and cotton to a less extent. For this reason wool can be worn longer next the skin, remaining in reality clean. Clothes that are to be kept in good condition, if made of wool, as men's coats, cannot be washed: for this reason the custom has gradually been formed of wearing under clothing, which absorbs condensible substances especially, and is then washed, keeping the exterior clothing for a long time clean. As porous substances have an oxidising power, it is probable, that if not too much organic matter is supplied, the exterior clothing, well aired, may be kept absolutely clean, not merely by our ordinary practice of brushing and dusting, but also by oxidation, in the same way as Dr. Stenhouse has shown oxidation to take place in pores of charcoal. The instant removal of the breath and other exhalations is of great importance. This properly comes under the head of warming and ventilating. Walter Brennan, C.E., in his "History of Warming and Ventilating," gives a remarkable amount of information. There have been many mistakes as to the effect of overcrowding; its evils have actually been denied. The facts are very decided. Isolated houses may be crowded so much as to produce diseases, or they may be so badly ventilated without crowding as to have the same result. In this way persons in the country may have all the disadvantages of a crowded town. Again, a town-house well ventilated may have many of the advantages of the country, because, although the air is not of the purest, it may never be allowed to sink below the average purity of the external air. Indeed, freedom from disease is obtained in towns better in all cases than where there is a malarious atmosphere outside the town: this, of course, is well known; and at the same time diseases from putrefaction, caused by want of space and cleanliness, are cured by leaving a town. Persons slightly exposed to the odour of water-closets in towns are frequently subjected to disease, the unoxidised air poisoning them, whilst persons working in the open air escape, although labouring amongst the excreta themselves. Again, persons living in the house are exposed to the excreta a day or two old, whilst, in the case of nightmen, it has frequently passed its worst stage when they approach it. The stage giving off sulphuretted hydrogen is by no means the worst, perhaps one of the most innocent of the unpleasant stages, unless this gas be very strong, when it is fatal. But even in the minutest quantity this gas is hurtful to persons continuously exposed.

* "*Miner's consumption*," as the disease which destroys the miner is named, prevails also in the lead mines of the northern counties, which are usually shallow.—(*Ed.*)

The mode of removing excreta is an important point. Most inquirers have decided against leaving them in a town, and against allowing them near a house. These conclusions are especially valuable for town houses. We have in some towns whole streets of middens behind the houses, and the air behind is always inferior to the front air. The process of carting refuse is also a great evil in a town. No plan removes filth so rapidly as that with water. Many people object to it, because we have not yet learnt to make good sewers. Sewers should be tight. The Board of Health introduced small and rapid streams in the sewers, objecting to the canal-like sewers, which are as bad as cesspools, on account of the enormous amount of deposit in them, and are reservoirs of foul air from the amount of putrefaction going on within them. Many persons, not seeing this evil, have desired again to return to the no-plan of middens, not seeing what a deplorable result has been attained in Paris, where although using air-tight vessels to remove the refuse, they render most of the houses redolent of night-soil. The towns treated on the rapid removal system are models of cleanliness, and we do not doubt the speedy increase of the plan, especially as carried out by Robert Rawlinson, C.E. It must be confessed, however, that the great objection to the plan is one which is not to be despised. There is too much water used; if the water flows into the streams they are spoiled, and it is scarcely possible to put it on land. This difficulty must be met, or the plan so admirable for towns will be found destructive to countries. There is one way of meeting it, that is, by making the liquid denser, and so having it so strong as to be a valuable manure. By a double system of drainage this might be effected, the rain water going in a separate sewer. *F. O. Glassford* proposes a water-closet which shall hold the excreta till they are mixed up to a thickish liquid with water; he then removes it by pipes to certain reservoirs, and makes solid manure from it by sulphuric acid and evaporation, a plan which he has found to answer. Dr. Joule proposes large iron tanks for each block of houses, to be emptied daily, and disinfected on being emptied. All such plans must be inferior to the cleanliness caused by abundant water. We must learn to remove our filth from our towns, or they will be as unwholesome as they once were. Nothing but abundant water can make the largest city in the world (London) the healthiest of large cities.

The assertion of the Board of Health is that combined works, comprising a water-pipe for the service of each house, a sink, a drain, and a waste-pipe, and a soil pan or water-closet apparatus, may be laid down and maintained in action at a cost not exceeding on the average three halfpence per week, or less than half the average expense of cleansing the cesspool for any single tenement. This seems borne out by the example of several towns under the care of engineers penetrated with the spirit which dictated the changes. To the above amount has been added water supply, which has increased the sum to threepence per week.

Sewers must certainly not leak, or they must be disinfected. Dr. Angus Smith proposed long ago that they should be disinfected nearly from their sources. In other words, disinfectants should flow through all the great sewers, and so bring them to the rivers in a state where putrefaction is impossible. The advantage of this would be great. When Mr. McDougall was showing his plan of disinfecting sewers to the Board of Works, the smell of the substance he used when he tried it in excess was perceived in the houses along the line of the sewer, showing clearly that the present sewers allow their filthy smells to go into the air of houses. He completely destroyed the sewer smell. To prevent bad air in sewers, some persons, and amongst others some in the Board of Health, have proposed ventilation, and have thus polluted towns with the air which, after all, may be better where it was. To obviate this, they sometimes filter the air through charcoal before allowing it to escape. No plan will succeed but that which, by preventing putrefaction, prevents entirely the formation of foul air. At present all the lines of sewers are unclean; they may all be cleaned by antiputrescent substances. If every family used them, even the smallest drains would be disinfected with universal benefit. Of course the Thames would cease to putrefy if the larger sewers were all treated in this way.

When the excretions are allowed to accumulate in a town behind the houses, as in Leeds and many other large manufacturing towns, they must of course be periodically removed, as the amount of impure vapour is very much in proportion to the surface exposed. There is little improvement caused by slightly diminishing the solid contents. When removed, it must be taken either to deposits in the town, as at Manchester, or deposits out of the town, as at Paris. It cannot, except in small towns, be removed directly to the land, as the demand is not regular. In both cases the removal is a great grievance, and the places of deposit are unseemly, especially near Paris, at Bondy, where a great district becomes uninhabitable. If removed by water, either the streams must be polluted, or sewers must be carried along the streams very far. If the sewer matter is first disinfected in the sewers, it will flow without disturbing any one; and if not so much diluted with surface matter as at present, it might be put at once on the land, without any one knowing by the smell that it differed from pure water.

Since Edwin Chadwick, C.B., and Dr. Southwood Smith, whether under the name of the Board of Health, or Sanitary Commissioners, or other name, stimulated the country to sanitary purposes, the supply of water and every other progress relating to health has undergone a great change. Professor Clark first showed the advantages of soft water; and, wherever it can be obtained, it is now used in towns. Every town which can obtain it has now a supply of water; and the supply in many is constant. The loss of labour to a family where water is obliged to be carried from a well is sometimes equal to that of one person for at least one third of a day. And even with this loss there is an insufficient supply, which adds to the inconveniences of a household, and the loss of comfort and of health. As towns enlarge, and as houses become higher, the necessity for a supply being introduced into houses increases. In Glasgow there is a supply from Loch Katrine, 34 miles distant. The supply in Scotch houses must be taken to the highest storey of the houses, on account of the system of living in flats, and because in the large towns almost every family has a water-closet and a bath.

The cleaning of the surface of streets is another important point in sanitary economy. Abundance of water for this purpose would be a great advantage; but the plan is not introduced here. The Whitworth sweeping machine was a good cleanser, but it was very heavy, and the cartage became expensive. Hand sweeping is still resorted to. If disinfecting agents were put into the water-carts which watered the streets, the putrefaction going on there in great abundance would be arrested, and the disinfected matter would flow into the sewers, which would then be free from impure air, and would run into the river in a state that would not corrupt. This was also proposed, in addition to the method alluded to of disinfecting sewers, and by the same persons. After the towns and their immediate neighbourhoods have been purified, it is needful to purify the land. The great sources of malaria are not known; but it is abundantly known that badly-drained land, especially at a high temperature, is productive of malaria; and that even at a moderate temperature malaria causes intermittent attacks. Drainage has greatly removed ague from this country; it has cleared the land; and the atmosphere has become brighter, because the dried land has not produced so many fogs as that which was cold and wet. The clearing of swamps was a labour of Hercules, no less valuable now. The agricultural or money value of land has, at the same time, greatly increased.

Towns.—It has been shown that a death-rate of 22 per thousand yearly prevails in England, but that in large manufacturing towns it rises to 34, and in certain parts of them even to 45, whilst in small and healthy places it is as low as 17, and in some cases even less so. The loss of life is great, and the loss of property also. A great object of sanitary reformers has been to show that to improve health has been to improve property. There can be no doubt of it. Disease causes much loss of time and labour, and diminishes the power of a country in which it exists. We may very fairly calculate from the amount of deaths the amount of disease. To improve our health is to improve our happiness and our wealth, as well as our capacities for both. Although in some country places malaria may cause illness, and ignorance may in various ways induce most unwholesome habits, there is less fear of disease on an average far from a town, because of the tendency of persons to live out of doors, breathing pure air, for in most places it is pure. In towns we are not only apt to be more shut up, and to have less exercise, but we are exposed to all the impurities which arise from the neighbourhood of multitudes, as well as from the vapours and gases from manufactures. Many chemists have found it difficult to tell the difference between town and country air, and have denied any difference; but it is now proved abundantly. The very rain of towns where much coal is burnt is so acid, that a drop falling on litmus renders it red. Blood shaken with the air of towns takes a different shade from that shaken with pure air. The air of Manchester contains about 0·0000934 of sulphurous acid, partly sulphuric, into which the first changes. Dr. Angus Smith has shown a method of measuring the amount of impurity in the air by means of a very dilute solution of permanganate of potash. His results are obtained by filling a bottle with the air of the place, merely by pumping the air out and allowing the air around to enter. A little permanganate is poured into the bottle, and it is decolorised; more is added until the colour remains. By this means comparative amounts of oxidisable matter are readily measured. A pigstye required 109 measures; air from the centre of Manchester air, on an average 58; air over the Thames, when the putrid stage had just passed, 43; London, 29; after a storm at Camden Town, 12; fields near Manchester, 13·7; German Ocean, 3·3; Hospice of St. Bernard, in a fog, 2·8; Lake of Lucerne, calm, 1·4. When sulphurous acid and sulphuretted hydrogen are present, the action is instantaneous: when organic matters only are present, the result is obtained more slowly. The difference between town and country air is remarkable. The author hopes to make the experiment suitable for daily use in hospitals. The bottle used contains about 100 cubic; the solution of permanganate is graduated by a standard solution of oxalic acid, of which 1000 grains contain 1 of anhydrous oxalic acid. 5 grains of this solution decompose 600 grains of the solution of permanganate.

To prevent impurities in the air of towns is extremely difficult. Manufactures must not be crippled; certain noxious operations are not allowed, and complaints well substantiated against any offensive works compel their removal. The method of absorbing noxious gases of some kinds is now becoming usual. The coke towers for absorbing muriatic acid began a great change in this respect. They have been used for sulphuric acid itself, nitrous fumes, sulphurous acid, sulphuretted hydrogen, &c. In manufacturing towns there is little sulphuretted hydrogen — it is decomposed rapidly by the sulphurous acid. A mode of absorbing this latter acid from coal smoke would be a great blessing to all. But this would not remove all the evil; coals send out black soot in such abundance that the whole of a town is darkened, everything clean is made impure, and the people find that cleaning is a hopeless task. This might readily be burnt, but even then we have other difficulties. Ashes rise up in great amount, and fall down again in a perpetual shower of dust. It is these solid matters as well as the gases which render our towns unwholesome. If the smoke could be washed it would remove all these evils, but the loss of a draught to the fire is then a consequence not yet practically overcome. When coals are burnt with abundance of lime, no sulphur is given off, but the use of this cannot become general. We are very much in want of a more economical and wholesome method of obtaining from coals the power which is in them.

Mr. Spence of Manchester, proposes to connect all the furnaces of the city with the sewers, and thereby to burn the gases and to ventilate the sewers at the same time. He believes that one chimney will ventilate readily 500 houses, including the house drains and sewers also.

The following advantages to be derived from the drainage of suburban land have been mentioned by the Board of Health: — 1. The removal of that excess of moisture which prevents the permeation of the soil by air, and obstructs the free assimilation of nourishing matter by the plants. 2. Facilitating the absorption of manure by the soil, and so diminishing its loss by surface evaporation, and being washed away by heavy rains. 3. Preventing the lowering of the temperature and the chilling of the vegetation, which diminishes the effect of solar warmth, not on the surface only, but at the depth occupied by the roots of plants. 4. Removing obstructions to the free working of the land, arising from the surface being at certain times, from excess of moisture, too soft to be worked upon, and liable to be poched by cattle. 5. Preventing injuries to cattle or stock, corresponding to the effects produced on human beings by marsh miasm, chills and colds, inducing a general low state of health, and in extreme cases the rot or typhus. 6. Diminishing damp at the foundations of houses, cattle sheds, and farm steadings, which cause their decay and dilapidation, as well as discomfort and disease to inmates and cattle.

The Board of Health, in its excessive desire to remove all refuse by water, has often exaggerated the evils of every other aid to cleanliness. Water is unquestionably the best, but it cannot always be obtained. In some climates it is not to be found in abundance, and in some weather it is only to be had by the use of heat. When the cold is great there is no fear of putrefaction or putrid gases; in warm places, or even in temperate, the use of disinfectants before removing the putrid matter is much to be desired. The Board of Health has not feared to send putrid matter into a river, believing it better there than in the town; it desires the water to be put instantly on the land, and to be disinfected by the land. It is well known that the process of doing this is often offensive. It is also known that large quantities of this matter cannot be disposed of at all times. It has been said that if the liquid were diminished by the rain-fall, it might be manageable. There is another method of diminishing its amount. At Carlisle it was found that the water was almost pure at certain hours of the day, and at all hours of the night. By allowing the more impure only to run into the sewers, the quantity not only becomes manageable, but the quality becomes more valuable. This is an important point, but one which will probably be less apparent in such a place as London, where the changes occurring from hour to hour cannot be so great as in smaller places. In Carlisle the sewage is deodorised and used on the meadows, and a great problem seems there and elsewhere to have begun its solution.

Sanitary economy has proceeded chiefly under the impression that the pollution of the air is the evil most to be dreaded. That this idea is correct there are very many proofs; but that there are numerous other evils affecting our large towns, it is unwise to deny. Polluted air causes damp and close cellars, and unventilated garrets and other rooms, to be unwholesome, as well as all rooms without proper openings, without chimneys, and without opening sashes to the windows. In a word, polluted air rises from close places and dirty places; want of light, too, is an evil under which all living creatures suffer. Great and crowded towns are subject most to all these evils, but in them also the habits of the people come into consideration. In many of the manufacturing towns the people obtain much larger wages than in the country places, but their houses are badly furnished, and their clothes, for every-day at least, are extremely filthy, whilst their love of pleasure is excessive. It is commonly supposed that the love of pleasure exists among the rich, but it is unquestionably one of the greatest evils *oppressing* the poor in all large towns, because their cultivation of mind has not kept pace with their knowledge of the external appliances of civilisation.

A deficient intellectual and moral condition are the great causes both of poverty and bad health, for both go together in almost exact proportions. It must never be expected that pure air alone can make men healthy. The mind, as well as the body, must be freed from irregularities. Abundant wages, which are equal to facilities of health, have rendered our working classes inferior in some cases, both in body and in mind, because they have not had education to resist indulgence. These classes will often contrast badly with a poor but cleanly rural population, calm in mind, without a desire for excitement. The subject is here only slightly touched, it needs a volume: sanitary economy, or the method by which man best adapts his place of abode to the conditions of external nature, must ever be a study of the most absorbing interest.—R. A. S.

SAPAN WOOD, or EAST INDIAN DYE WOOD, or BUCKUM WOOD, is a species of the *Cæsalpinia* genus, to which Brazil wood belongs. It is so called by the French, because it comes to them from Japan, which they corruptly pronounce Sapan. It is imported in pieces like the Brazil wood, to which it is far inferior for dyeing. The decoction under the name of sapan liquor is used in calico printing for red colours. In general, sapan wood is too unsound to be employed for turning.

SAP GREEN. The juice of the berries of the *Rhamnus catharticus*, or common buckthorn.

SAPPHIRE. The *Sapphire*, *Ruby*, *Oriental Amethyst*, *Oriental Emerald*, and *Oriental Topaz*, are gems next in value and hardness to diamond; and they all consist of nearly pure alumina or clay, with a minute portion of iron as the colouring matter. The following analyses show the affinity in composition of the most precious bodies with others in little relative estimation.

	Sapphire.	Corundum Stone.	Emery.
Alumina or clay	98·5	89·50	86·0
Silica	0·0	5·50	3·0
Oxide of iron	1·0	1·25	4·0
Lime	0·5	0·00	0·0
	100·0	96·25	93·0

Salamstone is a variety which consists of small transparent crystals, generally six-sided prisms, of pale reddish and bluish colours. The corundum of Battagammana is frequently found in large six-sided prisms: it is commonly of a brown colour, whence it is called by the natives *curundu gallé*, cinnamon stone. The hair-brown and reddish-brown crystals are called adamantine spar. Sapphire and salamstone are chiefly met with in secondary repositories, as in the sand of rivers, &c., accompanied by crystals and grains of octahedral iron-ore and of several species of gems. Corundum is found in imbedded crystals in a rock, consisting of indianite. Adamantine spar occurs in a sort of granite.

The finest varieties of sapphire come from Pegu, where they occur in the Capelan mountains near Syrian. Some have been found also at Hohenstein in Saxony, Bilin in Bohemia, Puy in France, and in several other countries. The red variety, the ruby, is most highly valued. Its colour is between a bright scarlet and crimson. A perfect ruby above 3½ carats is more valuable than a diamond of the same weight. If it weigh 1 carat, it is worth 10 guineas; 2 carats, 40 guineas; 3 carats, 150 guineas; 6 carats, above 1000 guineas. A deep coloured ruby, exceeding 20 carats in weight, is generally called a carbuncle; of which 108 were said to be in the throne of the Great Mogul, weighing from 100 to 200 carats each; but this statement is probably incorrect. The largest oriental ruby known to be in the world, was brought from

China to Prince Gargarin, governor of Siberia. It came afterwards into the possession of Prince Menzikoff, and constitutes now a jewel in the imperial crown of Russia.

A good blue sapphire of 10 carats is valued at 50 guineas. If it weighs 20 carats, its value is 200 guineas; but under 10 carats, the price may be estimated by multiplying the square of its weight in carats into half a guinea; thus, one of four carats would be worth $4^2 \times \frac{1}{2}G. = 8$ guineas. It has been said that the blue sapphire is superior in hardness to the red, but this is probably a mistake arising from confounding the corundum ruby with the spinelle ruby. A sapphire of a barbel blue colour, weighing 6 carats, was disposed of in Paris by public sale, for 70*l.* sterling; and another of an indigo blue, weighing 6 carats and 3 grains, brought 60*l.*; both of which sums much exceed what the preceding rule assigns, from which we may perceive how far fancy may go in such matters. The sapphire of Brazil is merely a blue tourmaline, as its specific gravity and inferior hardness show. White sapphires are sometimes so pure, that when properly cut and polished they have been passed for diamonds.

The yellow and green sapphires are much prized under the names of oriental topaz and emerald. The specimens which exhibit all these colours associated in one stone are highly valued, as they prove the mineralogical identity of these varieties.

Besides these shades of colour, sapphires often emit a beautiful play of colours, or *chatoiement*, when held in different positions relative to the eye or incident light; and some likewise present star-like radiations, whence they are called star-stones or *asterias;* sending forth 6 or even 12 rays, that change their place with the position of the stone. This property, so remarkable in certain blue sapphires, is not however peculiar to these gems. It seems to belong to transparent minerals which have a rhomboid for their nucleus, and arises from the combination of certain circumstances in their cutting and structure. Lapidaries often expose the light-blue variety of sapphire to the action of fire, in order to render it white and more brilliant; but with regard to those found at Expailly in France, fire deepens their colour.

SARD. A variety of chalcedony of a dark reddish-brown colour, almost approaching to black by reflected light, and very deep red, inclining to blood-red, by transmitted light. It is found under the same conditions as cornelian, but is rarer and more highly esteemed, and therefore fetches a higher price. The name is derived either from Sarx (*Greek*, flesh), in allusion to its colour, or from Sardis in Lydia, whence it is said to have been first brought. It should be remarked, however, that the sard presents, in its interior and in the middle of its ground, concentric zones, or small nebulosities, which are not to be seen in the red cornelian, properly so called. The ancients certainly knew our sard, since they have left us a great many of them engraved, but they seem to have associated under the title *sarda* both the sardoine of the French, and our cornelians and chalcedonies. Pliny says that the sarda came from the neighbourhood of a city of that name in Lydia, and from the environs of Babylon. Among the engraved sards which exist in the collection of antiques in the Bibliothèque Royale of Paris, there is an Apollo remarkable for its fine colour and great size. When the stone forms a part of the agate-onyx, it is called sardonyx. For further details upon Gems, and the art of cutting and engraving them, see LAPIDARY.—H. W. B.

SARDONYX. A variety of onyx, composed of alternate layers of sard and white chalcedony.—H. W. B.

SATIN (Eng., Fr. and Germ.) is the name of a silk stuff, first imported from China, which is distinguishable by its very smooth, polished, and glossy surface. It is woven upon a loom with at least five-leaved healds or heddles, and as many corresponding treddles. These are so mounted as to rise and fall four at a time, raising and depressing alternately four yarns of the warp, across the whole of which the weft is thrown by the shuttle, so as to produce a uniform smooth texture, instead of the chequered work resulting from intermediate decussations, as in common webs. Satins are woven with the glossy or right side undermost, because the four-fifths of the warp, which are always left there during the action of the healds, serve to support the shuttle in its race. Were they woven in the reverse way, the scanty fifth part of the warp threads could either not support, or would be too much worn by the shuttle. See TEXTILE FABRICS.

SATURATION is the term employed to express the condition of a body which has taken its full dose or chemical proportion of any other substance with which it can combine: as water with a salt, or an acid with an alkali. See *Ure's Dictionary of Chemistry* for a development of the principles and peculiarities attending this process.

SATURN, EXTRACT OF. The old name of the acetate of lead.

SAWS. Saws are formed from plates of sheet steel, and are toothed, not by hand, but by means of a press and tools. Circular saws have the advantage of being divided in their teeth very accurately by means of a division plate; this prevents irregularity of size, and imparts smoothness and uniformity of action. The larger sizes of circular saws are made in segments and connected together by means of dove-tails. All saws are hardened and tempered in oil; their irregularities are removed by hammering on blocks, and they are equalised by grinding. The several forms of teeth do not, as the casual observer may imagine, depend upon taste, but are those best fitted for cutting through the particular section, quality, or hardness of the material to be cut. The "set" of the saw consists in inclining the teeth at the particular angle known to be the best to facilitate the exit of the sawdust, and thereby allow the saw to operate more freely. Iron bars, shaftings, &c., are cut to length by a steel circular saw, in its soft state, the iron to be cut being presented to the saw red-hot; the saw rotates at a prodigious rate, and is kept in cutting condition, or cool, by its lower edge being immersed in water. A bar, two inches in diameter, is cut through in a few seconds. Consult *Holtzappfel* on this subject.

SCAGLIOLA is merely ornamental plaster-work, produced by applying a pap made of finely-ground calcined gypsum, mixed with a weak solution of Flanders glue, upon any figure formed of laths nailed together, or occasionally upon brickwork, and bestudding its surface, while soft, with splinters (*scagliole*) of spar, marble, granite, bits of concrete-coloured gypsum, or veins of clay, in a semi-fluid state. The substances employed to colour the spots and patches are the several ochres, boles, *terra di Sienna*, chrome yellow, &c. The surface, if it be that of a column, is turned smooth upon a lathe, polished with stones of different fineness, and finished with some plaster-pap, to give it lustre. Pilasters and other flat surfaces are smoothed by a carpenter's plane, with the chisel finely serrated, and afterwards polished with plaster by friction. The glue is the cause of the gloss, but makes the surface apt to be injured by moisture, or even damp air. See STONE, ARTIFICIAL.

SCARLET DYE. (*Teinture en écarlate*, Fr.; *Scharlachfârberei*, Germ.) Scarlet is usually given at two successive operations. The boilers (see DYEING) are made of block tin, but their bottoms are formed occasionally of copper.

1. *The bouillon or the colouring bath.*—For 100 pounds of cloth, put into the water, when it is little more than lukewarm, 6 pounds of argal, and stir it well. When the water becomes too hot for the hand, throw into it with agitation, 1 pound of cochineal in fine powder. An instant afterwards, pour in 5 pounds of the clear mordant (see MORDANT), stir the whole thoroughly as soon as the bath begins to boil, introduce the cloth, and wince it briskly for two or three rotations, and then more slowly. At the end of a two-hours' boil, the cloth is to be taken out, allowed to become perfectly cool, and well washed at the river, or winced in a current of pure water.

2. *The rougie, or finishing dye.*—The bouillon bath is emptied and replaced with water for the *rougie.* When it is on the point of boiling, 5½ pounds of cochineal in fine powder are to be thrown in, and mixed with care; when the crust, which forms upon the surface, opens of itself in several places, 14 pounds of solution of tin (muriate of tin) are to be added. Should the liquor be likely to boil over the edges of the kettle, a little cold water is to be added. When the bath has become uniform, the cloth is to be put in, taking care to wince it briskly for two or three turns; then to boil it bodily for an hour, thrusting it under the liquor with a rod whenever it rises to the surface. It is lastly taken out, aired, washed at the river, and dried.

Below will be found the tables of the composition of the *bouillon* and the *rougie*.

M. Lenormand states that he has made experiments of verification upon all the formulæ of the following tables, and declares his conviction that the finest tint may be obtained by taking the *bouillon* of Scheffer, and the *rougie* No. 4 of Poërner.

Tables of the Composition of the Bouillon and Rougie for 100 *pounds of Cloth or Wool.*

Composition of the Bouillon.

M. Robiquet has given the following prescription for making a *printing scarlet*, for well-whitened woollen cloth. Boil a pound of pulverised cochineal in 4 pints of water down to 2 pints, and pass the decoction through a sieve. Repeat the boiling three times upon the residuum, mix the 8 pints of decoction, thicken them properly with 2 pounds of starch, and boil into a paste. Let it cool down to 104° F., then add 4 ounces of the solution of tin, and 2 ounces of ordinary muriate of tin. When a ponceau red is wanted, 2 ounces of pounded turmeric should be added.

A solution of chlorate of potassa is said to beautify scarlet cloth in a remarkable manner. See Lac Dye, Aniline, Murexide.

SCHEELE'S GREEN is a pulverulent arsenite of copper, which may be prepared as follows:—Form, first, an arsenite of potassa, by adding gradually 11 ounces of arsenious acid to 2 pounds of carbonate of potassa, dissolved in 10 pounds of boiling water; next, dissolve 2 pounds of crystallised sulphate of copper in 30 pounds of water; filter each solution, then pour the first progressively into the second, as long as it produces a rich grass-green precipitate. This being thrown upon a filter-cloth, and edulcorated with warm water, will afford 1 pound 6 ounces of this beautiful pigment. It consists of, oxide of copper 28·51, and of arsenious acid 71·46. This green is applied by an analogous double decomposition to cloth. See Calico-printing. Much discussion has arisen relative to the use of this salt in paper-hangings, it having been supposed by many persons to have produced ill effects on those exposed to the atmosphere of such rooms. Under Arsenic, this question has been discussed. The editor was then under an impression that Dr. Alfred S. Taylor supposed the arsenite of copper to escape from the paper by volatilisation. Dr. Taylor writes to correct this, —it is his impression that dust is mechanically removed; and from his own experience he advances no further than this.

SCHMELZE. A kind of glass prepared in Bohemia, chiefly for the purpose of receiving the red colour imparted by the oxide of gold. See Glass.

SCHWEINFURTH GREEN is a more beautiful and velvety pigment than the Scheele's green. It was discovered in 1814, by MM. Rusz and Sattler, at Schweinfurth, and remained for many years a profitable secret in their hands. M. Liebig having made its composition known in 1822, it has been since prepared in a great many colour-works. Braconnot published, about the same time, another process for manufacturing the same pigment. Its preparation is very simple, but its formation is accompanied with some interesting circumstances. On mixing equal parts of acetate of copper and arsenious acid, each in a boiling concentrated solution, a bulky olive-green precipitate is immediately produced; while much acetic acid is set free. The powder thus obtained, appears to be a compound of arsenious acid and oxide of copper, in a peculiar state; since when decomposed by sulphuric acid, no acetic odour is exhaled. Its colour is not changed by drying, by exposure to air, or by being heated in water. But, if it be boiled in the acidulous liquor from which it was precipitated, it soon changes its colour, as well as its state of aggregation, and forms a new deposit in the form of a dense granular beautiful green powder. As fine a colour is produced by ebullition during five or six minutes, as is obtained at the end of several hours by mixing the two boiling solutions, and allowing the whole to cool together. In the latter case, the precipitate, which is slight and flocky at first, becomes denser by degrees; it next betrays green spots, which progressively increase, till the mass grows altogether of a crystalline constitution, and of a still more beautiful tint than if formed by ebullition.

When cold water is added to the mixed solutions immediately after the precipitate takes place, the development of the colour is retarded, with the effect of making it much finer. The best mode of procedure is to add to the blended solutions their own bulk of cold water, and to fill a globe up to the neck with the mixture, in order to prevent the formation of any such pellicle on the surface, as might by falling to the bottom, excite premature crystallisation. Thus the reaction continues during two or three days with the happiest effect. The difference of tint produced by these variations arises merely from the different sizes of the crystalline particles: for when the several powders are levigated upon a porphyry slab to the same degree, they have the same shade. Schweinfurth green, according to M. Ehrmann's researches, in the 31st *Bulletin de la Societée Industrielle Mulhausen*, consists of oxide of copper 31·666, arsenious acid 58 699, acetic acid 10·294. Kastner has given the following prescription for making this pigment; — for 8 parts of arsenious acid, take from 9 to 10 of verdigris; diffuse the latter through water at 120° F., and pass the pap through a sieve; then mix it with the arsenical solution, and set the mixture aside, till the reaction of the ingredients shall produce the wished-for shade of colour. If a yellowish tint be desired, more arsenic must be used. By digesting Scheele's green in acetic acid, a variety of Schweinfurth green may be obtained.

Both of the above colours are rank poisons. The first was detected a few years ago, as the colouring matter of some Parisian *bonbons*, by the *conseil de salubrité;* since which the confectioners were prohibited from using it by the French government. The Prussian government have also enacted a law against the use of the arsenical greens in paper-hangings.

SCOPARINE. $C^{42}H^{22}O^{20}$ (?). A base found by Stenhous in the broom plant, *Spartium scoparium.*

SCOURING. This art is that which is employed for removing grease spots, &c., from clothes and furniture, which require skill beyond that of the laundry. It is divided into two distinct branches, viz. French and English cleaning. We will first give an outline of English cleaning, although the other (French) has no more to do with the French than the English, except in name; and that is kept because many people would not fancy the things were done properly if done by an English process.

Gentlemen's clothes, such as trowsers, coats, &c., are treated in the following manner. They are stretched on a board, and the spots of grease, &c., first taken out by rubbing the spots well with a brush and cold strong soap liquor; they are then done all over with the same, but the grease spots are done first, because they require more rubbing, of course, than the other parts, and when all the substance was wet they would not be so easily distinguished. After treatment with the strong soap liquor, the soap is worked by a weaker soap liquor; the articles are then well washed off with warm water, and treated with ammonia (*if black*), solution of common salt, or dilute acid, according to circumstances. They are then drained, beaten out with a little size, pressed and dried.

Ladies' articles of dress, as shawls, and woollen dresses.—The spots are first removed by rubbing them on the board with very strong soap liquor; they are then put into a strong soap liquor, and well worked about in it; then taken out and treated with a weaker soap liquor, to work out the soap, &c.; rinsed with warm and cold water alternately; treated with solution of common salt or very weak acid, to maintain the colours. They are starched, if necessary, and ironed. Woollen dresses that are taken to pieces are calendered instead of ironing.

Silk dresses, &c., are always taken to pieces, and each piece done separately, and as quickly as possible. If there are any spots of grease, they are taken out first, as above mentioned. Each piece, after the spots are removed, is immediately placed in a strong soap liquor, and well worked about in it, and then into a thinner soap liquor; well washed out with cold water, and treated with solution of common salt, or very weak acid, or both, as required; each piece is then neatly folded and wrung separately, again folded smoothly and placed in dry sheets, and pressed, so as to remove all dampness from them; they are then put into a frame, a little size or sugar and water used to stiffen and glaze; lastly, dried while on the frame by a charcoal fire.

Furniture, as curtains, &c.—These things are put into a tub, with a strong cold soap liquor, and well punched about with a large wooden punch made on purpose; and a great deal depends upon this being properly done. They are then treated in the same manner in a weaker soap liquor, well rinsed with water, treated with common salt or weak acid, as required, wrung out, and dried. Woollen furniture will generally require to be treated several times with the first strong soap liquor, to remove the dirt, but for cotton furniture once will be generally sufficient.

Carpets.—These are well beaten, then laid down on the floor of the dye-house, and *well* scrubbed with strong cold soap liquor, by means of a long-handled brush or broom; then treated with a weaker soap liquor; well rinsed with water, by throwing pails of water over them, and still rubbing with the brush; treated with water, to which a *very small quantity* of sulphuric acid has been added, to retain the colours; rinsed again, hung up to drain, and then hung up in a warm room to dry.

A great point in this kind of cleaning is to use *strong cold soap liquors;* and this cannot be done with ordinary soaps, as they congeal when cold, and on this account

Field's soap is the principal soap which is used, because it is made from oil and does not congeal, and I rather expect is made from the *olein* obtained in the manufacture of composite candles.

French cleaning is what is called *dry cleaning*. In this process the articles are put into camphine and worked about in it, drained, sheeted, and dried. The camphine dissolves the grease, &c., and does not injure the colours; but when things are very dirty, it does not clean so effectually as the English method. It is, however, the only process that can be employed in some cases, as in cleaning kid gloves.—H. K. B.

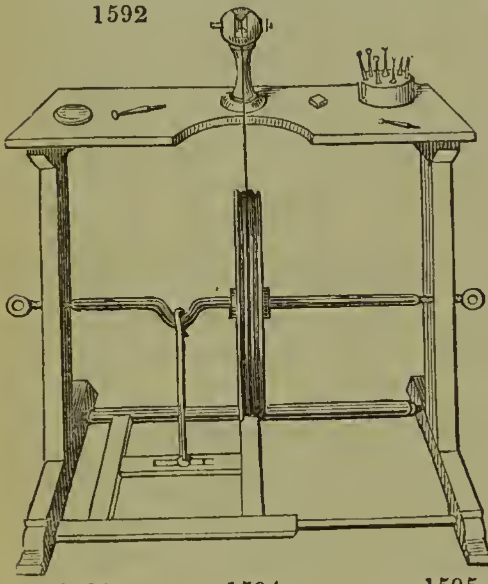
SCREWS. The elementary idea of the form of the screw is obtained by regarding it as a continuous circular wedge; and it is readily modelled by wrapping a wedge-formed piece of paper around a cylinder; the edge of the paper then represents the line of the screw.

The use of the screw is well known to all; and the system of cutting a rod of iron or steel into a screw scarcely requires any description. The manipulatory details and the tools used in their manufacture are admirably and most fully described in *Holtzapffel's Turning and Mechanical Manipulation.*

SEAL ENGRAVING. The art of *engraving gems* is one of extreme nicety. The stone having received its desired form from the lapidary, the engraver fixes it by cement to the end of a wooden handle, and then draws the outline of his subject, with a brass needle or a diamond, upon its smooth surface.

Fig. 1592 represents the whole of the seal engraver's lathe. It consists of a table on which is fixed the mill, a small horizontal cylinder of steel, into one of whose extremities the tool is inserted, and which is made to revolve by the usual fly-wheel, driven by a treddle. The tools that may be fitted to the mill-cylinder are the following: *fig.* 1593 a hollow cylinder, for describing circles, and for boring; *fig.* 1594 a knobbed tool, or rod terminated by a small ball; *fig.* 1595 a stem terminated with a cutting disc, whose edge may be either rounded, square, or sharp; being in the last case called a saw.

1592



1593 1594 1595

Having fixed the tool best adapted to his style of work in the mill, the artist applies to its cutting point, or edge, some diamond powder, mixed up with olive oil; and turning the wheel, he holds the stone against the tool, so as to produce the wished-for delineation and erosion. A similar apparatus is used for engraving on glass.

In order to give the highest degree of polish to the engraving, tools of boxwood, pewter, or copper, bedaubed with moistened tripoli or rotten-stone, and lastly, a brush, are fastened to the mill. These are worked like the above steel instruments. Modern engravings on precious stones have not in general the same fine polish as the ancient.

Several varieties of machine have been of late years introduced to facilitate the processes of engraving gems. Many of them involve the pentagraph, so that a seal may be engraved by the machine at once, either larger or smaller than the original from which it is copied. Most of these engraving machines are upon the principles described under CARVING BY MACHINERY.

SEAL; SEAL OIL; SEAL FISHERY. See OILS.

SEALING-WAX. (*Cire à cacheter*, Fr.; *Siegellack*, Germ.) The Hindoos from time immemorial have possessed the resin lac, and were long accustomed to use it for sealing manuscripts before it was known in Europe. It was first imported from the East into Venice, and then into Spain; in which country sealing-wax became the object of a considerable commerce, under the name of Spanish-wax.

If shell-lac be compounded into sealing-wax, immediately after it has been separated by fusion from the palest qualities of stick or seed lac, it then forms a better and less brittle article than when the shell-lac is fused a second time. Hence sealing-wax, rightly prepared in the East Indies, deserves a preference over what can be made in other countries, where the lac is not indigenous. Shellac can be restored in some degree, however, to a plastic and tenacious state by melting it with a very small portion of turpentine. The palest shell-lac is to be selected for bright-coloured sealing-wax, the dark kind being reserved for black.

The following proportions may be followed for making red sealing-wax :—Take 4 ounces of shell-lac, 1 ounce of Venice turpentine, and 3 ounces of vermilion. Melt the lac in a copper pan suspended over a clear charcoal fire, then pour the turpentine slowly into it, and soon afterwards add the vermilion, stirring briskly all the time of the mixture with a rod in either hand. In forming the round sticks of sealing-wax, a certain portion of the mass should be weighed while it is ductile, divided into the desired number of pieces, and then rolled out upon a warm marble slab, by means of a smooth wooden block, like that used by apothecaries for rolling a mass of pills. The oval sticks of sealing-wax are cast in moulds, with the above compound in a state of fusion. The marks of the lines of junction of the mould-box may be afterwards removed by holding the sticks over a clear fire, or passing them over a blue gas-flame. Marbled sealing-wax is made by mixing two, three, or more coloured kinds of it, while they are in a semi-fluid state. From the viscidity of the several masses, their incorporation is left incomplete, so as to produce the appearance of marbling. Gold sealing-wax is made simply by stirring gold-coloured mica spangles into the melted resins. Wax may be scented by introducing a little essential oil, essence of musk, or other perfume. If 1 part of balsam of Peru be melted along with 99 parts of the sealing-wax composition, an agreeable fragrance will be exhaled in the act of sealing with it. Either lamp black or ivory black serves for the colouring matter of black wax. Sealing-wax is often adulterated with rosin; in which case it runs into thin drops at the flame of a candle.

The following proportions are stated to form good sealing-wax : —

Red No. 1.— 4 oz. Venetian turpentine, 6 oz. shell-lac, ¾ oz. colophony, 1¾ oz. cinnabar, &c.

Red No. 2. — 4 oz. turpentine, 5½ oz. shell-lac, 1½ oz. colophony, 1¼ oz. cinnabar, magnesia to colour.

Fine Black — 4½ oz. Venetian turpentine, 9 oz. shell-lac, ½ oz. colophony, lamp-black mixed with oil of turpentine as much as is required.

Black — 4 oz. Venetian turpentine, 8 oz. shell-lac, 3 oz. colophony, lamp-black, and oil of turpentine.

Yellow — 2 oz. Venetian turpentine, 4 oz. shell-lac, 1¼ oz. colophony, ¾ oz. king's yellow.

Dark Brown — 4 oz. Venetian turpentine, 7½ oz. shell-lac, 1½ oz. brown English earth (ochre).

Light Brown — 4 oz. Venetian turpentine, 7½ oz. shell-lac, 1 oz. brown earth, ½ oz. cinnabar.

Dark Blue — 3 oz. Venetian turpentine, 7 oz. fine shell-lac, 1 oz. colophony, 1 oz. mineral blue.

Green — 2 oz. Venetian turpentine, 4 oz. shell-lac, 1¼ oz. colophony, ½ oz. king's yellow, ¼ oz. mountain blue.

Gold — 4 oz. Venetian turpentine, 8 oz. shell-lac, 14 sheets of genuine leaf gold, ½ oz. bronze, ½ oz. magnesia with oil of turpentine.

SEA WATER. The following has been given as the average composition of sea-water in 100 parts :—

Chloride of sodium	2·50
Chloride of magnesium	0·35
Sulphate of magnesia	0·58
Carbonates of lime and of magnesia	0·02
Sulphate of lime	0·01

Dr. John Davy informs us that carbonate of lime is chiefly found in sea-water near the coast. Dr. George Wilson proved the existence of fluorine in the waters of the German Ocean, and Foret Lammr obtained it from sea-water collected near Copenhagen; Malaguti and Durocher have detected silver in sea-salt, and Mr. Field has shown that the copper sheathing of ships separates silver, in the process of time, from the waters of the ocean.

Lead and copper have also been detected in sea-water, and in the ashes of some marine plants. These metals are said to exist in the sea-water in the form of chlorides, and to arise from the native sulphides of the metals by the action of the chlorine in the water (?). See Water, Distilled; Waters, Mineral.

SECRETAGE. A process in which mercury or some of its salts is employed to impart to the fur of animals the property of felting, which they did not previously possess. See Fur; Mercury.

SEGGAR, or SAGGER, is the cylindric or oval case of fire-clay, in which fine stoneware is enclosed while being baked in the kiln.

SELENITE. Hydrated sulphate of lime. See Alabaster and Gypsum.

SELENIUM, from Σελήνη, the moon, is a peculiar principle, discovered by Berzelius, in 1817. It occurs sparingly in combination with several metals, as lead, cobalt, copper, and quicksilver, in the Harz, at Tilkerode; with copper and silver (*Eukairite*) in Sweden, with tellurium and bismuth in Norway, with tellurium and gold in Siebenbürgen, in several copper and iron pyrites, and with sulphur in the volcanic products of the Lipari Islands. Selenium has been found likewise in a red sediment which forms upon the bottoms of the lead chambers in which oil of vitriol has been made from a peculiar pyrites, or pyritous sulphur. The extraction of selenium from that deposit is a very complex process.

Selenium, after being fused and slowly cooled, appears of a bluish-grey colour, with a glistening surfaec; but it is a reddish brown, and of metallic lustre when quickly cooled. It is brittle, not very hard, and has little tendency to assume the crystalline state. Selenium is dark-red in powder, and transparent, with a ruby cast, in thin scales. Its specific gravity is 4·30. It softens at the temperature of 176° F., is of a pasty consistency at 212°, becomes liquid at a somewhat higher heat, forming in close vessels dark-yellow vapours, which condense into black drops; but in the air the fumes have a cinnabar-red colour. See Ure's *Dictionary of Chemistry*.

SELTZER WATER. See SODA-WATER, and WATERS, MINERAL.

SEMOULE. The name given in France to denote the large hard grains of wheat flour retained in the bolting machine after the fine flour has been passed through its meshes. The best semoule is obtained from the wheat of the southern parts of Europe. With the semoule the fine white Parisian bread called *gruau* is baked. Skilful millers contrive to produce a great proportion of semoule from the large-grained wheat of Naples and Odessa.

Granular preparations of wheat deprived of bran are known in this country as *semolina*, *soujee*, and *manna-croup*.

SENEGAL GUM. This gum is produced from the *Acacia Senegal*, a tree or shrub found in Arabia and the interior of Africa. See ACACIA.

SEPIA is a pigment prepared from a black juice secreted by certain glands of the cuttle-fish, which the animal ejects to darken the water when it is pursued. One part of it is capable of making 1000 parts of water nearly opaque. All the varieties of this mollusca secrete the same juice; but the *Sepia officinalis*, the *Sepia ioligo*, and the *Sepia tunicata*, are chiefly sought after for making the pigment. The first, which occurs abundantly in the Mediterranean, affords most colour: the sac containing it being extracted, the juice is to be dried as quickly as possible, because it runs rapidly into putrefaction. Though insoluble in water, it is extremely diffusible through it, and is very slowly deposited. Caustic alkalies dissolve the sepia, and turn it brown; but in proportion as the alkali becomes carbonated by exposure to air, the sepia falls to the bottom of the vessel. Chlorine blanches it slowly. It consists of carbon in an extremely divided state, along with albumine, gelatine, and phosphate of lime.

The dried native sepia is prepared for the painter, by first triturating it with a little caustic lye, then adding more lye, boiling the liquid for half an hour, filtering, next saturating the alkali with an acid, separating the precipitate, washing it with water, and finally drying it with a gentle heat. The pigment is of a brown colour, and a fine grain.

SEPTARIA (from septum, *a division*), called anciently *ludus Helmontii* (the *quoits* of Van Helmont, from their form), are calcareous concretions intersected by veins of calc spar, which, when calcined and ground to powder, form an excellent hydraulic cement. See MORTAR, HYDRAULIC. They are calcareous mudstones, which appear to have accumulated around decomposing animal and vegetable matter; and the veins of calc spar are the resnlt of a subsequent infiltration of water holding lime in solution into the cracks which were caused by the shrinking of the mass, during the process of solidification.

From the regular arrangement of these cracks, which generally assume pentagonal forms, resembling in appearance the divisions in the shell of a tortoise, septaria have received the common name of turtle-stones or fossil tortoises. The turtle-stones found in the Oxford Clay at Weymouth, when cut into slabs and polished, form very handsome tables. The number of veins of calc spar, upon which their beauty depends, renders these turtle-stones unfit for forming an hydraulic cement, in consequence of their furnishing too great a quantity of lime when calcined. Septaria fit for furnishing cement are dredged in large quantities in Chichester harbour, and off the coast of Hampshire, and are also procured from Harwich, Sheppy, and several other places. A stratum of septarian stone, forming the Broad Bench on the coast of Dorsetshire, affords an excellent cement, and is largely quarried.—H. W. B.

SERPENTINE, is a mineral of the magnesian family, being a hydrated silicate of magnesia, composed of silicate 43·64, magnesia 43·35, water 13·01 = 100. Its colour is chiefly green, seldom of a uniform tint, but generally of several shades arranged in dotted, striped, and clouded delineations. For this reason it has received the name of serpentine (or ophiolite, from ophis, *a serpent*, and lithos, *stone*), from the fancied resemblance which it bears to the skin of a serpent, both in colour and in its spotted or mottled arrangement. Specific gravity, 2·5 to 2·6. It is slightly unctuous to the touch, sectile, and tough; and therefore easily cut into ornamental forms. It has been divided into precious or noble serpentine, comprising the purer translucent and massive varieties, with a rich olive-green colour, and common serpentine, or the opaque varieties, forming extensive rock masses, like those of the Lizard in Cornwall, of Anglesea, Portsoy in Banffshire, Unst and Fetlar in Shetland, and Zöblitz in Saxony.

Serpentine, though so soft as to be scratched by calcareous spar, and to be turned in the lathe, takes a good polish, and forms a very beautiful ornamental stone. At Zöblitz it has long been manufactured into a variety of articles, which find their way all over Germany; and within the last few years works have been established in Cornwall, where, by means of powerful machinery, it is made into columns, vases, chimney-pieces, and other ornamental articles. The serpentine of Portsoy is also a very beautiful stone, and was formerly exported for manufacturing into similar objects. The Cornish Serpentine and Steatite were also sent to Bristol in considerable quantities, where they were formerly, but are no longer, used in the manufacture of carbonate of magnesia. Serpentine is used with advantage for the backs of grates, the lining of stoves and furnaces, and the bottoms of bakers' ovens.—H. W. B.

SESAMUM OIL, or TEEL OIL. See Oils.

SEWING MACHINES. The history of these ingenious inventions has been so well told by Professor Willis, in his report on the machinery for woven fabrics of the Paris Exhibition, that we do not hesitate to borrow from it.

At the Paris Exhibition in 1854, fourteen exhibitors came provided with sewing machines. They were of different characters, and have been divided by Mr. Willis into four classes.

Under the first class came the machines in which the needle is passed completely through the stuff, as in hand working: "It is so natural, in the first attempts to make an automatic imitation of handiwork, that the imitation shall be a slavish one, that we need not be surprised to find the earlier machines contrived to grasp a common needle, push it through the stuff, and pull it out on the other side."

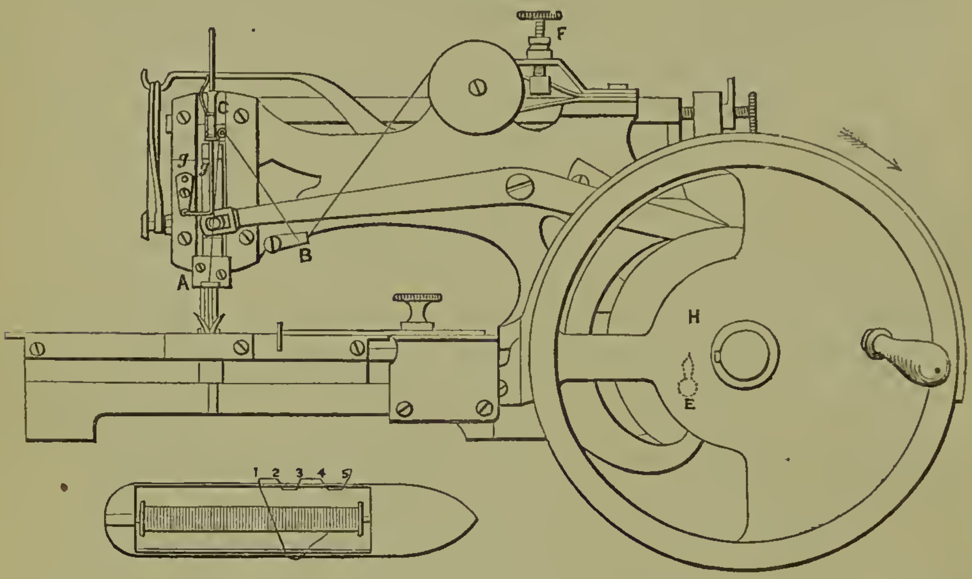
Thomas Stone and James Henderson, and some others, patented machines of this kind, which proved abortive. M. Heilmann exhibited an embroidering machine in 1834, in which "150, more or less, of needles are made to work simultaneously, and embroider each the same flower or device upon a piece of stuff or silk stretched in a frame and guided by a pentagraph." See Embroidering Machine. Several embroidering machines have been from time to time introduced.

The second class of sewing machine was that known as the chain-stitch, or "crochet." This is wrought by a so-called crochet needle, which terminates with a hook; the needle is grasped by the opposite end, and the hook pushed through the stuff, so as to catch hold of a thread below, and, being then withdrawn, brings with it a small loop of the thread; the hook of the needle retaining this loop is then repassed through the stuff at a short distance in advance of the former passage, catches a new loop, and is again withdrawn, bringing with it the second loop, which thus passes through the first. Such a series is called chain-stitch, and may be used either to connect two pieces together, or as an embroidery stitch, for which it is well adapted by its ornamental and braid-like appearance. M. Thimonnier patented in 1830 the first machine of this character. M. Magnin was associated with Thimonnier in 1848 in a patent for improvements, and in 1851 it was exhibited in London.

In 1849 Morey and Johnson patented a sewing machine in this country, in which a needle with an eye near the point, perpendicular to the cloth, was combined with a hooked instrument parallel to the cloth, for effecting the same purpose as the crochet needle. Mr. Singer improved on this, and he introduced a contrivance by which his machine forms a kind of knot at every eighth stitch.

The third class of sewing machines is wrought by two threads, and, as the stitch produced by them is known in America as the *mail-bag stitch*, it may be presumed it was employed by the makers of that article before the introduction of the machine. In the usual mechanical arrangement for its production, a vertical needle, having the eye very near the point, is constantly supplied with thread from a bobbin, and is carried by a bar, which is capable of an up-and-down motion. The cloth being placed below the needle, the latter descends, pierces it, and forms below it a small loop, with the thread carried down by its eye. A small shuttle, which has a horizontal motion beneath the cloth, is now caused to pass through this loop, carrying with it its own thread. The needle rises, but the loop is retained by the shuttle thread. The cloth being next advanced through the space of a stitch, the needle descends again, and a fresh loop is made. This process being repeated along the line of the seam, it results that the upper thread sends down a loop through such needle hole, and that the lower thread passes through all these loops, and thus secures the work. The first machine for producing this stitch was invented by Walter Hind, of New York, in 1834. Several patents for producing this stitch have been obtained. Howe's patent was one of the most practical. Mr. Thomas of London became the possessor of Howe's patent. This was improved; and a new patent obtained in June, 1846, which was modified in December of that year. This machine has been extensively used. This invention, says the patentee, consists in certain novel arrangements of machinery, whereby fabrics of various textures may be sewn together in such a manner as to produce a firm and lasting seam. By this invention a shuttle, when the point of the needle has entered the cloth or other fabric under operation and formed a loop of thread, passes through that loop and leaves a thread on the face of the cloth, by which means the needle when it is withdrawn from the cloth, instead of drawing back the thread with it, leaves a tightened loop on the opposite side of the cloth to that at which it entered. The fabric then passing forward to the distance of the length of the stitch required is again pierced with the needle, and a stitch is in like manner produced. A drawing of this machine is shown in *fig.* 1596, which will be understood from the following description.

1596



1. *The needle.* Place the needle in the slide A, with its flat side towards the shuttle, and the grooved side in front. Turn the wheel of the machine round till the line *g* on the gun-metal slide is level with the line *g* on the iron cheek. Place the *eye* of the needle level with the top of the shuttle box, and screw the needle fast.

2. If the eye is above the box when the marks correspond, the needle is too high; if the eye cannot be seen, the needle is too low.

The needle should pass down the centre of the hole in the shuttle box; but if it does not, it can be made to do so by bending.

4. *The needle thread* runs from the top of the reel, through the rings B, C, and through the eye of the needle.

5. *The shuttle.* It is necessary that the first coil of cotton be wound closely on the bobbin, or it will be difficult to make it lie side by side like that on ordinary reels. The reels should not be filled above the brass, and the cotton or silk should be free from knots, which sometimes pull the wire out of the shuttle.

6. The thread must run from the under side of the bobbin, round the wire and out through holes, Nos. 1, 2, and 3. If the thread is not tight enough, miss No. 3 and let it come out through Nos. 4 or 5, or it may be drawn through five holes. Put the shuttle in the box, turn the wheel round once, then pull the end of the needle thread and draw up the shuttle thread through the hole in the plate. Place the cloth under the mover, and the machine is ready for work. The proper time for turning the work to sew a corner, &c., is when the spring at the top is lifted off.

7. The length of stitch is regulated by the screw E at back of machine.

8. The tightness of the needle thread is regulated by the screw F.

9. The tightness of the shuttle thead is regulated by passing the thread through more or less holes.

11. The quantity of thread pulled off the reel for each stitch is regulated by the

position of the piece of brass B. The lower the hole at its end the greater the quantity pulled off: when the cloth is thick, more thread is used, and the end of the brass B should be lowered; when thin, raised. It should be in such a position that the trumpet C is drawn nearly down to the pin on the slide when the shuttle passes through the loop.

A patent was obtained by John Thomas Jones, of Glasgow, in February, 1859, for a sewing machine presenting many novelties and improvements. Mr. Jones's patent well explains his machine, we therefore transfer his description to our pages.

The machine consists, under one modification, of an open frame, having a platform top upon which the sewing or stitching operations are carried on. Beneath this platform, and near one end of it, is a short transverse horizontal first motion shaft running in bearings in the framing and carrying a long crank, a connecting rod from which is jointed at its opposite end, directly to the shuttle driver or slide piece, working in a horizontal guide recess beneath the opposite or front end of the platform or table. The first motion shaft has also another and shorter crank upon it, the stud pin of which is connected to the pin of the longer crank by an overhanging link piece, provision being made for the adjustment of the relative positions of the two cranks as regards their sequence of revolution. It is this shorter crank which actuates the needle movement, the pin being entered into a differentially slotted or operated cam piece, forming the pendent lower end of a bent lever, working on a stud centre, in the interior of the overhead bracket or pillar arm of the framing. The centre on which this lever works is in the horizontal part of the overhead bracket arm, and its opposite or free working end has a rectangular slot in it to embrace a rectangular block of metal working freely upon a lateral centre stud upon the vertical needle-carrying bar. In this way the needle has imparted to it a differential reciprocatory vertical movement, the peculiar connection of the needle bar with the actuating lever having the effect of marking the needle in the most accurate manner, and preventing jarring and wear. These are the whole of the primary movements for working the stitches, which may be of various kinds, as made up from the combined action of the needle and shuttle, or thread-carrier; the form of the slotted piece or operated cam in the end of the needle lever, being variable to suit any required peculiarity of needle movement, the main elements of which are a direct up-and-down motion without a stop or rest, until at the termination of the down stroke, when a short rise takes place, succeeded by a rest to allow of the due looping and stitching of the thread. The feed of the fabric to be sewed is effected by the operation of a short vertical lever piece with a cranked and slotted lower end, where it is set on a fixed stud in the framing. This feed lever has a roughened or toothed upper end, the teeth or asperities being set or inclined in the direction of the fabric's traverse. After each stitching action, the feed lever being lowered just beneath the operating level, is raised up so as to press firmly against the under side of the fabric, and nip it between the stationary spring pressed above. This elevation of the roughened face is effected by the traverse of the shuttle-carrier, which at its back stroke comes against the inclined tail of a short horizontal lever set on a stud in the framing, and having its opposite bent end bearing against the lower end of the feed lever, at the part where it is carried by its slot upon the holding stud. At the commencement of the return of the shuttle, an inclined piece upon the shuttle carrier bears against a lateral stud upon one end of a short rocking or oscillatory shaft set in bearings in the framing, the other end of the shaft having a lever arm bearing against the side of the feed lever. In this way the feed lever is traversed forward in its elevated position, carrying forward the fabric for the succeeding stitch. The adjustment of the spring presser is effected by an upper screw in the end of the bracket arm of the framing, the lower end of the screw bearing upon a lateral pressing piece which rests or abuts on the top end of a flattened helical spring upon the presser bar. The latter can be set up clear out of work by means of a small cam lever set on a stud in the stationary guide of the presser bar, the cam bearing against a lateral stud in the bar, so that by setting the lever up or down, the cam is correspondingly turned, and the lever set up or down, as required. The actual pressing or resisting foot of the bar is a bent piece of metal screwed on to the bar, and being thus removable to allow of various forms of feet guides, or presser surface pieces, being put on to suit varieties of forms of stitching.

This machine, or a modification of it, is available for working a duplex, or other stitching action without involving further modification of the prime movers. In working a duplex arrangement, two needles and two shuttles are used, each needle and shuttle working independently, so as to allow of sewing in two different and independent lines with one set of actuating parts. To aid the shuttle action there is attached to its side a flat curved blade spring, one end of which is free, but hooked into a hole in the body of the shuttle. Thus, as the shuttle traverses forward, the sewing thread is drawn beneath the hooked end portion of the spring, so as to be nipped against the shuttle. The thread is thus held, and the proper loop is secured at the part immediately outside the nipped portion. With this arrangement the needle can never work on the wrong side of the shuttle thread. Provision is also made for securing an independent shuttle thread controller. This is a nipper or retainer worked from any convenient part of the mechanism, but entirely independent of the shuttle movement. This may be arranged in various ways, the object being the variable and efficient control or retention of the thread, without interfering in any way with the fixed and determined action of the shuttle. Instead of fixing a horizontal shuttle race, or guide track, in the framing, the shuttle driver is itself made the race or carrier, so as to secure both offices in one detail or arrangement. A hook or finger, actuated by any convenient part of the movement, is also used for retaining the needle thread for any desired time after being passed through the fabric; this facilitates the movement or action of the needle bar. The shuttle race, when one is used, is made quite independent of the machine, so that it can be changed at any time to suit various sized shuttles by merely slipping in or taking out the part. The portion of the framing carrying the shuttle race is cast in one piece with the main body of the platform, but the table or plate on which the stitching takes place is a loose piece slotted down the middle for the working movements, and fitted into its position by pins cast upon it, and entered into corresponding recesses in the main base.

There exists a fourth class of sewing machines, which produce more complex stitches than the preceding. These are formed by sewing two threads, which mutually interlace each other in chain stitch, so as to avoid the unravelling to which the simple chain stitch is subject, and also are intended to meet an objection which is urged against the shuttle stitch machines, on the ground that, as the shuttle must be small to enable it to pass through the loop formed by the needle thread, so the bobbin carried by the shuttle can only obtain a moderate length of thread. Thus the operation is stopped at short intervals to supply fresh bobbins to the shuttle. Several patents have been obtained for compound chain stitch machines: two in America, in 1851 and 1852, by Grover and Baker; another in 1852 by Avery; and another by M. Journaux Le Blond.

Mr. Willis, in concluding his report, very justly remarks, "In England, as in France, all the most promising American patents have been repatented, and the use of the machine appears to be slowly and gradually extending itself. The sewing machine is doubtless yet in its infancy; but it has acquired so prominent a position, and shown itself to be so useful, as to deserve the time and attention of able mechanists. Its imperfections will therefore be, if possible, gradually removed, and it may take its place in the series of manufacturing mechanism as a most useful agent."

SHAFT, in *mining*, signifies a perpendicular or slightly inclined pit. See MINING.

SHAGREEN. (*Chagrin*, Fr. and Germ.) The true oriental shagreen is essentially different from all modifications of leather and parchment. It approaches the latter somewhat, indeed, in its nature, since it consists of a dried skin, not combined with any tanning or foreign matter whatever. Its distinguishing characteristic is having the grain or hair side covered over with small rough round specks or granulations.

It is prepared from the skins of horses, wild asses, and camels; of strips cut along the chine, from the neck towards the tail, apparently because this stronger and thicker portion of the skin is best adapted to the operations about to be described. These fillets are to be steeped in water till the epidermis becomes loose, and the hairs easily come away by the roots; after which they are to be stretched upon a board, and dressed with the currier's fleshing-knife. They must be kept continually moist, and extended by cords attached to their edges, with the flesh side uppermost upon the board. Each strip now resembles a wet bladder, and is to be stretched in an open square wooden frame by means of strings tied to its edges, till it be as smooth and tense as a drum-head. For this purpose it must be moistened and extended from time to time in the frame.

The grain or hair side of the moist strip of skin must next be sprinkled over with a kind of seed called *Allabuta*, which are to be forced into its surface either by tramping with the feet, or with a simple press, a piece of felt or other thick stuff being laid upon the seeds. The seeds belong probably to the *Chenapodium album*. They are lenticular, hard, of a shining black colour, farinaceous within, about the size of poppy seed, and are sometimes used to represent the eyes in wax figures.

The skin is exposed to dry in the shade, with the seeds indented into its surface; after which it is freed from them by shaking it, and beating upon its other side with a stick. The outside will be then horny, and pitted with small hollows corresponding to the shape and number of the seeds.

In order to make the next process intelligible, we must advert to another analogous and well-known operation. When we make impressions in fine-grained dry wood with steel punches or letters of any kind, then plane away the wood till we come to the level of the bottom of these impressions, afterwards steep the wood in water, the condensed or punched points will swell above the surface, and place the letters in relief. Snuff-boxes have been sometimes marked with prominent figures in this way. Now shagreen is treated in a similar manner.

The strip of skin is stretched in an inclined plane, with its upper edge attached to hooks and its under one loaded with weights, in which position it is thinned off with a proper semi-luna knife, but not so much as to touch the bottom of the seed-pits or depressions. By maceration in water, the skin is then made to swell, and the pits become prominent over the surface which had been shaved. The swelling is completed by steeping the strips in a warm solution of soda, after which they are cleansed by the action of salt brine, and then dyed.

In the East the following processes are pursued. Entirely white shagreen is obtained by imbuing the skin with a solution of alum, covering it with the dough made with Turkey wheat, and after a time washing this away with a solution of alum. The strips are now rubbed with grease or suet, to diminish their rigidity, then worked carefully in hot water, curried with a blunt knife, and afterwards dried. They are dyed red with decoction of cochineal or kermes, and green with fine copper filings and sal ammoniac, the solution of this salt being first applied, then the filings being strewed upon the skin, which must be rolled up and loaded with weights for some time; blue is given with indigo, quicklime, soda, and honey; and black, with galls and copperas.

Shagreen is also prepared from the skin of the shark.

SHALE, or SLATE-CLAY, is an important stratiform member of the coal-measures. See COAL.

SHAMOY, or CHAMOIS LEATHER. See LEATHER.

SHAWL MANUFACTURE. Shawls were originally, and still continue to be woven in the centre of India, from the fine silky wool of the Thibet goat; and the most precious of them still come from Cashmere. The wool is beautifully rich and soft to the touch, and is superior to the finest continental lamb's wool. It is also divisible into qualities. In the admirable report on this subject, in the *Jurors' Reports of the Great Exhibition*, it is remarked:—"The source from which this article has sprung is well known to be the ancient and beautiful fabric of the valley of Kashmir, where the excellence of the raw material stands to this day unrivalled, although its manufacture has been, and still is, carefully prosecuted in many parts of the world. The great beauty of the eastern tissue, considering the rudeness of the means of machinery employed, as compared with those which are now available to the European manufacturer, is a marvel in the eyes of the most experienced." The manufacture of shawls was first begun in this country, at Norwich, by Mr. Barrow and Alderman Watson, in 1784. They copied the Indian style, but the process was very slow, and the result consequently costly. Mr. John Harvey, of Norwich, followed up the enterprise with Piedmont silk warp and fine worsted shoot; but the designs were darned by hand. It was not until 1805 that a shawl was produced entirely by the loom at Norwich. In Paisley and Edinburgh the manufacture was introduced about the same time. At Paisley the manufacture is still continued, especially the manufacture of shawls of the Indian pattern, from real Kashmir wool. In 1802, a manufacture of shaws was commenced in Paris, and this led Jacquard to the invention of his loom (see JACQUARD LOOM), with which now all kinds of shawls are woven. For the mode of manufacture, the respective articles, SILK, TEXTILE FABRICS, and WEAVING will be sufficiently descriptive.

The varieties of shawls produced may be grouped as follows:—

Woven shawls of India, or of Indian style, made in Europe.

Barége shawls, made of wool, an imitation of shawls made in the Pyrenees, by the peasantry of a place so called.

Crape shawls, made of silk, in imitation of the Chinese fabrics.

Grenadines, made of silk of a peculiar twist.

Levantines and Albanians, made of silk and spun silk, to resemble the scarves worn in the Levant and Albania.

Chenille shawls; a novel application of silk, frequently combined with cotton.

Chiné shawls; a printed warp before weaving.

Woollen shawls; ordinary kinds.

Tartan plaids. The manufacture of these appears to be very ancient. In 1570, an ancient Scottish manuscript gives a list of the colours of the plaids worn by the different clans. In 1747, the weaving of this distinctive dress was prohibited by Act of Parliament, and the grey shepherd's mauds were made instead. In 1782, this Act was repealed; but tartans did not become fashionable until the visit of George IV. to Scotland, in 1822; after which, the Stirling fancy plaids began to be made. In 1828, clan tartan shawls became fashionable, and the Galashiels weavers took up the trade. Paisley commenced to weave these shawls about eighteen years since, and it has since then extended to many other parts, both at home and in other countries.

SHEATHING OF SHIPS. For this purpose many different metals and metallic alloys have been lately proposed. From a train of researches made by Dr. Ure for an eminent copper company, a few years ago, upon various specimens of sheathing which had been exposed upon ships during many voyages, it appeared that copper containing a minute, but definite proportion of tin, was by far the most durable.

The process of coppering vessels, which has of late years been generally adopted in order to protect their bottoms from the injurious effects of insects in hot countries, and prevent the adherence of barnacles, &c., which greatly impede the progress of the vessels, had been open to many objections; for not only was the prime cost of the material very great, but the expense of rolling it into sheets, and the frequent renewal of parts which had been injured during the voyage, made this copper covering a serious item in the expenses attendant upon fitting out ships.

In order to make this application of copper still more general, Sir Humphry Davy turned his attention to the subject, and endeavoured to devise some method of counteracting the rapid oxidation which took place on its exposure to the sea water, as it was rare for the copper bottom of a ship to last longer than five or six years. Experiment proved to Sir H. Davy that if a portion of zinc were applied to the copper it would by its electrical relations prevent the process of oxidation in the copper. A vessel sheathed with copper and zinc plates was accordingly sent a voyage to a distant part of the world, from whence it returned with its copper perfectly uninjured by the salt water, but in as foul a state as if there had been no sheathing upon the bottom of the vessel. The presence of the zinc had prevented the oxidation of the copper which was necessary to resist the marine deposit. The problem, therefore, still remained to be solved, whether any metallic composition could be found for the sheathing of ships capable of preventing the bottom from fouling, and at the same time resisting the process of oxidation. To the solution of this problem Mr. Muntz, who was a metal-roller at Birmingham, directed his attention, and commenced a series of experiments, which resulted in his taking out a patent in 1832. This invention, slowly, but steadily, attracted the notice of the shipping interest of the country, and it appeared that in 1834, in the port of London, twenty ships were sheathed with metal prepared by Muntz's patent process. The number gradually increased, until in 1843 there were in the same port 257 vessels sheathed with the new composition. The improved metal sheathing was a mixture of copper and zinc, which was cheaper than copper, more easily worked, and lasted longer than the pure metal. In the specification of Mr. Muntz's patent, the nature of his invention is thus described: — "I take that quality of copper known to the trade by the appellation of 'best selected copper,' and that quality of zinc known in England as 'foreign zinc,' and melt them together in the usual manner, in any proportions between 50 per cent. of copper to 50 per cent. of zinc, and 63 per cent. of copper to 37 per cent. of zinc, both of which extremes, and all intermediate proportions, will roll at a red heat; but, as too large a proportion of copper increases the difficulty of working the metal, and too large a proportion of zinc renders the metal too hard when cold, and not sufficiently liable to oxidation, I prefer the alloy to consist of about 60 per cent. of copper to 40 per cent. of zinc." See ALLOYS.

Various preparations have been introduced for the purpose of coating the sheating on the bottoms of ships; amongst others that of Mr. Peacock appears to be highly approved of by shipowners. The secret of all of them is the presence of a metallic oxide which is offensive to both the vegetable and animal organisms.

SHELLS. Hollow projectiles filled with combustible materials. See ARTILLERY.

SHERRY WINE. See WINE.

SHIFT. *A miners' term*, used in Alston Moor and the Northern mines. A *shift* is the quantity of lead ore contained in six or eight waggons, and amounts to about 240 kibbles of 14 quarts each; each waggon in a six-waggon "shift" contains 40 such kibbles; while in an eight-waggon "shift" each waggon contains only 30 kibbles.

SHINGLING. Condensing the iron bloom by heavy hammers. See IRON.

SHODDY, properly so called, is the refuse of the willowing and scribbling process in the preparation of mungo and wool, and is sold in large quantities for manure.

SHODEING. *Shodes* (from the Teutonic word *shutten*, to pour forth) are loose stones; applied to such as are of a mineral character. Shodeing, is tracing those loose stones from the valley in which they may be found to the mineral lode from which they have been removed. In this manner many mineral lodes are discovered.

SIENITE, or SYENITE, is a granular aggregated compound rock, consisting of felspar and hornblende, sometimes mixed with a little quartz and mica. It takes its name from the city of Syene, in the Thebaid, near the cataracts of the Nile, where this rock abounds. It is an excellent building-stone, and was imported in large quantities from Egypt by the Romans, for the architectural and statuary decorations of their capital. Hornblende is the characteristic ingredient, and serves to distinquish sienite from granite, with which it has been sometimes confounded; though the felspar, which is red, is the more abundant constituent. The Egyptian Sienite, containing but little hornblende, with a good deal of quartz and mica, approaches most nearly to granite. It is equally metalliferous with porphyry; in the island of Cyprus, it is rich in copper; and in Hungary, it contains many valuable gold and silver mines. Sienite forms a considerable part of the Criffle, a hill in Galloway. The so called granites of Leicestershire more nearly approach sienites. A careful study of the rocks of the Grooby, Markham, and Bardon Hill quarries, will show a gradual change of the granitic rock through sienite, into a green stone porphyry. This stone is extensively used in the metropolis and other large towns for "pitching" and paving.

SIENNA. Clay coloured by the peroxide of iron and manganese. It is known as raw and burnt Sienna, according to the treatment it has received. It is a good artists' colour.

SILESIAN LINENS. See FLAX and LINEN.

SILEX. Quartz, pure flint.

SILICA. SILICIC ACID. SiO^3. This substance exists nearly pure in rock crystal, chalcedony, opal, agate, and many other minerals; and it is an important constituent of a very large class.

It may be obtained perfectly pure by precipitation from any of its combinations. Silicic acid forms a class of salts termed silicates, which are generally formed by fusing silicic acid with the bases. Those silicates in which the acid predominates are insoluble in water, and constitute the different varieties of glass. See GLASS.

If soluble silica is ignited it is no longer soluble. This and several other peculiarities prove that silica exists in two states.—See *Ure's Dictionary of Chemistry*.

Some curious natural deposits of silica are found in nature. Way has lately discovered at Farnham large deposits of silica, in the condition in which it is readily soluble in hot solutions of caustic potash, or soda. These beds are situated at the base of the chalk formations, between the Upper Green Sand and the Gault Clay. Mr. Way proposes to employ those beds as a convenient source of silicate of lime for agricultural purposes. He found that a mixture of slaked lime with the powdered rock, when made into a thin paste and left for some weeks, is entirely converted into silicate of lime. The action is promoted by the presence of 2 or 3 per cent. of carbonate of soda; the latter appearing to act as the carrier between the silica and the lime. Similar deposits had been previously found by Sauvage in the *Départment des Ardennes*.

Siliceous deposits are often formed from warm springs. In the Island of Terceira a deposit of this kind contains 77·05 of silicic acid. The hot springs of New Zealand deposit a crust containing 75 of silica; and some springs in the Azores leave precipitated a stratum containing 67·6 of silica.

The Dinnas sand, Glamorganshire, is remarkable. Some samples are actually pure silica, and most of it gives 91·95 of silicic acid; the sand of Penderyn, in the same county, giving 94·05 silica. A similar deposit is found near Landudno, in North Wales. See STONE, ARTIFICIAL.

SILICATES. Compounds of silicic acid (*silica*, *oxide of silicon* or *silicium*), with earthy, alkaline, or metallic bases. In mineralogical arrangements these have been divided into *anhydrous silicates*, which include, as Dana classifies them, the *augite* section, the *garnet* section, the *mica* section, the *felspar* section, and some others; and the *hydrous silicates*, which include the *talc* section, the *serpentine* section, the *chlorite* section, the *calamine* section, the *datholite*, and others.

An interesting paper on hydraulic cements has been submitted to the Academy of Sciences by M. F. Kuhlmann, showing the advantage that may be derived from the combination of silicates with mortars and cements in general, and especially with those that are intended to resist the action of sea water. It is well known that the first effect of water on cements is that of forming hydrates; after which a gradual contraction takes place, producing a degree of hardness, which increases in proportion as the contraction is slower, and there is more silex or alumina in the cement. Now, M. Kuhlmann has observed that if alumina or its silicate, or else magnesia, whether caustic or carbonated, be kneaded into a paste with a solution of silicate of potash or soda, the compounds resulting therefrom will bear a perfect resemblance to the natural silicates, such as felspar, talcose slate, magnesite, &c., and will, by repose and slow contraction, become hard and semi-transparent, resisting in a high degree the erosive effects of water. If slaked lime be added to the said compounds they acquire the properties of hydraulic cements. M. Vicat, junr., having shown that calcined magnesia added to a cement would resist the action of sulphate of magnesia, M. Kuhlmann has endeavoured to turn this observation to account, by mixing calcined dolomites (which contain magnesia) with mortar, containing the alkaline silicates. This composition he finds very advantageous, since most of the salts contained in sea water must contribute towards the preservation of such cements. In fact, the chloride of magnesium, as well as the sulphate of magnesia, will be decomposed and form a layer of silicate of magnesia on the surface of the cement; in the same manner, the sulphate of lime must, being in contact with the silicate of potash or soda, form a silicate of lime; and all these silicates strongly resist the action of sea water. As for sea salt, which is a chloride of sodium, M. Kuhlmann proves that, in the proportion in which it exists in sea water, it will slowly decompose the silicate of potash contained in the cement and leave the silex free. The compositions proposed have therefore the singular property, not only of resisting the action of sea water, but of actually becoming more insoluble the longer they are in contact with it. A cement composed of 30 parts of rich lime, 50 of sand, 15 of uncalcined clay, and 5 of powdered silicate of potash, is recommended by M. Kuhlmann as having all the requisite hydraulic properties, especially for cisterns intended for spring water. In marine constructions care should be taken to add an excess of silicate to those portions of cement which are exposed to the immediate contact of the sea.

SILICATISATION. The process of impregnating bodies with silica. See Stone, Artificial; and Stone, Preserving.

SILICON, or SILICIUM. The base of silica or flint. It was first obtained by Berzelius in 1823. Silicon is obtained by heating the double fluoride of potassium and silicon with sufficient potassium to combine with the whole of the fluorine, and afterwards washing the mass with cold water, until no alkaline reaction is observable, then boiling with water to decompose any of the double fluoride which may not have been acted upon, and finally washing the silicon perfectly with hot water.

Silicon is a dark brown powder, heavier than water, infusible before the blowpipe, non-volatile, increasing in density when considerably heated. Silicon, boron, and carbon exhibit great similarity.

SILK MANUFACTURE. (*Fabrique de soie*, Fr.; *Seidenfabrik*, Germ.) This may be divided into two branches: 1. the production of raw silk; 2. its filature and preparation in the mill, for the purposes of the weaver. The threads, as spun by the silk-worm, and wound up in its cocoon, are all twins, in consequence of the twin orifice in the nose of the insect through which they are projected. These two threads are laid parallel to each other, and are glued more or less evenly together by a kind of glossy varnish, which also envelopes them, constituting nearly 25 per cent. of their weight. Each ultimate filament measures about $\frac{1}{2000}$ of an inch in average fine silk, and the pair measures of course fully $\frac{1}{1000}$ of an inch. In the raw silk, as imported from Italy, France, China, &c., several of these twin filaments are slightly twisted and agglutinated to form one thread, called single.

The specific gravity of silk is 1·300, water being 1·000. It is by far the most tenacious or the strongest of all textile fibres, a thread of it of a certain diameter being nearly three times stronger than a thread of flax, and twice stronger than hemp. Some varieties of silk are perfectly white, but the general colour in the native state is a golden yellow.

The production of silk was unknown in Europe till the sixth century, when two monks, who brought some eggs of the silkworm from China or India to Constantinople, were encouraged to breed the insect, and cultivate its cocoons, by the Emperor Justinian. Several silk manufactures were in consequence established in Athens, Thebes, and Corinth, not only for rearing the worm upon mulberry-leaves, but for unwinding its cocoons, for twisting their filaments into stronger threads, and weaving these into robes. The Venetians having then and long afterwards intimate commercial relations with the Greek empire, supplied the whole of western Europe with silk goods, and derived great riches from the trade.

About 1130, Roger II., king of Sicily, set up a silk manufacture at Palermo, and another in Calabria, conducted by artisans whom he had seized and carried off as prisoners of war in his expedition to the Holy Land. From these countries, the silk industry soon spread throughout Italy. It seems to have been introduced into Spain at a very early period, by the Moors, particularly in Murcia, Cordova, and Granada. The last town, indeed, possesses a flourishing silk trade when it was taken by Ferdinand in the 15th century. The French having been supplied with workmen from Milan, commenced, in 1521, the silk manufacture; but it was not till 1564 that they began successfully to produce the silk itself, when Traucat, a working-gardener at

Nismes, formed the first nursery of white mulberry-trees, and with such success, that in a few years he was enabled to propagate them over many of the southern provinces of France. Prior to this time, some French noblemen on their return from the conquest of Naples, had introduced a few silkworms with the mulberry into Dauphiny; but the business had not prospered in their hands. The mulberry plantations were greatly encouraged by Henry IV.; and since then they have been the source of most beneficial employment to the French people. James I. was most solicitous to introduce the breeding of silkworms into England, and in a speech from the throne he earnestly recommended his subjects to plant mulberry-trees; but he totally failed in the project. This country does not seem to be well adapted for this species of husbandry, on account of the great prevalence of blighting east winds during the months of April and May, when the worms require a plentiful supply of mulberry-leaves. The manufacture of silk goods, however, made great progress during that king's peaceful and pompous reign. In 1629 it had become so considerable in London that the silk-throwsters of the city and suburbs were formed into a public corporation. So early as 1661 they employed 40,000 persons. The revocation of the edict of Nantes, in 1685, contributed in a remarkable manner to the increase of the English silk trade, by the influx of a large colony of skilful French weavers, who settled in Spitalfields. The great silk-throwing mill mounted at Derby, in 1719, also served to promote the extension of this branch of manufacture; for soon afterwards, in the year 1730, the English silk goods bore a higher price in Italy than those made by the Italians, according to the testimony of Keysler.

The silkworm, called by entomologists *Phalæna bombyx mori*, is, like its kindred species, subject to four metamorphoses. The egg, fostered by the genial warmth of spring, sends forth a caterpillar, which, in its progressive enlargement, casts its skin either three or four times, according to the variety of the insect. Having acquired its full size in the course of 25 or 30 days, and ceasing to eat during the remainder of its life, it begins to discharge a viscid secretion, in the form of pulpy twin filaments, from its nose, which harden in the air. These threads are instinctively coiled into an ovoid nest round itself, called a cocoon, which serves as a defence against living enemies and changes of temperature. Here it soon changes into the chrysalis or nymph state, in which it lies swaddled, as it were, for about 15 or 20 days. Then it bursts its cearments, and comes forth furnished with appropriate wings, antennæ, and feet, for living in its new element, the atmosphere. The male and the female moths couple together at this time, and terminate their union by a speedy death, their whole existence being limited to two months. The cocoons are completly formed in the course of three or four days; the finest being reserved as seed worms. From these cocoons, after an interval of 18 or 20 days, the moth makes its appearance, perforating its tomb by knocking with its head against one end of the cocoon, after softening it with saliva, and thus rendering the filaments more easily torn asunder by its claws. Such moths or aurelias are collected and placed upon a piece of soft cloth, where they couple and lay their eggs.

The eggs, or grains as they are usually termed, are enveloped in a liquid which causes them to adhere to the piece of cloth or paper on which the female lays them. From this glue they are readily freed, by dipping them in cold water, and wiping them dry. They are best preserved in the *ovum* state at a temperature of about 55° F. If the heat of spring advances rapidly in April, it must not be suffered to act on the eggs, otherwise it might hatch the caterpillars long before the mulberry has sent forth its leaves to nourish them. Another reason for keeping back their incubation is, that they may be hatched together in large broods, and not by small numbers in succession. The eggs are made up into small packets, of an ounce, or somewhat more, which in the south of France are generally attached to the girdles of the women during the day, and placed under their pillows at night. They are, of course, carefully examined from time to time. In large establishments, they are placed in an appropriate stove-room, where they are exposed to a temperature gradually increased till it reaches the 86th degree of Fahrenheit's scale, which temperature it must not exceed. Aided by this heat, nature completes her mysterious work of incubation in eight or ten days. The teeming eggs are now covered with a sheet of paper pierced with numerous holes, about one-twelfth of an inch in diameter. Through these apertures the new-hatched worms creep upwards instinctively, to get at the tender mulberry leaves strewed over the paper.

The nursery where the worms are reared, is called by the French a *magnanière*; it ought to be a well-aired chamber, free from damp, excess of cold or heat, rats and other vermin. It should be ventilated occasionally, to purify the atmosphere from the noisome emanations produced by the excrements of the caterpillars and the decayed leaves. The scaffolding of the wicker-work shelves should be substantial; and they should be from 15 to 18 inches apart. A separate small apartment should be allotted to the sickly worms. Immediately before each moulting, the appetite of the worms begins to flag; it ceases altogether at that period of cutaneous metamorphosis, but revives speedily after the skin is fairly cast, because the internal parts of the animal are thereby allowed freely to develope themselves. At the end of the second age, the worms are half an inch long; and should then be transferred from the small room in which they were first hatched, into the proper apartment where they are to be brought to maturity and set to spin their balls. On occasion of changing their abode, they must be well cleansed from the litter, laid upon beds of fresh leaves, and supplied with an abundance of food every six hours in succession. In shifting their bed, a piece of network being laid over the wicker plates, and covered with leaves, the worms will creep up over them; when they may be transferred in a body upon the net. The litter, as well as the sickly worms, may thus be readily removed, without handling a single healthy one. After the third age, they may be fed with entire leaves; because they are now exceedingly voracious, and must not be subsequently stinted in their diet. The exposure of chloride of lime, spread thin upon plates, to the air of the *magnanière*, has been found useful in counteracting the tendency which sometimes appears of an epidemic disease among the silkworms, from the fetid exhalations of the dead and dying.

When they have ceased to eat, either in the fourth or fifth age, according to the variety of the *bombyx*, and when they display the spinning instinct by crawling up among the twigs of heath, &c., they are not long in beginning to construct their cocoons, by throwing the thread in different directions, so as to form the floss, *filoselle*, or outer open network, which constitutes the *bourre* or silk for carding and spinning.

The cocoons destined for filature, must not be allowed to remain for many days with the worms alive within them; for should the chrysalis have leisure to grow mature or come out, the filaments at one end would be cut through, and thus lose almost all their value. It is therefore necessary to extinguish the life of the animal by heat, which is done either by exposing the cocoons for a few days to sunshine, by placing them in a hot oven, or in the steam of boiling water. A heat of 202° F. is sufficient for effecting this purpose, and it may be best administered by plunging tin cases filled with the cocoons into water heated to that pitch.

80 pounds French (88 Eng.) of cocoons, are the average produce from one ounce of eggs, or 100 from an ounce and a quarter; but M. Folzer of Alsace obtained no less than 165 pounds. The silk obtained from a cocoon is from 750 to 1150 feet long. The varnish by which the coils are glued slightly together, is soluble in warm water.

The silk husbandry, as it may be called, is completed in France within six weeks from the end of April, and thus affords the most rapid of agricultural returns, requiring merely the advance of a little capital for the purchase of the leaf. In buying up cocoons, and in the filature, indeed, capital may be often laid out to great advantage. The most hazardous period in the process of breeding the worms, is at the third and fourth moulting; for upon the sixth day of the third age, and the seventh day of the fourth, they in general eat nothing at all. On the first day of the fourth age, the worms proceeding from one ounce of eggs will, according to Bonafons, consume upon an average twenty-three pounds and a quarter of mulberry leaves; on the first of the fifth age, they will consume forty-two pounds; on the sixth day of the same age, they acquire their maximum voracity, devouring no less than 223 pounds. From this date their appetite continually decreases, till on the tenth day of this age they consume only fifty-six pounds. The space which they occupy upon the wicker tables, being at their birth only nine feet square, becomes eventually 239 feet. In general, the more food they consume the more silk will they produce.

A mulberry-tree is valued, in Provence, at from 6*d.* to 10*d.*; it is planted out of the nursery at four years of age; it is begun to be stripped in the fifth year, and affords an increasing crop of leaves till the twentieth. It yields from 1 cwt. to 30 cwt. of leaves, according to its magnitude and mode of cultivation. One ounce of silkworm eggs is worth in France about 2½ francs; it requires for its due development into cocoons about 15 cwt. of mulberry leaves, which cost upon an average 3 francs per cwt. in a favourable season. One ounce of eggs is calculated, as I have said, to produce from 80 to 100 pounds of cocoons, of the value of 1 fr. 25 centimes per pound, or 125 francs in the whole. About 8 pounds of reeled raw silk, worth 18 francs a pound, are obtained from these 100 pounds of cocoons.

There are three denominations of raw silk; viz., organzine, *trame* (shute or tram), and floss. Organzine serves for the warp of the best silk stuffs, and is considerably twisted; tram is made usually from inferior silk, and is very slightly twisted, in order that it may spread more, and cover better in the weft; floss, or *bourre*, consists of the shorter broken silk, which is carded and spun like cotton. Organzine and trame may contain from 3 to 30 twin filaments of the worm; the former possesses a double twist, the component filaments being first twisted in one direction, and the compound thread in the opposite; the latter receives merely a slender single twist. Each twin filament gradually diminishes in thickness and strength, from the surface of the cocoon, where the animal begins its work in a state of vigour, to the centre, where it finishes it, in a state of debility and exhaustion; because it can receive no food from the moment of its beginning to spin by spouting forth its silky substance. The winder is attentive to this progressive attenuation, and introduces the commencement of some cocoons to compensate for the termination of others. The quality of raw silk depends, therefore, very much upon the skill and care bestowed upon its filature.

The quality of the raw silk is determined by first winding off 400 ells of it, equal to 475 metres, round a drum one ell in circumference, and then weighing that length. The weight is expressed in grains, 24 of which constitute one denier; 24 deniers constitute one ounce; and 16 ounces make one pound, *poids de marc*. This is the Lyons rule for valuing silk. The weight of a thread of raw silk 400 ells long, is two grains and a half, when five twin filaments have been reeled and associated together.

Raw silk is so absorbent of moisture, that it may be increased ten per cent. in weight by this means. This property has led to falsifications; which are detected by enclosing weighed portions of the suspected silk in a wire-cloth cage, and exposing it to a stove-heat of about 78° F. for 24 hours, with a current of air. The loss of weight which it thereby undergoes, demonstrates the amount of the fraud. There is an office in Lyons called the *Condition*, where this assay is made, and by the report of which the silk is bought and sold. The law of France requires, that all the silk tried by the *Condition* must be worked up into fabrics in that country.

Switzerland. There are silk-stuff factories in the canton of Bâle: but the trade of this town lies in the manufacture of silk ribbons. In this and the neighbouring canton of Bâle-Champagne there are about 4,000 looms, which give employment to 16,000 workmen as weavers, dyers, &c. Manual labour is extremely cheap, enabling the manufacturer to sell at a very low rate. The principal part of the manufacturers of this canton employ their own capital, and have not to surmount those difficulties and disadvantages inseparable from the employment of borrowed capital. The medium annual produce of the manufactures of Bâle is about 20,000,000 of francs, part of which is imported into most European countries, America, and the colonies. The principal articles of manufacture are plain taffeta, ribbons, plain satin, and figured ribbons: in all these articles, Bâle mantains an incontestable superiority.

The silk trade in Switzerland has grown and prospered without the aid of protective duties, and it is a remarkable fact that the difficulties occasioned by the high prohibitive customs, instead of being prejudicial, have been of advantage, by increasing the active genius and emulation of the manufacturers, and inducing them to seek more distant and more favourable outlets for their goods. The morality, activity, and commercial knowledge of the Swiss may be considered the basis of their success in this most important branch of trade.

The production of silk is conducted on the most important scale in the Lombardo-Venetian States; next in order of importance comes the Tyrol: the same business is also carried on in the military frontier, Görz and Gradiska, and also in Istria and Trieste, in Dalmatia and south of Hungary. Trials have likewise been made in Lower Austria, Bohemia, and Carniola. The productions of cocoons amount on an average annually,

In Lombardy	to 250,000 cwt.
In Venice	200,000
The Tyrol	28,000
The other provinces	12,000
Total	490,000 cwt.

Or, in round numbers, 500,000 cwt.

The cocoons are prepared at the reeling establishment into raw silk. From the result of inquiries, it would appear that Lombardy comprises 3,060 reeling establishments, which employ 79,500 workpeople, without taking into calculation the smaller establishments, which are not included in this enumeration. The entire production amounts to 2,512,000 Vienna lbs.; and since 12 lbs. of cocoons yield 1 lb. of raw silk there are required for this aggregate of raw silk 300,400 cwt. of cocoons. The quantity of cocoons required in excess of the quantity produced, an excess of nearly 50,000 cwt., is covered by the production of the Venetian provinces, chiefly by that of Verona.

Within the province of Venice, the reeling establishments are pretty numerous, but of less extent. The nearest approximation in reference to this matter is obtained by taking the extent of the production at one-half of that in Lombardy. The remainder of the cocoons produced in the province undergo further preparation in Lombardy, and partly in the Tyrol also, whilst a portion of those obtained in Görz and Gradiska, as well as in Istria, are prepared in Venetian reeling establishments.

The number and the performance of the reeling machines in the Tyrol are accurately known. In the year 1848 South Tyrol contained 559 of such reeling establishments. These employed 13,000 hands, and turned out 265,700 lbs. of raw silk from 31,900 Vienna cwt. of cocoons. The supply of cocoons required beyond that furnished by the production of the country was drawn from the Venetian provinces.

The reeling establishments in the remaining provinces produce conjointly from 10,000 cwt. of cocoons 75,000 Vienna lbs. of raw silk.

The whole production of raw silk obtained in the Austrian monarchy is about 4,108,700, and the waste about 716,400 lbs. The number of working hands employed in the reeling establishments is not less than 160,000 (or if their term of occupation be reduced to 270 days in the year, 30,000 only). Besides the products already enumerated, about 900 cwt. of cocoons are annually imported into Lombardy, principally from Switzerland and the neighbouring Italian States, and are prepared in the Lombardy reeling establishments. The quantity of silk produced is thus increased to an aggregate of 4,116,200 lbs.

The raw silk undergoes further preparation in the throwing mills, but the whole mass of the production is not thus worked up within the monarchy, for the exports of raw silk are found considerably to exceed the imports. On an average of the five years 1843 to 1847, the annual imports with Austria were 110,000 Vienna lbs. of raw silk (through Venice, Switzerland, and the adjacent Italian States), whilst 70,000 lbs. of this commodity were exported, for the most part to Switzerland, the adjacent, states of Italy, and Southern Germany. Hence it results that a balance of raw silk, amounting to 589.000 lbs., have been taken off by foreign consumption, and that the other 3,518,800 Vienna lbs. are retained by the Austrian monarchy, and more than two-thirds thereof are worked up in Lombardy. In 1817, that province reckoned 500 throwing mills, with 1,239,000 spindles; and of these 702,100 were for spinning, and 507,209 for twisting. In the throwing mills themselves, 12,000 hands were employed (namely. 4,400 men, 5,500 women, and 2.100 children), and, moreover, there were occupied 31,800 female winders. The production yielded was 989,000 Vienna lbs. of tram, and 1,189,700 lbs. of thrown silk; for this aggregate of production 2,256,200 lbs. of raw silk were used. The floss silk was to the weight of 76,000 lbs.

The working of the throwing mills of Venice produced, in proportion to those of Lombardy, almost similar results to those above indicated in reference to the reeling establishments; only the production of tram greatly preponderates. The number of persons employed in the throwing mills, both within and without doors, were 20,000; their production was above 960,000 Vienna lbs., and the consumption of raw silk by the conversion into this quantity was 1,009,000 lbs., giving waste (floss) to the amount of 47,400 lbs.

There are (1851) in the Tyrol 55 throwing mills, with 125,047 spindles; 85,583 of which latter are for spinning, and 39,464 for twisting. In these mills 500 men and 1,200 women and children are employed. The production there, including that of the smaller throwing mills, which give occupation to 500 workmen, amount to 220,400 Vienna lbs. of thrown silk, for which 231,400 Vienna lbs. of raw silk have to be worked up.

Of the remainder of the raw silk (23,200 lbs.) about 14,000 lbs. are distributed through the other southern provinces, and the remaining 9,200 lbs. appropriated to other purposes.

Thus we find a resulting total of production equal to 3,374,000 Vienna lbs. of thrown silk.

In the Journal of the Asiatic Society of Bengal, for January, 1837, there are two very valuable papers upon silkworms; the first, upon those of Assam, by Mr. Thomas Hugon, stationed at Nowgong; the second, by Dr. Helfer, upon those which are indigenous to India. Besides the *Bombyx mori*, the Doctor enumerates the following seven species, formerly unknown:—1. The wild silkworm of the central provinces, a moth not larger than the *Bombyx mori*. 2. The Joree silkworm of Assam, *Bombyx religiosa*, which spins a cocoon of a fine filament, with much lustre. It lives upon the pipul tree (*Ficus religiosa*), which abounds in India, and ought therefore to be turned to account in breeding this valuable moth. 3. *Saturnia Silhetica*, which inhabits the Cassia mountains in Silhet and Dacca, where its large cocoons are spun into silk. 4. A still larger *Saturnia*, one of the greatest moths in existence, measuring ten inches from the one end of the wing to the other ; observed by Mr. Grant, in *Chirra Punjee*. 5. *Saturnia paphia*, or the Tusseh silkworm, is the most common of the native species, and furnishes the cloth usually worn by Europeans in India. It has not hitherto been domesticated, but millions of its cocoons are annually collected in the jungles, and brought to the silk factories near Calcutta and Bhagelpur. It feeds most commonly on the hair-tree (*Zizyphus jujuba*), but it prefers the *Terminalia alata*, or Assam tree, and the *Bombax heptaphyllum*. It is called *Kouthuri mooga*, in Assam. 6. Another *Saturnia*, from the neighbourhood of Comereolly. 7. *Saturnia Assamensis*, with a cocoon of yellow-brown colour, different from all others, called *mooga*, in Assam ; which, although it can be reared in houses, thrives best in the open air upon trees, of which seven different kinds afford it food. The *Mazankoory mooga*, which feeds on the Adakoory tree, produces a fine silk, which is nearly white, and fetches 50 per cent. more than the fawn-coloured. The trees of the first year's growth produce by far the most valuable cocoons. The mooga which inhabits the soom-tree, is found principally in the forests of the plains, and in the villages. The tree grows to a large size, and yields three crops of leaves in the year. The silk is of a light fawn colour, and ranks next in value to the Mazankoory. There are generally five breeds of mooga worms in the year ; 1, in January and February ; 2, in May and June ; 3, in June and July ; 4, in August and September ; 5, in October ; the first and last being the most valuable.

The Assamese select for breeding, such cocoons only as have been begun to be formed in the largest number on the same day, usually the second or third after the commencement ; those which contain males being distinguishable by a more pointed end. They are put in a closed basket suspended from the roof ; the moths, as they come forth, having room to move about, after a day, the females (known only by their large body) are taken out, and tied to small wisps of thatching-straw, selected always from over the hearth, its darkened colour being thought more acceptable to the insect. If out of a batch, there should be but few males, the wisps with the females tied to them are exposed outside at night ; and the males thrown away in the neighbourhood find their way to them. These wisps are hung upon a string tied across the roof, to keep them from vermin. The eggs laid after the first three days are said to produce weak worms. The wisps are taken out morning and evening, and exposed to the sunshine, and in ten days after being laid, a few of them are hatched. The wisps being then hung up to the tree, the young worms find their way to the leaves. The ants, whose bite is fatal to the worm in its early stages, are destroyed by rubbing the trunk of the tree with molasses, and tying dead fish and toads to it, to attract these rapacious insects in large numbers, when they are destroyed with fire ; a process which needs to be repeated several times. The ground under the trees is also well cleared, to render it easy to pick up and replace the worms which fall down. They are prevented from coming to the ground by tying fresh plantain-leaves round the trunk, over whose slippery surface they cannot crawl ; and they are transferred from exhausted trees to fresh ones, on bamboo platters tied to long poles. The worms require to be constantly watched and protected from the depredations of both day and night birds, as well as rats and other vermin. During their moultings, they remain on the branches ; but when about beginning to spin, they come down the trunk, and being stopped by the plantain-leaves, are there collected in baskets, which are afterwards put under bunches of dry leaves, suspended from the roof, into which the worms crawl, and form their cocoons—several being clustered together : this accident, due to the practice of crowding the worms together, which is most injudicious, rendering it impossible to wind off their silk in continuous threads, as in the filatures of Italy, France, and even Bengal, the silk is, therefore, spun like flax, instead of being unwound in single filaments. After four days the proper cocoons are selected for the next breed, and the rest are uncoiled. The total duration of a breed varies from 60 to 70 days; divided into the following periods.—

Four moultings, with one day's illness attending each - - -	20
From fourth moulting to beginning of cocoon - - - - -	10
In the cocoon 20, as a moth 6, hatching of eggs 10 - - - -	36
	66

On being tapped with the finger, the body renders a hollow sound ; the quality of which shows whether they have come down for want of leaves on the tree, or from their having ceased feeding.

As the chrysalis is not soon killed by exposure to the sun, the cocoons are put on stages, covered up with leaves, and exposed to the hot air from grass burned under them : they are next boiled for about an hour in a solution of the potash made from incinerated rice-stalks; then taken out, and laid on cloth folded over them to keep them warm. The floss being removed by hand, they are then thrown into a basin of hot water to be unwound; which is done in a very rude and wasteful way.

The plantations for the mooga silkworm in Lower Assam, amount to 5000 acres, besides what the forests contain; and yield 1500 maunds of 84 lbs. each per annum. Upper Assam is more productive.

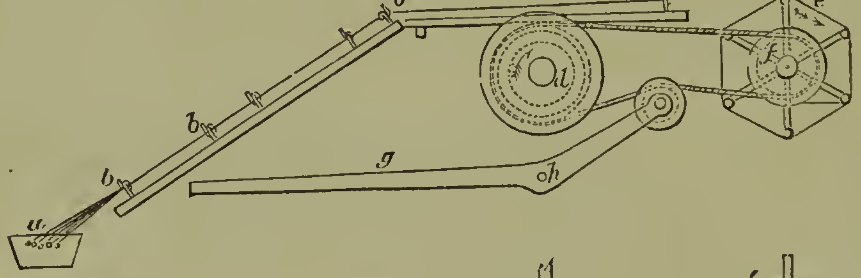
The cocoon of the *Kouthuri mooga* is of the size of a fowl's egg. It is a wild species, and affords filaments much valued for fishing-lines. See SILKWORM GUT.

8. The *Arrindy*, or *Eria* worm, and moth, is reared over a great part of Hindustan, but entirely within doors. It is fed principally on the *Hera*, or *Palma christi* leaves, and gives sometimes 12 broods of spun silk in the course of a year. It affords a fibre which looks rough at first; but when woven becomes soft and silky, after repeated washings. The poorest people are clothed with stuff made of it, which is so durable as to descend from mother to daughter. The cocoons are put in a closed basket, and hung up in the house, out of reach of rats and insects. When the moths come forth, they are allowed to move about in the basket for twenty-four hours; after which the females are tied to long reeds or canes, twenty or twenty-five to each, and these are hung up in the house. The eggs laid the first three days, amounting to about 200, alone are kept; they are tied up in a cloth, and suspended to the roof till a few begin to hatch. These eggs are white, and of the size of turnip-seed. When a few of the worms are hatched, the cloths are put on small bamboo platters hung up in the house, in which they are fed with tender leaves. After the second moulting, they are removed to bunches of leaves suspended above the ground, beneath which a mat is laid to receive them when they fall. When they cease to feed, they are thrown into baskets full of dry leaves, among which they form their cocoons, two or three being often joined together. Upon this injudicious practice I have already animadverted.

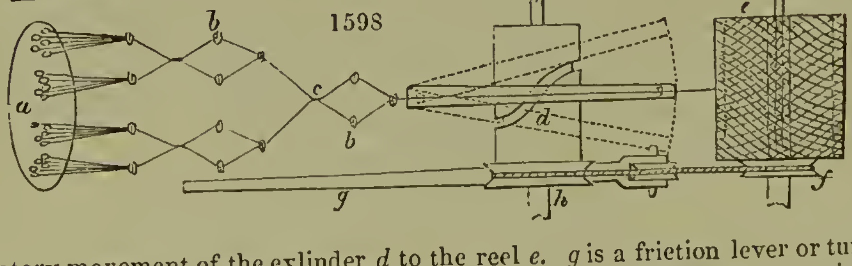
9. The *Saturnia trifenestrata*, has a yellow cocoon of a remarkable silky lustre. It lives on the soom-tree in Assam, but seems not to be much used.

The mechanism of the silk filature, as lately improved in France, is very ingenious. *Figs.* 1597 and 1598 exhibit it in plan and longitudinal view. *a* is an oblong copper basin containing water heated by a stove or by steam. It is usually divided by transverse partitions into several compartments, containing 20 cocoons, of which there are five in one group, as shown in the figure. *b*, *b*, are wires with hooks or eyelets at their ends, through which the filaments run, apart, and are kept from ravelling. *c*, *c*, the points where the filaments cross and rub each other, on purpose to clean their surfaces. *d* is a spiral groove, working upon a pin point, to give the traverse motion alternately to right and left, whereby the thread is spread evenly over the surface of the reel *e*. *f*, *f*, are the pulleys, which by means of cords transmit

1597



1598



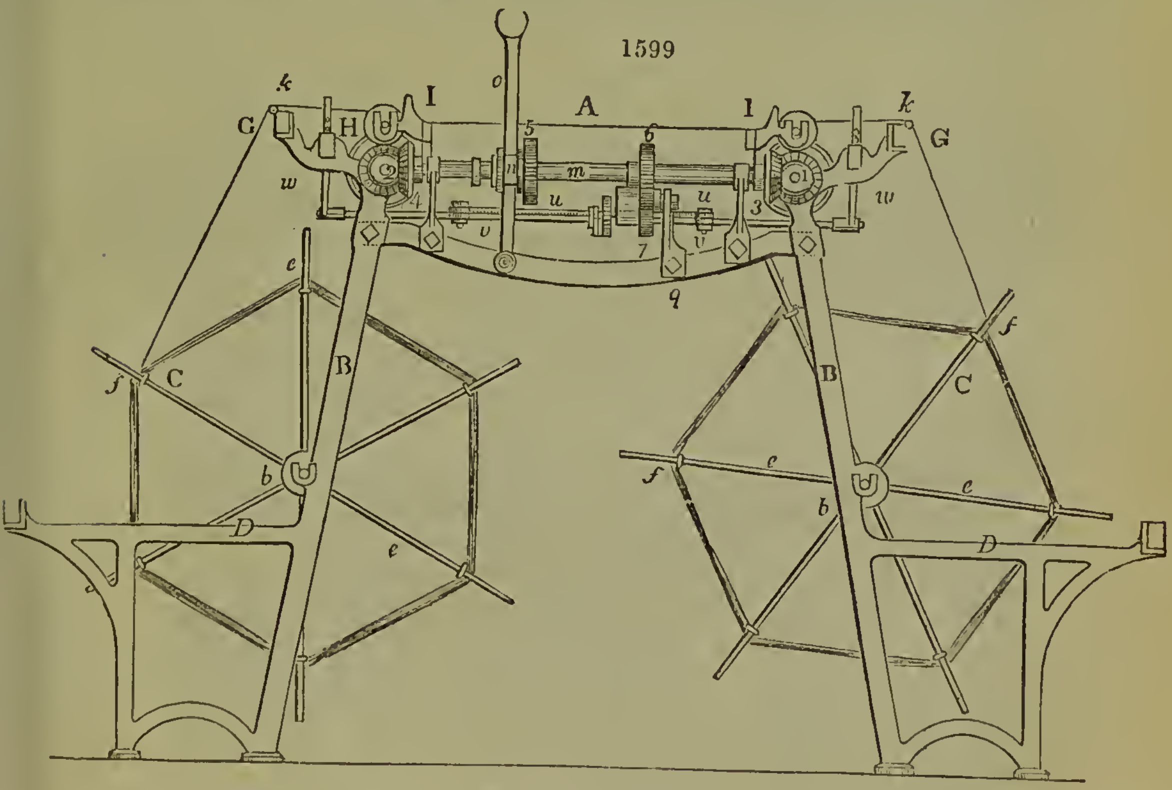
the rotatory movement of the cylinder *d* to the reel *e*. *g* is a friction lever or tumbler, for lightening or slackening the endless cord, in the act of starting or stopping the winding operation. Every apartment of a large filature contains usually a series of such reels as the above, all driven by one prime mover; each of which, however, may, by means of the tumbler lever, be stopped at pleasure. The reeler is careful to remove any slight adhesions, by the application of a brush in the progress of her work.

The expense of reeling the excellent Cevennes silk is only 3 francs and 50 centimes per Alais pound; from 4 to 5 cocoons going to one thread. That pound is 92 hundredths of our avoirdupois pound. In Italy, the cost of reeling silk is much higher, being 7 Italian livres per pound, when 3 to 4 cocoons go to the formation of one thread; and 6 livres when there are from 4 to 5 cocoons. The first of these raw silks will have a *titre* of 20 to 24 deniers; the last, of 24 to 28. If 5 to 6 cocoons go to one thread, the titre will be from 26 to 32 deniers, according to the quality of the cocoons. The Italian livre is worth 7½*d.* English. The woman employed at the kettle receives one livre and five sous per day; and the girl who turns the reel gets thirteen sous a day; both receiving board and lodging in addition. In June, July, and August, they work 16 hours a day, and then they wind a *rubo* or ten pounds weight of cocoons, which yield from 1-5th to 1-6th of silk, when the quality of good. The whole expenses amount to from 6 to 7 livres upon every ten pounds of cocoons; which is about 2*s.* 8*d.* per English pound of raw silk.

The raw silk, as imported into this country in hanks from the filatures, requires to be regularly wound upon bobbins, doubled, twisted, and reeled in our silk mills. These processes are called *throwing* silk, and their proprietors are called silk *throwsters*; terms probably derived from the appearance of swinging or tossing which the silk threads exhibit during their rapid movements among the machinery of the mills.

It was in Manchester that throwing-mills received the greatest improvement upon the ancient Italian plan, which had been originally introduced into this country by Sir Thomas Lombe, and erected at Derby. That improvement is chiefly due to the eminent factory engineers, Messrs. Fairbairn and Lillie, who transferred to silk the elegant mechanism of the throstle, so well known in the cotton trade. Still, throughout the silk districts of France the throwing mills are generally small, not many of them turning off more than 1000 pounds of organzine per annum, and not involving 5000*l.* of capital. The average price of throwing organzine in that country, where the throwster is not answerable for loss, is 7 francs; of throwing trame, from 4 fr. to 5 fr. (per kilogramme ?) Where the throwster is accountable for loss, the price is from 10 fr. to 11 fr. for organzine, and from 6 to 7 for trame. In Italy, throwing adds 3*s.* 9*d.* to the price of raw silk, upon an average. I should imagine, from the perfection and speed of the silk-throwing machinery in this country, as about to be described, that the cost of converting a pound of raw silk either into organzine or *trame* must be considerably under any of the above sums.

1599



SILK-THROWING MILL.

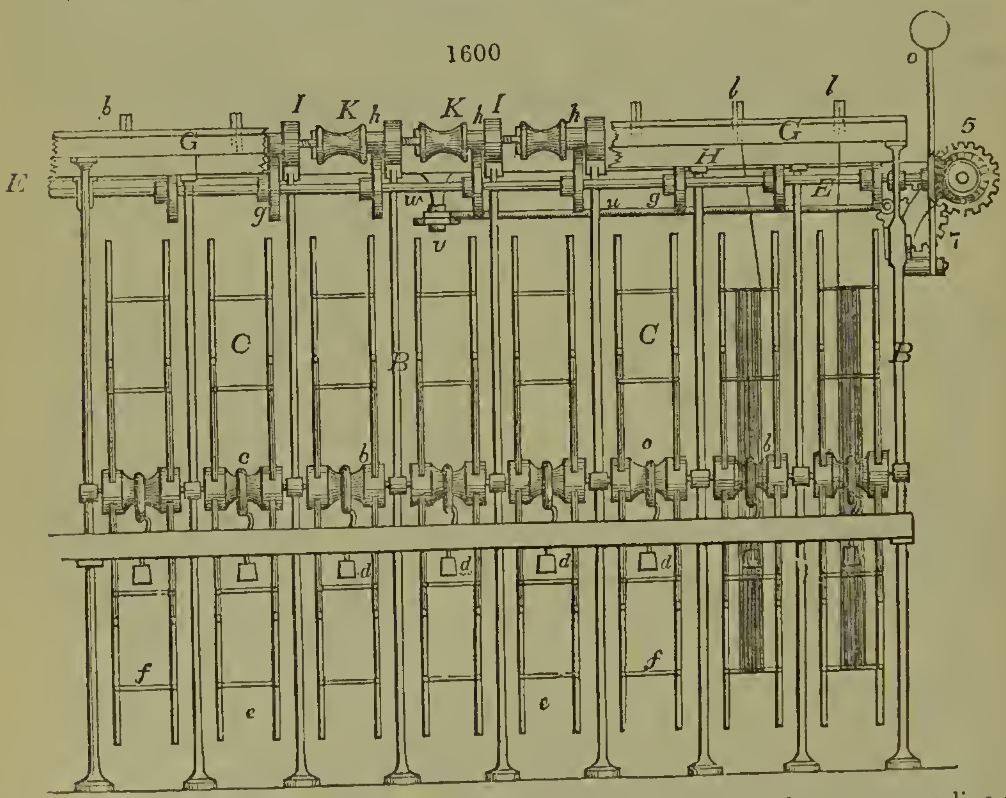
The first process to which the silk is subjected, is winding the skeins, as imported, off upon bobbins. The mechanism which effects this winding off and on, is technieally called the *engine*, or swift. The bobbins to which the silk is transferred, are wooden cylinders, of such thickness as may not injure the silk by sudden flexure, and which may also receive a great length of thread without having their diameter materially increased, or their surface velocity changed. *Fig.* 1599 is an end view of the silk-throwing machine, or *engine*, in which the two large hexagonal reels, called swifts, are seen in section, as well as the table between them, to which the bobbins and impelling mechanism are attached. The skeins are put upon these reels, from which the silk is gradually unwound by the traction of the revolving bobbins. One principal object of attention, is to distribute the thread over the length of the bobbin-cylinder in a spiral or oblique direction, so that the end of the slender semi-transparent thread may be readily found when it breaks. As the bobbins revolve with uniform velocity, they would soon wind on too fast, were their diameters so small at first as to become greatly thicker when they are filled. They are therefore made large, are not covered thick, but are frequently changed. The motion is communicated to that end of the engine shown in the figure.

The wooden table A, shown here in cross section, is sometimes of great length, extending 20 feet, or more, according to the size of the apartment. Upon this the skeins are laid out. It is supported by the two strong slanting legs B, B, to which the bearings of the light reel C are made fast. These reels are called *swifts*, apparently by the same etymological casuistry as *lucus a non lucendo;* for they turn with reluctant and irregular slowness; yet they do their work much quicker than any of the old apparatus, and in this respect may deserve their name. At every eighth or tenth leg there is a projecting horizontal piece D, which carries at its end another horizontal bar *a*, called the knee rail, at right angles to the former. This protects the slender reels or swifts from the knees of the operatives.

These swifts have a strong wooden shaft *b*, with an iron axis passing longitudinally through it, round which they revolve, in brass bearings fixed near to the middle of the legs B. Upon the middle of the shaft *b*, a loose ring is hung, shown under *c*, in *fig.* 1600 to which a light weight *d*, is suspended, for imparting friction to the reel, and thus preventing it from turning round, unless it be drawn with a gentle force, such as the traction of the thread in the act of winding upon the bobbin.

Fig. 1600 is a front view of the engine. B, B, are the legs, placed at their appropriate distances (scale $1\frac{1}{2}$ inch to the foot); C, C, are the swifts. By comparing *figs.* 1599 and 1600 the structure of the swifts will be fully understood. From the wooden shaft *b*, six slender wooden (or iron) spokes *e*, *e*, proceed, at equal angles to each other;

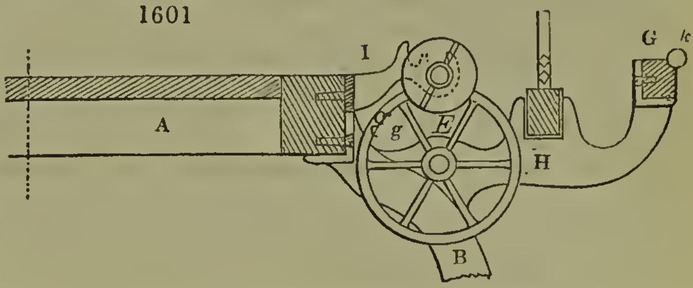
1600



which are bound together by a cord *f*, near their free ends, upon the transverse line *f* of which cord, the silk thread is wound in a hexagonal form; due tension being given to the circumferential cords, by sliding them out from the centre. Slendor wooden rods are set between each pair of spokes, to stay them, and to keep the cord tight. E is one of the two horizontal shafts, placed upon each side of the *engine*, to which are affixed a number of light iron pulleys *g*, *g* (shown on a double scale in *fig.* 1601). These serve, by friction, to drive the bobbins which rest upon their peripheries.

To the table A, *fig.* 1599, are screwed the light cast-iron slot bearings, I, I, wherein the horizontal spindles or skewers rest, upon which the bobbins revolve. The spindles (see F, *fig.* 1603) carry upon one end a little wooden pulley *h*, whereby they press and revolve upon the larger driving pulleys *g*, of the shaft E. These pulleys are called *stars* by our workmen. The other ends of the spindles, or skewers, are cut into screws, for attaching the swivel nuts *i* (*fig.* 1603), by which the bobbins K, K, are made fast to their respective spindles.

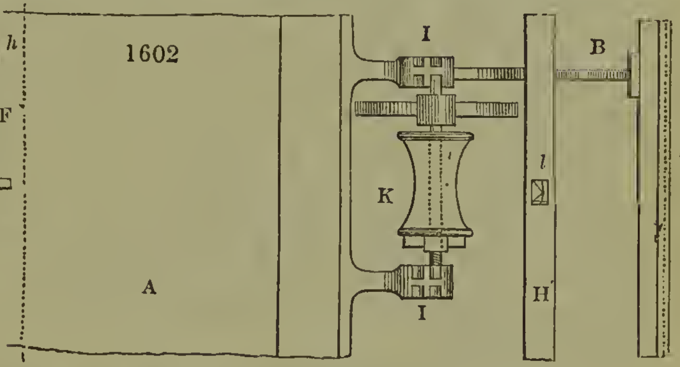
1601



Besides the slots, above described, in which the spindles rest when their friction pulleys, *h*, are in contact with the moving stars *g*, there is another set of slots in the bearings, into which the ends of the spindles may be occasionally laid, so as to be above the line of contact of the rubbing periphery of the star *g*, in case the thread of any bobbin breaks. Whenever the girl has mended the thread, she replaces the bobbin-spindle in its deeper slot bearings, thereby bringing its pulley once more into contact with the star, and causing it to revolve.

1603

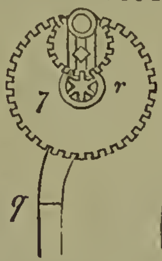
1602



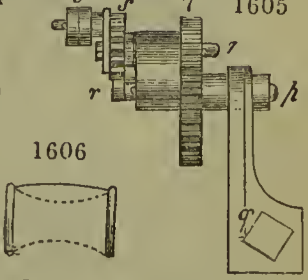
G is a long ruler or bar of wood, which is supported upon every eighth or twelfth leg B, B. (The figure being, for convenience of the page, contracted in length, shows it at every sixth leg.) To the edge of that bar the smooth glass rods *k*, are made fast, over which the threads glide from the swifts, in their way to the bobbins. H is the guide bar, which has a slow traverse or seesaw motion, sliding in slots at the top of the legs B, where they support the bars G. Upon the guide bar H, the guide pieces *l*, *l*, are made fast. These consist of two narrow, thin, upright plates of iron, placed endwise together, their contiguous edges being smooth, parallel, and capable of approximation to any degree by a screw, so as to increase or diminish at pleasure the ordinary width of the vertical slit that separates them. Through this slit the silk thread must pass, and, if rough or knotty, will be either cleaned or broken; in the latter case, it is neatly mended by the attendant girl.

The motions of the various parts of the *engine* are given as follows. Upon the end of the machine, represented in *fig.* 1599, there are attached to the shafts E (*fig.* 1600), the bevel wheels 1 and 2, which are set in motion by the bevel wheels 3 and 4, respectively. These latter wheels are fixed upon the shaft *m*, *fig.* 1599; *m* is moved by the main steam shaft which runs parallel to it, and at the same height through the length of the *engine* apartment, so as to drive the whole range of the machines. 5 is a loose wheel or pulley upon the shaft *m*, working in gear with a wheel upon the steam shaft, and which may be connected by the clutch *n*, through the hand lever or gearing rod *o* (*figs.* 1599 and 1600), when the engine is to be set at work. 6 is a spur wheel upon the shaft *m*, by which the stud wheel 7, is driven, in order to give the traverse motion to the guide bar H. This wheel is represented, with its appendages, in double size, *figs.* 1604 and 1605, with its boss upon a stud, *p*, secured to the bracket *q*. In an eccentric hole of the same boss, another stud, *r*, revolves, upon

1604



1605



1606

which the little wheel *s*, is fixed. This wheel *s* is in gear with a pinion cut upon the end of the fixed stud *p*; and upon it is screwed the little crank *t*, whose collar is connected by two rods *u* (*figs.* 1599 and 1600), to a cross-piece *v*, which unites the two arms *w*, that are fixed upon the guide bar H, on both sides of the machine. By the revolution of wheel 7, the wheel *s* will cause the pinion of the fixed stud *p* to turn round. If that wheel bear to the pinion the proportion of 4 to 1, then the wheel *s* will make, at each revolution of the wheel 7, one-fourth of a revolution; whereby the crank *t* will also rotate through one fourth of a turn, so as to be brought nearer to the centre of the stud, and to draw the guide bar so much less to one side of its mean position. At the next revolution of wheel 7, the crank *t* will move through another quadrant, and come still nearer to the central position, drawing the guide bars still less aside, and therefore causing the bobbins to wind on more thread in their middle than towards their ends. The contrary effect would ensue, were the guide bars moved by a single or simple crank. After four revolutions of the wheel 7, the crank *t* will stand once more as shown in *fig.* 1605, having moved the bar H through the whole extent of its traverse. The bobbins, when filled, have the appearance represented in *fig.* 1606; the thread having been laid on them all the time in diagonal lines, so as never to coincide with each other.

Doubling is the next operation of the silk throwster. In this process, the threads of two or three of the bobbins, filled as above, are wound together in contact upon a single bobbin. An ingenious device is here employed to stop the winding-on the moment that one of these parallel threads happens to break. Instead of the swifts or reels, a creel is here mounted for receiving the bobbins from the former machine, two or three being placed in one line over each other, according as the threads are to be doubled or trebled. Though this machine is in many respects like the *engine*, it has some additional parts, whereby the bobbins are set at rest, as above mentioned, when one of the doubling threads gets broken.

Fig. 1607 is an end view, from which it will be perceived that the machine is, like the preceding, a double one, with two working sides.

Fig. 1608 is a front view of a considerable portion of the machine.

Fig. 1609 shows part of a cross section, to explain minutely the mode of winding upon a single bobbin.

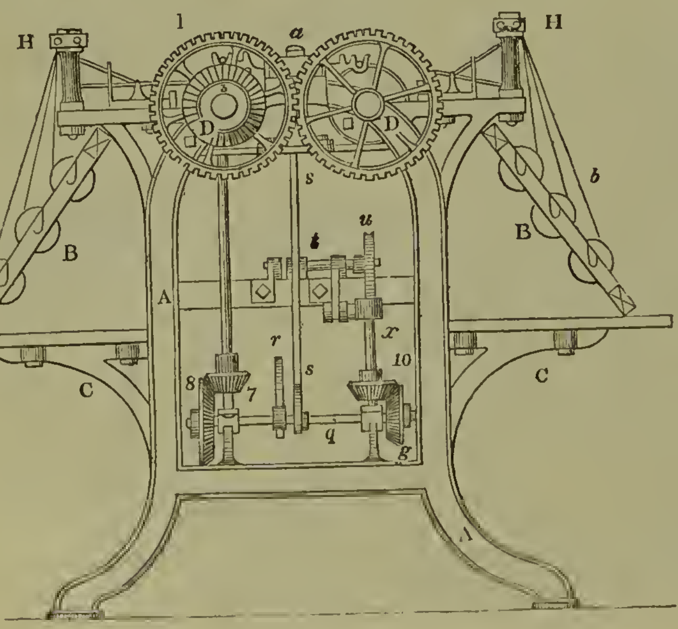
Fig. 1611 is the plan of the parts shown in *fig.* 1609; these two figures being drawn to double the scale of *figs.* 1607 and 1608.

A, A, *figs.* 1607 and 1608 are the end frames, connected at their tops by a wooden stretcher, or *bar-beam*, *a*, which extends through the whole length of the machine; this bar is shown also in *figs.* 1609 and 1611.

B, B, are the creels upon each side of the machine, or bobbin bearers, resting upon wooden beams or boards, made fast to the arms or brackets C, about the middle of the frames A.

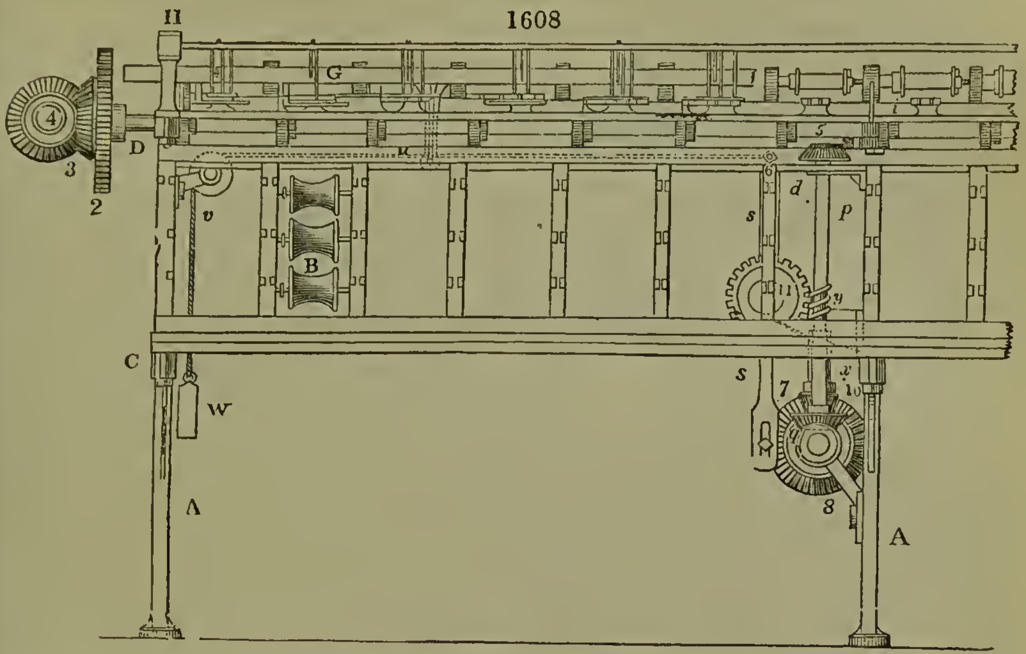
D, D, are two horizontal iron shafts, which pervade the whole machine, and carry a series of light movable pulleys, called *stars*, *c*, *c* (*figs.* 1609, 1611), which serve to drive the bobbins, E, E, whose fixed pulleys rest upon their peripheries, and are therefore turned simply by friction. These bobbins are screwed by swivel nuts, *e*, *e*, upon spindles, as in the silk engine. Besides the small friction pulley or boss, *d*, seen best in *fig.* 1611, by which they rest upon the star pulleys *c*, *c*, a little ratchet wheel *f*, is attached to the other end of each bobbin. This is also shown by itself at *f*, in *fig.* 1610.

1607



The spindles with their bobbins revolve in two slot-bearings F. F, *fig.* 1611, screwed to the bar-beam *a*, which is supported by two or three intermediate upright frames, such as A′. The slot-bearings F, have also a second slot, in which the spindle with the bobbin is laid at rest, out of contact of the *star* wheel, while its broken thread is being mended. G is the guide bar (to which the cleaner slit pieces *g*,

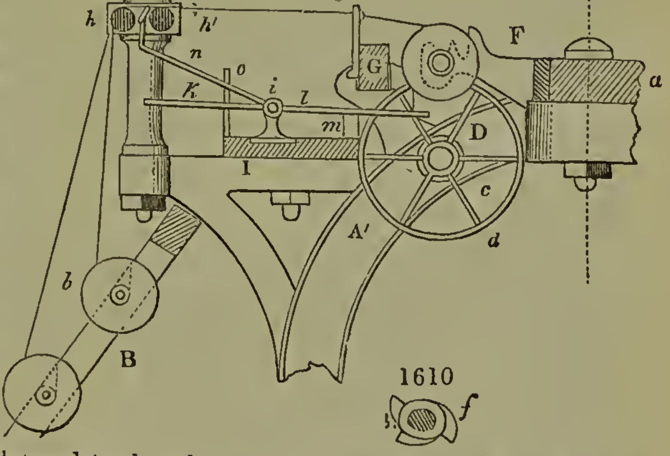
1608



g, are attached), for making the thread traverse to the right and the left, for its proper distribution over the surface of the bobbin. The guide bar of the doubling machine is moved with a slower traverse than in the engine; otherwise, in consequence of the different obliquities of the paths, the single threads would be readily broken. *h*, *h*, is a pair of smooth rods of iron or brass, placed parallel to each of the two sides of the machine, and made fast to the standards H, H, which are screwed to brackets projecting from the frames A, A′. Over these rods the silk threads glide, in their passage to the guide wires *g*, *g*, and the bobbins E, E.

I, I, is the *lever board* upon each side of the machine, upon which the slight brass bearings or fulcrums *i*, *i*, one for each bobbin in the creel, are made fast. This board bears the *balance-lever* *k*, *l*, with the *fallers* *n*, *n*, *n*, which act as dexterous fingers, and stop the bobbin from winding-on the instant a thread may chance to break. The levers *k*, *l*, swing upon a fine wire axis, which passes through their props *i*, *i*, their arms being shaped rectangularly, as shown at *k*, *k*′ (1611). The arm *l*, being heavier than the arm *k*, naturally rests upon the ridge bar *m*, of the lever board I. *n*, *n*, *n*, are three wires, resting at one of their ends upon the axis of the fulcrum *i*, *i*, and having each of their other hooked ends suspended by one of the silk threads, as it passes over the front steel rod *h*, and under *h*′. These faller wires, or stop fingers, are guided truly in their up-and-down motions with the thread, by a cleaner-plate *o*, having a vertical slit in its middle. Hence, whenever any thread happens to break, in its way to a winding-on bobbin E, the wire, *n*, which hung by its eyelet end to that thread, as it passed through between the steel rods in the line of *h*, *h*′, falls upon the lighter arm of the balance lever *k*, *l*, weighs down that arm *k*, consequently jerks up the arm *l*, which pitches its tip or end into one of the three notches of the ratchet or catch wheel *f* (*figs.* 1610 and 1611), fixed to the end of the bobbin. Thus its motion is instantaneously arrested, till the girl has had leisure to mend the thread, when she again hangs up the faller wire *n*, and restores the lever *k*, *l*, to its horizontal position. If, meanwhile, she took occasion to remove the winding bobbin out of the sunk slot-bearing,

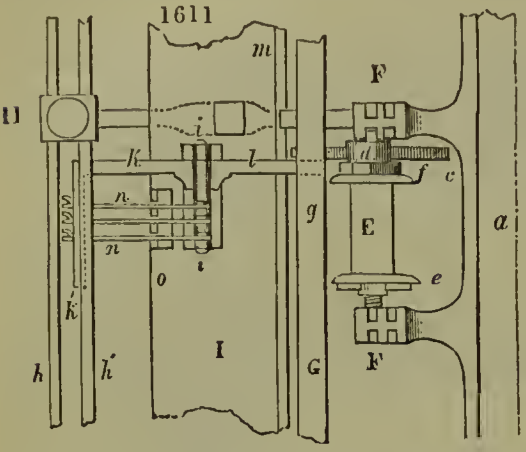
1609



1610

where pulley *d* touches the *star* wheel *c*, into the right-hand upper slot of repose, she must now shift it into its slot of rotation.

1611

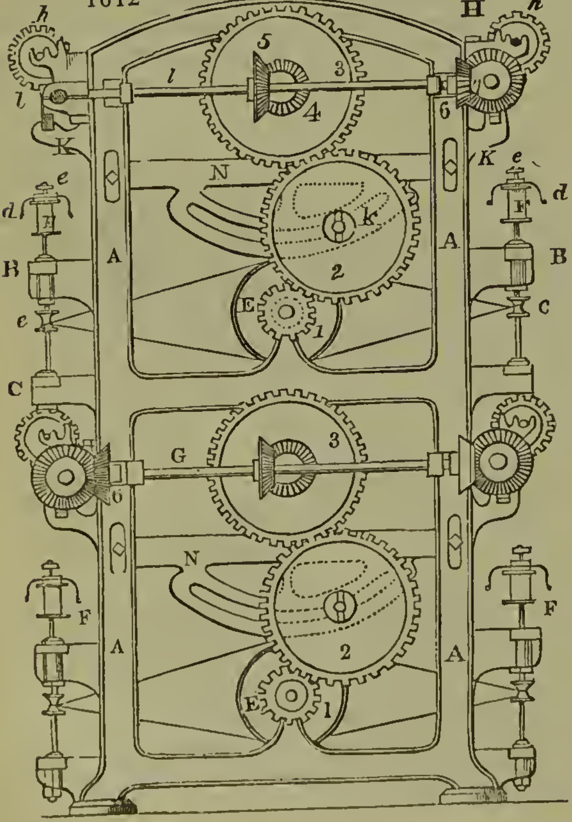


The motions are given to the doubling machine in a very simple way. Upon the end of the frame, represented *fig.* 1607, the shafts D, D, bear two spur wheels 1 and 2, which work into each other. To the wheel 1, is attached the bevel wheel 3, driven by another bevel wheel 4 (*fig.* 1608), fixed to a shaft that extends the whole length of the apartment, and serves, therefore to drive a whole range of machines. The wheel 4 may be put in gear with the shaft, by a clutch and gear-handle, as in the silk *engine*, and thereby it drives two shafts, by the one transmitting its movement to the other.

The traverse motion of the guide bar G, is effected as follows:—Upon one of the shafts D, there is a bevel wheel 5, driving the bevel wheel 6, upon the top of the upright shaft *p* (*fig.* 1608, to the right of the middle); whence the motion is transmitted to the horizontal shaft *q*, below, by means of the bevel wheels 7 and 8. Upon this shaft *q*, there is a heart-wheel *r*, working against a roller which is fixed to the end of the lever *s*, whose fulcrum is at *t*, *fig.* 1607. The other end of the lever *s*, is connected by two rods (shown by dotted lines in *fig.* 1608) to a brass piece which joins the arms *u* (*fig.*1608), of the guide bars G. To the same cross piece a cord is attached, which goes over a roller *v*, and suspends a weight W, by means of which the lever *s*, is pressed into contact with the heart-wheel *r*. The fulcrum *t*, of the lever *s*, is a shaft which is turned somewhat eccentric, and has a very slow rotatory motion. Thus the guide bar, after each traverse, necessarily winds the silk in variable lines to the side of the preceding threads.

The motion is given to this shaft in the following way. Upon the horizontal shaft *q*, there is a bevel wheel *g* (*figs.* 1607 and 1608), which drives the wheel 10 upon the shaft *x*; on whose upper end, the worm *y* works in the wheel 11, made fast to the said eccentric shaft *t*; round which the lever *s*, swings or oscillates, causing the guide bars to traverse.

1612



The spinning silk-mill.—The machine which twists the silk threads, either in their single or doubled state, is called the spinning mill. When the raw singles are first twisted in one direction, next doubled, and then twisted together in the opposite direction, an exceedingly wiry, compact thread, is produced, called *organzine*. In the spinning mill, either the singles or the doubled silk, while being unwound from one set of bobbins, and wound upon another set, is subjected to a regular twisting operation; in which process the thread is conducted as usual through guides, and coiled diagonally upon the bobbins by a proper mechanism.

Fig. 1612 exhibits an end view of the spinning mill; in which four working lines are shown; two tiers upon each side, one above the other. Some spinning mills have three working tiers upon each side; but as the highest tier must be reached by a ladder or platform, this construction is considered by many to be injudicious.

Fig. 1613, is a front view, where, as in the former figure, the two working lines are shown.

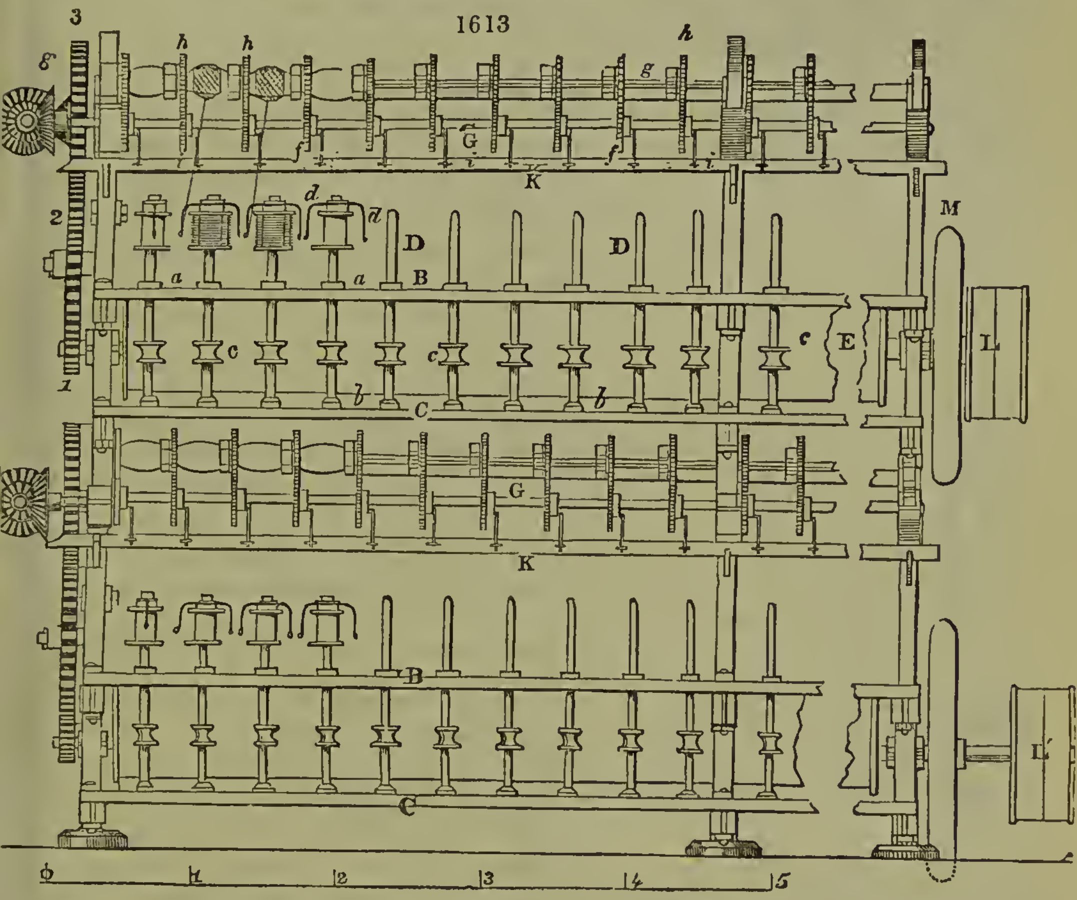
Fig. 1614, is a cross section of a part of the machine, to illustrate the construction and play of the working parts; *figs.* 1620, 1621, are other views of *fig.* 1614.

Fig. 1615, shows a single part of the machine, by which the bobbins are made to revolve.

Figs. 1615, and 1617, show a different mode of giving the traverse to the guide bars, than that represented in *fig.* 1614.

Figs. 1618, and 1619, show the shape of the full bobbins, produced by the action of these two different traverse motions.

1613



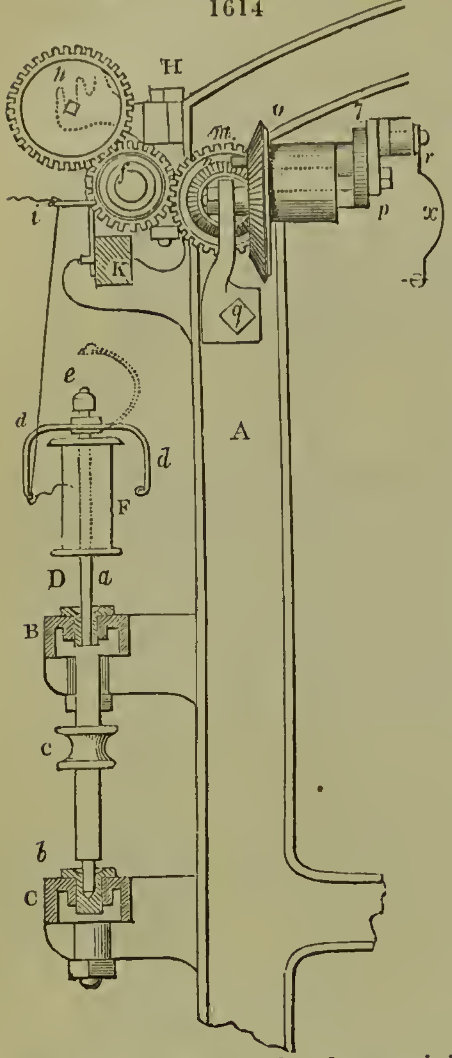
The upper part of the machine being exactly the same as the under part, it will be sufficient to explain the construction and operation of one of them.

A, A, are the end upright frames or standards, between which are two or three intermediate standards, according to the length of the machine. They are all connected at their sides by beams B and C, which extend the whole length of the machines. D, D, are the spindles, whose top bearings *a*, *a*, are made fast to the beams B, and their bottoms turn in hard brass steps, fixed to the bar C. These two bars together are called by the workmen the spindle box. The standards A, A, are bound with cross bars N, N.

c, *c*, are the wharves or whorls, turned by a band from the horizontal tin cylinder in the lines of E, E, *fig.* 1613, lying in the middle line between the two parallel rows of spindles D, D. F, F are the bobbins containing the untwisted double silk, which are simply pressed down upon the taper end of the spindles. *d*, *d* are little flyers, or forked wings of wire, attached to washers of wood, which revolve loose upon the tops of the said bobbins F, and round the spindles. One of the wings is sometimes bent upwards, to serve as a guide to the silk, as shown by dotted lines in *fig.* 1614. *e*, *e*, are pieces of wood pressed upon the tops of the spindles, to prevent the flyers from starting off by the centrifugal force. G are horizontal shafts bearing a number of little spur wheels *f*, *f*. H are slot bearings, similar to those of the doubling-machine, which are fixed to the end and middle frames. In these slots, the light square cast-iron shafts or spindles *g*, *fig.* 1602, are laid, on whose end the spur wheel *h* is cast; and when the shaft *g* lies in the front slot of its bearing, it is in gear with the wheel *f*, upon the shaft G; but when it is laid in the back slot, it is out of gear, and at rest. See F, F, *fig.* 1612.

Upon these little cast-iron shafts or spindles *g*, *fig.* 1616, the bobbins or blocks I, are thrust, for receiving by winding-on the twisted or spun silk. These blocks are made of a large diameter, in order that the silk fibres may not be too much bent; and they are but slightly filled at each successive charge, lest, by increasing their diameter too much, they should produce too rapid an increase in the rate of winding, with proportional diminution in the twist, and risk of stretching or tearing the silk. They are therefore the more frequently changed. K, K, are the guide bars, with the guides *i*, *i*, through which the silk passes, being drawn by the revolving bobbins I, and delivered or laid on by the flyers *d*, *d*, from the rotatory twisting-bobbins F. The operation of the machine is therefore simple, and the motions are given to the parts in a manner equally so.

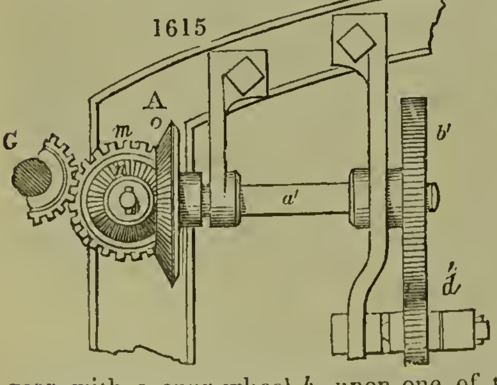
1614



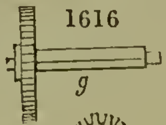
Upon the shaft of the tin cylinder or drum, exterior to the frame, the usual fast and loose pulleys or riggers, L, L′, are mounted, for driving the whole machine. These riggers are often called steam-pulleys by the workmen, from their being connected by bands with the steam-driven shaft of the factory. In order to allow the riggers upon the shafts of the upper and the under drums to be driven from the same pulley upon the main shaft, the axis of the under drum is prolonged at L, L′, and supported at its end, directly from the floor, by an upright bearing. Upon the shafts of the tin cylinders there is also a fly-wheel M, to equalise the motion. Upon the other ends of these shafts, namely, at the end of the spinning-mill, represented in *fig.* 1612, the pinions 1, are fixed, which drive the wheels 3, by means of the intermediate or carrier wheel, 2, called also the plate wheel, from its being hollowed somewhat like a trencher. 1 is called the change-pinion, because it is changed for another of a different size and different number of teeth, when a change in the velocity of wheels 2 and 3 is to be made. To allow a greater or smaller pinion to be applied at 1, the wheel 2 is mounted upon a stud *k*, which is movable in a slot concentric with the axis of the wheel 3. This slot is a branch from the cross bar N. The smaller the change-pinion is, the nearer will the stud *k* approach to the vertical line joining the centres of wheels 1 and 3; and the more slowly will the plate wheel 2 be driven. To the spur wheel 3, a bevel wheel 4, is fixed, with which the other also revolves loose upon a stud. The bevel wheel 5, upon the shaft *l*, is driven by the bevel wheel 4; and it communicates motion, by the bevel wheels 6 and 7, to each of the horizontal shafts G, G, extending along the upper and under tiers of the machine. At the left-hand side of the top part of *fig.* 1613, the two wheels 6 and 7 are omitted, on purpose to show the bearings of the shaft G, as also the slot-bearings for carrying the shafts or skewers of the bobbins.

If it be desired to communicate twist in the opposite direction to that which would be given by the actual arrangement of the wheels, it is necessary merely to transpose the carrier wheel 2, from its present position on the right hand of pinion 1, to the left of it, and to drive the tin cylinder by a crossed or close strap, instead of a straight or open one.

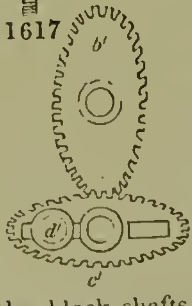
1615



1616



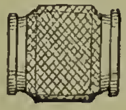
1617



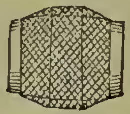
The traverse motion of the guide is given here in a similar way to that of the engine (*fig.* 1599). Near one of the middle or cross-frames of the machine (see *fig.* 1614), the wheel *f*. in gear with a spur wheel *h*, upon one of the block-shafts, drives also a spur wheel *m*, that revolves upon a stud, to which wheel is fixed a bevel wheel *n*, in gear with the bevel wheel *o*. To wheel *o*, the same mechanism is attached as was described under *figs.* 1612, and 1613, and which is here marked with the same letters.

To the crank-knob *r*, *fig.* 1614, a rod *x*, is attached, which moves or traverses the guide-bar belonging to that part of the machine: to each machine one such apparatus is fitted. In *figs.* 1615, and 1617, another mode of traversing the guide-bar is shown, which is generally used for the coarser qualities of silk. Near to one of the middle frames, one of the wheels *f*, in gear with the spur-wheel *m*, and the bevel-wheel *n*, both revolving on one stud, gives motion also to the wheel *o*, fixed upon a shaft *a'*, at whose other end the elliptical wheel *b'* is fixed, which drives a second elliptical wheel *c'*, in such a way that the larger diameter of the one plays in gear with the smaller diameter of the other; the teeth being so cut as to take into each other in all positions. The crank-piece *d'* is screwed upon the face of the wheel *c'*, at such a distance from its centre as may be necessary to give the desired length of traverse motion to the guide-bar, for laying the silk spirally upon the blocks. The purpose of the elliptical wheel is to modify the simple crank motion, which would wind on more silk at the ends of the bobbins than in their middle, and to effect an equality of winding on over the whole surface of the blocks.

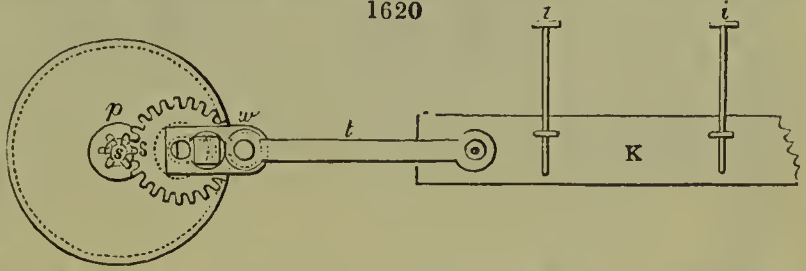
1618



1619

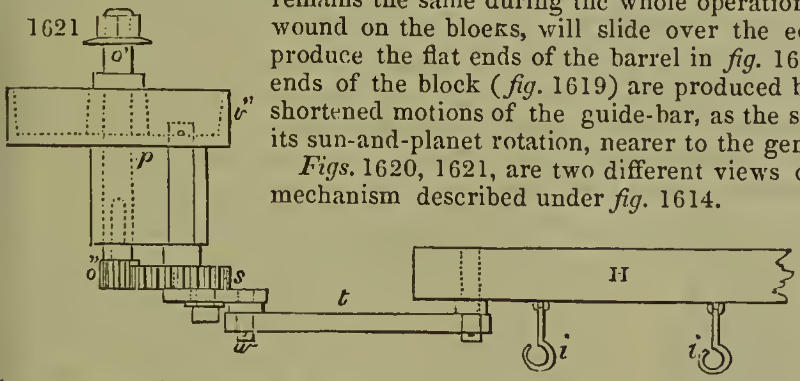


1620



In *fig.* 1620, the elliptical wheels are shown in front, to illustrate their mode of operating upon each other. *Fig.* 1618, is a block filled by the motion of the eccentric, *fig.* 1614; and *fig.* 1619, is a block filled by the elliptical mechanism. As the length of the motions of the bar in the latter construction remains the same during the whole operation, the silk, as it is wound on the blocks, will slide over the edges, and thereby produce the flat ends of the barrel in *fig.* 1618. The conical ends of the block (*fig.* 1619) are produced by the continually shortened motions of the guide-bar, as the stud approaches in its sun-and-planet rotation, nearer to the general centre.

1621



Figs. 1620, 1621, are two different views of the differential mechanism described under *fig.* 1614.

The bent wire *x*, *fig.* 1614, is called the guide iron. It is attached at one end to the pivot of the sun-and-planet wheel-work *t*, *s*, *o*, and at the other to the guide-bar *f*, *f*, *fig.* 1613. The silk threads pass through the guides, as already explained. By the motion communicated to the guide-bar (*guider*), the diamond-pattern is produced, as shown in *fig.* 1618.

The Silk Automatic Reel.

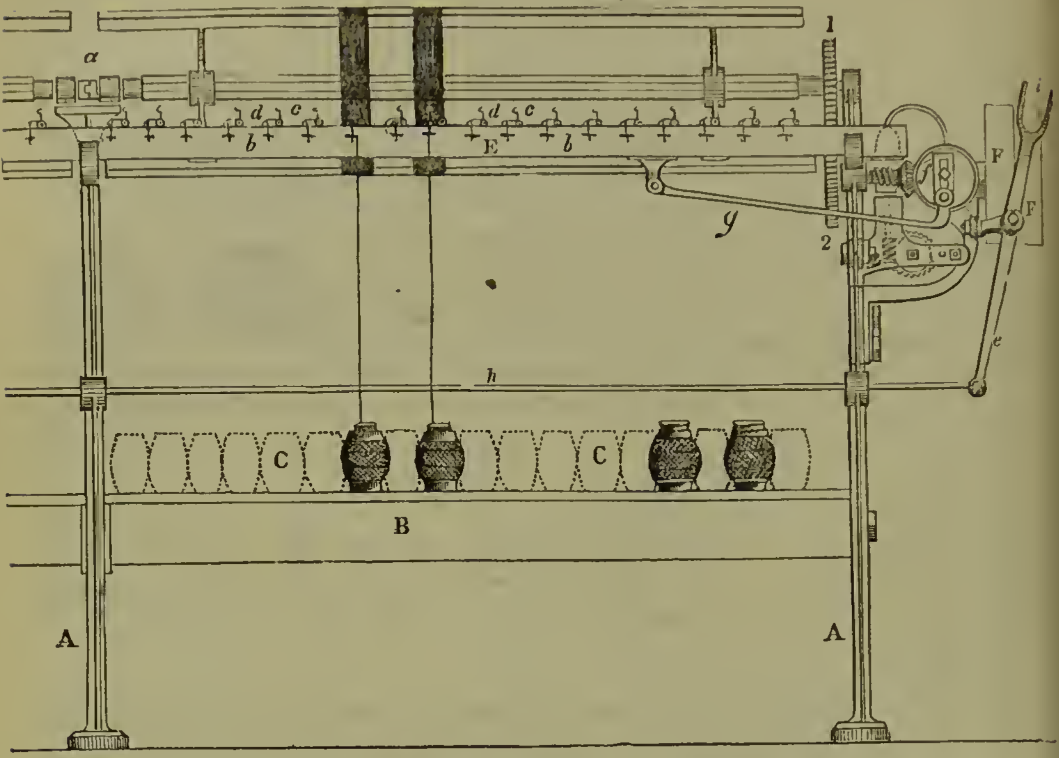
In this machine, the silk is unwound from the blocks of the throwing-mill, and formed into hanks for the market. The blocks being of a large size, would be productive of much friction, if made to revolve upon skewers thrust through them, and would cause frequent breakage of the silk. They are, therefore, set with their axes upright upon a board, and the silk is drawn from their surface, just as the weft is from a cop in the shuttle. On this account the previous winding-on must be executed in a very regular manner; and preferably as represented in *fig.* 1618.

Fig. 1622, is a front view of the reel; little more than one half of it being shown.

Fig. 1623, is an end view. Here the steam-pulleys are omitted, for fear of obstructing the view of the more essential parts. A, A, are the two end framings, connected by mahogany stretchers, which form the table B, for receiving the bobbins C, C, which are sometimes weighted at top with a lump of lead to prevent their tumbling. D is the reel consisting of four long laths of wood, which are fixed upon iron frames, attached to an octagonal wooden shaft. The arm which sustains one of these laths is capable of being bent inwards by loosening a tightening hook, so as to permit the hanks, when finished, to be taken off, as in every common reel.

The machine consists of two equal parts coupled together at *a*, to facilitate the removal of the silk from either half of the reel; the attendant first lifting the one part and then the other. E, is the guide bar, which by a traverse motion causes the silk

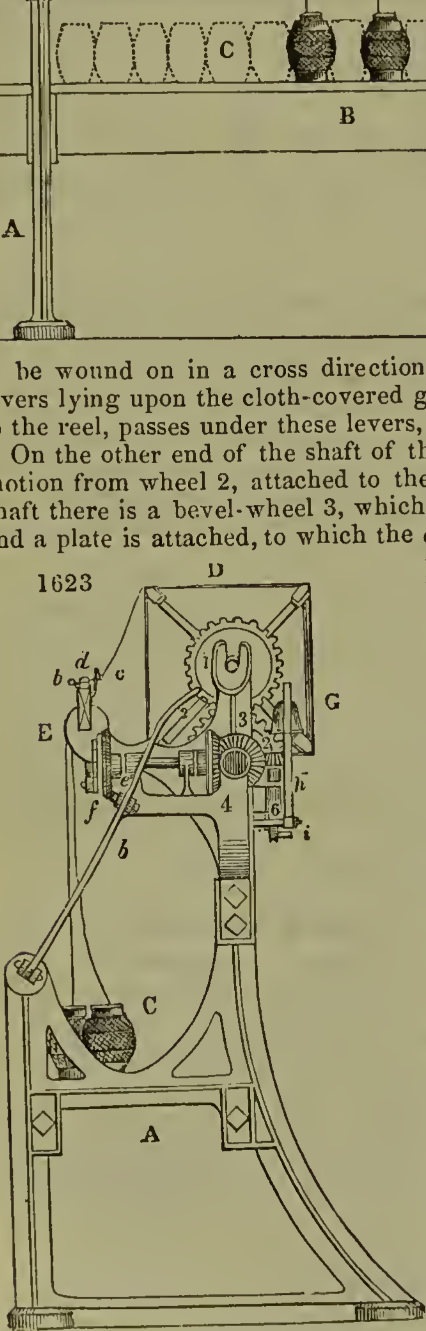
1622



to be wound on in a cross direction. *b* and *c*, are the wire guides, and *d* are little levers lying upon the cloth-covered guide bar E. The silk in its way from the block to the reel, passes under these levers, by which it is cleaned from loose fibres.

On the other end of the shaft of the reel, the spur-wheel 1 is fixed, which derives motion from wheel 2, attached to the shaft of the steam pulley F. Upon the same shaft there is a bevel-wheel 3, which impels the wheel 4 upon the shaft *e*; to whose end a plate is attached, to which the crank *f* is screwed, in such a way as to give the proper length of traverse motion to the guide bar E, connected to that crank or eccentric stud by the jointed rod *g*. Upon the shaft of the steam-pulleys F, there is a worm or endless screw, to the left of *f*, *fig.* 1622, which works in a wheel 5, attached to the short upright shaft *h* (*fig.* 1623). At the end of *h*, there is another worm, which works in a wheel, 6; at whose circumference there is a stud, *i*, which strikes once at every revolution against an arm attached to a bell, seen to the left, G; thus announcing to the reel-tenter that a measured length of silk has been wound upon her reel. *e*, is a rod or handle, by which the fork *l*, with the strap, may be moved upon the fast or loose pulley, so as to set on or arrest the motion at pleasure.

1623



Throwsters submit their silk to scouring and steaming processes. They soak the hanks, as imported, in lukewarm soap-water in a tub; but the bobbins of the twisted single silk from the spinning mill are enclosed within a wooden chest and exposed to the opening action of steam for about ten minutes. They are then immersed in a cistern of warm water, from which they are transferred to the doubling frame.

The wages of the work-people in the silk-throwing mills of Italy are about one half of their wages in Manchester; but this difference is much more than counterbalanced by the superior machinery of our mills. In 1832, there was a power equal to 342 horses engaged in the silk-throwing mills of Manchester; and of about 100 in the mills of Derby. The power employed in the other silk mills of England and Scotland has not been recorded.

There is a peculiar kind of silk called *marabout*, containing generally three threads, made from the white Novi raw silk. From its whiteness, it takes the most lively and delicate colours without the discharge of its gum. After being made into tram by the single twist upon the spinning mill, it is reeled into hanks, and sent to the dyer without further preparation. After being dyed, the throwster re-winds and re-twists it upon the spinning mill, in order to give it the whipcord hardness which constitutes the peculiar feature of marabout. The cost of the raw Novi silk is 19*s.* 6*d.* a pound; of throwing it into tram, 2*s.* 6*d.*; of dyeing, 2*s.*; of re-winding and re-twisting, after it has been dyed, about 5*s.*; of waste, 2*s.*, or 10 per cent.; the total of which sum is 31*s.*; being the price of one pound of marabout in 1832.

Dr. Ure published in the former editions of this Dictionary a chemical examination of some Indian silks; this inquiry brought out some curious facts, showing that the silks had been impregnated with earthy and other matters in India; but as possibly the conditions leading to this inquiry have entirely passed away, the statement is not preserved.

At present the United Kingdom draws its supply of the raw material for manufacture principally from the East Indies; and France, Italy, Turkey, and China, also supply a considerable amount. Ten years since, the annual imports for home consumption amounted to the large sum of 4,734,755 lbs.

In 1857, the enormous quantity of 12,077,931 lbs. of silk in its several conditions of raw, waste, and thrown, was imported into this country. The manufacture employs upwards of 33,000 individuals, and is carried on in above 300 silk factories.

The following represents the condition of our Import and Export trade in silk of five years, commencing with 1854:—

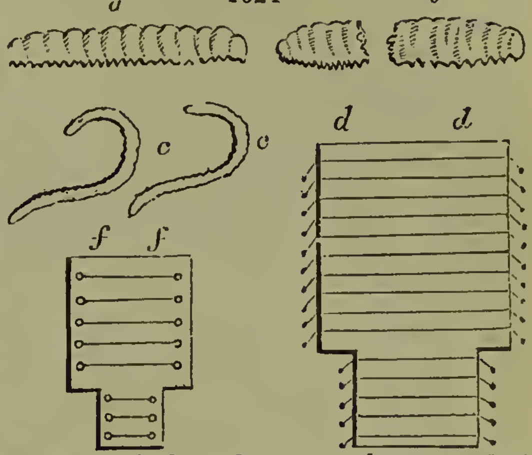
Indian and European manufactures are not included in these exports.

SILKWORM GUT, for angling, is made as follows:—Select a number of the best and largest silkworms, just when they are beginning to spin; which is known by their refusing to eat, and having a fine silk thread hanging from their mouths. Immerse them in strong vinegar, and cover them closely for twelve hours, if the weather be warm, but two or three hours longer, if it be cool. When taken out, and pulled asunder, two transparent guts will be observed, of a yellow green colour, as thick as a small straw, bent double. The rest of the entrails resembles boiled spinage, and therefore can occasion no mistake as to the silk-gut. If this be soft, or break upon stretching it, it is a proof that the worm has not been long enough under the influence of the vinegar. When the gut is fit to draw out, the one end of it is to be dipped into the vinegar, and the other end is to be stretched gently to the proper length. When thus drawn out, it must be kept extended on a thin piece of board, by putting its extremities into slits in the end of the wood, or fastening them to pins, and then exposed in the sun to dry. Thus genuine silk-gut is made in Spain. From the manner in which it is dried, the ends are always more or less compressed or attenuated. *Fig.* 1624, *a*, is the silkworm; *b*, the worm torn asunder; *c*, *c*, the guts; *d*, *d*, a board slit at the ends, with the gut to dry; *f*, *f*, boards with wooden pegs, for the same purpose.

1624



SILVER (*Argent*, Fr.; *Silber*, Germ.) was formerly called a *perfect* metal, because heat alone revived its oxide, and because it could pass unchanged through trials by fire, which apparently destroyed most other metals. The distinctions, perfect, imperfect, and noble, are now justly rejected. The bodies of this class are all equal in metallic nature, each being endowed merely with different relations to other forms of matter, which serve to characterise it, and to give it a peculiar value.

When pure and planished, silver is the brightest of the metals. Its specific gravity in the ingot is 10·47; but, when condensed under the hammer or in the coining press, it becomes 10·6. It melts at a bright red heat, at a temperature estimated by some as equal to 1280° Fahr., and by others to 22° Wedgewood. It is exceedingly malleable and ductile; affording leaves not more than $\frac{1}{100000}$ of an inch thick, and wire far finer than a human hair.

By Sickingen's experiments, its tenacity is, to that of gold and platinum, as the number 19, 15, and $26\frac{1}{4}$; so that it has an intermediate strength between these two metals. Pure atmospheric air does not affect silver, but that of houses impregnated with sulphuretted hydrogen, soon tarnishes it with a film of brown sulphide. It is distinguished chemically from gold and platinum by its ready solubility in nitric acid, and from almost all other metals, by its saline solutions affording a curdy precipitate with a most minute quantity of sea salt or any soluble chloride.

Silver occurs in nature under many forms:—

1. *Native silver* possesses most of the above properties; yet, on account of its being more or less alloyed with other metals, it differs a little in malleability, lustre, density, &c. It sometimes occurs crystallised in wedge-form octahedrons, in cubes, and cubo-octahedrons. At other times it is found in dendritic shapes, or arborescences, resulting from minute crystals implanted upon each other. But more usually it presents itself in small grains without determinable form, or in amorphous masses of various magnitude.

The *gangues* (mineral matrices) of native silver are so numerous, that it may be said to occur in all kinds of rock. At one time it appears as if filtered into their fissures, at another as having vegetated on their surface, and at a third, as if impasted in their substance. Such varieties are met with principally in the mines of Peru.

The native metal is found in almost all the silver mines now worked; but especially in those of Kongsberg in Norway, in carbonate and fluate of lime, &c.; at Schlangenberg in Siberia, in a sulphate of barytа; at Allémont, in a ferruginous clay, &c.

The metals most usually associated with silver in the native alloy, are gold, copper, arsenic, and iron. At Andreasberg and Guadalcanal it is alloyed with about five per cent. of arsenic. The auriferous native silver is the rarest; it has a brass-yellow colour.

2. *Antimonial silver.*—This rare ore is yellowish blue; destitute of malleability;

and very brittle; spec. grav. 9·5. It melts before the blowpipe, and affords white fumes of oxide of antimony: being readily distinguished from arsenical iron and arsenical cobalt by its lamellar fracture. It consists of from 76 to 84 of silver, and from 24 to 16 of antimony.

3. *Mixed antimonial silver.*— At the blowpipe it emits a strong garlic smell. Its constituents are, silver 16, iron 44, arsenic 35, antimony 4. It occurs at Andreasberg.

4. *Sulphide of silver.*— This is an opaque substance, of a dark-grey or leaden hue; slightly malleable, and easily cut with a knife, when it betrays a metallic lustre. The silver is easily separated by the blowpipe. It consists of 13 of sulphur to 89 of silver, by experiment; 13 to 87 are the theoretic proportions. Its spec. grav. is 6·9. It occurs crystallised in most silver mines, but especially in those of Freyberg, Joachimsthal in Bohemia, Schemnitz, in Hungary, and Mexico.

5. *Red sulphide of silver; silver glance.*— Its spec. grav. is 5·7. It contains from 84 to 86 of silver.

6. *Sulphide of silver with bismuth.* — Its constituents are, lead 35, bismuth 27, silver 15, sulphur 16, with a little iron and copper. It is rare.

7. *Antimoniated sulphide of silver*, the red silver of many mineralogists, is an ore remarkable for its lustre, colour, and the variety of its forms. It is friable, easily scraped by the knife, and affords a powder of a lively crimson red. Its colour in mass is brilliant red, dark red, or even metallic reddish-black. It crystallises in a variety of forms. Its constituents are, — silver from 56 to 62; antimony from 16 to 20; sulphur from 11 to 14; and oxygen from 8 to 10. It is found in almost all silver mines; but principally in those of Freyberg, Saint Marie aux Mines, and Guadalcanal.

8. *Black sulphide of silver*, is blackish, brittle, cellular, affording globules of silver at the blowpipe. It is found only in certain mines, at Allémont, Freyberg; more abundantly in the silver mines of Peru and Mexico. The Spaniards call it *negrillo.*

9. *Chloride of silver, or horn silver.*— In consequence of its semi-transparent aspect, its yellowish or greenish colour, and such softness that it may be cut with the nail, this ore has been compared to horn, and may be easily recognised. It melts at the flame of a candle, and may be reduced when heated along with iron or black flux, which are distinctive characters. It is seldom crystallised; but occurs chiefly in irregular forms, sometimes covering the native silver with a thick crust, as in Peru and Mexico. its density is only 4·74. It is found in considerable quantities at North Dolcoath in Cornwall.

Chloride of silver sometimes contains 60 or 70 per cent. of clay; and is then called butter-milk ore by the German miners. The blowpipe causes globules of silver to sweat out of it. This ore is rather rare. It occurs in the mines of Potosi, of Annaberg, Freyberg, Allémont, Schlangenberg, in Siberia, &c.

10. *Carbonate of silver*, a species little known, has been found hitherto only in the mine of S. Wenceslas near Wolfache.

Large quantities of silver are annually obtained in Europe by the treatment of argentiferous galena, but the New Continent, which produces for the most part ores containing but a small proportion of lead, is estimated to furnish twelve times more silver than the Old.

The following description of the extraction and treatment of silver ores in Mexico is chiefly derived from a paper published by Mr. J. Phillips, in the year 1846:—

The states of Mexico in which silver mines have been worked to the greatest extent are those of Mexico, Guanaxuato, Zacatecas, Guadalajara, San Luis Potosi, Oajaca, Valladolid, and Sonora. The three first, however, have always held, and at present hold, the first rank.

The principal mines nearest to the capital are those of Pachuca, Attotonilco el Chico, and Real del Monte, situated about 60 miles due north; the last named at an elevation of 9,300 feet above the level of the sea.

Farther north, bearing somewhat to the westward, are the mines and city of Guanaxuato, about 240 miles from the capital, 6000 feet above the sea level; and still farther north, about 190 miles frem Guanaxuato, in latitude 23°, are the mines and city of Zacatecas, distant from which about 35 miles are the productive mines of Fresnillo. There are many other mining districts, but those I have mentioned are the only ones producing silver in any great abundance, the others yielding but a comparatively small produce.

In the districts of Real del Monte and Zacatecas the silver veins are very numerous, and cross each other in various places, but generally speaking at the same angle. Thus the principal veins at Real del Monte run in a direction nearly east and west, while the cross veins run north and south: the dip, or inclination of the former, being to the south, and of the latter to the west. The rule however, does not hold good in the neighbouring mines of Pachuca, where the veins cross each other at an acute angle.

At Zacatecas, Fresnillo, and Plateros the surface of the ground may be seen intersected by innumerable veins, most of them producing silver in more or less abundance. There is, however, both in Zacatecas and Real del Monte, one leading vein larger and more productive than the others. That most famous in Zacatecas is called the Veta Grande, and that in Real del Monte is known by the name of the Biscaina.

In the district of Guanaxuato the case is different, for there we do not find a large number of veins, as in the others, but the riches are concentrated in one enormous vein which traverses the country for upwards of eight miles.

This is the largest known vein in Mexico, attaining in some places, a width of 50 varas, or 150 feet. All the principal mines of Guanaxuato are upon this vein, producing eight or nine millions of dollars annually.

The silver veins of Mexico are found in primitive and transition rocks. Thus the Veta Madre of Guanaxuato passes through clay-slate, containing beds of syenite and porphyry. It is thrown out of its course, or dislocated by the conglomerate hill of Sirena, but is again met with on the other side where the mine of El Cedro was opened by the Anglo-Mexican Company.

The veins of Zacatecas occur in greenstone and clay-slate, and are most productive in the former of those rocks. Those of Fresnillo and Plateros are met with in a similar formation.

At Real del Monte, Pachuca, and Attotonilco el Chico, all the veins are found passing through porphyry of various tints, but chiefly grey and green porphyry.

The formerly rich mine of El Doctor occurred in Alpine limestone, of which that district is chiefly composed.

The mines of Bolaños occur in amygdaloid and porphyry, in connection with a channel of steatite or soapstone. There is only one principal vein, as in Guanaxuato.

There are several varieties of silver ores, or ores containing silver, obtained from the Mexican mines; the principal of which are the sulphide of silver, chloride of silver, ruby silver, native silver, argentiferous pyrites and argentiferous galena.

Ruby and native silver, argentiferous pyrites, and galena have been found in Guanaxuato. Zacatecas is rich in the three first of these classes; the mine of Gallega, in this district, yielded a very large quantity of magnificent specimens of ruby silver. The greater proportion of the ore from the mines of San Clemente and San Nicholas is argentiferous pyrites, with native silver; the latter mine especially has recently produced some extraordinary specimens of native silver, weighing 25lbs. each. Zimapan produces a considerable quantity of argentiferous galena. This variety, in fact, occurs, though sparingly, in most of the other mining districts. Chloride of silver has been found at Fresnillo, and is still found at Catorce, where the ores also contain bromide of silver.

The several varieties, however, bear but a small proportion to the great mass of the silver ores of Mexico, which consists of a grey sulphide, generally more or less combined with other metals, and disseminated in minute particles throughout the matrix, in most instances composed of quartz, or in intimate connection with it. By far the largest portion then of the precious metal is obtained in every mining district of Mexico from the sulphide.

In some mines which have been explored to a great depth, and which are much troubled with water, as in Real del Monte, Bolaños, and Fresnillo, steam-engines have been introduced, and so long as an adequate power is applied, maintain the drainage of the mines without difficulty.

We now proceed to state some of the peculiar features observable in the working of the mines of Mexico, confining our attention to the mines of Guanaxuato, Zacatecas (including Fresnillo), and Real del Monte. The mines of Guanaxuato are situated upon one vein of great length and width. It should be understood that this vein, like all mineral veins, is not productive of silver ore throughout its whole extent, but the ore occurs in branches and bunches, leaving intermediate spaces of dead or unproductive ground; and as an ordinary mine level seldom exceeds 6 feet in width, it is clear that a level like this would not explore a vein of such dimensions as that of Guanaxuato, while the expense of cross cutting, as miners term it, would require more capital than the owners of the mine are willing to risk, or able, in many instances, to spare. Hence, there sprung up in Guanaxuato a system of working well adapted to the circumstances noticed, and being based upon the principle that the hope of reward acts as a stimulus to exertion, has been attended with the best effects, and led to the discovery of some of the richest deposits of ore.

This system is called that of the "buscones" or seekers, who are the working miners. These men, at their own risk, work in the mines under certain restrictions, and following up such indications as may appear to them favourable, oftentimes meet with a valuable course of ore, but frequently work for months, earning scarcely enough for bare subsistence. While thus employed the buscon receives half the produce of the ore he breaks; and it may be readily conceived that if he should fall in with a rich deposit, his gains would be very large: thus, instances have been known where a man has obtained, in this way, 1000 or 1500 dollars in a month.

The owners of the mine, however, have the option of taking away such a discovery out of the hands of the miner, after a short notice, and working it on their own account, or, as it is termed, hacienda account, when they pay the miners a dollar per day each, without any share of the ore. To do this, however, the mine must be rich, and as it is, a very large portion of the ore in Guanaxuato is raised by the buscones, who divide the produce equally with the owners.

The ore being broken and separated as much as possible from the rocky parts underground, is tied up in the "botas" of bullocks' hides, which are drawn to the surface by the malacates, in the same manner as the water. In some of the Guanaxuato mines, labourers are employed to take the ore to the surface, and these will carry on their backs from 2 to 3 cwt., and perform several journeys in a day from the bottom of a mine 400 or 500 yards in depth. At the mine of Mellado there is a very excellent double tramroad, on an inclined plane of timber, upon which the ore is drawn up in waggons to a height of 200 varas from the bottom of the mine, where the diagonal joins the perpendicular shaft at about the same depth from surface: each carriage will contain 160 arrobas of 25 lbs. The power applied is that of a malacate working underground; and here at 200 yards from the surface, and shut out from the light of day, one is surprised to behold a storehouse and stabling, with all the necessary appurtenances for thirty-six horses, employed in moving the machine above mentioned, nine horses working at a time.

Having brought the ore to the surface, it is conveyed to the mine yard, and placed in separate heaps, under the eye of the buscon or miner, who prepares it for sale. At a stated time the auctioneer appears, accompanied by a clerk; he walks round to the heaps of ore in succession, and sells them in the following manner:—

Standing before the heap of ore to which he invites attention, those who come to purchase come forward and whisper into his ear the price they severally offer. When all have done, he declares aloud the name of the highest bidder, and the price, which are entered in a book by the clerk; and the same process is followed throughout until all the ore is sold.

In Zacatecas the mines have not been found productive at so great a depth as those of Guanaxuato; and the veins being smaller and the deposits of ore more within reach of an ordinary level, there are not the same reasons for holding out similar inducements to the working miner to seek for ore at his own risk. Hence, most of the works of trial in the Zacatecas mines are carried on by the proprietors, and the miner is paid according to the quantity of ore he raises, this varying from 9 reals to 2½ dollars, or 4*s.* 6*d.* to 10*s.* per carga of 300 lbs., as circumstances may render necessary. Even in this district, however, it has lately been deemed expedient to introduce the system of Guanaxuato into some of the mines. The instances known to me are those of the mines of San Clemente and San Nicolas*, where the effect has been to increase the produce; but there is a peculiarity about these particular veins which renders such a system beneficial; they are very changeable, often separated into narrow branches, or showing mere threads of ore, and frequently again widening and yielding very rich bunches; besides which they are so cut up by cross courses that more than ordinary encouragement is needful to carry on works of research.

The practice in the Real del Monte differs from both the others, but assimilates a little towards the Guanaxuato system, inasmuch as the miner has a share of the ore called *partido*. This partido system has prevailed from a very early period, and has led to many broils and disturbances with the miners.

The method of extracting the silver from the ore, at the establishments maintained for that purpose, called haciendas de beneficio, or haciendas de Plata, of which there are many of great extent in the country, is thus carried forward. The haciendas Nueva in Fresnillo, of Sauceda in Zacatecas, of Barrera in Guanaxuata, and of Regla at Real del Monte, are the principal establishments of this kind at present in use. That in Fresnillo is the largest used for amalgamation only, the outer walls being 492 varas in length, by 412 varas in width. It was erected at a cost of 300,000 dollars, and is very complete in all its arrangements.

The Hacienda de Regla combines very extensive smelting works with those for amalgamation.

The ore being placed in heaps in the yard is broken by hammers into pieces of

* The *partido* or miner's share is at present one third of the ore.

moderate size, and carefully picked; the richer parts being set aside for smelting, and the poorer for amalgamation.

In the smelting process, the ore after being crushed, is mixed with slag or remains from former smeltings, litharge or oxide of lead, and a little iron ore and lime. These are put into the furnace with charcoal, and the silver is brought down with the lead, the two metals being afterwards separated in refining furnaces. The German high furnace is usually employed, although the Castilian furnace described in the article on lead-smelting, would probably be found preferable.

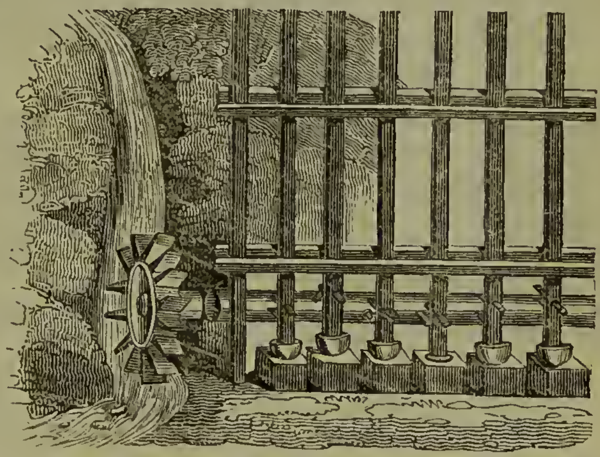
It is estimated that about an eighth part of the silver produced in Mexico is obtained by smelting; but as only the richest ores are subjected to this process, on account of the expense, which is from £15 to £20 per ton, except in a district like Zimapan, where lead ore is abundant, the proportion which the quantity of ore smelted bears when compared with that reduced by amalgamation must be very small indeed.

The process of amalgamation, to which attention is now more particularly directed, depends upon the great affinity of quicksilver for silver. In order, however, to make this known property available, certain operations are requisite, to reduce the silver contained in the ore to such a state that the quicksilver will readily combine with it.

After the breaking and dressing by hand the ore is crushed, either by crushing rollers or more generally by stamps, called in Mexico, *molinos*. The stamps are similar in principle to those used in the tin mines of Cornwall, but not so powerful, and are worked either by water-power or by mules. As the ore is crushed, it falls through small holes of about the size of peas, perforated in strong hides stretched in a slope on either side of the machine placed over a pit which receives the fine ore, from whence it is conveyed to the *arrastres* or grinding mills.

These stamping-mills are sometimes driven by a small breast water-wheel, of five feet diameter, and one foot broad. *Fig.* 1625 will give a sufficient idea of their construction. The long horizontal shaft, fixed on the axis of the wheel, is furnished with 5 or 6 cams placed at different situations round the shaft, so as to act in succession on the projecting teeth of the upright rods or pestles. Each of these weighs 200 pounds, and works in a corresponding oblong mortar of stone or wood.

1625



The arrastre or tahona, as it is called in the northern districts, is exceedingly simple, but for so rude a machine is very effective. Baron Humboldt, in alluding to it, says that he never saw ore so finely pulverised as he saw it in Mexico. In Guanaxuato, where there is much gold in the ore, this is particularly observable.

The arrastre consists in the first place of a strong wooden post moving on a spindle in a beam above it, and resting on an iron pivot beneath, turning in an iron socket on the top of a small post of hard wood which rises about a foot above the ground in the centre of the arrastre. See Ore Dressing.

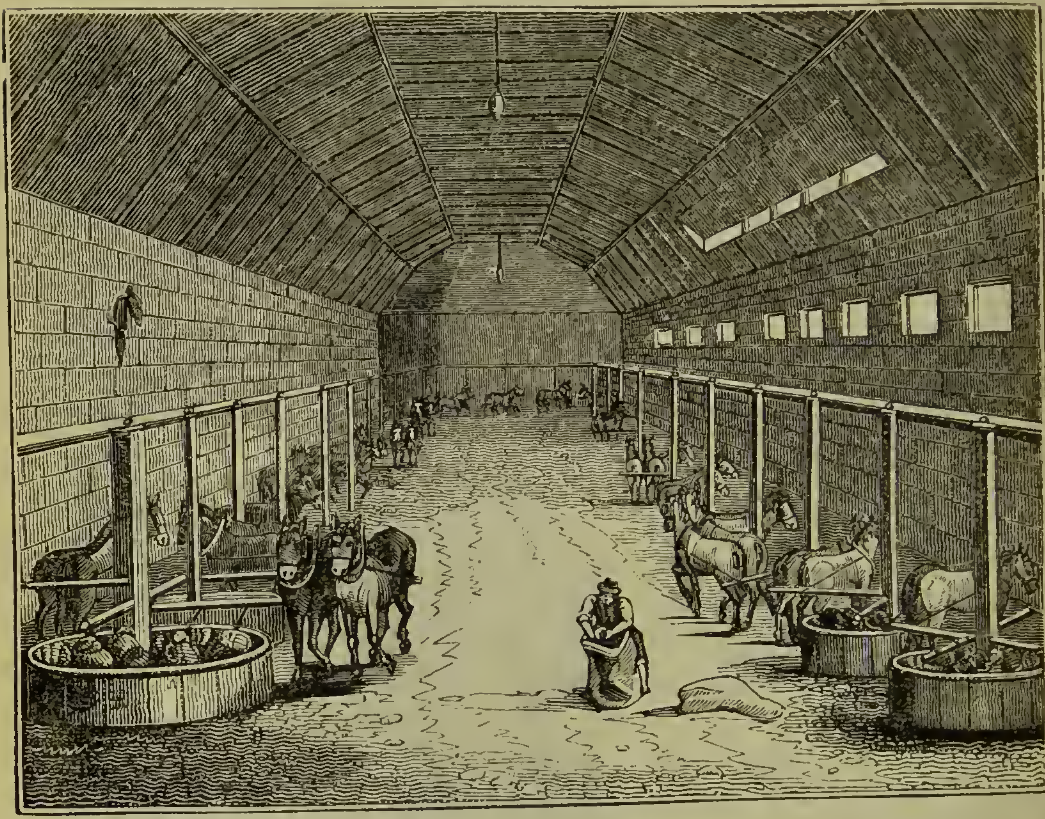
These arrastres are usually arranged in rows in a large gallery or shed, as will be seen by reference to *fig.* 1626, which represents the gallery of the Hacienda of Salgado.

A machine has been introduced at Real del Monte which has superseded the old Mexican arrastres. This machine is similar in principle to some of the grinding mills of this country, and to the trapiche of Peru. It consists of two large circular edge stones faced with iron, and moving over iron bottoms, the ore being crushed and ground with water between the two metal surfaces. The machine is turned by twelve mules in the twenty-four hours, four mules working at a time, and the quantity ground to a fine slime is sixty quintals, or about ten times the quantity ground by a common arrastre; and there is reason to believe that the quantity might be doubled by the use of water or steam-power, as the number of revolutions would be increased.

The ore being brought into a finely-divided state, is allowed to run out of the arrastre into shallow tanks or reservoirs, where it remains exposed to the sun until a larger portion of the water has evaporated, when it has the appearance of thick mud; and in this state the process is proceeded with.

The "lama," as it is called, or slime, is now laid out on the *patio*, or amalgamation floor (which is in some places boarded, and in others paved with flat stones), in large masses called *tortas*, forty to fifty feet in diameter, and about a foot thick, consisting frequently of sixty to seventy tons of ore; and so extensive are the floors that a large number of these tortas are seen in progress at the same time. Thus, at the Hacienda de Regla, the patio, which is boarded and carefully caulked, to render it water-tight, is capable of containing ten of these tortas, of about sixty tons each and fifty feet in diameter. The Hacienda de Barrera, in Guanaxuato, will hold eighteen tortas of seventy to seventy-five tons each. The Hacienda Sauceda at Zacatecas will contain twenty-four tortas of sixty tons each; and the patio floor of the Hacienda Nueva, at Fresnillo, is still larger, being 180 varas in length by as many in width, and capable of containing sixty-four tortas of seventy tons each!

1626



Having laid out the masses of ore in the patio, the operations necessary to produce the chemical changes commence. The first ingredient introduced is salt, which is put into the torta in the proportion of fifty lbs. to every ton of ore (but varying in different districts), and a number of mules are made to tread it, so that it may become dissolved in the water, and intimately blended with the mass. On the following day another ingredient is introduced, called in Mexico *magistral*. It is common copper pyrites or sulphide of copper and iron pulverised and calcined, which converts it into a sulphate. About twenty-five lbs. of this magistral are added for every ton of ore in the *torta*, and the mules are again put in and tread the mass for several hours. Chemical action now commences: the salt, magistral and metallic sulphurets are decomposed, and new combinations are in progress. Quicksilver is then introduced, being spread over the *torta* in very small particles, which is effected by passing it through a coarse cloth. The quantity required is six times the estimated weight of the silver contained in the ore, or three lbs. for every marc of eight oz.

The quicksilver being spread over the surface the mules are once more put in, and tread the whole until it is well mixed. This treading is called the *repaso*, and is repeated every other day, or less often, according to the judgment of the *azoguero* or superintendent, until the operation is completed.

But it is in the progress of the operation that the skill of the *azoguero* is most required, because he must attend to certain signs or appearances which present themselves to him, and upon which depend the success of his work, whether as it regards the produce of silver or the economy of quicksilver and other materials and time. For this purpose he has a small quantity of the *torta* put on one side, upon which he operates before adding materials to the *torta* itself; this is called a *guia*, or guide. In order to ascertain how the chemical action in the *torta* proceeds, he collects a small quantity of the slime and washes it in a small bowl, and by the signs presented by the quicksilver and amalgam he, from his practical knowledge of the subject, is able to judge as to the state of the *torta;* whether it requires more magistral or quicksilver; or whether it has had too much magistral, in which case it is hot, and a little lime must be put in to decompose the excess of bichloride of copper. This simple plan is termed the *tentadura*, by which in fact the *azoguero* is guided throughout the amalgamation process.

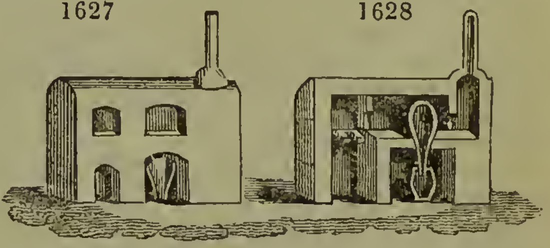
When at length he finds that quicksilver is no longer absorbed, the operation is considered complete, and the *torta rendida*, or ready to be washed, and sometimes lime is added to stop further action. A large quantity of quicksilver is then thrown in, and is called *el bano*, or bath, which combining with the amalgam, causes it to separate the more readily from the slime in the washing. The time required to complete the process varies from ten to thirty days; but in some places is often considerably more, according to climate and the nature of the ore.

The amalgam has now to be separated from the mass, which is done at Real del Monte by washing it in a large square vat, in which several men keep constantly stirring it with their feet, while at the same time a stream of water is made to pass through. By this means the lighter particles of the mud flow out into canals furnished with basins, called *apuros*, to catch all stray amalgam and quicksilver, and the great body of the amalgam remains at the bottom of the vat.

In Guanaxuato, the process of washing is more perfect. They have three circular vats called *tinas*, in which the ore is stirred by means of long wooden teeth fixed in cross bars attached to a vertical shaft, the whole turned by a simple machine, worked by mules. The slime has to pass through the third vat before being carried entirely away, so that a very small portion indeed of the amalgam escapes. The process of washing is somewhat similar in Zacatecas, but there they use but one *tina* or vat."

The amalgam is carried in bowls into the *asogueria*, where it is subjected to straining through the strong canvas bottom of a leathern bag. The hard mass left in the bag is moulded into wedge-shaped masses of 30 lbs., which are arranged in the burning house (*fig.* 1627), to the number of 11, upon a solid copper stand, called *baso*, having a round hole in its centre. Over this row of wedges several others are built; and the whole pile is called *pina*. Each circular range is firmly bound round with a rope. The base is placed over a pipe which leads to a small tank of water for condensing the quicksilver; a cylindrical space being left in the middle of the *pina*, to give free egress to the mercurial vapours.

1627 1628



Mr. J. C. Bowring, who has had many years' experience in the reduction of the ores of silver, both in Peru and Mexico, and has devoted much time and attention to an examination of the subject, disputes the theory of the amalgamation process hitherto received.

In reference to this subject, he remarks:—

"The theory of the chemical decompositions which take place in the Mexican amalgamation process has hitherto been supposed to be, that the bichloride of copper which is formed by the contact of magistral and common salt, abandons its chlorine to the silver, the sulphur of which combines with the copper, and the chloride of silver is decomposed by the mercury with which the precious metal becomes amalgamated. The following considerations, however, will disprove this theory:—

"1. Ores containing silver combined only with chlorine, are considered by Mexican miners as those most difficult of reduction, and the loss of mercury caused by them is at least treble that experienced in those which contain only sulphurets, and the process is much more tedious. To practical men also the appearance of the amalgams proceeding from these different combinations of silver, when assays are taken out of the tortas, are a convincing proof that the theories of their reduction cannot possibly be similar, for in the chloride the quicksilver is instantly attacked, and its globules are very difficult to be united by friction, on account of their being covered with a thin coating of protochloride (calomel), whereas, when operating upon sulphurets, the mercury is always bright (except at the very beginning of the process), and does not separate into globules, unless, indeed, too large a quantity of magistral has been used, when the appearance becomes similar, though in a slighter degree, to that when chloride of silver has been reduced.

"Various plans have been imagined to diminish or even entirely to do away with the loss of mercury, on the hypothesis that chloride of silver is formed, and in ores containing this native combination, as those of the district of Catorce, great advantages are derived by boiling them in copper vessels, as by the contact of this metal the chloride is decomposed before the mercury is added, thus rendering the loss of this scarcely appreciable. Upon this class of ores many of the plans proposed by European chemists have been successfully tried, but all have invariably failed when sulphides of silver have been attempted to be reduced by them.

"2. Although the experiments of M. Boussingault prove that a *strong* solution of the bichloride of copper mixed with one of salt, placed in contact with sulphide of silver, form, after some lapse of time, chloride of silver and sulphide of copper, still in practice this cannot be the case, for in many instances a solution of less than *one ounce* of sulphate of copper is required in *seventy pounds* of water, and even in the ores most difficult of reduction the quantity is rarely more than *eight ounces.* Numberless experiments have been made in Mexico to bring this principle into practice, but after leaving the ore for two months exposed to the action of a solution of bichloride of copper in one of salt, a trace even of chloride of silver is rarely to be found; and then, on adding the mercury, the process lasts as long as in ordinary cases, when it is put in before the sulphate of copper. From the constant failure of these trials it is evident that the theory on which they are founded must be fallacious.

"The presence of mercury being thus necessary, not merely as the means of collecting the particles of silver disseminated through the ore, but also as a chemical agent, the action of bichloride of copper upon it must be considered. By this action, which takes place instantaneously, a protochloride of both metals is formed, and that of the copper by absorbing oxygen from the atmosphere becomes converted into an oxychloride, which by giving up its oxygen to the sulphur combined with the silver, leaves this in a metallic state, and free to amalgamate with the mercury. This is proved by boiling native sulphuret of silver with oxychloride of copper in a solution of common salt, when metallic silver will be obtained; or as a more practical experiment, by mixing some rich ore with these materials and mercury at the ordinary temperature; in about an hour the whole of the silver will have become amalgamated, when on separating all the soluble salts by filtration, on the addition of chloride of barium, sulphate of barytes will be precipitated, equivalent in quantity to that of the sulphur which has been acidified; it will thus be made evident that the sulphuric acid can only have been formed by the decomposition of the sulphuret of silver, and could not have existed if this metal had become combined with chlorine according to the old theory of the process.

"The action of oxychloride of copper in the reduction of silver ores seems to be continuous, and its theory thus offers some analogy to that of the manufacture of sulphuric acid; by giving up its oxygen to the sulphur previously combined with the silver the oxychloride of copper is converted into a protochloride, and this into a bichloride by the action of the chlorine which is evolved by the decomposition of the salt when attacked by the sulphuric acid that has been formed. This bichloride is again decomposed by the mercury, and first a proto and then an oxychloride of copper is formed; the sulphur of the silver becomes acidified, and the action is continued in the same manner until the whole of the metal is amalgamated.

"The imperfections in the Mexican amalgamation process arise chiefly from the small quantity of oxychloride of copper that can be employed; for by using too large a proportion of the sulphate the mercury becomes sensibly attacked, and when its surface is not perfectly clean it will not take up the particles of silver. The use of salt in the tortas has always been supposed to be to dissolve the chloride of silver formed during the process, but its real object is to assist, first, in the formation of the oxychloride of copper, and to dissolve it afterwards, thus rendering it more fit to act upon the sulphide of silver."

A large bell-shaped cover, called *capellina*, is now hoisted up, and carefully lowered over the *pina*, by means of pulleys. A strong lute of ashes, saltierra, and lama is applied to its lower edge, and made to fit very closely to the plate on which the base stands. A wall of fire-bricks is then built loosely round the capellina, and this space is filled with burning charcoal, which is thrice replenished, to keep it burning all night. After the heat has been applied 20 hours, the bricks and ashes are removed, the luting broken, and the capellina hoisted up. The burned silver is then found in a hard mass, which is broken up, weighed, and carried to the casting-house, to be formed into bars.

It will be observed that quicksilver performs a very important part in the process of amalgamation, the silver being through its agency collected from the ore: but this is only done at an enormous loss of its own bulk, occasioned in part mechanically from its minute subdivision through such an immense mass of matter, but principally from the chemical action upon it during the reducing process. The consumption of quicksilver varies in different districts, according to the nature of the ores, the climate, and the practical skill attained by the operator.

In some places and on some ore the loss of quicksilver is as low as ten ounces for every marc of silver produced, while in others it exceeds 20 ounces; the average loss may, however, be taken to be a pound of quicksilver for every half pound of silver extracted.

Gay Lussac, Boussingault, Karsten, and several other chemists of note have offered solutions of the amalgamation enigma of Mexico and Peru. The following seems to be the most probable *rationale* of the successive steps of the process:

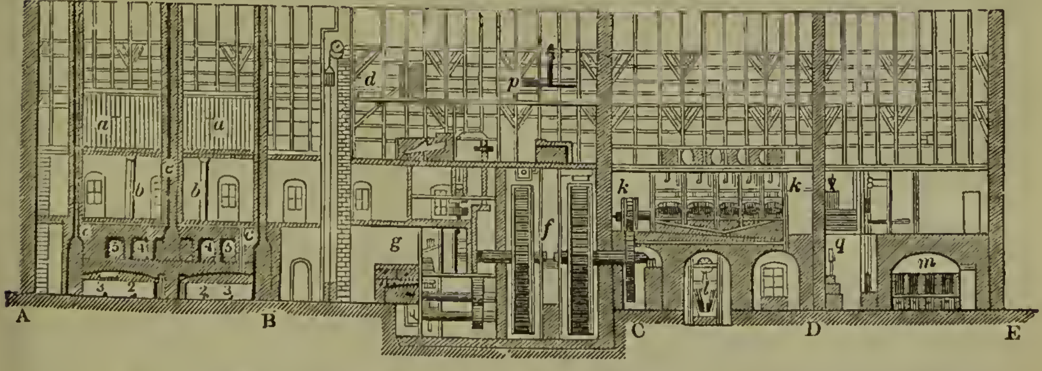
The addition of the *magistral* (powder of the roasted copper pyrites), is not for the purpose of disengaging hydrochloric acid from the sea salt (*saltierra*), as has been supposed, since nothing of the kind actually takes place; but, by reciprocal or compound affinity, it serves to form chloride of copper, and chloride of iron, upon the one hand, and sulphate of soda, upon the other. Were sulphuric acid to be used instead of the magistral, as certain novices have prescribed, it would certainly prove injurious, by causing muriatic acid to exhale. Since the ores contain only at times oxide of silver, but always a great abundance of oxide of iron, the acid would partly carry off both, but leave the chloride of silver in a freer state. A magistral, such as sulphate of iron, which is not in a condition to generate the chlorides, will not suit the present purpose; only such metallic sulphates are useful as are ready to be transformed into chlorides by the *saltierra.* This is peculiarly the case with sulphate of copper. Its deuto-chloride gives up chlorine to the silver, becomes in consequence a protochloride, while the chloride of silver, thus formed, is revived, and amalgamated with the quicksilver present, by electro-chemical agency which is excited by the saline menstruum; just as the voltaic pile of copper and silver is rendered active by a solution of sea salt. A portion of chloride of mercury will be simultaneously formed, to be decomposed in its turn by the sulphate of silver resulting from the mutual action of the acidified pyrites, and the silver or its oxide in the ore. An addition of quicklime counteracts the injurious effect of too much magistral, by decomposing the resulting sulphate of copper. Quicksilver, when introduced in too great quantities, is apt to cool the mass too much, and thereby enfeebles the operation of the deuto-chloride of copper upon the silver.

There is a method of extracting silver from its ores by what is called *imbibition.* This is exceedingly simple, consisting in depriving, as far as possible, the silver of its gangue, then melting it with about its own weight of lead. The alloy thus procured, contains the silver, which is separated by cupellation, &c., as described under ores of *lead.* In this way the silver is obtained at Kongsberg in Norway.

The amalgamation works at Halsbrücke, near Freyberg, for the treatment of silver ores by mercury, have been justly admired as a model of convenience and regularity; and we will extend this subject with a sketch of their general distribution.

Fig. 1629 presents a vertical section of this great *usine* or *hüttenwerk,* subdivided

1629



into four main departments. The first, A, B, is devoted to the preparation and roasting of the matters intended for amalgamation. The second, B, C, is occupied with two successive siftings and the milling. The third, C, D, includes the amalgamation apartment above, and the wash-house of the residuums below. And in the fourth, D, E, is placed the distilling apparatus, where the amalgam is finally delivered.

Thus, from one extremity of this building to the other, the workshops follow in the order of the processes; and the whole, over a length of 180 feet, seems to be a natural laboratory, through which the materials pass, as it were of themselves, from their crude to their refined condition; so skilfully economised and methodical are the labours of the workmen; such are the regularity, precision, concert, and facility, which pervade this long series of combinations, carriages, movements, and metamorphoses of matter.

Here we distinguish the following objects:—

1. In division A, B; *a*, *a*, is the magazine of salt; *b*, *b*, is the hall of preparation of the ores; on the floor of which they are sorted, interstratified, and mixed with salt; *c*, *c*, are the roasting furnaces; in each of which we see, 1, the fireplace; 2, 3, the reverberatory hearth, divided into two portions, one a little higher than the other, and more distant from the fireplace, called the *drier*. The materials to be calcined fall into it through a chimney, 6. The other part, 2, of the hearth is the calcining area. Above the furnace are chambers of sublimation, 4, 5, for condensing any volatile matters which may escape by the opening 7. *c* is the main chimney.

2. In the division B, C, we have *d*, the floor for the coarse sifting; beneath, that for the fine sieves; from which the matters fall into the hopper, whence they pass down to *g*, the mill-house, in which they are ground to flour, exactly as in a corn-mill, and are afterwards bolted through sieves. *p*, *f*, is the wheel machinery of the mill.

3. The compartment C, D, is the amalgamation house, properly speaking, where the casks are seen in their places. The washing of the residuums is effected in the shop *l*, below. *k*, *k*, is the compartment of revolving casks.

3. In the division D, E, the distillation process is carried on. There are four similar furnaces, represented in different states, for the sake of illustration. The wooden drawer is seen below, supporting the cast-iron basin, in which the tripod with its candelabra for bearing the amalgam saucers is placed. *q* is a store chamber.

At B, are placed the pulleys and windlass for raising the roasted ore, to be sifted and ground; as also for raising the milled flour, to be transported to the amalgamation casks. At D, the crane stands for raising the iron bells that cover the amalgamation candelabra.

Details of the Amalgamation Process, as practised at Halsbrücke.—All ores which contain more than 7 lbs. of lead, or 1 lb. of copper, per cent., are excluded from this reviving operation (*anquickverfahren*); because the lead would render the amalgam very impure, and the copper would be wasted. They are sorted for the amalgamation, in such away that the mixture of the poorer and richer ores may contain 7½, or, at most, 8 loths (of ½ oz. each) of silver per 100 lbs. The most usual constituents of the ores are, sulphur, silver, antimonial silver (speissglanzsilber), bismuth, sulphides of arsenic, of copper, iron, lead (nickel, cobalt), zinc, with several earthy minerals. It is essential that the ores to be amalgamated shall contain a certain proportion of sulphur, in order that they may decompose enough sea salt in the roasting to disengage as much chlorine as to convert all the silver present into chloride. With this view, ores poor in sulphur are mixed with those that are richer, to make up a determinate average. The ore-post is laid upon the *bed-floor*, in a rectangular heap, about 17 ells long, and 4½ ells broad (13 yards and 3½); and upon that layer the requisite quantity of salt is let down from the floor above, through a wooden funnel; 40 cwts. of salt being allotted to 400 cwts. of ore. The heap being made up with alternate strata to the desired magnitude, must be then well mixed, and formed into small bings, called *roast-posts*, weighing each from 3½ to 4½ cwts. The annual consumption of salt at Halsbrücke is 6000 cwts., and is supplied by the Prussian salt-works.

Roasting of the Amalgamation Ores.—The furnaces appropriated to the roasting of the ore-posts are of a reverberatory class, provided with soot chambers. They are built alongside the *bed-floor*, and connected with it by a brick tunnel. The prepared ground ore (*erzmehl*) is spread out upon the hearth, and dried with incessant turnings over; then the fire is raised so as to kindle the sulphur, and keep the ore red hot for one or two hours; during which time, dense white-grey vapours of arsenic, antimony, and water, are exhaled. The desulphuration next begins, with the appearance of a blue flame. This continues for three hours, during which the ignition is kept up; and the mass is diligently turned over, in order to present new surfaces, and prevent caking. Whenever sulphurous acid ceases to be formed, the finishing calcination is to be commenced with increased firing; the object being now to decompose the sea salt by means of the metallic sulphates that have been generated, and to convert them into chlorides, with the simultaneous production of sulphate of soda. The stirring is to be continued till the proofs taken from the hearth no longer betray the smell of sulphurous, but only of hydrochloric acid gas. This roasting stage commonly lasts three quarters of an hour, 13 or 14 furnaces are worked at the same time at Halsbrücke; and each turns out in a week upon an average 5 tons. Out of the *nicht* chambers of soot vaults of the furnaces, from 96 to 100 cwts. of ore dust are obtained, containing 32 marcs (16 lbs.) of silver. This dust is to be treated like unroasted ore.

The fuel of the first fire is pitcoal; of the finishing one, fir-wood. Of the former $115\frac{1}{2}$ cubic feet, and of the latter, $294\frac{1}{4}$, are, upon an average, consumed for every 100 cwts. of ore.

During the last roasting, the ore increases in bulk by one fourth, becomes in consequence a lighter powder, and of a brown colour. When this process is completed, the ore is raked out upon the stone pavement, allowed to cool, then screened in close sieve-boxes, in order to separate the finer powder from the lumps. These are to be bruised, mixed with sea salt, and subjected to another calcination. The finer powder alone is taken to the millstones, of which there are 14 pairs in the establishment. The stones are of granite, and make from 100 to 120 revolutions per minute. The roasted ore, after it has passed through the bolter of the mill, must be as impalpable as the finest flour.

The Amalgamation. — This (the *verquicken*) is performed in 20 horizontal casks, arranged in 4 rows, each turning upon a shaft which passes through its axis; and all driven by the water-wheel shown in the middle of *fig.* 1629. The casks are 2 feet 10 inches long, 2 feet 8 inches wide, inside measure, and are provided with iron ends. The staves are $3\frac{1}{2}$ inches thick, and are bound together with iron hoops. They have a double bung-hole, one formed within the other, secured by an iron plug fastened with screws. They are filled by means of a wooden spout terminated by a canvas hose; through which 10 cwts. of the bolted ore-flour (*erzmehl*) are introduced after 3 cwts. of water have been poured in. To this mixture, from $\frac{3}{4}$ to $\frac{7}{8}$ of a cwt. of pieces of iron, $1\frac{1}{2}$ inch square, and $\frac{3}{8}$ thick are added. When these pieces get dissolved, they are replaced by others. The casks being two thirds full, are set to revolve for $1\frac{1}{2}$ or 2 hours, till the ore-powder and water become a uniform pap; when 5 cwts. of quicksilver are poured into each of them. The casks being again made tight, are put in gear with the driving machinery, and kept constantly revolving for 14 or 16 hours, at the rate of 20 or 22 turns per minute. During this time they are twice stopped and opened, in order to see whether the pap be of the proper consistence; for if too thick, the globules of quicksilver do not readily combine with the particles of ore; and if too thin, they fall and rest at the bottom. In the first case, some water must be added; in the second, ore. During the rotation, the temperature rises, so that even in winter it sometimes stands so high as 104° F.

The chemical changes which occur in the casks are the following: — The metallic chlorides present in the roasted ore are decomposed by the iron, whence results chloride of iron, whilst the deutochloride of copper is reduced partly to protochloride, and partly to metallic copper, which throw down metallic silver. The mercury dissolves the silver, copper, lead, antimony, in a complex amalgam. If the iron is not present in sufficient quantity, or if it has not been worked with the ore long enough to convert the copper deutochloride into a protochloride, previously to the addition of the mercury, more or less of the last metal will be wasted by its conversion into protochloride (calomel). The water holds in solution sulphate of soda, undecomposed sea salt, with chlorides of iron, manganese, &c.

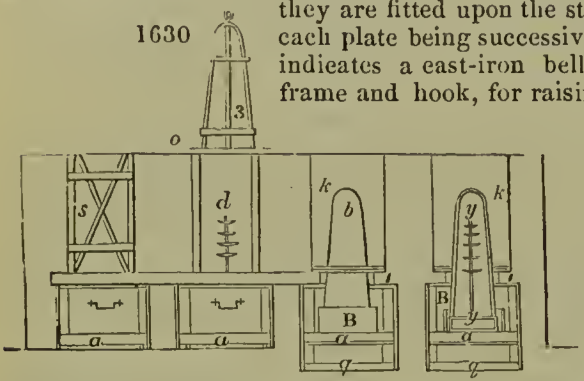
As soon as the revivification is complete, the casks must be filled with water, set to revolve slowly (about 6 or 8 times in the minute), by which in the course of an hour, or an hour and a half at most, a great part of the amalgam will have collected at the bottom; and in consequence of the dilution, the portion of horn silver held in solution by the sea salt will fall down and be decomposed. Into the small plug in the centre of the bung, a tube with a stopcock is now to be inserted, to discharge the amalgam into its appropriate chamber. The cock must be stopped whenever the brown muddy residuum begins to flow. The main bung being then opened, the remaining contents of the casks are emptied into the *wash-tun*, while the pieces of iron are kept back. The residuary ore is found to be deprived of its silver to within $\frac{5}{32}$ or $\frac{7}{40}$ of an ounce per cwt. The emptying of all the casks, and charging them again, takes 2 hours; and the whole process is finished within 18 or 20 hours; namely, 1 hour for charging, 14 to 16 hours for amalgamating; $1\frac{1}{2}$ hour for diluting; 1 hour for emptying. In 14 days, 3200 cwts. of ore are amalgamated. For working 100 cwts. of ore, $14\frac{1}{2}$ lbs. of iron are required; and for every pound of silver obtained, 3 ounces of mercury are consumed.

Trials have been made to conduct the amalgamation process in iron casks, heated to 150° or 160° Fahrenheit, over a fire; but though the desilvering was more complete, the loss of mercury was so much greater as to more than counterbalance that advantage.

Treatment of the Amalgam. — It is first received in a moist canvas bag, through which the thin uncombined quicksilver spontaneously passes. The bag is then tied up and subjected to pressure. Out of 20 casks. from 3 to $3\frac{1}{2}$ cwts. of solid amalgam are thus procured, which usually consist of 1 part of an alloy, containing silver of 12 or 13 *loths* (in 16), and 6 parts of quicksilver. The foreign metals in that alloy are, copper, lead, gold, antimony, cobalt, nickel, bismuth, zinc, arsenic, and iron. The filtered quicksilver contains moreover 2 to 3 loths of silver in the cwt.

Fig. 1630 represents the apparatus for distilling the amalgam in the Halsbrücke works; marked *m* in *fig.* 1629. *a* is the wooden drawer, sliding in grooves upon the basis *q*; B is an open basin or box of cast iron, laid in the wooden drawer; *y* is a kind of iron candelabra, supported upon four feet, and set in the basin B; under *d* are five dishes or plates, of wrought iron, with a hole in the centre of each, by which they are fitted upon the stem of the candelabra, 3 inches apart, each plate being successively smaller than the one below it. 3 indicates a cast-iron bell, furnished with a wrought-iron frame and hook, for raising it by means of a pulley and cord. *s* is a sheet-iron door for closing the stove, whenever the bell has been set in its place.

1630



The box, *a*, and the basin, B, above it, are filled with water, which must be continually renewed, through a pipe in the side of the wooden box, so that the iron basin may be kept always submersed and cool. The drawer *a*, being properly placed, and the plates under *d* being charged with balls of amalgam (weighing altogether 3 cwts.), the bell 3 is to be let down into the water, as at *y*, and rested upon the lower part of the candelabra. Upon the ledge 1, which defines the bottom of the fireplace, a circular plate of iron is laid, having a hole in its middle for the bell to pass through. Upon this plate chips of fir-wood are kindled, then the door *s*, which is lined with clay, is closed and luted tight The fuel is now placed in the vacant space *k*, round the upper part of the bell. The fire must be fed in most gradually, first with turf, then with charcoal; whenever the bell gets red, the mercury volatilises, and condenses in globules into the bottom of the basin B. At the end of 8 hours, should no more drops of mercury be heard to fall into the water, the fire is stopped. When the bell has become cool, it is lifted off; the plates are removed from the candelabra *d*; and this being taken out, the drawer *a* is slid away from the furnace. The mercury is drained, dried, and sent again into the amalgamation works. The silver is fused and refined by cupellation.

From 3 cwts. of amalgam, distilled under the bell, from 95 to 100 marcs (½ lbs.) of *teller* silver (dish silver) are procured, containing from 10 to 13½ parts of fine silver out of 16; one fifth part of the metal being copper. The *teller* silver is refined in quantities of 160 or 170 marcs, in black-lead crucibles filled within two inches of their brims, and submitted to brisk ignition. The molten mass exhales some vapours, and throws up a liquid slag, which being skimmed off, the surface is to be strewed over with charcoal powder, and covered with a lid. The heat having been briskly urged for a short time, the charcoal is then removed along with any fresh slag that may have risen, in order to observe whether the vapours have ceased. If not, fresh charcoal must be again applied, the crucible must be covered, and the heat increased, till fumes are no longer produced, and the surface of the silver becomes tranquil. Finally, the alloy, which contains a little gold, and much copper, being now from 11 to 13 *löthig* (that is, holding from 11 to 13 parts of fine silver in 16 parts), is cast into iron moulds, in ingots of 60 marcs. The loss of weight by evaporation and skimming of the slag amounts to 2 per cent.; the loss in silver is inconsiderable.

The dust from the furnace (*tiegelöfen*) is collected in a large condensation chamber of the chimney, and affords from 40 to 50 marcs of silver per cwt. The slags and old crucibles are ground and sent to the small amalgamation mill.

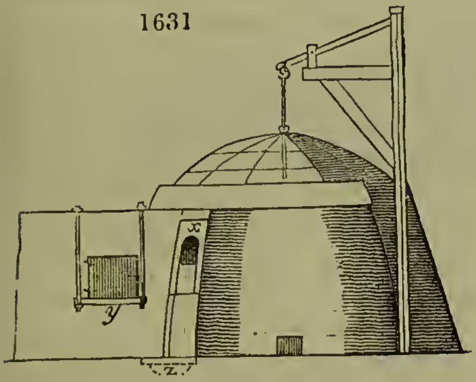
The earthy residuum of the amalgamation casks being submitted to a second amalgamation, affords out of 100 cwts. about 2 lbs. of coarse silver. This is first fused along with three or four per cent. of a mixture of potash and calcined quicksalz (impure sulphate of soda), and then refined. The supernatant liquor that is drawn out of the tanks in which the contents of the casks are allowed to settle, consists chiefly of sulphate of soda, along with some common salt, sulphates of iron and manganese, and a little phosphate, arseniate, and fluate of soda. The earthy deposit contains from ¼ to $\frac{9}{32}$ of a *loth* of silver per cwt., but no economical method of extracting this small quantity has yet been contrived.

The most extensive amalgamation works in Europe are probably those of La Bella Raguel, in which are treated the ores obtained from the mines of Hiendelencina, situated in the province of Guadalajura, Spain. In that establishment the ores are chiefly washed in revolving calciners, and are subsequently treated in barrels, of which sixty are employed.

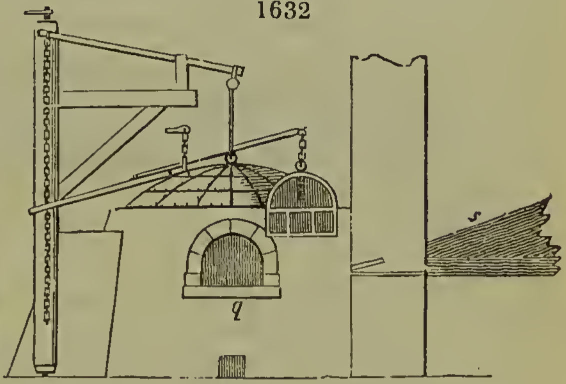
Instead of treating silver ore by the aid of mercury, they are sometimes operated on by a saturated solution of common salt. This process depends on the fact that chloride of silver is soluble in boiling and saturated solutions of this menstruum, and again deposited on cooling and dilution.

Argentiferous or *rich lead* is treated in Germany by the cupellation furnace represented in *figs.* 1631, 1632, 1633, and 1634. These figures exhibit the cupellation furnace of the principal smelting work in the Harz, where the following parts must be distinguished; (*fig.* 1633) 1, masonry of the foundation; 2, flues for the escape of moisture; 3, stone covers of the flues; 4, bed of hard-rammed scoriæ; 5, bricks set on edge, to form the permanent area of the furnace; 6, the sole, formed of wood ashes, washed, dried, and beaten down; *k*, dome of iron plate, movable by a crane, and susceptible of being lined two inches thick with loam; *n*, *n*, tuyères for two bellows, *s*, having valves suspended before their orifices to break and spread the blast; *q*, door for introducing into the furnace the charge of lead, equal to 84 quintals

1631

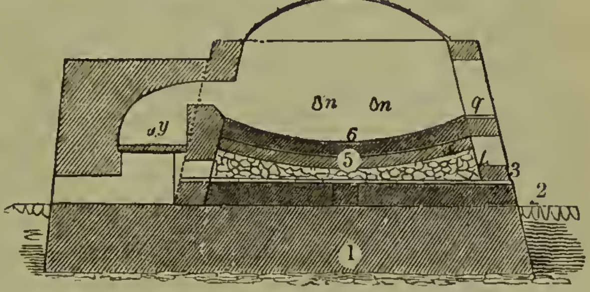


1632



at a time; *s*, *fig.* 1632, two bellows, like those of a smith's forge; *y*, door of the fire-place, through which billets of wood are thrown on the grate; *x*, small aperture or door, for giving issue to the frothy scum of the cupellation, and the litharge; *z*, basin of safety, usually covered with a stone slab, over which the litharge falls: in case of accident the basin is laid open to admit the *rich lead*.

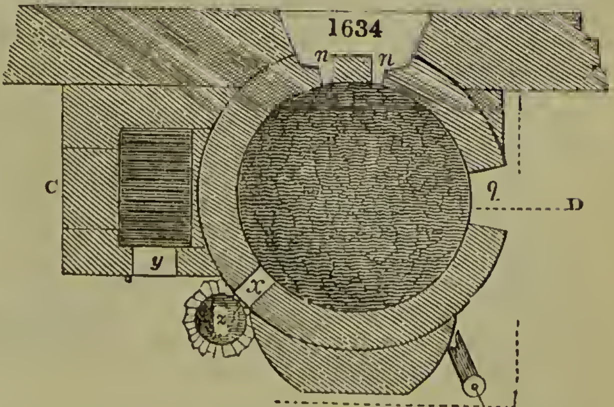
1633



The following is the mode of conducting the cupellation: — Before putting the lead into the furnace, a floor is made in it of ashes beat carefully down (see *fig.* 1633); and there is left in the centre of this floor a circular space, somewhat lower than the rest of the hearth, where the silver ought to gather at the end of the operation. The cupel is fully 6 feet in diameter.

In forming the floor of a cupel, 35 cubic feet of washed wood ashes, usually got from the soap works, are employed. The preparation of the floor requires two and a half hours' work; and when it is completed, and the movable dome of iron plate has been lined with loam, 84 quintals (cwt.) of lead are laid on the floor, 42 quintals being placed in the part of the furnace farthest from the bellows, and 42 near to the fire bridge; to these, scoriæ containing lead and silver are added, in order to lose nothing. The movable lid is now luted on the furnace, and heat is slowly applied in the fireplace by burning fagots of fir-wood; this is gradually raised. Section *fig.* 1633, is in the line C, D, of *fig.* 1634.

1634



At the end of three hours, the whole lead being melted, the instant is watched for when no more ebullition can be perceived on the surface of the bath or melted metal, then, but not sooner, the bellows are set a-playing on the surface at the rate of four or five strokes per minute, to favour the oxidation.

In five hours, reckoned from the commencement of the process, the fire is smartly raised; when a greyish froth (*abstrich*) is made to issue from the small aperture *x*, of the furnace. This is found to be a brittle mixture of oxidised metals and impurities. The workman now glides the rake over the surface of the bath, so as to draw the froth out of the furnace; and as it issues, powdered charcoal is strewed upon it at the aperture *x*, to cause its coagulation. The froth skimming lasts for about an hour and a half.

After this time the litharge begins to form, and it is also let off by the small opening *x*, its issue being aided by a hook. In proportion as the floor of the furnace gets impregnated with litharge, the workman digs in it a gutter for the escape of the liquid litharge: it falls in front of the small aperture, and concretes in stalactitic forms.

By means of the two movable valves suspended before the tuyères *n*, *n* (*fig.* 1634), the workman can direct the blast as he wishes over the surface of the metal. The wind should be made to cause a slight curl on the liquid, so as to produce circular undulations, and gradually propel a portion of the litharge generated towards the edges of the cupel, and allow this to retain its shape till the end of the operation. The stream of air should drive the greater part of the litharge towards the small opening *x*, where the workman deepens the outlet for it, in proportion as the level of the metallic bath descends. Litharge is thus obtained during about twelve hours; after which period the cake of silver begins to take shape in the centre of the cupel.

Towards the end of the operation, when no more than 4 additional quintals of litharge can be looked for, and when it forms solely in the neighbourhood of the silver cake in the middle of the floor, great care must be taken to set apart the latter portions, because they contain silver. About this period the fire is increased, and the workman places before the little opening *x*, a brick, to serve as a mound against the efflux of litharge. The use of this brick is,—1, to hinder the escape of the silver in case of any accident; for example, should an explosion take place in the furnace; 2, to reserve a magazine of litharge, should that still circulating round the silver cake be suddenly absorbed by the cupel, for in this dilemma the litharge must be raked back on the silver; 3, to prevent the escape of the water that must be thrown on the silver at the end of the process.

When the argentiferous litharge, collected in the above small magazine, is to be removed, it is let out in the form of a jet, by the dexterous use of the iron hook.

Lastly, after twenty hours, the silver cake is seen to be well formed, and nearly circular. The moment for stopping the fire and the bellows is indicated by the sudden disappearance of the coloured particles of oxide of lead, which, in the latter moments of oxidation, undulate with extreme rapidity over the slightly convex surface of the silver bath, moving from the centre to the circumference. The phenomenon of their total disappearance is called the *lightning*, or *brightening*. Whenever this occurs, the plate of silver being perfectly clean, there is introduced into the furnace by the door *q*, a wooden spout, along which water, previously heated, is carefully poured on the silver.

The cupellation of 84 quintals of argentiferous lead takes in general eighteen or twenty hours. The promptitude of the operation depends on the degree of purity of the leads employed, and on the address of the operator, with whom also lies the economy of fuel. A good workman completes the cupellation of 84 quintals with 300 billets, each equivalent to a cubic foot and $\frac{8}{10}$ths of wood (Harz measure); others consume 400 billets, or more. In general, the cupellation of 100 quintals of lead, executed at the rate of 84 quintal charges, occasions a consumption of 790 cubic feet of resinous wood billets.

The products of the charge are as follows:—

1. Silver, holding in 100 marcs, 7 marcs and 3 loths of alloy -	24 to 30 marcs.
2. Pure litharge, containing from 88 to 90 per cent. of lead -	50 „ 60 quintals.
3. Impure litharge, holding a little silver - - - -	2 „ 6
4. Skimmings of the cupellation - - - - -	4 „ 8
5. Floor of the furnace impregnated with litharge - -	22 „ 30

NOTE.— *The marc is* 7 *oz.* 2 *dwts.* 4 *gr. English troy; and the loth is half an ounce.* 16 *loths make a marc.* 100 *lbs. Cologne are equal to* 103 *lbs. avoirdupois; and the above quintal contains* 116 *Cologne lbs.*

The loss of lead inevitable by this operation is estimated at 4 parts in 100. It has been diminished as much as possible in the Frankenscharn works of the Harz, by leading the smoke into long flues, where the lead fumes are condensed into a metallic soot. The silver cake receives a final purification at the Mint, in a cupel on a smaller scale.

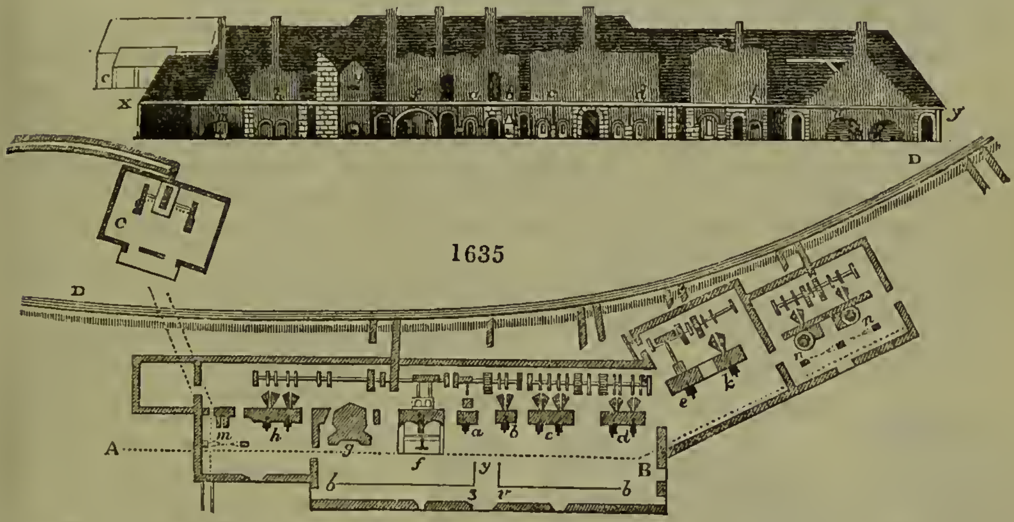
From numerous experiments in the great way, it has been found that not more than 100 quintals of lead can be profitably cupelled at one operation, however large the furnace, and however powerful and multiplied the bellows and tuyères may be; for the loss on either the lead or the silver, or on both, would be increased. In one attempt, no less than 500 quintals were acted on, in a furnace with two fire-places, and four escapes for the litharge; but the silver remained disseminated through the lead, and the *lightning* could not be brought on. The chief object in view was economy of fuel.

Reduction of the litharge.—This is sometimes executed in a slag-hearth, with the aid of wood charcoal.

The following is the train of operations by which the cupriferous galena *schlich*, or ground ore is reduced in the district of Clausthal, into lead, copper, and silver. The works of Frankenscharn have a front fully 400 feet long.

Fig. 1635 exhibits the plan and elevation of these smelting-works, near Clausthal, in the Harz, for lead ores containing copper and silver, where about 84,000 cwts. of

Silver-smelting Works of Frankenscharn, near Clausthal.

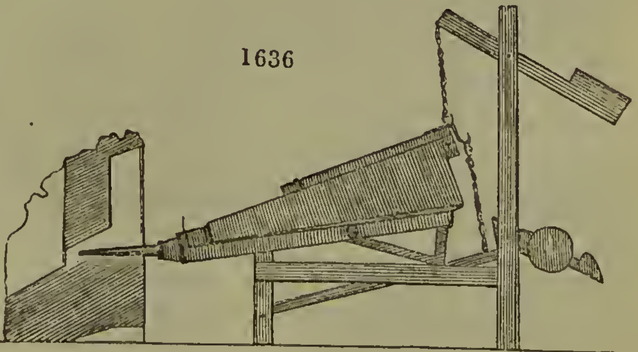


schlich (each of 123 Cologne pounds) are treated every year. This quantity is the produce of 30 distinct mines, as also of nearly as many stamp and preparation works. All these different *schlichs*, which belong to so many different joint-stock companies, are mixed and worked together in the same series of metallurgic operations; the resulting mixture being considered as one and the same ore belonging to a single undertaking; but in virtue of the order which prevails in this royal establishment, the rights of each of the companies, and consequently of each shareholder, are equitably regulated. A vigorous control is exercised between the mines and the stamps, as also between the stamps and the smelting-houses; while the cost of the metallurgic operations is placed under the officers of the crown, and distributed, upon just principles, among the several mines, according to the quantities of metal furnished by each.

The following is the series of operations:—

1. The fusion of the schlich; 2, the roasting of the matts under a shed, and their treatment by four successive remeltings; 3, the treatment of the resulting black copper; 4, the liquation; 5, the reliquation (*ressuage*); 6, the refining of the copper; 7, the cupellation of the silver; 8, the reduction of the litharge into lead. The 5th and 6th processes are carried on at the smelting works of Altenau.

1636



The buildings are shown at A, B, C, and the impelling stream of water at D; the upper figure being the elevation; the lower, the plan of the works.

a, is a melting furnace, with a cylinder bellows behind it; *b*, *c*, *d*, furnaces similar to the preceding, with wooden bellows, such as *fig.* 1636; *e*, is a furnace for the same purpose, with three tuyères, and a cylinder bellows; *f*, the large furnace of fusion, also with three tuyères; *g*, a furnace with seven tuyères, now seldom used; *h*, low furnaces, like the English slag-hearths (*krummofen*), employed for working the last *mattes*; *k*, slag-hearths for reducing the litharge; *m*, the area of the liquation; *n*, *n*, cupellation furnaces.

x, *y*, a floor which separates the principal smelting-houses into two stories; the materials destined for charging the furnaces being deposited in beds upon the upper floor, to which they are carried by means of two inclined planes, terraced in front of the range of buildings.

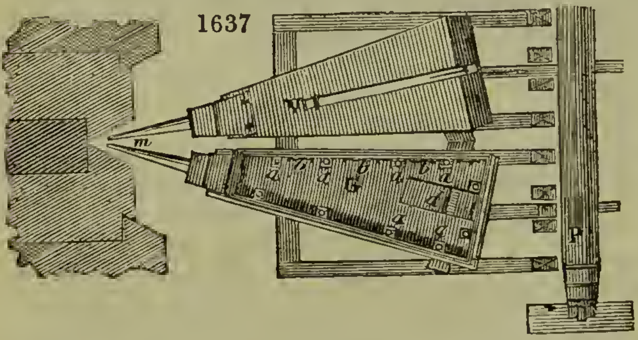
Here 89,600 quintals of schlich are annually smelted, which furnish —

Marketable lead - - - - - - - -	20,907 quintals.
Marketable litharge, containing 90 per cent. of lead -	7,555
Silver, about - - - - - - - - -	67
Copper (finally purified in the works of Altenau) -	35
Total product - - - -	28,564

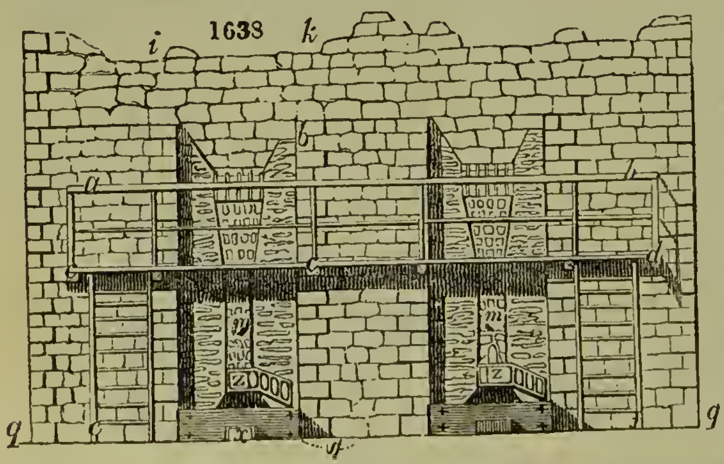
This weight amounts to one twenty-fifth of the weight of ore raised for the service of the establishment. Eight parts of ore furnish, on an average, about one of schlich. The bellows are constructed wholly of wood, without any leather; an improvement made by a bishop of Bamberg, about the year 1620. After receiving different modifications, they were adopted, towards 1730, in almost all the smelting-works of the continent, except in a few places, as Carniola, where local circumstances permitted a water blowing-machine to be erected. These pyramidal shaped bellows, composed of movable wooden boxes, have, however, many imperfections: their size must often be inconveniently large, in order to furnish an adequate stream of air; they do not drive into the furnace all the air which they contain; they require frequent repairs; and, working with great friction, they waste much mechanical power.

Fig. 1637 represents such wooden bellows, consisting of two chests or boxes, fitted into each other; the upper or moving one being called the *fly*, the lower or fixed one the *seat* (*gite*). In the bottom of the *gite*, there is an orifice furnished with a clack-valve *d*, opening inwards when the *fly* is raised, and shutting when it falls. In order that the air included in the capacity of the two chests may have no other outlet than the nose-pipe *m*, the upper portion of the *gite* is provided at its four sides with small square slips of wood *c*, *c*, *c*, which are pressed against the sides of the *fly* by strong springs of iron wire *b*, *b*, *b*, while they are retained upon the *gite* by means of small square pieces of wood *a*, *a*, *a*, *a*. The latter *a*, *a*, are perforated in the centre, and adjusted upon rectangular stems, called *buchettes*; they are attached, at their lower ends, to the upright sides of the *gite* G. P is the driving-shaft of a water-wheel, which, by means of cams or tappets, depresses the fly, while the counterweight Q, *fig.* 1622, raises it again.

1637



1638



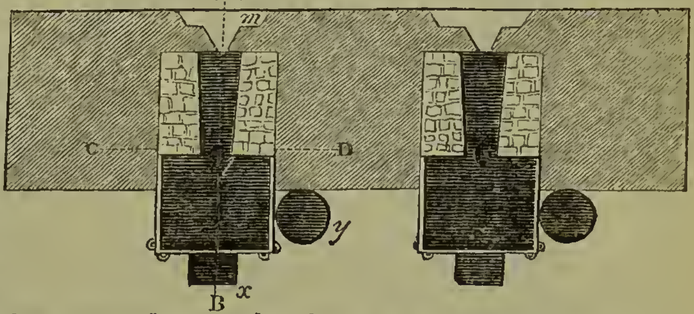
Figs. 1638 to 1641 represent the moderately high (*demihauts*, or *half-blast*) furnaces employed in the works of the Lower Harz, near Goslar, for smelting the silvery lead ore extracted from the mine of Rammelsberg.

Fig. 1638 is the front elevation of the twin furnaces, built in one body of masonry; *fig.* 1639 is a plan taken at the level of the tuyères.

Figs. 1640 and 1641 exhibit two vertical sections; the former in the line A, B, the latter in the line C, D, of *fig.* 1639. In these four figures the following objects may be distinguished:—

a, b, c, d, a balcony or platform, which leads to the place of charging *n*; *e, f,* wooden stairs, by which the workmen charging mount from the ground *p, q,* of the works, to the platform; *g, h,* brickwork of the furnaces; *i, k,* wall of the smelting-works, against which they are supported; *l,* upper basin of reception, hollowed out of the *brasque* (or bed of ground charcoal and clay) 6; *m,* arch of the tuyère V, by which each furnace receives the blast of two bellows; *n,* place of charging, which takes place through the upper orifice *n, o,* of the basin *n, o,* V, *t,* of the furnace: *t,* a sloping gutter, seen in *fig.* 1640, formed of slates cemented together with clay.

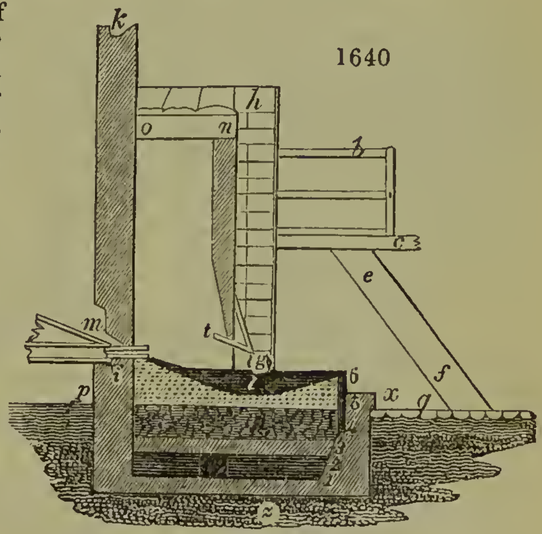
1639



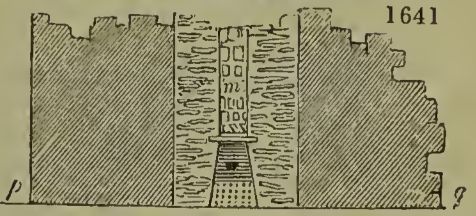
In *figs.* 1640 and 1641, *z,* is the brickwork of the foundations; *m,* conduits for the exhalation of moisture; 4, a layer of slags, rammed above; 5, a bed of clay, rammed above the slags; 6, a brasque, composed of one part of clay, and two parts of ground charcoal, which forms the sole of the furnace.

The refinery furnace, or *treibheerd,* of Fredrickshütte, near Tarnowitz, in Upper Silesia, is represented in *figs.* 1642 and 1643. *a,* is the bottom, made of slag or cinders; *b,* the foundation, of fire-bricks; *c,* the body of the hearth proper, composed of a mixture of 7 parts of dolomite, and 1 of fire-clay, in bulk; *d,* the grate of the air furnace; *e,* the fire-bridge; *f,* the dome or cap, made of iron plate strengthened with bars, and lined with clay-lute, to protect the metal from burning; *g,* the door of the fireplace; *h,* the ash-pit; *i,* the tap-hole; *k, k,* the flue, which is divided by partitions into several channels; *l,* the chimney; *m,* a damper-plate for regulating the draught; *n,* a back valve, for admitting air to cool the furnace, and brushes to sweep the flues; *o,* *tuyère* of copper, which by means of an iron wedge may be sloped more or less towards the hearth; *p,* the *schnepper,* a round piece of sheet iron, hung before the *eye* of the *tuyère,* to break and spread the blast; *q,* outlet for the glassy litharge.

1640



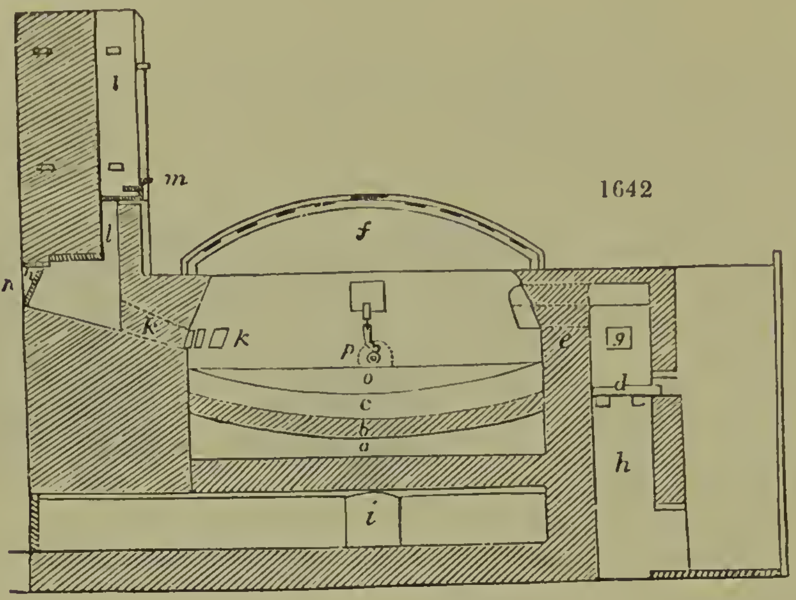
1641



Lime-marl has been found to answer well for making the body of the hearth-sole as it absorbs litharge freely, without combining with it. A basin-shaped hollow is formed in the centre, for receiving the silver at the end of the process; and a gutter is made across the hearth for running off the *glätte* or fluid litharge.

Figs. 1644 to 1646 represent the eliquation hearth of Neustadt. *Fig.* 1644 is a cross section; *fig.* 1645 is a front view; and *fig.* 1646 a longitudinal section. It is formed by two walls *a, a,* 3½ feet high, placed from ½ to 1 foot apart, sloped off at top with iron plates, 3 inches thick, and 18 inches broad, called *saigerscharten,* or refining plates, *b, b,* inclined 3 inches towards each other in the middle, so as to leave at the lowest point a slit 2½ inches wide between them, through which the lead, as it sweats out by the heat, is allowed to fall into the space between the two walls C, called the *saigergasse,* (sweating-gutter). The sole of this channel slopes down towards the front, so that the liquefied metal may run off into a crucible or pot. Upon one of the long sides, and each of the shorter ones, of the hearth the walls *d, d,* are raised two feet high, and upon these the liquation lumps rest; upon the other long side, where there is no wall, there is an opening for admitting these lumps into the hearth.

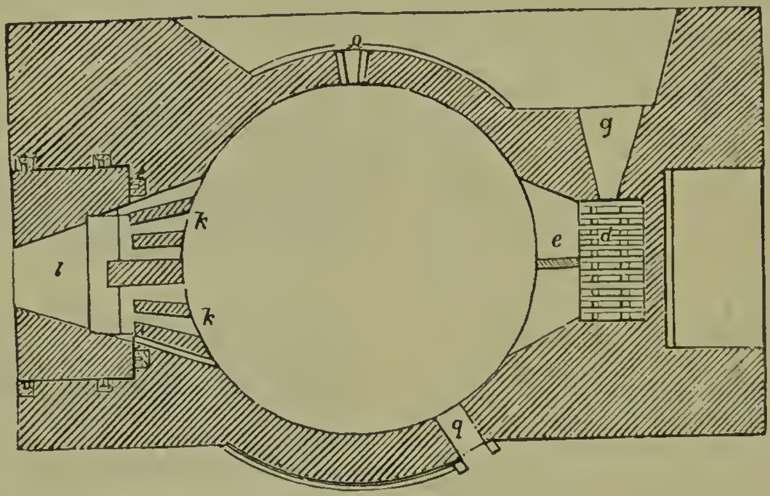
1642



The openings are then shut with a sheet or cast iron plate *e*, which, by means of a chain, pulley, and counter-weight, may be easily raised and lowered. *f* is a passage for increasing the draught of air.

Figs. 1647, and 1648 represent the refining furnaces of Frederickshütte, near Tarnowitz; *a*, is the fire-door; *b*, the grate; *c*, the door for introducing the silver; *d*, the movable test, resting upon a couple of iron rods, *e*, *e*, which are let at their ends into the brickwork. They lie lower than would seem to be necessary; but this is done in order to be able to place the surface of the test at any desired level, by placing tiles, *f*, *f*, under it; *g*, the flue, leading to a chimney 18 feet high. For the refining of 100 marks of *blicksilber*, of the fineness of 15½ loths (half ounces) per cwt., 3 cubic feet of pit-coal are required. The test or cupel must be heated before the impure silver and soft lead are put into it.

1643

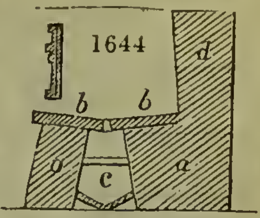


At these smelting-houses from 150 to 160 cwt. of *work-lead* (lead containing silver) are operated on at a time.

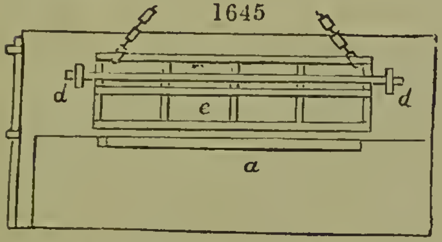
For the English method of refining silver, see article Lead Smelting. It may, however, be here stated that a method of desilverising by the use of metallic zinc has been somewhat recently introduced into some of the metallurgic establishments of the country.

Parkes's process for desilverising lead.—This invention is dependent on the property possessed by metallic zinc of uniting with the silver contained in argentiferous lead, and forming with it an alloy which can be readily skimmed from the surface of the metallic bath. In an establishment where the process is employed, the lead treated does not usually contain more than from 10 to 15 oz. per ton, and is frequently obtained by the reduction of litharge resulting from testing off lead of a higher produce.

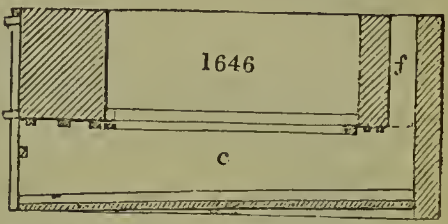
1644



1645

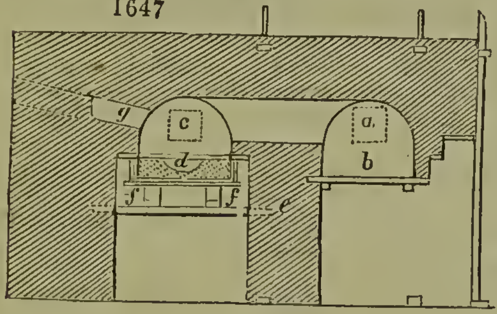


1646

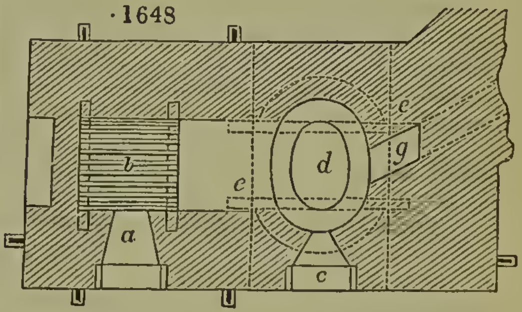


Six or seven tons of the lead to be desilverised are first melted in a large cast-iron pot, close to which is fixed a smaller one for fusing the zinc. The melted lead is then skimmed and a sample taken for assay.

1647



1648



Some zinc is also melted in the smaller pot above referred to, and added to the lead in the proportion of from 1½ to 2 pounds to each ounce of silver contained in the lead operated on, and the alloy is well stirred for from one to two hours. The fire is afterwards withdrawn and the metal allowed to rest until a scum rises on the surface, which is removed by means of a perforated ladle similar to that employed in Pattinson's process.

When this crust no longer forms, the lead is ladled into a gutter, which conducts it into a reverberatory furnace, of which the bottom is composed of a large cast-iron pan, where it is kept for some hours at a low red heat, for the purpose of expelling the last traces of zinc, either by oxidation or volatilisation.

The lead when sufficiently purified is tapped into an iron pot and boiled with green wood, as is usual in tin smelting. The quality of the lead thus purified is said to be exceedingly good, and nearly the whole of the silver is separated.

The scum from the pots contains a considerable amount of lead, which is separated by heating it in an inclined iron retort. As soon as this becomes sufficiently heated, the greater portion of the lead runs out into a mould placed for its reception, and carries with it silver to the amount of about 1000 oz. per ton; this is treated directly in the test furnace. The residues found in the retort are subsequently treated, after being mixed with small coal, in pots made with fire-clay, and the zinc distilled from it in the ordinary way.

The residue, after distillation, contains about 600 oz. of silver per ton, together with lead, copper, arsenic, and nickel, if these metals were originally present in the lead operated on. The quantity of zinc recovered by distillation is said to be about one-half of that originally employed.

The further treatment of the alloy of zinc and silver consists in melting it with lead; and as soon as a sufficient quantity of the mixture has been obtained, it is treated by cupellations in the usual way. The advantage stated to be obtained by the frying process consists in the concentration of the silver in a small quantity of lead with but few operations. The loss of lead by this process is estimated at about one per cent.—

The Produce of Silver from the Lead Ores of the United Kingdom.

In 1801, the quantity of pure gold produced in America was 46,331 lbs.; in Europe and Northern Asia (exclusive of China and Japan), 4,916 lbs.; total produce, 51,247 lbs.=55,910 lbs. British standard gold = 2,612,200*l.*

In 1846, the quantity of pure gold produced in America was 25,503 lbs.; in Europe, Africa, and Asia (exclusive of China and Japan), 89,171 lbs.; total produce, 114,674 lbs.= 125,108 lbs. British standard gold=5,846,772*l.*

In 1850, the quantity of pure gold produced in America was 261,731 lbs.; in Europe, Africa, and Asia (exclusive of China and Japan), 104,219 lbs.; total produce, 365,950 lbs.=399,247 lbs. British standard gold=18,654,322*l.*

* Those countries marked thus (*) have no silver mines at work; the silver stated is estimated as having existed in the native gold, to the average amount of 8 per cent.

SILVER, ASSAY FOR. *Estimation of silver contained in lead ores.* Many varieties of lead ore contain silver, and it is consequently necessary, in order to judge of their commercial value, to ascertain the exact amount of this metal which they afford. This is effected by the process of *Cupellation:* an operation founded on the fact that when an alloy of lead and silver is exposed to a current of air, when in a state of fusion, the silver neither gives off perceptible vapours nor becomes sensibly oxidised, whilst the lead rapidly absorbs oxygen and becomes converted into a fusible oxide.

In order therefore to separate the silver that may be present in buttons resulting from ordinary lead assays, it is only necessary to expose them on some suitable porous medium, to such a temperature as will rapidly oxidise the lead. The litharge produced is absorbed by the porous body on which the assay is supported, and nothing but a small button of silver ultimately remains on the test. These supports or cupels are made of bone-ash, slightly moistened with a little water, and consolidated by being pressed into a mould. The furnace employed for this purpose is described in the article ASSAY; as is also the *muffle* or D-shaped retort in which the cupels are heated.

As soon as the muffle has become red hot, six or eight cupels that have been drying in the mouth of the opening are introduced by means of proper tongs, and the bottom of the muffle is covered with a thin layer of bone-ash, in order to prevent its being attacked in case of any portion of litharge coming in contact with it during the progress of the subsequent operations. The open end of the muffle is now closed by means of a proper door, and the cupels are thus rapidly heated to the temperature of the muffle itself. When this has been effected the door is removed, and into each of the cupels is introduced by the aid of slender steel tongs a button of the lead to be assayed. The mouth of the muffle is again closed during a few minutes to facilitate the fusion of the alloy, and on its removal each of the cupels will be found to contain a bright metallic globule, in which state the assay is said to be uncovered. The lead is now quickly converted into litharge, which is absorbed by the cupel as fast as it is produced, whilst at the same time there arises a white vapour that fills the muffle and is gradually carried off by the door and through the openings in the sides and end. A circular stain is at the same time formed around the globule of metal, which gradually extends and penetrates into the substance of the cupel. When nearly the whole of the lead has thus been removed, the remaining bead of alloy appears to become agitated by a rapid motion, which seems to make it revolve with great rapidity. At this stage the motion will be observed suddenly to cease, and the button, after having for an instant emitted a bright flash of light, becomes immovable. This is called the *brightening* of the assay, and a button of silver now remains on the cupel.

If the cupel were now abruptly removed from the muffle, the metallic globule would be liable to *vegetate*, by which a portion of the metal might be thrown off, and a certain amount of loss be thereby entailed. To prevent this, the cupel in which the assay has brightened should be immediately covered by another, kept red-hot for that purpose. The two are now gradually withdrawn together, and, after having sufficiently cooled, the upper cupel is removed, and the globule of silver detached and weighed.

From the fact that silver becomes sensibly volatile at very elevated temperatures, it becomes necessary to make cupellations of this metal at the lowest possible heat at which they can be effected. The temperature best fitted for this operation is obtained when the muffle is at a full red heat, and the vapours which arise from the assays curl gradually away, and are finally removed by the draught. When the muffle is heated to whiteness, and the vapours rise to the top of the arch, the heat is too great: and when, on the contrary, the fumes lie over the bottom, and the sides of the openings in the muffle begin to darken, either a little more fuel must be added or the draught increased.

If an assay has been properly conducted, the button of silver obtained is round, bright, and smooth on its upper surface, and beneath should be crystalline and of a dead-white colour; it is easily removed from the cupel, and readily freed from litharge. The globule is now laid hold of by a pair of fine pliers and flattened on a small steel anvil, by which the oxide of lead which may have attached itself to it, becomes pulverised, and is removed by rubbing with a small hard brush. The flattened disc is then examined, in order to be sure that it is perfectly clean, and afterwards weighed in a balance capable of turning with one-thousandth of a grain.

The fuel employed consists of hard coke broken into small pieces.

When the ores of lead, in addition to silver, contain gold, the button remaining on the cupel is an alloy of these metals.

For commercial purposes, the silver contained in any given ore or alloy is estimated in ounces, pennyweights, and grains, one ton of ore or alloy being usually taken as the standard of unity.

Table showing the weight of silver to the ton of ore or alloy corresponding to the weight in grains obtained from 400 *grains of the substance operated on.*

If 400 grains give fine metal,	One ton will yield			If 400 grains give fine metal,	One ton will yield

Assay of silver ores not containing lead. — In the assay of ores belonging to this class, it is usual to obtain the silver they afford in the form of an alloy with lead; and this is subsequently passed to the cupel in the ordinary way.

Ores of silver in which the metals exist in the form of oxides are commonly fused with a mixture of litharge, red lead, and powdered charcoal, by which an alloy of lead is obtained, which is afterwards treated by cupellation. The amount of litharge employed must be varied according to circumstances, as the resulting button should not be too small, since in that case a portion of the silver might be lost in the slag; nor too large, as the cupellation would then occupy a long time, and a loss through volatilisation be the result.

In most cases, if 400 grains of ore be operated on, a button of 200 grains will be a convenient weight for cupellation; this may be obtained by the addition of 400 grains of litharge, and from 7 to 8 grains of pulverised charcoal. This is to be well mixed with 200 grains of carbonate of soda, and introduced into an earthen crucible, of which it should not fill more than one-half the capacity. This is covered by a layer of borax, and fused in the assay furnace, taking care to remove it from the fire as soon as a perfectly liquid slag has been obtained, since the unreduced litharge might otherwise cut through the crucible and spoil the assay. When cold, the pot is broken, and the button cupelled in the ordinary way.

In this, and all other similar experiments, it is necessary to ascertain the proportion of silver contained in the lead obtained from the litharge used, in order to make the requisite deduction from the results obtained. When fine litharge is employed the resulting lead contains so small an amount of silver, that for many commercial purposes it may be disregarded.

When other minerals than oxides are to be examined, the addition of charcoal becomes in many cases unnecessary, since litharge readily attacks all the sulphides, arsenio-sulphides, &c., and oxidises many of their constituents, whilst a proportionate quantity of metallic lead is set free. The slags thus formed contain the excess of litharge, and the button of alloy obtained is cupelled. The proportion of oxide of lead to be added to ores of this description varies in accordance with the amounts of oxidisable substances present; but it must always be added in excess in order to prevent any chance of loss of silver from the action of sulphides in the slags.

The only objection to this method of assay is the large quantity of lead produced for cupellation,—since iron pyrites afford by the reduction of the litharge 8½ parts of lead, whilst sulphide of antimony and grey copper ore yield from 6 to 7 parts. This inconvenience may be obviated by the previous oxidation of the mineral, either by roasting, or by the aid of nitre, by the judicious employment of which buttons of almost any required weight may be obtained.

Should this reagent be employed in excess, it would cause the oxidation of all the metallic and combustible substances present, not even excepting the silver.

When, however, the mixture contains at the same time a large excess of litharge and the quantity of nitre added is not sufficient to decompose the whole of the sulphides, a reaction takes place between the undecomposed sulphide and the oxide of lead added, which gives rise to the formation of metallic lead, and this combining with the silver, affords a button of alloy, which may be treated by cupellation.

The quantity of nitre to be used for this purpose will depend on the nature and richness of the ores under examination; but it must be remembered that 2½ parts of nitre will decompose and completely oxidise pure iron pyrites, whilst 1½ and ⅔rds of its weight are in the case of sulphide of antimony and galena respectively sufficient.

In cases when the excess of sulphur present is very great, a partial roasting of the ore is preferable to the addition of a large quantity of nitre.

Instead of operating according to any of the processes above described, it is sometimes found advantageous to expel the whole of the arsenic and sulphur, by a careful roasting, and then to fuse the residue with a mixture of litharge, carbonate of soda and borax, taking care to add a sufficient amount of some reducing flux to obtain a button of convenient size.

When in addition to silver the mineral operated on contains gold, the button obtained by cupellation will consist of a mixture of these metals, which may be separated by the aid of nitric acid. See Assay.

Scorification.—Instead of operations as above described, silver ores are sometimes treated by scorification. In that case, they are mixed with granulated lead and exposed in small refractory saucers to a strong heat in an ordinary muffle furnace. After a sufficient amount of the lead has become oxidised, and the resulting litharge has formed a fusible slag with the gangue of the ore, the metallic lead is poured into a suitable mould, and afterwards subjected to cupellation. When the granulated lead employed for this purpose contains silver, due allowance for its presence must be made in the result obtained.

Simple process for the reduction of silver to a metallic state by means of sugar.—The silver of coin is first reduced to the state of chloride, and the weight of the alloy thus ascertained; the chloride, after having been well washed and freed from copper, is to be put into a stoppered wide-necked bottle; a quantity of refined sugar, or sugar-candy, is then added, equal in weight to the alloy. This is mixed with an equal volume of a solution, composed of 60 grammes of good hydrate of potash, and 150 grammes of distilled water, which will yield solution of potash of 25° Beaumé, or thereabouts: after closing the bottle the mixture is to be agitated, and then left for 24 hours, shaking it occasionally, to favour the reaction. After this period has elapsed, it is to be washed several times, until the last washings, filtered, are not affected by nitrate of silver, a test which should be preceded by that of red litmus paper, which ought not to become blue, or show any change whatever. This done, the contents of the bottle are to be transferred to a porcelain capsule, by the help of a little distilled water, then, after being allowed to deposit, the excess of liquid is poured off, and the silver dried in a stove.

By these means we obtain that to which Dr. Ure gave the name of *grey silver*. This silver consists of some bright spangles, which become more brilliant on friction. It does not contain any impurities, with the exception of a small quantity of oxide, and a few atoms of chloride of silver. This latter produces a slight turbidity in the liquor, when dissolved in perfectly pure nitric acid, and diluted with distilled water. This turbidity does not, however, prevent the formation of pure nitrate of silver; as the chloride being only in suspension in the liquid, it is sufficient to filter it on a small portion of well washed asbestos, in order to obtain an unobjectionable liquor. The nitrate of silver will not contain any trace of other metals, as none are used in the reduction of the chloride of silver, and by the reduction of this salt the silver is completely separated from the iron and copper which the solution might contain. Thus the nitric acid of commerce may be employed, without inconvenience, for dissolving the alloy.

The *grey silver* almost always contains a small quantity of oxide; this is easily verified by the addition of ammonia, which, after digestion on the metal and filtration, produces a slight turbidity on adding nitric acid, which is caused by the separation of the dissolved chloride of silver; the turbidity is then increased by the addition of a small quantity of chloride of sodium to the nitrate of ammonia previously formed; thus, then, is the oxide of silver dissolved in the liquor in the state of ammoniacal nitrate, which is precipitated in the form of insoluble chloride.

Oxide of silver not being an impurity in the uses to which pure silver is applied in laboratories, we may consider the *grey silver* obtained in the manner above described as more pure and with less loss than any of those prepared up to the present time, by the reduction of chloride of silver; *and without the necessity of melting, a troublesome* operation, and one of much inconvenience in a laboratory.

SILVER, BROMIDE OF (AgBr), is occasionally found native. If a soluble bromide is added to a solution of nitrate of silver, a precipitate of bromide of silver is formed of a very pale yellow colour. This salt changes readily under the action of the solar rays, and for photographic purposes possesses many very important properties, of which photographers have not availed themselves. This is mainly owing to the neglect of scientific investigation amongst the body of photographic artists, which is exceedingly to be regretted.

SILVER, CHLORIDE OF, is obtained by adding hydrochloric acid, or any soluble chloride, to a solution of nitrate of silver. A curdy precipitate falls, quite insoluble in water, which being dried and heated to dull redness, fuses into a semi-transparent grey mass, called, from its appearance, *horn-silver*. Chloride of silver dissolves readily in water of ammonia, and crystallises in proportion as the ammonia evaporates. It is not decomposed by a red heat, even when mixed with calcined charcoal; but when hydrogen or steam is passed over the fused chloride, hydrochloric acid exhales, and silver remains. When fused along with potassa (or its carbonate), the silver is also revived; while oxygen (or also carbonic acid) gas is liberated, and chloride of potassium is formed. Alkaline solutions do not decompose chloride of silver. When this compound is exposed to light, it suffers a partial decomposition, hydrochloric acid being disengaged.

The best way of reducing the chloride of silver, says Mohr, is to mix it with one-third of its weight of colophony (black rosin), and to heat the mixture moderately in a crucible till the flame ceases to have a greenish-blue colour; then suddenly to increase the fire, so as to melt the metal into an ingot.

The subchloride may be directly formed by pouring a solution of deuto-chloride of copper or iron upon silver leaf. The metal is speedily changed into black spangles, which, being immediately washed and dried, constitute subchloride of silver. If the contact of the solutions be prolonged, chloride would be formed.

SILVER, HYPOSULPHITE OF. This salt is formed in the process of fixing photographic pictures with *hyposulphite of soda* (which see). Solutions of the hyposulphite of soda, potash, or lime, which are bitter salts, dissolve chloride of silver into liquids possessing a remarkable sweetness.

SILVER, IODIDE OF. (AgI.) This compound of iodine and silver, which is obtained when a solution of an iodide is added to nitrate of silver, is a pale yellow powder. It is also found native, but not in large quantities. This silver salt is remarkable, like some other metallic compounds, for changing its colour alternately with heat and cold. If a sheet of white paper be washed over with a solution of nitrate of silver, and afterwards with a somewhat dilute solution of iodide of potassium, it will immediately assume the pale yellow tint of the cold silver iodide. On placing the paper before the fire, it will change colour from a pale primrose to a gaudy brilliant yellow, like the sun-flower; and on being cooled, it will again resume the primrose hue. These alternations may be repeated indefinitely, like those with the salts of cobalt, provided too great a heat be not applied. The pressure of a finger upon the hot yellow paper makes a white spot, by cooling it quickly. Iodide of silver, when pure, is very slowly darkened when exposed to sunshine; but if in combination with any organic compound it changes colour with much rapidity. From this property it furnishes one of the most valuable of our photographic agents. (See PHOTOGRAPHY.) It is the active material in the calotype, the collodion, the Daguerreotype, and other processes.

SILVER, NITRATE OF. ($AgNO^6$.) This salt was known to Geber, and was chiefly used in medicine; but since the discovery of photography, this salt has been made on a very large scale. It is found in commerce in two different forms, viz. crystallised, and in sticks, the former being more general; in sticks it is called "lunar caustic," and is used by the surgeon. It is prepared by digesting metallic silver with moderately strong nitric acid; the silver speedily dissolves, especially if heat be applied. Some of the nitric acid is decomposed, yielding oxygen to the silver, and liberating binoxide of nitrogen, which, in contact with the air, abstracts oxygen and forms red vapours of hyponitric acid.

$$\underbrace{3Ag.}_{\text{Silver.}} + \underbrace{4HNO^6}_{\text{Nitric acid.}} = \underbrace{3Ag.NO^6}_{\text{Nitrate of silver.}} + \underbrace{NO^2}_{\text{Binoxide of nitrogen.}} + \underbrace{4HO.}_{\text{Water.}}$$

The clear solution is evaporated, either to the crystallising point or to dryness—if for *caustic*—fused and cast into sticks. If ordinary standard silver be used, the solution will contain some nitrate of copper; in this case it must be evaporated to dryness, and gradually heated till all the nitrate of copper is decomposed, which may be known by taking a little of the salt, dissolving in water, and adding excess of ammonia; when, if copper be still present, the solution will have a blue tint. When all the copper is thus rendered insoluble, the fused mass is dissolved in distilled water, evaporated and crystallised. When pure, nitrate of silver is white; the crystals are transparent, colourless, hexangular tables, or right rhombic prisms, very soluble in water, requiring only their own weight of cold water and half that quantity of boiling water for solution; they are also readily soluble in hot alcohol, but the greater portion is again deposited on cooling. Nitrate of silver possesses a strongly metallic and bitter taste. It is not deliquescent, and when free from organic matter is not decomposed by light (*Scanlan*). The dark colour of the outside of the ordinary sticks of the shops is caused by the decomposition of the nitrate by the paper in which they are wrapped, as the presence of organic matter reduces the silver to the metallic state. Nitrate of silver is frequently adulterated to a considerable extent, principally with nitrate of potash, but sometimes with other nitrates. The price at which it is sometimes sold is proof enough that it is largely adulterated; for instance, it may sometimes be bought for 3*s*. an ounce; at that price it does not pay for the silver alone that *should be* in it: we will prove this. Every ounce (437·5 grains) of pure nitrate of silver contains 278 grains of pure silver, and this itself, without taking notice of nitric acid and time of preparation, is worth 3*s*. 2*d*. This clearly proves there must be considerable adulteration; but although the adulterating substances do not interfere generally with the photographic processes, it is certain that no advantage can be gained by buying it at so low a price. The way to detect the adulteration is to precipitate the silver by hydrochloric acid, and evaporate the filtered liquid to dryness, when, if the salt is pure, there will be no residue.

As many, who use much nitrate of silver in photography, &c., throw away the residues, and hence in course of time waste much silver, it will not be out of place here to show how it may be saved and made again into nitrate of silver fit for use. If the papers, on which there is silver, are preserved, the silver can be obtained by merely burning them, and may be fused in a porcelain crucible into one lump. In the case of the nitrate of silver baths, when too weak for further use, the silver may be precipitated in the form of chloride, by adding hydrochloric acid. The chloride of silver thus obtained may be easily reduced to the metallic state. 1st, by digesting the moist chloride with metallic zinc and dilute sulphuric acid; the hydrogen which is thus liberated reduces the silver to the metallic state, which remains in the form of a black powder, and when well washed with water may be dissolved in nitric acid, evaporated and crystallised. 2nd, by digesting it by the aid of heat with a caustic alkali and tartaric acid, when it will also be reduced to metallic silver, and will remain as a black powder, which may be treated as above. 3rd, by collecting the precipitated chloride of silver on a filter, washing well with water, and drying; the dry chloride is then mixed with four or five times its weight of a mixture of carbonate of potash and carbonate of soda, and subjected to a white heat in a porcelain crucible; the silver will be reduced to the metallic state, and will be found as a metallic button at the bottom of the crucible when cold, and may be easily detached and washed; and is then fit to dissolve in nitric acid, &c.—H. K. B.

SILVER, OXIDE OF. There are two oxides of silver; the *protoxide* (AgO), and the peroxide AgO^2. 1. The first is obtained by adding solution of caustic potassa, or lime-water, to a solution of nitrate of silver. The precipitate has a brownish-grey colour, which darkens when dried, and contains no combined water. Its specific gravity is 7·143. On exposure to the sun it gives out a certain quantity of oxygen, and becomes a black powder. This oxide is an energetic base; being slightly soluble in pure water, reacting like the alkalies upon reddened litmus paper, and displacing, from their combinations with the alkalies, a portion of the acids with which it forms insoluble compounds. It is insoluble in the caustic lyes of potassa or soda. By combination with caustic ammonia, it forms *fulminating silver*. See Fulminating Silver. The second, or peroxide, is formed when a very dilute solution of nitrate of silver is decomposed by the voltaic current; dark grey lustrous needles of the peroxide of silver are formed around the positive pole.

SILVER, SULPHATE OF, may be prepared by boiling sulphuric acid upon the metal. See Refining of Gold and Silver. It dissolves in 88 parts of boiling water, but the greater part of the salt crystallises in small needles as the solution cools. It consists of 118 parts of oxide, combined with 40 parts of dry acid.

SILVER, SULPHIDE OF, which exists native, may be readily prepared by fusing its constituents together; and it forms spontaneously upon the surface of silver exposed to the air of inhabited places. The tarnish may be easily removed by rubbing the metal with a solution of *cameleon mineral*, prepared by calcining peroxide of manganese with nitre. Sulphide of silver is a powerful sulpho-base; since though it be heated to redness in close vessels, it retains the volatile sulphides, whose combinations with the alkalies are decomposed at that temperature. It consists of 87·04 of silver, and 12·96 of sulphur.

SILVER LEAF is made in precisely the same way as *gold leaf*. See GOLD BEATING.

SILVERING is the art of covering the surfaces of bodies with a thin film of silver. When silver leaf is to be applied, the methods prescribed for gold leaf are suitable. Among the metals, copper or brass are those on which the silverer most commonly operates. Iron is seldom silvered; but the processes for both metals are essentially the same. The white alloy of nickel is now often plated.

The principal steps of this operation are the following:—

1. The *smoothing down* the sharp edges, and polishing the surface of the copper; called *emorfiler* by the French artists.

2. The *annealing*; or, making the piece to be silvered red hot, and then plunging it in a very dilute nitric acid, till it be bright and clean.

3. *Pumicing*; or, clearing up the surface with pumice-stone and water.

4. The *warming*, to such a degree merely as, when it touches water, it may make a slight hissing sound; in which state it is dipped in the very weak aquafortis, whereby it acquires minute insensible asperities, sufficient to retain the silver leaves that are to be applied.

5. The *hatching*. When these small asperities are inadequate for giving due solidity to the silvering, the plane surfaces must be hatched all over with a graving tool; but the chased surfaces need not be touched.

6. The *blueing*, consists in heating the piece till its copper or brass colour changes to blue. In heating, they are placed in hot tools made of iron, called *mandrins* in France.

7. The *charging*, the workman's term for silvering. This operation consists in placing the silver leaves on the heated piece, and fixing them to its surface by burnishers of steel, of various forms. The workman begins by applying the leaves double. Should any part darken in the heating, it must be cleared up by the scratch-brush.

The silverer always works two pieces at once; so that he may heat the one, while burnishing the other. After applying two silver leaves, he must heat up the piece to the same degree, as at first, and he then fixes on with the burnisher four additional leaves of silver; and he goes on *charging* in the same way, 4 or 6 leaves at a time, till he has applied, one over another, 30, 40, 50, or 60 leaves, according to the desired solidity of the silvering. He then burnishes down with great pressure and address, till he has given the surface a uniform silvery aspect.

Silvering by the precipitated chloride of silver. — The white curd obtained by adding a solution of common salt to one of nitrate of silver is to be well washed and dried. One part of this powder is to be mixed with 3 parts of good pearlash, 1 of washed whiting, and one and a half of sea-salt. After cleaning the surface of the brass, it is to be rubbed with a bit of soft leather, or cork moistened with water, and dipped in the above powder. After the silvering, it should be thoroughly washed with water, dried, and immediately varnished. Some use a mixture of 1 part of the silver precipitate, with 10 of cream of tartar, and this mixture also answers very well.

Others give a coating of silver by applying with friction, in the moistened state, a mixture of 1 part of silver powder precipitated by copper, 2 parts of cream of tartar, and as much common salt. The piece must be immediately washed in tepid water very faintly alkalised, then in slightly warm pure water, and finally wiped dry before the fire. See PLATED MANUFACTURE, and ELECTROTYPE.

The inferior kinds of plated buttons get their silver coating in the following way:— 2 ounces of chloride of silver are mixed up with 1 ounce of corrosive sublimate, 3 pounds of common salt, and 3 pounds of sulphate of zinc, with water, into a paste. The buttons being cleaned, are smeared over with that mixture, and exposed to a moderate degree of heat, which is eventually raised nearly to redness, so as to expel the mercury from the amalgam formed by the reaction of the horn silver and the corrosive sublimate. The copper button thus acquires a silvery surface, which is brightened by clearing and burnishing.

Leather is silvered by applying a coat of parchment size, or spirit varnish, to the surface, and then the silver leaf, with pressure.

SILVERING OF GLASS. See MIRRORS.

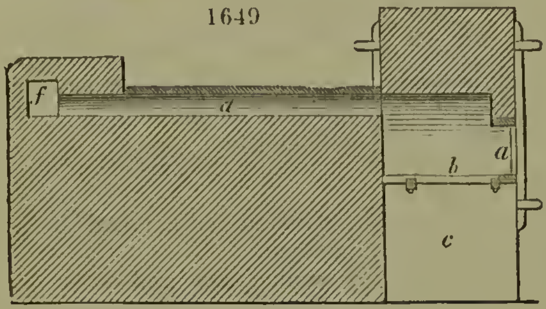
SIMILOR. A name given to a rich-coloured brass, composed of 3 oz. zinc to 1 lb. of copper. See BRASS.

SINAMINE. $C^8H^6N^2$. An alkaloid, produced by the action of the oxides of mercury or lead, on thiosinamine.—C. G. W.

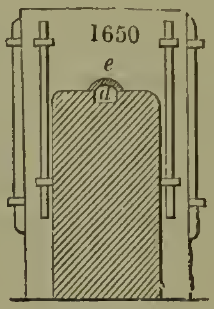
SINAPINE. $C^{32}H^{23}NO^{10}$. A base existing (in the state of hydrosulphocyanate) in white mustard.—C. G. W.

SINGEING. In the article BLEACHING, Vol. I. page 325, the modern and most approved singeing apparatus is described. The old furnace for singeing cotton goods is represented in longitudinal section, *fig.* 1649, and in a transverse one in *fig.* 1650. *a* is

1649



1650

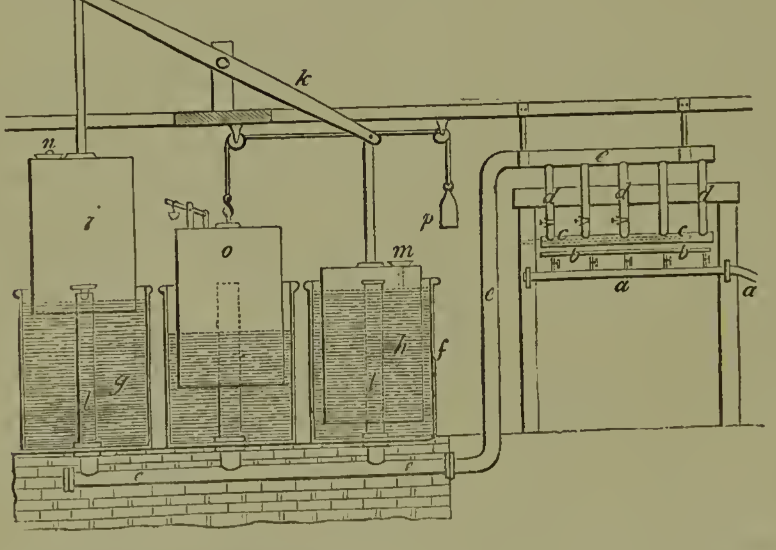


the fire-door ; *b*, the grate ; *c*, the ashpit ; *d*, a flue, 6 inches broad, and 2½ high, over which a hollow semi-cylindrical mass of cast iron *e*, is laid, 1 inch thick at the sides, and 2½ thick at the top curvature. The flame passes along the fire flue *d*, into a side opening *f*, in the chimney. The goods are swept swiftly over this ignited piece of iron, with considerable friction, by mean of a wooden roller, and a swing frame for raising them at any moment out of contact.

In some shops, semi-cylinders of copper, three-quarters of an inch thick, have been substituted for those of iron, in singeing goods prior to bleaching them. The former last three months, and do 1,500 pieces with one ton of coal; while the latter, which are an inch and a half thick. wear out in a week, and do no more than from 500 to 600 pieces with the same weight of fuel.

In the early part of the year 1818, Mr. Samuel Hall introduced the plan for removing the downy fibres of the cotton thread from the interstices of bobbinet lace, or muslins, by singeing the lace with the flame of a gas-burner. And in 1823 he modified this process by causing a strong current of air to draw the flame of the gas through the interstices of the lace, as it passes over the burner, by means of an

1651



aperture in a tube placed immediately above the row of gas-jets, which tube communicates with an air-pump or exhauster.

Fig. 1651 shows the construction of the apparatus complete, and manner in which it operates ; *a*, *a*, is a gas-pipe, supplied by an ordinary gasometer ; from this pipe several small ones extend upwards to the long burner *b*, *b*. This burner is a horizontal tube, perforated with many small holes in the upper side, through which, as jets, the gas passes ; and when it is ignited, the bobbinet lace, or other material intended to be singed, is extended and drawn rapidly over the flame, by means of rollers, which are not shown in the figure.

The simple burning of the gas, even with a draught chimney, is found not to be at all times efficacious. There is now introduced a hollow tube *c*, *c*, with a slit or opening, immediately over the row of burners; and this tube, by means of the pipes *d*, *d*, *d*, communicates with the pipe *e*, *e*, *e*, which leads to the exhausting apparatus.

This exhausting apparatus consists of two tanks, *f* and *g*, nearly filled with water, and two inverted boxes or vessels, *h* and *i*, which are suspended by rods to the vibrating beam *k*; each of the boxes is furnished with a valve opening upwards; *l*, *l*, are pipes extending from the horizontal part of the pipe *e*, up into the boxes or vessels *h* and *i*, which pipes have valves at their tops, also opening upward. When the vessel *h* descends, the water in the tank forces out the air contained within the vessel at the valve *m*; but when that vessel rises again, the valve *m* being closed, the air is drawn from the pipe *e*, through the pipe *l*. The same takes place in the vessel *i*, from which the air in its descent is expelled through the valve *n*, and in its ascent draws the air through the pipe *l*, from the pipe *e*. By these means, a partial exhaustion is effected in the pipe *e*, *e*, and the tube *c*, *c*; to supply which, the air rushes with considerable force through the long opening of the tube *c*, *c*, and carries with it the flame of the gas-burners. The bobbinet lace, or other goods, being now drawn over the flame between the burner *b*, *b*, and the exhausted tube *c*, *c*, by means of rollers, as above said, the flame of the gas is forced through the interstices of the fabric, and all the fine filaments and loose fibres of the thread are burnt off, without damaging the substance of the goods.

To adjust the draught from the gas-burners, there are stop-cocks introduced into several of the pipes *d*; and to regulate the action of the exhausting apparatus, an air vessel *o* is suspended by a cord or chain passing over pulleys, and balanced by a weight *p*. There is also a scraper introduced into the tube *c*, which is made, by any convenient contrivance, to revolve and slide backwards and forwards, for the purpose of removing any light matter that may arise from the goods singed, and which would otherwise obstruct the air passage. Two of these draught tubes *c* may be adapted and united to the exhausting apparatus, when a double row of burners is employed, and the inclination of the flame may be directed upwards, downwards, or sideways, according to the position of the slit in the draught tube, by which means any description of goods may, if required, be singed on both sides at one operation.

SIZE. A solution of gelatinous matter, usually made from skin, employed for the purpose of giving adhesiveness to certain substances, which could not be otherwise secured to surfaces. See GELATINE and GLUE.

SIZING OF PAPER. See PAPER.

SKIN. (*Peau*, Fr.; *Haut*, Germ.) The external membrane of animal bodies, consists of three layers: 1, the epidermis, scarf-skin (*Oberhaut*, Germ.); 2, the vascular organ, or papillary body, which performs the secretions; and 3, the true skin (*Lederhaut*, Germ.), of which leather is made. The skin proper, or dermoid substance, is a tissue of innumerable very delicate fibres, crossing each other in every possible direction, with small orifices between them, which are larger on its internal than on its external surface. The conical channels thus produced are not straight, but oblique, and filled with cellular membrane; they receive vessels and nerves which pass out through the skin (*cutis vera*), and are distributed upon the secretory organ. The fibrous texture of the skin is composed of the same animal matter as the serous membranes, the cartilages, and the cellular tissue; the whole possessing the property of dissolving in boiling water, and being, thereby, converted into glue. See GLUE, LEATHER, TAN, and FURS. The skins of animals are imported for the preparation of furs, for use, and ornament, and for the manufacture of leather.

The following statement of our importations in 1858 show the importance of this branch of trade:—

SKINS, FURS, PELTS and TAILS, undressed:

	Number.	Computed real value.
Bear	13,885	£15,349
Beaver	108,315	34,336
Coney	218,279	3,638
Deer	98,779	13,016
Ermine	201,334	10,057

SLAG (*Laitier*, Fr.; *Schlacke*, Germ.) is the vitreous mass which covers the fused metal in the smelting-hearths. In the iron-works it is commonly called *cinder*. Slags consist, in general, of bi-silicates of lime and magnesia, along with the oxides of iron and other metals; being analogous in composition, and having the same crystalline form as the mineral *pyroxene*.

The following, selected from the analyses of Percy and Forbes, show the composition of iron furnace slags:—

Silica - - - - -	28·32	42·06	39·52	29·60
Alumina - - - - -	24·24	12·93	15·11	41·28
Lime - - - - -	40·12	32·53	32·52	0·47
Magnesia - - - - -	2·79	1·06	3.49	0·35
Protoxide of manganese -	0·07	2·26	2·89	1·13
Protoxide of iron - -	0·27	4·94	2·02	48·43
Sesquioxide of iron - -	—	—	—	17·11
Potash with traces of soda -	0·64	2·69	1·06	—
Sulphate of lime - -	0·26	—	—	—
Sulphide of calcium - -	3·38	1·03	2·15	—
Phosphoric acid - -	—	0·31	—	1·34
Sulphide of iron - -	—	—	—	1·61
Loss - -	—	0·19	1·24	—
	100·09	100·00	100·00	101·32

Of the last of these, Dr. Percy remarks:—

"An immense quantity of iron slag, *far richer than many iron ores*, is annually thrown away, and it may be that the presence of phosphoric acid in sensible quantity is one of the causes which prevents the re-smelting of this slag to advantage. The fact has not yet sufficiently attracted the attention of those engaged in the manufacture of iron. The discovery of a method of extracting economically good iron from these rich slags would be of great advantage to the country, and could not fail amply to reward its author."—*Report of the Sixteenth Meeting of the British Association*, 1847.

SLATES. (*Ardoises*, Fr.; *Schiefern*, Germ.) The substances belonging to this class may be distributed into the following species:—

1. Mica-schist, occasionally used for covering houses.
2. Roofing slate.
3. Whet slate.
4. Polishing slate.
5. Drawing slate, or black chalk,
6. Adhesive slate.
7. Bituminous shale.
8. Slate-clay.

1. *Mica-schist*, improperly called *Mica-slate*.— This is a mountain rock of vast

continuity and extent, of a schistose texture, composed of the minerals mica and quartz, the mica being generally predominant.

2. *Roofing slate.* — This substance is closely connected with mica; so that uninterrupted transitions may be found between these rocks in many mountain chains. It is a simple schistose mass, of a bluish-grey or greyish-black colour, of various shades, and a shining, somewhat pearly internal lustre on the faces, but of a dead colour in the cross fracture.

This slate is extensively distributed in Great Britain. It skirts the Highlands of Scotland, from Loch Lomond by Callender, Comrie, and Dunkeld; resting on, and gradually passing into mica-slate throughout the whole of that territory. Roofing-slate occurs on the western side of England, in the counties of Cornwall and Devon; in various parts of North Wales and Anglesea; in the north-east parts of Yorkshire, near Ingleton, and in Swaledale; as also in the counties of Cumberland and Westmorland. It is likewise met with in the counties of Wicklow and other mountainous districts of Ireland.

All the best beds of roofing-slate improve in quality as they lie deeper under the surface; near to which, indeed, they have little value. This variety of slate is found in the Cambrian, Silurian, and Devonian formations.

A good roofing-slate should split readily into thin even laminæ; it should not be absorbent of water either on its face or endwise, a property evinced by its not increasing perceptibly in weight after immersing in water; and it should be sound, compact, and not apt to disintegrate in the air. The slate raised at Eisdale, on the west coast of Argyleshire, is very durable. The slates of Penrhyn and other quarries in North Wales, are very celebrated; those of Delabole in Cornwall are also well known and much esteemed.

Cleaving and dressing of the slates.— The splitter begins by dividing the block, cut lengthwise, to a proper size, which he rests on end, and steadies between his knees. He uses a mallet and a chisel, which he introduces into the stone in a direction parallel to the *folia*. By this means he reduces it into several manageable pieces, and he gives to each the requisite length, by cutting cross grooves on the flat face, and then striking the slab with the chisel. It is afterwards split into thinner sections, by finer chisels dexterously applied to the edges. The slab is then dressed to the proper shape, by being laid on a block of wood, and having its projecting parts at the ends and sides cut off with a species of hatchet or chopping-knife. It deserves to be noticed that blocks of slate may lose their property of divisibility into thin laminæ. This happens from long exposure to the air, after they have been quarried. The workmen say, then, that they have lost their waters. For this reason, the number of splitters ought to be always proportionate to the number of block-hewers. Frost renders the blocks more fissile; but a supervening thaw renders them quite refractory. A new frost restores the faculty of splitting, though not to the same degree; and the workmen therefore avail themselves of it without delay. A succession of frosts and thaws renders the quarried blocks quite intractable.

3. *Whet slate, or Turkey hone*, is a slaty rock, containing a great proportion of quartz, in which the component particles, the same as in clay-slate and mica-slate, but in different proportions, are so very small as to be indiscernible.

4. *Polishing slate.* Colour, cream-yellow, in alternate stripes; massive; composition impalpable; principal fracture, slaty, thin and straight; cross fracture, fine earthy; feels fine, but meagre; adheres little, if at all, to the tongue; is very soft, passing into friable; specific gravity in the dry state, 1·6; when imbued with moisture, 1·9. It is supposed to have been formed from the ashes of burnt coal. It is found at Planitz, near Zwickau, and at Kutschlin near Bilin in Bohemia.

5. *Drawing slate, or black chalk*, has a greyish black colour; is very soft, sectile, easily broken, and adheres slightly to the tongue; spec. grav. 2·11. The streak is glistening. It occurs in beds in primitive and transition clay-slate; also in secondary formations, as in the coal-measures of most countries. It is used in crayon drawing. Its trace upon paper is regular and black. The best kinds are found in Spain, Italy, and France. Some good black chalk occurs also in Caernarvonshire and in the island of Islay.

6. *Adhesive slate* has a light greenish-gray colour, is easily broken or exfoliated, has a shining streak, adheres strongly to the tongue, and absorbs water rapidly, with the emission of air-bubbles and a crackling sound.

7. *Bituminous shale* is a species of soft, sectile slate-clay, much impregnated with bitumen, which occurs in the coal-measures. See KIMMERIDGE SHALE.

8. *Slate-clay* has a grey or greyish-yellow colour; is massive, with a dull glimmering lustre from spangles of mica interspersed. Its slaty fracture approaches at times to earthy; fragments, tabular; soft, sectile, and very frangible; specific gravity, 2·6. It adheres to the tongue, and crumbles down when immersed for some time in

water. It is found as an alternating bed in the coal-measures. When breathed upon, it emits a strong argillaceous odour. When free from lime and iron, it forms an excellent material for making refractory fire-bricks, being an infusible compound of alumina and silica; one of the best examples of which is the schist known by the name of Stourbridge clay. See CLAY.

SLIDES. A miner's term for a dislocation of the strata, which is evidenced by the sliding of one portion of the rock over the other. These slides are often, but not always, filled with a softer matter than the rock, a clay in a greater or less state of induration.

SLIKENSIDES. The name given to smooth striated surfaces of rocks or of mineral lodes, indicating the grinding action of the movement of heavy masses. Many polished surfaces are called *slikensides* to which the term is evidently inapplicable.

SLOKE. The common name for *laver*. See ALGÆ.

SMALT. See COBALT.

SMELTING. The processes for obtaining the metals from the ores. These are described under the respective heads. See COPPER, IRON, LEAD, METALLURGY, SILVER, TIN, ZINC, &c.

SMOKE, prevention of, or consumption of.

Smoke is the more volatile portions of coal, passing off, charged with finely divided carbon, at a comparatively low temperature.

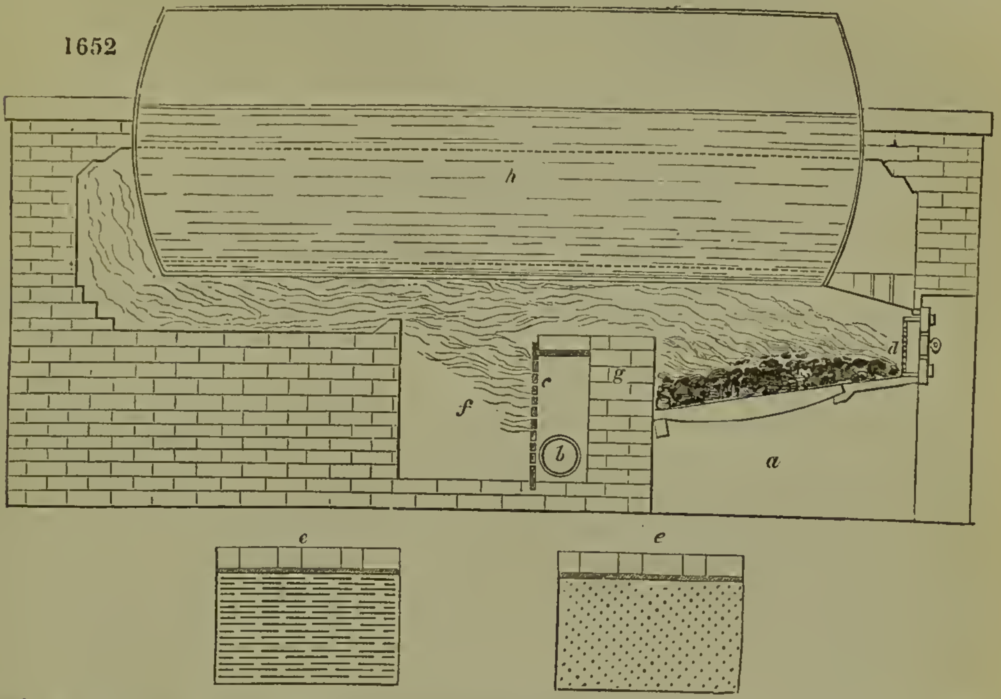
If the black smoke, which escapes from a furnace when a quantity of cold coals is thrown in upon an incandescent mass, can be made to pass over another portion of coal in active combustion, this carbon is *consumed*, *i. e.* combined with atmospheric oxygen, and converted into carbonic oxide, which burns, producing carbonic acid; and eventually escapes as colourless vapour.

One great cause, and perhaps the greatest cause of the annoyance of smoke in large towns is the carelessness of the man supplying fuel to the fire. Where coal is abundant the stoker usually piles an unnecessary quantity of fuel upon his fire, and this has the effect of reducing the heat, and of producing dense volumes of black smoke. Where coal is scarce and dear, as in Cornwall, careful stoking leads to an almost entire absence of smoke. A small quantity of coal is placed in front of the fire at a time, here it undergoes a coking process, the volatile carbon passing over the heated coal is burnt, and no visible smoke escapes. When the coal is thoroughly coked it is shovelled in over the fire, and a fresh portion of coal is placed in front, to undergo the same process.

Among the fifty several inventions which have been patented for effecting this purpose, with regard to steam boilers and other large furnaces, very few are sufficiently economical or effective. The first person who investigated this subject in a truly philosophical manner was Mr. Charles Wye Williams, managing director of the Dublin and Liverpool Steam Navigation Company, and he also has had the merit of constructing many furnaces, both for marine and land steam-engines, which thoroughly prevent the production of smoke, with increased energy of combustion, and a more or less considerable saving of fuel, according to the care of the stoker. The specific invention, for which he obtained a patent in 1840, consists in the introduction of a proper quantity of atmospheric air to the bridges and flame-beds of the furnaces, through a greater number of small orifices, connected with a common pipe or canal, whose area can be increased or diminished according as the circumstances of complete combustion may require, by means of an external valve. The operation of the air thus passed in small jets into the half-burned carburetted hydrogen gases over the fires, is their perfect combustion, the development of all the heat which they can produce, and the entire prevention of smoke. One of the many ingenious methods in which Mr. Williams has carried out the principles of what he justly calls his Argand furnace, is represented at *fig.* 1652, where *a* is the ash-pit of a steam-boiler furnace; *b* is the mouth of a tube which admits the external air into the chamber or iron box of distribution, *c*, placed immediately beyond the fire-bridge, *g*, and before the diffusion or mixing chamber, *f*. The front of the box is perforated either with round or oblong orifices, as shown in the two small figures *e*, *e* beneath *fig.* 1652; *d*, is the fire-door which may have its fire-brick lining also perforated. In some cases, the fire-door projects in front, and it, as well as the sides and arched top of the fire-place, are constructed of perforated fire-tiles, enclosed in common brickwork, with an intermediate space, into which the air may be admitted in regulated quantity through a movable valve in the door. Fire-places of this latter construction perform admirably, without smoke, with an economy of one-seventh of the coals usually consumed in producing a like amount of steam from an ordinary furnace; *h* is the steam boiler.

Very ample evidence was presented in a late session to the Smoke Prevention Committee of the House of Commons of the successful application of Mr. Williams's patent invention to many furnaces of the largest dimensions, more especially by Mr. Henry Houldsworth, of Manchester, who, mounting in the first flue a pyrometrical rod, which acted on an external dial index, succeeded in observing every variation of temperature produced by varying the introduction of the air-jets into the mass of ignited gases

1652



passing out of the furnace. He thereby demonstrated, that 20 per cent. more heat could be easily obtained from the fuel, when Mr. Williams's plan was in operation, than when the fire was left to burn in the usual way, and with the production of the usual volumes of smoke.

SOAP is a chemical compound, manufactured on a very extensive scale, forming, accordingly, a considerable article of commerce. It is a compound resulting from the combination of certain constituents derived from fats, oils, grease of various kinds, both animal and vegetable, with certain salifiable bases, which, in detergent soaps, are potash or soda.

Oils and fats consist chiefly of oleine and stearine, as in tallow, suet, and several vegetable fats; of margarine, which occurs in animal fats, in butter, in olive and other vegetable oils; of palmitine, which is found in palm oil, and so on with various other immediate principles, according to the nature of the fats and oils employed by the soap maker. Natural fatty substances, however, are never exclusively formed of one of these principles, but are, on the contrary, composed of several of them in various pro portions, oleine alone being a constant constituent in all of them.

Natural or neutral fats and oils, chemically considered, are really salts, sometimes called "glycerydes," that is to say, are combinations of acids, oleic, stearic, margaric acid, &c., with the oxide of a hypothetical radical called *glyceryle* (sweet principle of oils).

Stearine being, therefore, a combination of stearic acid with oxide of glyceryle, is a stearate of oxide of glyceryle.

Oleine is a combination of oleic acid with oxide of glyceryle, and is, therefore, an oleate of oxide of glyceryle.

Margarine is a combination of margaric acid and oxide of glyceryle, and is, therefore, a margarate of oxide of glyceryle, and so on with the other constituents of fats and oils.

Glycerine is a combination of oxide of glyceryle with water, which, in that case, plays the part of an acid to form a hydrate of oxide of glyceryle (glycerine).

Now, when neutral fats (namely, oleine, stearine, margarine, &c., or the fats or oils which they constitute) are treated by solutions of caustic alkalies, such as potash or soda, their constituents react upon each other, and combine with the potash or soda; and provided too great an excess of alkali has not been used, the fat or oil dissolves in the alkaline solution into a syrupy liquid, which on cooling forms a gelatinous mass, which is nothing else than an aqueous solution of soap mixed with the glycerine, which the treatment has set free.

The following equation, in which, for the sake of simplicity, one of these principles only, *stearine* and soda dissolved in water, are taken as examples, will clearly illustrate this interesting reaction:—

Stearine.

Stearate of oxide of glyceryle + soda + water
= stearate of soda + hydrate of oxide of glyceryle

hard soap. glycerine.

In the same way:—

Oleine.

Oleate of oxide of glyceryle + soda + water
= oleate of soda + hydrate of oxide of glyceryle

hard soap. glycerine.

and so on all the immediate principles of which the fat or oil employed is composed, splitting, that is to say, separating from this oxide of glyceryle to form a stearate, oleate, margarate, palmitate, &c., of soda or of potash, and glycerine (hydrate of oxide of glyceryle).

Soaps made with soda are hard; those made with potash are soft; the degree of hardness being so much greater as the melting point of the fats employed in their manufacture is higher, hence the more oleine a fatty matter contains, the softer the soap made with it will be, and *vice versâ*. The softest soap, therefore, would be that made altogether with oleine (oleic acid) and potash (oleate of potash); the hardest would be that made with stearine and soda (stearate of soda).

The fats or oils employed for the manufacture of soaps, are tallow, suet, palm oil, cocoa-nut oil, kitchen fat, bone grease, horse oil or fat, lard, butter, train oil, seal oil, and other fish oils, rape oil, poppy oil, linseed and hempseed oil, olive oil, oil of almonds, sesame, and ground nut oil, and *resin*. This last substance, though very soluble in alkaline menstrua, is not, however, susceptible, like fats, of being transformed into an acid, and will not, of course, saponify or form a proper soap by itself. The more caustic the alkali the less consistence has the resinous compound which is made with it. The employ of caustic alkalies, however, is not necessary with it, since it dissolves readily in aqueous solutions of carbonated alkalies, but even with carbonate of soda it forms only a viscid mass, owing to its great affinity for water, so that even after having been artificially dried in an oven, and thus rendered to a great extent hard, the mass deliquesces again spontaneously by exposure, and returns to the soft state. The drying oils, such as those of linseed and poppy, produce the softest soaps.

We said that by boiling fats or oils with an aqueous solution of potash or of soda a solution of soap was produced. The object of the soap-maker is to obtain the soap thus produced in a solid form, which is done by boiling the soapy mass so as to evaporate the excess of water to such a point that the soap may separate from the concentrated liquor and float on the surface thereof in a melted state, or by an admixture of common salt, soap being insoluble in lyes of a certain strength or degree of concentration, and in solutions of common salts of a certain strength, the glycerine remaining, of course, in solution in the liquor below the separated soap. Such is the theory of soap-making; but the *modus operandi* followed by practical soap-makers will be described presently.

On the Continent olive oil, mixed with about one-fifth of rape oil, is principally used in making hard soap. This addition of rape oil is always resorted to, because olive oil alone yields a soap so hard and so compact that it dissolves only with difficulty and slowly in water, which is not the case with rape oil and other oils of a similar nature, that is to say, with oils which become thick and viscid by exposure, and which on that account are called drying oils, experience having taught that the oils which dry the soonest by exposure, yield with soda a softer soap than that made with oils which, like olive oil, remain limpid for a long period under the influence of the air. The admixture of rape oil has, therefore, the effect of modifying the degree of hardness of the soap, and, therefore, of promoting its solubility. In England tallow is used instead of olive oil, the soap resulting from its treatment with soda is known under the name of *curd soap*, and is remarkable for the extreme difficulty with which it dissolves in water. The small white cubic, waxy, stubborn masses, which until a few years ago were generally met with on the washing-stand of bedrooms in hotels, and which for an indefinite period passed on from traveller to traveller, each in turn unsuccessfully attempting, by various devices and cunning immersions in water, to coax it into a lather, is *curd soap*. Rape or linseed oil, added in certain proportions to tallow, would modify this extreme hardness and difficult solubility, but it is now the general practice to qualify the tallow with cocoa-nut oil, an oil, which, converted into soap, has the property of absorbing incredible quantities of water, so that the soap into the manufacture of which it has entered lathers immediately. Cocoa-nut oil, however, acquires by saponification a most disagreeable odour (due to the formation of caprylic acid), which it imparts to all the soaps in the manufacture of which it enters, an odour which persists in spite of any perfume which may be added to mask it.

The admixture of one-fourth or one-fifth of resin with tallow, in the process of saponification, modifies also the hardness and considerably increases the solubility of curd soap, and this, in fact, constitutes the best *yellow soap*.

I said that soap was more or less hard in proportion as the melting point of the fats employed in its manufacture was higher or lower. There are certain fatty substances, technically called weak goods, such as kitchen fat, bone fat, horse oil, &c., which could hardly be used alone, still less with resin, the soap which they yield being too soft, and melting or dissolving away too rapidly in the washing-tub. This led me to think, that if a means could be devised of artificially hardening soap, a larger class of oleaginous and fatty substances could be rendered available, at any rate to a greater extent than they hitherto had been, and that, by thus extending the resources of the soap boiler, he should be enabled to produce a good and useful soap from the cheapest materials, and thus convert soaps of little commercial value into useful and economical products.

In making experiments with this view, I found that the introduction of a small quantity of melted crystals or sulphate of soda into the soap answered the purpose admirably, and that the salt in recrystallising, imparted to the soap, which otherwise would have been soft, a desirable hardness, and prevented its being wasted in the tub. The use of sulphate of soda acts, therefore, *inversely*, like the addition of rape oil, or linseed oil, or of resin to tallow, in the manufacture of soap. This process, which I patented in 1841, has been, since the removal of the duties on soap, extensively employed by soap makers, and continues to be highly approved of by the public. I shall describe further on the manner of practising this process, and the further improvements which I made to it in 1855.

Of the manufacture of hard soap.— The fat of this soap, in the northern countries of Europe, is usually tallow, and in the southern, coarse olive oil. Different species of grease are saponified by soda, with different degrees of facility; among oils, the olive, sweet almond, rapeseed, and castor oil; and among solid fats, tallow, bone grease, and butter, are most easily saponified. According to the practice of the United Kingdom, six or seven days are required to complete the formation of a pan of hard soap, and a day or two more for settling the impurities, if it contains resin. From 12 to 13 cwt. of tallow are estimated to produce one ton of good soap. Several years ago, in many manufactories the tallow used to be saponified with potash lyes, and the resulting soft soap was converted, in the course of the process, into hard soap, by the introduction of muriate of soda, or weak kelp lyes, in sufficient quantity to furnish the proper quantity of soda by the reaction of the potash upon the neutral salts. But the high price of potash, and the diminished price, as well as improved quality of the crude sodas, have led to their general adoption in soap-works.

The first step in the production of soap consists in obtaining a solution of soda, or what is termed caustic lye. For this purpose a given quantity of the soda ash above alluded to, is stratified with a quantity of recently-burnt, or quick-lime, in tanks of wrought-iron, or cylindrical cast-iron vats, from 6 to 7 feet wide and from 4 to 5 feet deep, the lowest layer being, of course, quick-lime. These vats have frequently a false bottom, perforated with holes, or else a coarse piece of matting is placed over the plug-hole, placed at the bottom of the said vats or tanks, which plug-hole is, of course, closed generally by a wooden plug. Water is then poured upon the whole mass until the tanks are full, and the whole is allowed to stand for twelve or eighteen hours. The plug being then withdrawn, the saturated solution of caustic soda flows down into a reservoir placed beneath, after which the plug is replaced, more water applied, and this operation is repeated five or six times, until, in fact, the soda is almost entirely extracted; the various liquors thus obtained, in a clear and caustic state, after infiltration through the beds of lime, being conveyed to separate and distinct reservoirs, distinguished from each other by the names of *first running*, *second running*, and so on; the last being, of course, the weakest.

Having in this way produced a series of caustic lyes of different degrees of strength, about 200 gallons of the weakest, which has a specific gravity of about 1·040, is pumped into the soap pan or boiler, or *copper*, as it is called, though generally made of cast iron, and about 1 ton of tallow is added, heat is applied, and after a gentle ebullition of about four hours, it will be found that the lye will have lost its causticity, or, in technical language, that it is *killed*, and that the fat is saponified, which is known by taking a portion of the mass on a trowel, when it will be observed that the liquid separates at once from the soapy mass, which it leaves in streaks on the trowel. The lyes thus used at first, if composed of pure soda, would contain about 4 per cent. of alkali, but from the presence of neutro-saline matter they seldom contain as much as 2 per cent.; in fact, a gallon may be estimated to contain not more than 2 ounces, so that 200 gallons contain 25 lbs. of real soda. The fire being withdrawn, the whole is now allowed to cool and remain at rest for about one hour, until the lye, now deprived of its alkali. and, therefore, called *spent lye*, settles to the bottom of the copper. This spent lye contains a portion of glycerine derived from the fat or tallow, together with the sulphate of soda and common salt of the soda ash, and is pumped off by means of an iron pump, which is lowered down into the lower pan of the soap copper, a practice which might be advantageously replaced by opening a cock which might be placed at the bottom of the copper, but which is retained as a remnant of that abominable system of excise which did not permit the spent lyes to be otherwise withdrawn, as the excise laws forbade any cock or aperture being placed or made at the bottom of soap coppers. This constitutes what is called an operation. A second similar charge of lye is now introduced into the pan along with a fresh quantity of tallow or of grease, and a similar boiling process is again repeated. Three or four such boilings may be practised in the course of a day by an active soap-boiler, with lyes of gradually increasing strength. Next day the same routine is renewed with stronger lyes, and so progressively until towards the sixth day the lye may have the density of 1·160, when a period arrives at which it will be found that the whole of the tallow or fat is completely saponified, that is to say, has combined with its full equivalent of soda. This point is well known to the workmen by the consistence of the compound; in effect it is sufficient to take a portion of the mass on a trowel, and to squeeze a little of the mass between the forefinger and thumb; if not quite and thoroughly finished it will still have a greasy feeling, but if done it will on cooling readily separate from the skin in hard scales — neither has it the taste peculiar to grease. A more certain mode, however, especially for those who have not acquired sufficient practice, is to decompose a portion of the saponified or partly saponified mass with an acid, and to ascertain whether the grease is *wholly soluble* in boiling spirits of wine, for if it is not thus wholly soluble, the saponification is imperfect. The addition of common salt for the separation of the spent lyes is essential to the proper granulation and separation of the soap, for otherwise the tallow and the lye would unite into a uniform emulsion, from which it would be very difficult afterwards to separate the spent lye; but as soap is quite insoluble in a solution of common salt, the partly saponified mass is thus brought to float on the surface, so that the spent lye precipitates to the bottom, whence, as we said, it is pumped off.

Assuming, however, that a perfect result has been secured, the soap has now to be brought to a marketable condition, and for this purpose it is boiled with a quantity of weak lye or water. As soon as combination has taken place, a quantity of very strong lye is added, until an incipient separation begins to show itself. The heat is now increased, and the boiling continued for a considerable time, the mass being prevented from boiling over the vessel by workmen armed with shovels, who dash the soap to and fro, so as to break the froth upon the surface and favour evaporation. At first the soap is divided into an innumerable number of small globules, each separate and distinct from its fellow; but as the boiling goes on, those gradually run together into larger and larger globules, till at last the soap is seen to assume a pasty consistence, and to unite in one uniform mass, through which the steam from below slowly forces its way in a series of bursts or little explosions. The process is now finished, and all that remains to be done is to shut down the lid of the copper, having previously extinguished the fire. In from one to two or three days, according to the nature and quantity of the soap in question, the lid is again raised, and the semifluid soap ladled from the precipitated lye by means of ladles; the product being thrown into a wooden or iron frame of specific dimensions, where its weight is estimated by measurement. In making common yellow or resin soap, the resin is usually added after the saponification of the tallow, in the proportion of one-third or one-fourth of the tallow employed. The subsequent operations are much about the same as those above described; but in addition just before closing the lid of the copper a quantity of water or weak lye is sprinkled over the melted soap, which carries down with it the mechanical impurities of the resin; and these constitute a dark layer of soap resting upon the lye, which is not poured into the frame with the rest, but is placed apart under the name "*niger*," and brings a less price. Good curd or white soap should contain of

Grease - - - - - - - -	61.0 parts
Soda - - - - - - - -	6·2 „
Water - - - - - - - -	32·8 „
	100

or consist of

Grease acid	1 atom	=315
Soda	1 atom	= 32
Water	17 atoms	=153

Resin soap has a more variable composition, but when not adulterated with water should contain about as follows:—

Grease and resin	60
Soda	6
Water	34
	100

Manufacture of mottled soap.—Soda which contains sulphurets is preferred for making the mottled or marbled soap, whereas the desulphuretted soda makes the best white curd soap. Mottling is usually given in the London soap-works, by introducing into the nearly finished soap in the pan a certain quantity of the strong lye of crude soda, through the rose spout of a watering-can. The dense sulphuretted liquor, in descending through the pasty mass, causes the marbled appearance. In France a small quantity of solution of sulphate of iron is added during the boiling of the soap, or rather with the first service of the lyes. The alkali seizes the acid of the sulphate, and sets the protoxide of iron free to mingle with the paste, to absorb more or less oxygen, and to produce thereby a variety of tints. A portion of oxide combines also with the stearine to form a metallic soap. When the oxide passes into the red state, it gives the tint called *manteau Isabelle.* As soon as the *mottler* has broken the paste, and made it pervious in all directions, he ceases to push his rake from right to left, but only plunges it perpendicularly till he reaches the lye; then he raises it suddenly in a vertical line, making it act like the stroke of a piston in a pump, whereby he lifts some of the lye, and spreads it over the surface of the paste. In its subsequent descent through the numerous fissures and channels on its way to the bottom of the pan, the coloured lye impregnates the soapy particles in various forms and degrees, whence a varied marbling results.

The best and most esteemed soap on the Continent is that known under the name of Marseilles soap, and it differs from the English mottled soap by a different disposition of the mottling, which in that soap is granitic instead of being streaky. It has also an agreeable odour, somewhat resembling that of the violet, whereas the English mottled soap, generally made of very coarse kitchen and bone fat, has an odour which reminds one of the fat employed. The best English mottled soap in which tallow is employed, has no unpleasant smell, and if bleached palm oil has been used it acquires an agreeable odour, analogous to that of the Marseilles soap, which is made of olive oil alone, or mixed with rape or other grain or seed oil, which, however, seldom exceeds 10 per cent., for otherwise it would not have the due proportion of blue to the white which is characteristic of soap made of genuine olive oil, the mottling becoming more closely granular when an undue proportion of grain has been used, a sign of depreciation which the dealers are perfectly well acquainted with, and of which they at once avail themselves, to compel the maker to reduce his price.

Pelouze and Frémy, in their *Traité de chimie générale*, give the following reliable observations:—

"The best olive oil for the use of the soap maker is Provence oil; that of Aix comes next; it is cheaper, but a same weight of it yields less soap than the other, and the latter has then a slight lemon yellow tinge. The oil from Calabre contains less margarine, and yields a softer soap.

"Two kinds of soda ash are used in Marseilles, the soft soda (*soude douce*) and the salted soda (*soude salée*), which contains a large quantity of common salt.

"To prepare the lye, the soft soda previously reduced into small lumps is mixed with 12 per cent. of slaked lime, and shovelled up into tanks of masonry of about 2 cubic yards' capacity, called *barquieux*, and the exhaustion of the mass with water gives lyes of various degrees of strength.

"The lye marking 12° is used for the first treatment, or *empâtage* of the oil, which is then submitted to a second and third treatment with a lye marking 15° or 20°, the object of which is to close the grains of the emulsive mass in process of saponification (*serrer l'empâtage*). The operation requires about twenty-four hours. During all the time of that operation a workman is constantly agitating the boiling mixture of the oil and lye by means of a long rake or crutch, called *râble*. The *empâtage* is generally practised in large conical tanks of masonry terminated at bottom by a copper pan, and capable of containing 12 or 13 tons of made soap, and the operation proceeds so much the more rapidly, as the soda lye employed contains less common salt, wherefore soft soda lye (*soude douce*) must be used at the beginning, as we said.

"The next operation is that called *relargage*, the object of which is to separate the large quantity of water which has been used to facilitate the *empâtage*. This separation of the water, or *relargage*, is effected by means of salted soda (that is to say, of soda ash, containing a good deal of common salt), of which as much is dissolved in water as will make a lye marking 20° or 25°. This salted lye is then gradually poured by a workman on the surface of the saponifying goods in the copper, while another workman is diffusing it in the mass by stirring the whole with a rake or crutch.

"The immediate effect of the salt thus added is to separate from the soapy mass the water in which it was dissolved, and which gave it a homogeneous and syrupy appearance, and to coagulate it, the soap being thereby curded or coagulated, and converted into a multitude of granules floating among the excess of water in which they were dissolved, and which the salt has separated. The whole being then left at rest for two or three hours, in order to give the grains of soap time to rise and agglomerate at the surface, a workman proceeds to the *épinage*, an operation which consists in withdrawing the liquid portion by removing a wooden plug placed at the lower part of the boiler."

In this country the *épinage* is generally performed by means of an iron pump plunging through the soap down to the pan at the bottom of the copper.

This *spent lye*, in well-conducted factories, retains but little alkali, and is generally thrown away; but as it contains a rather large quantity of salt, which, in France, is an expensive article, it might be, and is sometimes, kept and used for preparing fresh lyes.

After the first *épinage*, the soap is treated twice again with salt lye, followed of course by two *épinages;* but as the salt lye used in these two operations is not exhausted, it is always kept for preparing fresh lyes.

The cleansing, that is to say, the removing of the soap into the frames, takes place on the third day, at which time the operation called *madrage* is performed. For that purpose a plank is thrown across the boiler or copper, and two or three men standing on it, and therefore over the soapy mass in the copper, proceed to stir it up for two or three hours, by means of long crutches, which they alternately move up and down through it, the object being to keep the grains of soap well diffused through the liquid, weak lyes marking only 8° or 10°, or ordinary water, as the case may be, being sprinkled from time to time into the mass, until the grains of soap have reabsorbed a sufficient quantity of water and have swollen to such a size as to have a specific gravity very little greater than that of the liquid among which they float about. A skilful workman knows by the appearance of the soap grains whether he should use alkaline lyes or simply water, and this is indeed a most important point in the manufacture of *Marseilles* soap, for upon it the success of the operation depends in a commercial point of view, that is to say, all things being equal in other respects, a profit or loss on the batch of soap made will ensue. In effect, if too much water has been added the soap will lose either the whole, or too great a portion of its *mottling*. that is to say, the result will be either a dingy white curd, or a soap in which the white portions will predominate to too great an extent over the blue streaks, a circumstance which so far deteriorates the market value, the buyer shrewdly suspecting then that he would pay for water the price of soap. If, on the contrary, a sufficient quantity of water has not been added, the soap grains remaining hard and dry, will form more or less friable, thereby causing also a deterioration of price, the buyer knowing that such soap, by crumbling into small pieces every time he has to cut it with his knife in selling it to his customers, will considerably reduce his profit, or perhaps even entail a positive loss to him.

In the best conditions, that is to say, by employing the best Gallipoli oil for the purpose of producing Marseilles soap of first quality, 100 cwt. of olive oil yield 175 cwt. of mottled soap ; by using mixtures of olive and rape or other seed oils, the yield of soap is reduced to 170, or even less ; in either case the yield is reduced by 5 or 6 per cent. when old or fermented is employed instead of new good oil.

The manufacturing expenses are calculated at Marseilles at the rate of 17f. 25c. (nearly 13*s.* and 10*d.*) per 100 kilogrammes of fatty matter employed, which require 72 kilogrammes of soda for their saponification.

Mottled soap has a marbled, or streaky appearance, that is to say, it has veins of a bluish colour, and resembling granite in their disposition or arrangement. The size and number of these veins or speckles, and the proportion which they bear to the white ground of the soap, depend not only on the more or less rapid cooling of the soap after it has been cleansed, that is, transferred from the copper to the frame ; but also on the quality and kind of the fat, grease, or oil employed, and on the manner in which it has been treated in the copper. A soap which has not been sufficiently boiled at the last stage of the manufacture is always tender. The blue or slate-colour of the streaks or veins of mottled soap is due to the presence of an alumino-ferruginous soap interposed in the mass, and frequently also to that of sulphuret of iron, which is produced by the reaction of the alkaline sulphurets contained in the soda lye upon the iron, derived from the soda ash itself, and from the iron pans and other utensils employed in the manufacture, or which is even purposely introduced in the state of solution of protosulphate of iron. This introduction, however, is never resorted to, I believe, in this country. The veins or streaks disappear from the surface to the centre by keeping, because the iron becomes gradually peroxidised. A well-manufactured mottled soap cannot contain more than 33, 34, or at most 36 per cent. of water, whereas genuine curd soap contains 45, and yellow soap at least 52 per cent. of water, and sometimes considerably more than that. It is evident, in effect, that the mottling being due to the presence of sulphuret of iron held in the state partly of demisolution and of suspension, the addition of water would cause the colouring substances to subside, and a white, unicoloured, or fitted soap would be the result. This addition of water, technically called *fitting*, is made when the object of the manufacturer is to obtain a unicoloured soap, whether it be curd or yellow soap. After *fitting*, the soap contains, therefore, an additional quantity of water, which sometimes amounts to 55 per cent.: the interest of the consumer would, therefore, clearly be to buy mottled soap in preference to yellow or white soap; the mottling, when not artificially imitated, being a sure criterion of genuineness; for the addition of water, or of any other substance, would, as was just said, infallibly destroy the mottling. To yellow or curd soap, on the contrary, incredible quantities of water may be added. I have known five pails of water (15 gallons) added to a frame (10 cwt.) of already *fitted* soap, so that the soap, by this treatment, contained upwards of 60 per cent. of water, to which common salt had previously been added. The proportion of water in fitted soap has also been augmented, in some instances, by boiling the soap in high pressure boilers before *cleansing*. As cocoa-nut oil has the property of absorbing one-third more water, when made into soap, than any other material, its consumption by the soap maker has, within the last fifteen or twenty years, augmented to an extraordinary extent; and, moreover, the patent taken in 1857 by Messrs. Blake and Maxwell, of Liverpool, for the invention of Mr. Kottula, which we shall describe presently, has, I believe, increased the demand for that species of oil in a notable degree. We said that the mottling, inasmuch as it was indicative of genuineness, was the more economical soap to buy; unfortunately, mottled soap has the drawback of not being so readily soluble as yellow soap, and the goods washed with it are more difficult to rinse; but the process patented by Messrs. Blake and Maxwell enabling the manufacturer to manufacture with cocoa-nut oil a soap to which the mottling is artificially imparted, by means of ultramarine, black or brown oxide of manganese, in such a perfect manner as almost to defy detection, mottling has thus ceased to be a safe outward sign of genuineness, as far as regards the article which it pretends to represent. That description of soap, however, has specific qualities; it is almost perfectly neutral, and it will not bear more than a definite proportion of water; so that, although it contains more of that liquid than ordinary mottled soap,—more than a certain fixed quantity cannot be forced into it; so that it also forms a standard soap, like the ordinary mottled, although that standard is different from, and inferior to, the latter. The process in question is briefly as follows:—Take 80 cwt. of palm oil, made into soap in the usual way, with two changes of lye, grained with strong lye, or lye in the usual manner, but so that the lye leaves the curd perfectly free; pump the spent lye away, and add 32 cwt. of cocoa-nut oil, 60 cwt. of lye, at 20° of Beaumé's areometer, and then gradually 14 cwt. of lye, at 14° Beaumé. Boil until the whole mass is well saponified. Put now from 6 to 7 lbs. of ultramarine in water, or weak lye, stir the whole well, and pour it into the soap through the rose of a watering-pot; boil the whole for about half an hour, or an hour, and cleanse it in the ordinary wooden frames, or in iron frames surrounded by matting, or other covering, so that the soap may not cool too rapidly: the above proportions will yield 212 cwt. of soap, with a beautiful blue mottle.

Manufacture of yellow or rosin soap.—We have already said that rosin, though not capable of forming a soap with soda, readily dissolves in that alkali, either in the caustic or in the carbonated state, with which it forms a kind of soapy mass of a viscid or treacly nature; hence fat of some kind, in considerable proportion must be used along with the rosin, the *minimum* being equal parts; and then the soap is far from being good. As alkaline matter cannot be neutralised by rosin, it preserves its peculiar acrimony in a soap poor in fat, and is ready to act too powerfully upon woollen and all other animal fibres to which it is applied. It is said that rancid tallow serves to mask the strong odour of rosin in soap, more than any oil or other species of fat. From what we have just said, it is obviously needless to make the rosin used for yellow soaps pass through all the stages of the saponifying process; nor would this indeed be proper, as a portion of the rosin would be carried away, and wasted with the spent lyes. The best mode of proceeding, therefore, is first of all to make the hard soap in the usual manner, and at the last service or charge of lye, namely, when this ceases to be absorbed, and preserves in the boiling-pan its entire causticity, to add the proportion of rosin intended for the soap. In order to facilitate the solution of the rosin in the soap, it should be reduced to coarse powder, and well incorporated by stirring with the rake. The proportion of rosin is usually from one-third to one-fourth the weight of the tallow. The boil must be kept up for some time with an excess of caustic lye; and when the paste is found, on cooling a sample of it to acquire a solid consistence, and when diffused in a little water, not to leave a resinous varnish on the skin, we may consider the soap to be finished. The maker next proceeds to draw off the the superfluous lyes, and to purify the paste. For this purpose, a quantity of lyes at 80° B. being poured in, the mass is heated, worked well with a rake, then allowed to settle, and drained of its lyes. A second service of lyes at 4° B., is now introduced, and finally one at 2°; after each of which there is the usual agitation and period of repose. The pan being now skimmed, and the scum or *fob* removed for another operation, the soap is laded off by hand-pails into its frame-moulds. A little palm oil is occasionally employed in the manufacture of yellow soap, in order to correct the flavour of the rosin and brighten the colour. This soap, when well made, ought to be of a fine wax-yellow hue, be transparent upon the edges of the bars, dissolve readily in water, and afford even with hard pump-water, an excellent lather.

The frame-moulds for hard soap are composed of strong wooden bars, made into the form of a parallelogram, which are piled over each other, and bound together by screwed iron rods that pass through them. A square well is thus formed, which in large soap factories is sometimes 10 feet deep, and capable of containing a couple of tons of soap. For plain yellow or curd soaps iron frames are now used instead of wooden ones in almost every factory.

Mr. Sheridan some time since obtained a patent for combining silicate of soda with hard soap, by triturating them together in the hot and pasty state with a crutch in an iron pan. In this way from 10 to 30 per cent. of the silicate may be introduced. Such soap possesses very powerful detergent qualities, but it is apt to feel hard and be somewhat gritty in use. The silicated soda is prepared by boiling ground flints in a strong caustic lye, till the specific gravity of the compound rises to nearly double the density of water. It then contains about 35 grains of silica, and 46 of soda-hydrate, in 100 grains.*

Hard soap, after remaining two days in the frames, is at first divided horizontally into parallel tablets 3 or 4 inches thick, by a brass wire; and these tablets are again cut vertically into oblong nearly square bars, called wedges in Scotland.

The soap-pans used in the United Kingdom are made of cast iron, and in three separate pieces joined together by iron-rust cement. The following is their general form :—The two upper frustra of cones are called curbs; the third, or undermost, is the pan to which alone the heat is applied, and which, if it gets cracked in the course of boiling, may easily be lifted up within the conical pieces, by attaching chains or cords for raising it, without disturbing the masonry in which the curbs are firmly set. The surface of the hemispheral pan at the bottom, is in general about one-tenth part of the surface of the conical sides.

The white ordinary tallow soap of the London manufacturers, called curd soap, consists by my experiments, of fat, 52; soda, 6; water, 42; =100. Nine-tenths of the fat, at least, is tallow.

Dr. Normandy has examined several other soaps, and have found their composition somewhat different.

The foreign Castile soap of the apothecary has a specific gravity of 1·0705, and consists of—

Soda - - - - - -	9
Oily fat - - - - -	76·5
Water and colouring matter -	14·5
	100·0

English imitation of Castile soap, sp. gr. 0·9669, consists of—

Soda - - - - - -	10·5
Pasty-consistenced fat - -	75·2
Water, with a little colouring matter - - - -	14·3
	100·0

A perfumer's white soap was found to consist of—

Soda - - - - - -	9
Fatty matter - - - -	75
Water - - - - - -	16
	100

* By my own experiments upon the liquid silicate made at Mr. Gibbs's excellent soap factory.

Glasgow white soap—

Soda	6·4
Tallow	60·0
Water	33·6
	100·0

Glasgow brown rosin soap—

Soda	6·5
Fat and rosin	70·0
Water	23·5
	100·0

A London cocoa-nut oil soap was found to consist of—

Soda	4·5
Cocoa-nut lard	22·0
Water	73·5
	100·0

This remarkable soap was sufficiently solid; but it dissolved in hot water with extreme facility. It is called marine soap, because it washes linen with sea water.

A poppy-nut-oil hard soap consisted of—

Soda	7
Oil	76
Water	17
	100*

The soap known in France by the name of *soap in tables*, consists, according to M. Thenard's analysis, of—

Soda	4·6
Fatty matter	50·2
Water	45·2
	100

M. D'Arcet states the analysis of Marseilles soap at—

Soda	6
Oil	60
Water	34
	100

With respect to the manufacture of sulphated soap, the process is as follows:—

To every ton of soap made in the usual way and ready to be cleansed and crystallised, add sulphate of soda (Glauber salt) in the proportion of about 1 cwt. or more, according to the quality of the goods employed. The Glauber salt should first be dissolved by turning steam into it, or in a steam pan, in its own water of crystallisation; it is then added to the finished soap, and the whole must be crutched until the mass has become so stiff that it cannot be crutched any longer. In the evidence before the Privy Council, in the month of July, 1855, this process was found by their lordships of such public value that the patent right was extended for three years.

This process, however, has been superseded by another which Dr. Normandy patented in the month of August, 1855. In effect it had been found that whereas sulphate of soda is more soluble in lukewarm than in either cold or boiling water, the temperature of the weather in summer time interfered with or altogether prevented the formation of the crystals, and that as the crystals of this salt contain ten equivalents of water, the maker of sulphated soap was put to the trouble and expense of the carriage of this to him useless water of crystallisation.

Soft soap.—The manufacture of soft soap differs greatly from that of hard soap; as, in this case, nothing is separated from the mixture in the boiler; and the alkali employed is potash, and not soda. The mode of obtaining a caustic lye of potash is exactly the same as with soda, except that the weak lyes are used in place of water for a subsequent operation, and not pumped up into the boiler. The materials employed as fats are mixtures of the vegetable and animal oils, as rape, and the fish oil called "Southern." For the best kinds of soft soap, a little tallow is added to these, which produces a peculiar kind of mottling or crystallisation in the soap, that confers additional value upon it. These oils or fats are merely boiled with the strong caustic potash-lye, until thorough combination has taken place, and so much of the water of the lye is evaporated that, when a portion of the soap is poured upon a cold slab and allowed to rest for a few minutes, it assumes the consistence of soft butter. As soon as this happens, the whole is run out into little casks, where it cools; it is thus sent into the market. Of course no atomic arrangement can be traced in so variable a compound; and hence its analysis presents no point of interest. The employment of soft soap is daily becoming more and more limited. Soft soap usually contains as under:—

Fatty oils	43
Potash	10
Water	47
	100

but its composition differs greatly.

The principal difference between soaps with base of soda, and soaps with base of potash, depends upon their mode of combination with water. The former absorb a large quantity of it, and become solid; they are chemical hydrates. The others

* Dr. Normandy's experiments. See Fats, Oils, and Stearine.

experience a much feebler cohesive attraction; but they retain much more water in a state of mere mixture.

Three parts of fat afford, in general, fully five parts of soda soap, well dried in the open air; but three parts of fat or oil will afford from six to seven parts of potash soap of moderate consistence. This feebler cohesive force renders it apt to deliquesce, especially if there be a small excess of the alkali. It is therefore impossible to separate it from the lyes; and the washing or *relargage*, practised on the hard-soap process is inadmissible in the soft. Perhaps, however, this concentration or abstraction of water might be effected by using dense lyes of muriate of potash. Those of muriate or sulphate of soda change the potash into a soda soap, by double decomposition. From its superior solubility, more alkaline reaction, and lower price, potash soap is preferred for many purposes, and especially for scouring woollen yarns and stuffs.

Soft soaps are usually made in this country with whale, seal, olive, and linseed oils, and a certain quantity of tallow; ou the continent, with the oils of hempseed, sesame, rapeseed, linseed, poppy-seed, and colza; or with mixtures of several of these oils. When tallow is added, as in Great Britain, the object is to produce white and somewhat solid grains of stearic soap in the transparent mass, called figging, because the soap then resembles the granular texture of the fig.

The potash lyes should be made perfectly caustic, and of at least two different strengths; the weakest being of sp. gr. 1·05; and the strongest, 1·20, or even 1·25. Being made from the potashes of commerce, which contain seldom more than 60 per cent., and often less, of real alkali, the lyes correspond in specific gravity to double their alkaline strength; that is to say, a solution of pure potash of the same density would be fully twice as strong. The following is the process followed by respectable manufacturers of soft soap (*savon vert*, being naturally or artificially green) upon the continent.

A portion of the oil being poured into the pan, and heated to nearly the boiling point of water, a certain quantity of the weaker lye is introduced; the fire being kept up so as to bring the mixture to a boiling state. Then some more oil and lye are added alternately, till the whole quantity of oil destined for the pan is introduced. The ebullition is kept up iu the gentlest manner possible, and some stronger lye is occasionally added, till the workman judges the saponification to be perfect. The boiling becomes progressively less tumultuous, the frothy mass subsides, the paste grows transparent, and it gradually thickens. The operation is considered to be finished when the paste ceases to affect the tongue with an acrid pungency, when all milkiness and opacity disappear, and when a little of the soap placed to cool upou a glass-plate assumes the proper consistency.

A peculiar phenomenon may be remarked in the cooling, which affords a good criterion of the quality of the soap. When there is formed around the little patch, an opaque zone, a fraction of an inch broad, this is supposed to indicate complete saponification, and is called the *strength*; when it is absent, the soap is said to want its *strength*. When this zone soon vanishes after being distinctly seen, the soap is said to have *false* strength. When it occurs in the best form, the soap is perfect, and may be secured in that state by removing the fire, and then adding some good soap of a previous round to cool it down, and prevent further change by evaporation.

200 pounds of oil require for their saponification, 72 pounds of American potash of moderate quality, in lyes at 15° B.; and the product is 460 pounds of well-boiled soap.

If hempseed oil has not been employed, the soap will have a yellow colour, instead of the green, so much in request on the Continent. This tint is then given by the addition of a little indigo. This dye stuff is reduced to fine powder, and boiled for some hours in a considerable quantity of water, till the stick with which the water is stirred presents, on withdrawing it, a gilded pellicle over its whole surface. The indigo paste diffused through the liquid, is now ready to be incorporated with the soap in the pan before it stiffens by cooling.

M. Thenard states the composition of soft soap at — potash 9·5, + oil 44·0, + water 46·5, = 100.

Good soft soap of London manufacture yielded to me — potash 8·5, + oil and tallow 45, + water 46·5.

Belgian soft or green soap afforded me — potash 7, + oil 36, + water 57, = 100.

Scotch soft soap, being analysed, gave me — potash 8, + oil and tallow 47, + water 45.

Another well-made soap — potash 9, + oil and fat 34, + water 57.

A rapeseed oil soft soap from Scotland cousisted of — potash 10, + oil 51·66, + water 38·33.

An olive oil (Gallipoli) soft soap from ditto, contained—potash with a good deal of carbonic acid 10, oil 48, water 42, = 100.

A semi-hard soap from Verviers, for filling woollen cloth, called *savon économique*, consisted of — potash 11·5, + fat (solid) 62, + water 26·5, = 100.

The following is a common process in Scotland, by which good soft soap is made: —

273 gallons of whale or cod oil, and 4 cwt. of tallow, are put into the soap-pan, with 250 gallons of lye from American potash, of such alkaline strength that 1 gallon contains 6600 grains of real potash. Heat being applied to the bottom pan, the mixture froths up very much as it approaches the boiling temperature, but is prevented from boiling over by being beat down on the surface, within the iron curb or crib which surmounts the cauldron. Should it soon subside into a doughy-looking paste, we may infer that the lye has been too strong. Its proper appearance is that of a thin glue. We should now introduce about 42 gallons of a stronger lye, equivalent to 8700 gr. of potash per gallon; and after a short interval, an additional 42 gallons; and thus successively till nearly 600 such gallons have been added in the whole. After suitable boiling to saponify the fats, the proper quality of soap will be obtained, amounting in quantity to 100 firkins of 64 pounds each, from the above quantity of materials.

It is generally supposed, and I believe it to be true, from my own numerous experiments upon the subject, that it is a more difficult and delicate operation to make a fine soft soap of glassy transparency, interspersed with the figged granulations of stearate of potash, than to make hard soap of any kind.

Soft soap is made in Belgium as follows:— For a boil of 18 or 20 tons of 100 kilogrammes each, there is employed for the lyes, 1500 pounds of American potashes, and 500 to 600 pounds of quicklime.

The lye is prepared cold in cisterns of hewn stone, of which there are usually five in a range. The first contains the materials nearly exhausted of their alkali; and the last the potash in its entire state. The lye run off from the first is transferred into the second; and that of the second into the third; and so on to the fifth.

In conducting the *empatage* of the soap, they put into the pan, on the eve of the boiling-day, six *aimes* (one ohm = 30 gallons imperial) of oil of colza, in summer, but a mixture of that oil with linseed oil in winter, along with two aimes of potash lye at 13° B., and leave the mixture without heat during eight hours. After applying the fire, they continue to boil gently till the materials cease to swell up with the heat; after which lye of 16° or 17° must be introduced successively, in quantities of one quarter of an aime after another, till from 2 to 4 aimes be used. The boil is finished by pouring some lye of 20° B., so that the whole quantity may amount to 9½ aimes.

It is considered that the operation will be successful, if from the time of kindling the fire till the finish of the boil, only five hours elapse. In order to prevent the soap from boiling over, a wheel is kept revolving in the pan. The operator considers the soap to be finished, when it can no longer be drawn out into threads between the finger and thumb. He determines if it contains an excess of alkali, by taking a sample out during the boil, which he puts into a tin dish; when, if it gets covered with a skin, he pours fresh oil into the pan, and continues the boil till the soap is perfect. No wonder the Belgian soap is bad, amid such groping in the dark, without one ray of science!

Besides water, soap is often adulterated by gelatine, forming a soap sometimes called "bone soap," which is made by adding to the soap a solution of disintegrated bones, sinews, skins, hoofs, sprats, and other cheap fish in strong caustic soda; also by dextrine, potato starch, pumice stone, silica, plaster, clay, salt, chalk, carbonate of soda, &c., and by fats of another or inferior kind than those from which they are represented to have been made. These impurities or superadded materials and their amount may be ascertained in the following manner:

Estimation of the quantity of water:— Take about 1000 grains of the soap under examination, cut into small and thin slices, not only from the outside, which is always dryer, but from the interior of the sample, so that the whole may represent a fair average; mix the mass well together, and of this weigh accurately 100 grains; place it in an oven heated to a temperature of 212° Fahr., until it is quite dry, weighing it occasionally until no loss or diminution of weight is observed, the difference between the original and the last weight, the loss, indicates, of course, the proportion of water. The loss of water in mottled soap and in soft soap should not be more than 30 to 35 per cent.; in white or yellow soap from 36 to at most 50 per cent.

If the soap is sulphated, the amount of sulphate employed may be determined by taking 200 grains of the sample, dissolving it in a capsule with boiling water, adding to the boiling solution as much hydrochloric acid as is necessary to render the liquid strongly acid, and therefore to decompose the soap entirely, throwing the whole in a filter previously wetted with water, adding to the filtrate an excess of chloride of barium, washing thoroughly the white precipitate so produced, igniting and weighing it; every grain of sulphate of barytes thus obtained represents 1·467 grain of crystallised sulphate of soda.

If the soap contains clay, chalk, silica, dextrine, fecula, pumice stone, ochre, plaster, salt, gelatine, &c., dissolve 100 grains of the suspected soap in alcohol, with the help of a gentle heat; the alcohol will dissolve the soap and leave all these impurities in an insoluble state. Good mottled soap should not leave more than 1 per cent. of insoluble matter, and white or yellow soap still less. All soap to which earthy or siliceous matter has been added is opaque instead of transparent at the edges, as is the case with all genuine or fitted and sulphated soap. The drier the soap, the more transparent it is.

Bone soap, or glue soap, is recognised by its unpleasant odour of glue and its dark colour, its want of transparency at the edges; that made with the fat of the intestines of animals has a disgusting odour of *fæces.*

When uncombined silica has been added to soap, its presence may be readily detected by dissolving the suspected soap in alcohol, as before, when the silica will be left in an insoluble state; but if the silica is in the state of silicate of soda or of potash, it is necessary to proceed as follows:—dissolve a given weight of the suspected soap in boiling water, and decompose it by the gradual addition of moderately dilute hydrochloric acid, until the liquor is strongly acid; boil the whole for one or two minutes longer and allow it to cool in order that the fatty acids having separated and become hard, may be removed. Evaporate the acid liquor to *perfect dryness*, and the perfectly dry mass treated with boiling water will leave an insoluble residue which may be identified as silica by its grittiness, which is recognised by rubbing it in the capsule with a glass rod. This white residue should then be collected on a filter, washed, dried, ignited, and weighed.

The proportion of alkali (potash or soda) may be easily determined by an alkalimetrical assay as follows:—

Take 100 grains of the soap under examination, and dissolve them in about 2000 grains of boiling water; should any insoluble matter be left, decant carefully the superincumbent solution and test it with dilute sulphuric acid of the proper strength, exactly as described in the article on *alkalimetry.*

The proportion of alkali contained in soap may also be ascertained by incinerating a given weight of soap in an iron or platinum spoon, crucible, or capsule, treating the residue with water, filtering and submitting the filtrate to an alkalimetrical assay. This method, however, cannot be resorted to when the soap contains sulphates of alkalies, because the ignition would convert such salts, or a portion thereof, into carbonates of alkali, which by saturating a portion of the test-sulphuric acid would give an inaccurate result.

The proportion of oil or fat in soap is ascertained by adding 100 grains of pure white wax free from water to the soap solution, after supersaturation with an acid, and heating the whole until the wax has become perfectly liquid, and has become perfectly incorporated with the oil or fat which has separated by the treatment with an acid. The whole is then allowed to cool, and the waxy cake obtained is removed, heated in a weighed crucible or capsule to a temperature of about 220° Fahr. in order to expel all the water, after which the whole is weighed; the increase above 100 grains (the original weight of the wax) indicates, of course, the quantity of grease, fat, or oil contained in the soap. This addition of wax is necessary only when the fatty matter of the soap is too liquid to solidify well in cooling. Good soap ordinarily contains from 6 to 8 per cent. of soda; from 60 to 70 per cent. of fatty acids and rosin, and from 30 to 35 per cent. of water.

The nature of the fat of which a given sample of soap has been made is more difficult to detect, yet by saturating the aqueous solution of the mass under examination with an acid, collecting the fatty acids which then float on the surface, and observing their point of fusion, the operator at any rate will be thus enabled to ascertain whether the soap under examination is identical with the sample from which it may have been purchased, and whether it was made from tallow, or from oil, &c.

When the fatty acids which have been isolated and collected by decomposing the soap with an acid, as already described, are heated in a small capsule the odour evolved is often characteristic, or at least generally gives a clue to the nature of the fats or oils from which the soap has been made. This odour is often sufficiently perceptible at the moment when the aqueous solution of the soap is decomposed by the acid poured in. Cocoa-nut oil can always be detected when in proportions at all available to the soap maker by *tasting* the soap, that is to say by leaving the tongue in contact with the soap for a few moments, when a peculiar, very disagreeable and bitter flavour will become more or less perceptible.

Properly made soap should dissolve completely in pure water; if a film or oily matter is seen to float on the surface, it is a proof that all the fat is not saponified. Another test is that the fatty or oily acid separated by decomposing the aqueous solution of the soap by hydrochloric acid, should be *entirely* soluble in alcohol.

Soft soaps, as we said, are combinations of fats or oils with potash, or rather are solutions of a potash soap, in a ley of potash, and they therefore always contain a great excess of alkali, and a more or less considerable proportion of water; they contain also a certain quantity of chlorides, of sulphates, and all the glycerine which the saponifying process has set free. Soft soap in this country is generally used for fulling, and for cleansing and scouring woollen stuffs. In Belgium, Holland, and Germany it is used also for washing linen, which thereby acquires an almost intolerable odour of fish oil, which no amount of perfume can mask, fish oil being generally employed in the manufacture of that description of soap. The most esteemed soft soap, however, is that made from hempseed oil, which imparts to the soap a greenish colour, but this much prized colour is generally or very often artificially given to the soap made of other oil, which soap has a yellow colour, by means of a little indigo finely pulverised and previously boiled for some time in water.—A. N.

SOAP-BARK. Several months ago, a peculiar bark was introduced into the European trade, and recommended to be employed instead of soap for washing and cleaning printed goods, woollens, and silks, and especially for the delicate colours of ladies' dresses, &c.

This soap-bark is externally black coloured, but internally the liber consists of concentric layers of yellowish white. The bark is remarkable for its density, as it sinks in water. The cause of this is the great quantity of mineral substances in its ashes, there being 13·935 per cent. of the internal parts, dried at low temperature and 18·50 per cent. when dried at a 100° C. The ashes consist largely of carbonate of lime, which forms 2·60 per cent. of the 13·935, and appears as small crystalline needles, isolated or in groups, in the cells of the liber, not only between its concentric rings but in every part of it. They glitter in the sun, resembling, under the microscope, the arragonite form of the crystallised carbonate of lime.

The soap-wort (*Lychnis*, our *Saponaria*) is everywhere sold in the shops for scouring and cleaning dresses. Several of the family of the caryophyllaceous plants (*Dianthus*, *Lychnis*, *Gypsophila*, *Silene*) are remarkable for this property in a greater or less degree. By recent chemical means there has been extracted from these roots the *Saponine* (or *Struthiine*), a special substance, and to this, notwithstanding the very small quantity contained in the roots, the singular power is attributed of making emulsions, and of being used for soap in washing. The soap-wort of the Levant (*Gypsophila*) is, to this day, employed in the East for washing and cleaning silks and shawls. It was generally used in the Mediterranean districts of France and Spain; the French called it *herbe aux foulons* (the fuller's plant). The *Saponaire*, or *Savonnière* of the French, is the root of a kind of *Lychnis*.

The vegetable soap principle, or saponine, was found by Henry and Boutron Charland, in the bark of the *Quillaja saponaria*. *Le Quillay* is a tree of the family of Spiræaceous plants, a native of Huanuco, in Peru. Ferdinand Lebeuf made mention of this bark in 1850 (*Comptes rendus de l'Académie des Sciences à Paris*, xxxi. p. 652) for its richness in saponine, and recommended it for pharmaceutical use in preparing emulsions of oils, rosins, balsams, and several other medicaments. He mentions likewise the bark of the *Yallhoy* (*Monina polystachia*).

SOAPSTONE. See STEATITE.

SODA. (NaO.) This is the oxide of the metal sodium, and can only be obtained in the free state by the combustion of the metal itself in dry air or oxygen gas. Another oxide appears to exist, but its composition is uncertain and is of no commercial value. Soda (*oxide of sodium*), thus prepared, is a white solid, very much resembling the oxide of potassium (KO), and like it absorbs moisture rapidly, the whole of which cannot be again removed by heat alone, the hydrate (NaO,HO) remaining, which also greatly resembles the hydrate of potash (KO,HO). This hydrate of soda, which is largely used in the manufacture of soap, is not prepared from the anhydrous oxide, but by removing the carbonic acid from carbonate of soda by the means of hydrate of lime (CaO,HO). When required in the solid state, the carbonate of lime thus formed is allowed to settle, the clear supernatant liquid is poured off and evaporated to dryness, fused in a silver vessel, and cast into sticks, just as hydrate of potash.

The following is a table of the quantities of real soda (NaO) in the solutions of different specific gravities.—*By Richter.*

SODA ALUM. See ALUM.

SODA, BIBORATE. See BORACIC ACID, and BORAX.

For the other salts of soda which are not used in the arts, &c., see *Ure's Chemical Dictionary*.

SODA, BISULPHATE. ($NaSO^4,HSO^4$.) This is obtained in the same manner as bisulphate of potash, with which it corresponds.

SODA, CARBONATE OF (*Kohlensaures natron*, Germ.), is the soda of commerce in various states, either crystallised, in lumps, or in a crude powder called soda-ash. It exists in small quantities in certain mineral waters; as, for example, in those of Seltzer, Seydschutz, Carlsbad, and the volcanic springs of Iceland, especially the Geyser; it frequently occurs as an efflorescence in slender needles upon damp walls, being produced by the action of the lime upon the sea salt present in the mortar. The mineral soda is the sesquicarbonate, to be afterwards described.

Of manufactured soda, the variety most anciently known is barilla, the incinerated ash of the *Salsola-soda*. This plant is cultivated with great care by the Spaniards, especially in the vicinity of Alicant. The seed is sown in light low soils, which are embanked towards the sea shore, and furnished with sluices, for admitting an occasional overflow of salt water. When the plants are ripe, the crop is cut down and dried; the seeds are rubbed out and preserved; the rest of the plant is burnt in rude furnaces, at a temperature just sufficient to cause the ashes to enter into a state of semi-fusion, so as to concrete on cooling into cellular masses comparatively compact. The most valuable variety of this article is called *sweet barilla*. It has a greyish-blue colour, and becomes covered with a saline efflorescence when exposed for some time to the air. It is hard and difficult to break; when applied to the tongue, it excites a pungent alkaline taste.

Another method of manufacturing crude soda, is by burning sea-weed into *kelp*. Formerly, very large revenues were derived by the proprietors of the shores of the Scottish islands and Highlands, from the incineration of sea-weeds by their tenants, who usually paid their rents in kelp; but since the tax has been taken off salt, and the manufacture of a crude soda from it has been generally established, the price of kelp has fallen low, its principal use being now to obtain iodine. See IODINE.

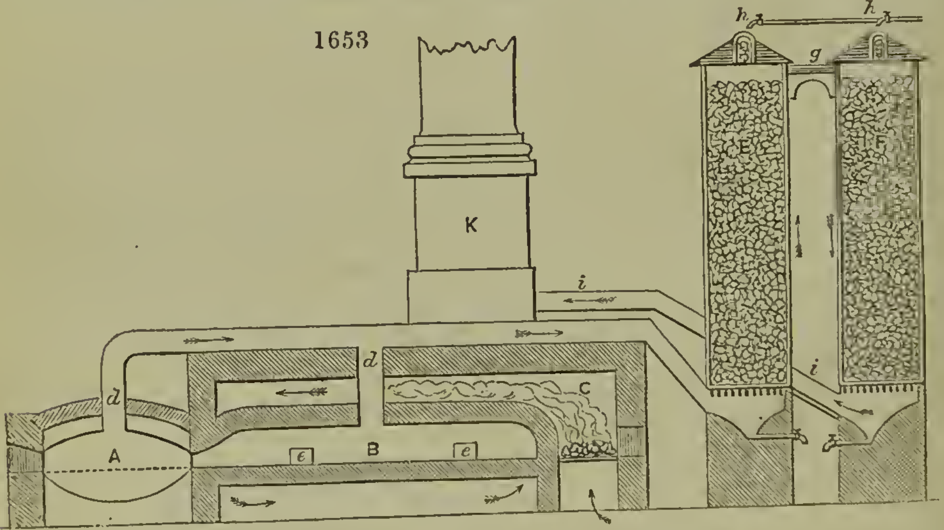
The crystals of soda carbonate, as well as the soda-ash of British commerce are now made altogether by the decomposition of sea salt.

SODA MANUFACTURE.

The manufacture divides itself into three branches:—1. The conversion of sea salt, or chloride of sodium, into sulphate of soda. 2. The decomposition of this sulphate into crude soda, called *black balls* by the workmen. 3. The purification of these balls, either into a dry white soda-ash or into crystals.

1. *Preparation of Sulphate of soda.* The decomposition of the common salt (*chloride of sodium*) by sulphuric acid is effected in furnaces of which fig. 1653 is a drawing,

1653



taken from Dr. Miller's *Elements of Chemistry*. A, the smaller of the two compartments which compose the furnace, is of cast iron; into this (*the decomposer*) from five to six hundred weight of common salt are introduced, and an equal weight of sulphuric acid, of specific gravity 1·6, is gradually mixed with it; a gentle heat being applied to the outside, enormous volumes of hydrochloric acid gas are disengaged, and pass off by the flue, *d*, to the condensing towers, E and F; these towers are filled with fragments of broken coke or stone, over which a continuous stream of water is caused to trickle slowly from *h h*. A steady current of air is drawn through the furnace and condensing towers, by connecting the first tower with the second, as represented at *g*, and the second tower with the main chimney, K, of the works. In the first bed of the furnace, about half of the common salt is decomposed, leaving a mixture of bisulphate of soda and common salt, which requires a greater heat for the expulsion of this latter portion of hydrochloric acid; for this purpose it is pushed through a door into the *roaster*, or second division, B, of the furnace.

The reaction in the first bed of the furnace is represented as follows:—

$$\underbrace{2NaCl}_{\text{Common salt.}} + \underbrace{2HSO^4}_{\text{Sulphuric acid.}} = \underbrace{NaSO^4\ HSO^4}_{\text{Bisulphate of soda.}} + \underbrace{HCl}_{\text{Hydrochloric acid.}} + \underbrace{NaCl.}_{\text{Common salt.}}$$

By the higher temperature obtained in this second part of the furnace, the bisulphate of soda reacts on the undecomposed chloride of sodium, yielding neutral sulphate of soda and a fresh quantity of hydrochloric acid.

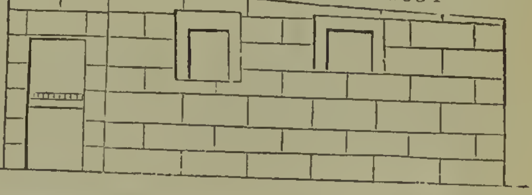
$$\underbrace{NaSO^4,\ HSO^4}_{\text{Bisulphate of soda.}} + \underbrace{NaCl}_{\text{Common salt.}} = \underbrace{2(NaSO^4)}_{\text{Sulphate of soda.}} + \underbrace{HCl.}_{\text{Hydrochloric acid.}}$$

The hydrochloric acid gas, as it is liberated from B, passes off through the flue, *d*, and is carried on to the condensing towers. Heat is applied to the outside of the roaster, B; the smoke, C, circulating in separate flues around the chamber, in the direction indicated by the arrows, but never coming into contact with the salt cake in B.

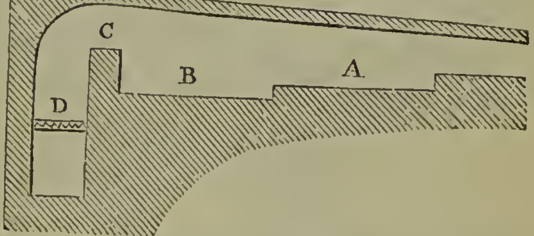
By the kindness of J. L. Bell, Esq., of Newcastle-upon-Tyne, we are enabled to give the process used at present in that district. It differs but little from that above described, with the exception that in the decomposition of the mixture of bisulphate of soda and common salt, in the second portion of the furnace, the smoke and products of combustion from the fire, are allowed to come in contact with the materials, and the hydrochloric acid which is then given off is carried to condensing towers filled with bricks over which water is continually slowly running, and the dilute hydrochloric acid, thus obtained, is used for the liberation of carbonic acid in the manufacture of bicarbonate of soda. The first part of the furnace is a circular metal pan, and the hydrochloric acid from this being unmixed with smoke, &c., is condensed apart from the other.

The next step in the manufacture is the decomposition of the sulphate of soda into sulphide of sodium, and its subsequent conversion into carbonate of soda. This is effected in the following manner. The dry sulphate of soda, obtained by the process above described, is mixed with small coal and chalk, or limestone, in about the following proportions; sulphate of soda 3 parts, chalk 3½ parts, and coal two parts. It is necessary that these materials should be first separately ground, and sifted into a tolerably fine powder, and then carefully mixed, as a great deal depends on the attention to these points. The mixture is then subjected to heat in a reverberatory furnace, *figs.* 1654, 1655, 1656.

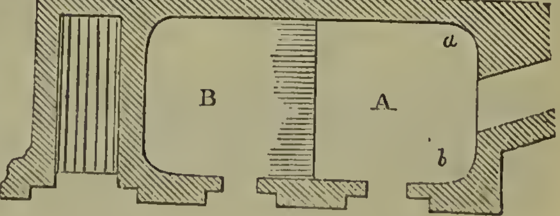
1654



1655



1656



In the section *fig.* 1655, there are two hearths in one furnace, the one elevated above the level of the other by the thickness of a brick, or about three inches. A is the preparatory shelf, where the mixture to be decomposed is first laid in order to be thoroughly heated, so that when transferred to the lower or decomposing hearth, B, it may not essentially chill it, and throw back the operation. C is the fire bridge, and D is the grate. In the horizontal section, or ground plan, *fig.* 1656, we see an opening in the front corresponding to each hearth. This is a door, as shown in the side view or elevation of the furnace, *fig.* 1654; and each door is shut by an iron square frame filled with a fire-tile or bricks, and suspended by a chain over a pulley fixed in any convenient place. See COAL, COKING OF. The workman, on pushing up the door lightly, makes it rise, because there is a counterweight at the other end of each chain, which balances the weight of the frame and bricks. In the ground plan, only one smoke-flue is shown; and this construction is preferred by many manufacturers; but others choose to have two flues, one from each shoulder, as at *a*, *b*; which two flues afterwards unite in one vertical chimney, from 25 to 40 feet high; because the draught of a soda furnace must be very sharp. Having sufficiently explained the construction of this improved furnace, we shall now proceed to describe the mode of making soda with it.

The quantity of this mixture required for a charge depends, of course, on the size of the furnace. This charge must be shovelled in upon the hearth, A, or shelf of preparation (*fig.* 1655); and whenever it has become hot (the furnace having been previously brought to bright ignition), it is to be transferred to the decomposing hearth or laboratory, B, by an iron tool, shaped exactly like an oar, called the spreader. This tool has the flattened part from 2 to 3 feet long, and the round part, for laying hold of and working by, from 6 to 7 feet long. Two other tools are used; one, a rake, bent down with a garden hoe at the end; and another, a small shovel, consisting of a long iron rod terminated like a piece of iron plate, about 6 inches long, 4 broad, sharpened and tipped with steel, for cleaning the bottom of the hearth from adhering cakes or crusts. Whenever the charge is shoved by the sliding motion of the oar down upon the working hearth, a fresh charge should be thrown into the preparation shelf, and evenly spread over its surface.

The hot and partially carbonised charge being also evenly spread upon the hearth, B, is to be left untouched for about ten minutes, during which time it becomes ignited, and begins to fuse upon the surface. A view may be taken of it through a peep-hole in the door which should be shut immediately, in order to prevent the reduction of the temperature. When the mass is seen to be in a state of incipient fusion, the workman takes the oar and turns it over breadth by breadth in regular layers, till he has reversed the position of the whole mass, placing on the surface the particles which were formerly in contact with the hearth. Having done this he immediately shuts the door, and lets the whole get another decomposing heat. After five or six minutes, jets of flame begin to issue from various parts of the pasty-consistenced mass. Now is the time to incorporate the materials together, turning and spreading by the oar, gathering them together by the rake, and then distributing them on the reverse part of the hearth; that is, the oar should transfer to the part next the fire-bridge the portion of the mass lying next the shelf, and *vice versâ*. The dexterous management of this transposition characterises a good soda-furnacer. A little practice and instruction will render this operation easy to a robust clever workman. After this transposition, incorporation, and spreading, the door may be shut again for a few minutes, to raise the heat for the finishing off. Lastly, the rake must be dexterously employed to mix, shift, spread, and incorporate. The jets, called *candles*, are very numerous, and bright at first; and whenever they begin to fade, the mass must be raked out into cast-iron moulds, placed under the door of the laboratory to receive the ignited paste.

One batch being thus worked off, the other, which has laid undisturbed on the shelf, is to be shoved down from A to B, and spread equally upon it, in order to be treated as above described. A third batch is then to be placed on the shelf.

The product thus obtained is called "black balls," which, of course, vary in their composition. The following is the composition, according to Richardson, of the Newcastle "black balls" from the balling furnaces:—

Carbonate of soda 9·89, *hydrate of soda* 25·64, *sulphide of calcium* 35·57, *carbonate of lime* 15·67, *sulphate of soda* 3·64, *chloride of sodium* 0·60, *sulphide of iron* 1·22, *silicate of magnesia* 0·88, *carbon* 4·28, *sand* 0·44, *and water* 2·17.

The *principal* changes which take place in this process may be represented by the following equations.

$$\underbrace{NaSO^4}_{\text{Sulphate of soda.}} + \underbrace{4C}_{\text{Carbon.}} = \underbrace{NaS}_{\text{Sulphide of sodium.}} + \underbrace{4CO}_{\text{Carbonic oxide.}}$$

then—

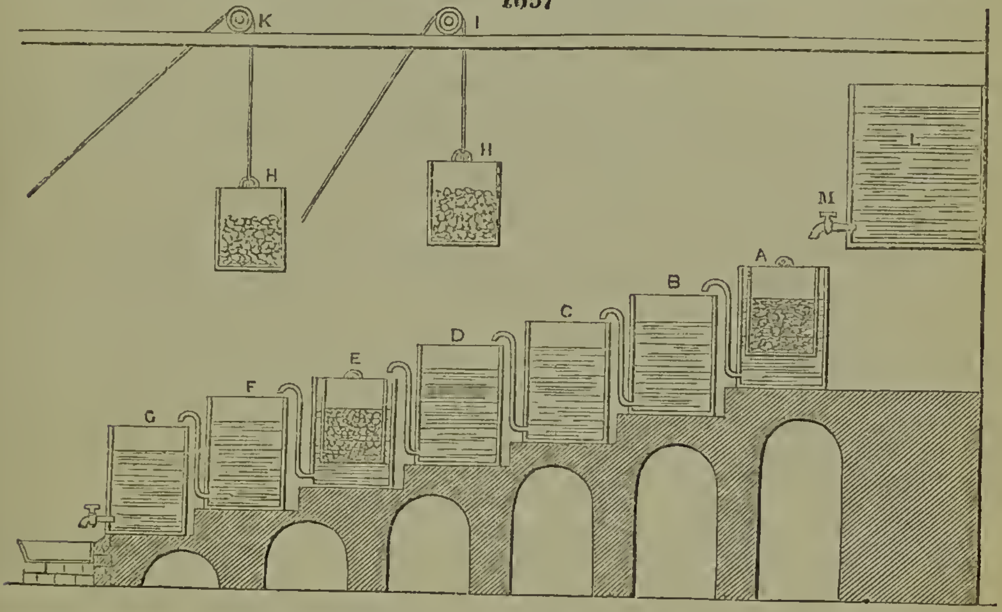
$$\underbrace{NaS}_{\text{Sulphide of sodium.}} + \underbrace{CaCO^3}_{\text{Chalk.}} = \underbrace{NaCO^3}_{\text{Carbonate of soda.}} + \underbrace{CaS}_{\text{Sulphide of calcium.}}$$

In the first place, the sulphate of soda is deoxidised by the coal, with the formation of sulphide of sodium and carbonic oxide, which latter takes fire and forms the candles, above mentioned; in the next place, the sulphide of sodium and carbonate of lime (chalk) decompose each other, forming carbonate of soda and sulphide of calcium; and from the fact of some of the chalk being converted into caustic lime by the heat of the furnace, there is also formed by it some caustic soda; the sulphide of calcium itself is only sparingly soluble in water, but is rendered still less so by the excess of lime which is present, forming with it an oxysulphide, which is much less soluble than the sulphide of calcium alone.

This *black ball* or *ball alkali*, is then treated with warm water to extract the soluble matters. This is effected in the district of Newcastle-on-Tyne in vessels 8 or 10 feet square and 5 or 6 feet deep, furnished with false bottoms; the first waters are strong enough for boiling down, for getting yellow salt, as it is termed; the after washings, which are weaker, are used for fresh quantities of "ball alkali." Care must be taken not to use the water too hot, as the oxysulphide of calcium would be decomposed, and the liquor thus take up much sulphide of calcium.

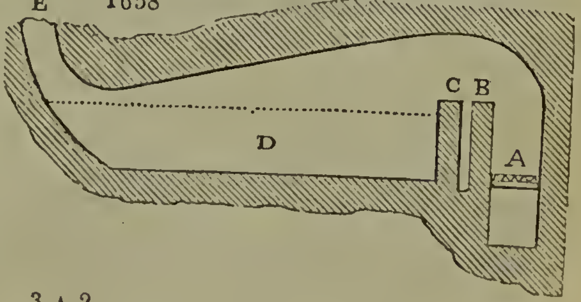
An apparatus used in some places for lixiviating the black ball is shown in the accompanying drawing, *fig.* 1657, taken from Dr. Miller's "Elements of Chemistry." Its object is to extract the largest quantity of soluble matter with the smallest quantity of water. The black ball is placed in perforated sheet-iron vessels, H H, which can be

1657



raised or lowered into outer lixiviating vessels, also made of iron, by means of the cords and pulleys, I, K. When a charge is received from the furnace, it is introduced into the lowest vessels, G, where it is submitted to the dissolving action of a liquid already highly charged with alkali from digestion upon the black ash contained in the tanks above it; after a certain time this charge is raised by the rope from G, into the tank F, where it is submitted to a weaker liquid, and so on, successively. The alkali at each stage becomes more completely exhausted, and the residue is successively submitted to the action of weaker lye, till at length, in A, it is acted on by water only, supplied from the cistern, L. When fresh water is admitted from M, to the top of the vessel, A, as it is specifically lighter than the saline solution, it lies upon its surface, and gradually displaces the solution from A, through the bent tube, whilst the water takes its place; the liquid thus displaced from it, acts in like manner upon that contained in B; and this displacement proceeds simultaneously through each successive tier of the arrangement, until the concentrated lye flows off from G, and is transferred to the evaporating pans. The residue which remains after this treatment contains nearly all the sulphur present in the ball alkali, in the form of oxysulphide of calcium, together with the other insoluble portions, and is of no value; it accumulates to an immense extent in large soda works, and is thus a source of annoyance. Many trials have been made to obtain the sulphur contained in it, and to use it for the reproduction of sulphuric acid, but without much success hitherto.

1658



The solution obtained by thus lixiviating the ball soda, contains principally carbonate of soda and hydrate of soda, as well as some sulphide and chloride of sodium, and a little sulphate of soda. It is allowed to settle; then the clear liquor is drawn off into evaporating vessels. These may be of two kinds. The surface-evaporating furnace, shown in *fig.* 1658, is a very admirable invention for economising vessels, time, and fuel. The grate A, and fire-place, are separated from the evaporating laboratory D, by a double fire-bridge B, C, having an interstitial space in the middle, to arrest the communication of a melting or igniting heat towards the lead-lined cistern D. This cistern may be 8, 10, or 20 feet long, according to the magnitude of the soda-work, and 4 feet or more wide. Its depth should be about 4 feet. It consists of sheet lead, of about 6 pounds weight to the square foot, and it is lined with one layer of bricks, set in Roman or hydraulic cement, both along the bottom and up the sides and ends. The lead comes up to the top of *c*, and the liquor, or lye, may be filled in to nearly that height. Things being thus arranged, a fire is kindled upon the grate A; the flame and hot air sweep along the surface of the liquor, raise its temperature there rapidly to the boiling point, and carry off the watery parts in vapour up the chimney E, which should be 15 or 20 feet high, to command a good draught. But, indeed, it will be most economical to build one high capacious chimney stalk, as is now done at Glasgow, Manchester, and Newcastle, and to lead the flues of the several furnaces above described into it. In this evaporating furnace the heavier and stronger lye goes to the bottom, as well as the impurities, where they remain undisturbed. Whenever the liquor has attained to the density of 1·3, or thereby, it is pumped up into evaporating cast-iron pans, of a flattened somewhat hemispherical shape, and evaporated to dryness while being diligently stirred with an iron rake and iron scraper.

This alkali gets partially carbonated by the above surface-evaporating furnace, and is an excellent article.

When pure carbonate is wanted, that dry mass must be mixed with its own bulk of ground coal, sawdust or charcoal, and thrown into a reverberatory furnace, like *fig.* 1640, but with the sole all upon one level. Here it must be exposed to a heat not exceeding 650° or 700° F.; that is, a little above the melting heat of lead; the only object being to volatilise the sulphur present in the mass, and carbonate the alkali. Now, it has been found, that if the heat be raised to distinct redness, the sulphur will not go off, but will continue in intimate union with the soda. This process is called calking, and the furnace is called a calker furnace. It may be 6 or 8 feet long, and 4 or 5 feet broad in the hearth, and requires only one door in its side, with a hanging iron frame filled with a fire-tile or bricks, as above described.

This carbonating process may be performed upon several cwts. of the impure soda mixed with sawdust, at a time. It takes three or four hours to finish the desulphuration; and it must be carefully turned over by the oar and the rake, in order to burn the coal into carbonic acid, and to present the carbonic acid to the particles of caustic soda diffused through the mass, so that it may combine with them.

When the blue flames cease, and the saline matters become white, in the midst of the coaly matter, the batch may be considered as completed. It is raked out, and when cooled, lixiviated in great iron cisterns with false bottoms, covered with mats. The watery solution being drawn off clear by a plug-hole, is evaporated either to dryness, in hemispherical cast-iron pans, as above described, or only to such a strength that it shows a pellicle upon its surface, when it may be run off into crystallising cisterns of cast-iron, or lead-lined wooden cisterns. The above dry carbonate is the best article for the glass manufacture.

Instead of this last process of roasting with sawdust, Gossage decomposes the sulphide of sodium present in the lye obtained from the ball soda, by means of the hydrated oxide of some metal, as of lead, thus forming sulphide of lead, and hydrate of soda; this is then converted into carbonate by passing a stream of carbonic acid through it. The precipitated sulphide of lead is decomposed by hydrochloric acid, thus generating sulphuretted hydrogen, which is burnt and converted into sulphuric acid; the lead is then converted again into hydrated oxide by means of lime. This process saves the trouble, time, and fuel used in evaporating to dryness twice as in the ordinary process.

Various attempts have been made to obtain processes which shall supersede the process above described, of manufacturing carbonate of soda from common salt, but none appear to have been successful to any great extent. We shall here mention some of them.

1. Sulphate of iron, being a cheap article, has been heated with common salt instead of using sulphuric acid; sulphate of soda is formed, and the chloride of iron, being volatile, passes away. The latter part of the process was of course similar to that above described. 2. By roasting iron or copper pyrites directly with chloride of sodium, sulphate of soda has been obtained, and it has been found possible by this means also to extract the metal from ores of copper or tin with advantage, which are otherwise too poor to work. Mr. Tilghman effects the decomposition of chloride of sodium by steam at a high temperature, in the presence of alumina. Precipitated alumina is made up into balls with chloride of sodium, and exposed to a current of

steam in a reverberatory furnace strongly heated. Hydrochloric acid is expelled and the alumina unites with the soda.

$$\underbrace{NaCl}_{\text{Chloride of sodium.}} + \underbrace{Al^2O^3}_{\text{Alumina.}} + \underbrace{HO}_{\text{Steam.}} = \underbrace{NaO,Al^2O^3}_{\text{Aluminate of soda.}} + \underbrace{HCl.}_{\text{Hydrochloric acid.}}$$

When cold, this compound of alumina and soda is decomposed by a current of carbonic acid, and the carbonate of soda is dissolved, and thus separated from the alumina, which may be again used. Another process is that patented by MM. Schlœsing and Rolland, which is as follows: they dissolve the chloride of sodium in water, and then pass ammonia into it, and afterwards carbonic acid; bicarbonate of ammonia is first produced, and then double decomposition takes place; chloride of ammonium is formed, and the more sparingly soluble bicarbonate of soda is precipitated in crystalline grains; it is then separated from the liquid and pressed, to free it as much as possible from the chloride.

$$\underbrace{NaCl}_{\text{Chloride of sodium.}} + \underbrace{NH^4CO^3,HCO^5}_{\text{Bicarbonate of ammonia.}} = \underbrace{NaCo^3,HCO^3}_{\text{Bicarbonate of soda.}} + \underbrace{NH^4Cl.}_{\text{Chloride of ammonium.}}$$

This bicarbonate of soda is converted into the monocarbonate by heat, and the carbonic acid thus evolved is used again; the solution, from which the bicarbonate has separated, is boiled to drive off any ammonia that it may contain, as carbonate of ammonia, which is collected; the solution is then boiled with lime, which liberates the ammonia from the chloride of ammonium, and thus little loss is sustained, the same ammonia serving continually, within certain limits, because, of course, some ammonia escapes and is unavoidably lost.

There are three carbonates of soda commonly known, viz., *monocarbonate, sesquicarbonate*, and *bicarbonate.*

Monocarbonate. $NaCO^3+10HO$. This is the salt which is obtained in the ordinary soda manufacture. In the crystalline state, it generally contains ten equivalents of water of crystallisation, sixty-three per cent., but has been obtained with only eight, five, and even one equivalent of water. It effloresces in a dry atmosphere, at the same time absorbing carbonic acid. It is very soluble in water, requiring only twice its weight of water at 60° for solution, and even melts in its own water of crystallisation when heated, and eventually by increase of temperature becomes anhydrous. It is generally found in commerce in large crystals, which belong to the oblique prismatic system. It is strongly alkaline, and acts on the skin, dissolving the outside cuticle. It is largely used in the manufacture of soap, glass, &c., and is generally too well known to require much description.

The soda trade made great progress in 1859, as compared with the two preceding years. In 1857, 1,538,988 cwts. were exported, of the value of 760,741*l.*; and in 1858, 1,618,289 cwts., of the value of 813,727*l.*; whilst last year the quantity was 2,027,609 cwts., and the value 1,024,283*l.*

Sesquicarbonate. $2NaCO^3,HCO^3$. This salt is frequently found native, and is described under NATRON (which see).

Bicarbonate. $NaCO^3,HCO^3$. This salt is found in some mineral waters, as those of Carlsbad and Seltzer; and is obtained from the waters of Vichy in large quantities. It is prepared by saturating the monocarbonate with carbonic acid, for which purpose several methods are employed.

1. *By passing carbonic acid into a solution of the monocarbonate.* A cold saturated solution of the monocarbonate of soda is made, and carbonic acid, obtained by the action of hydrochloric acid on marble or chalk, is passed into it; the bicarbonate forms and precipitates to a great extent, and is then collected, pressed to remove as much of the adhering liquid as possible. A fresh portion of the monocarbonate is dissolved in the mother liquor, and the passage of carbonic acid through it repeated. By this method a pure bicarbonate is obtained, but the process is costly.

2. *By exposing solid monocarbonate of soda to an atmosphere of carbonic acid gas.* This is known as Smith's process. The crystals of the monocarbonate are placed on shelves, slightly inclined to allow the water to run off, in a large box, containing a perforated false bottom; carbonic acid is passed into this box under pressure, which latter is scarcely necessary, since the monocarbonate so rapidly absorbs the carbonic acid. When the gas ceases to be absorbed, the salt is taken out and dried by a *gentle* heat.

The crystals are found to have lost their water of crystallisation, and to have become opaque and porous, and a bicarbonate, still, however, retaining their original shape. These are ground between stones like flour, care being taken to avoid the evolution of much heat.

This is the most economical process, but does not yield a perfectly pure product, yet, nevertheless, quite pure enough for ordinary purposes, the impurities contained in it being a little chloride of sodium and sulphate of soda, found in the original monocarbonate from which it was made, and even these are to a great extent dissolved and carried off by the water of crystallisation as it escapes.

3. Its formation by the action of bicarbonate of ammonia has been already described.

Bicarbonate of soda crystallises in rectangular four-sided prisms, which require about ten parts of cold water to dissolve them, and if the solution be boiled, it loses carbonic acid, becoming first sesquicarbonate, and ultimately monocarbonate. As usually met with in commerce this salt is a white powder. Its taste is slightly alkaline. It is largely used in medicine, for making seidlitz powders, &c., but the salt generally found in the shops is only a sesquicarbonate, or a mixture of bicarbonate and sesquicarbonate.—H. K. B.

SODA FELSPAR. Usually called *albite*; in which soda takes the place of potash. See FELSPAR.

SODA HYPOCHLORITE. (Na,ClO^2.) This is obtained in the same manner as hypochlorite of lime, or by decomposing a solution of this latter by carbonate of soda. Its uses are the same as the hypochlorite of lime.

SODA HYPOSULPHATE. See HYPOSULPHATE OF SODA.

SODA, HYPOSULPHITE. This is now largely prepared for photographic purposes. See HYPOSULPHITE of SODA.

SODA, NITRATE OF. (NaO,NO^5.) Syn. *cubic nitre*; Chile, *saltpetre*. (*Nitrate de soude*, Fr.; *Würfelsalpeter*, Germ.) This important salt is found native in immense quantities in Chili and Peru. It is, in some parts, found in beds of several feet in thickness. As found in nature it is tolerably pure, the principal impurities being chlorine, sulphuric acid, and lime. The following analyses may be quoted as representing the composition of various samples:—

	Wittstein.	Lecanu.	Hofstetter.
Nitrate of soda	99·633	96·698	94·291
Chloride of calcium	—	—	1·990
Chloride of sodium	0·367	1·302	—
Sulphate of potash	—	—	0·239
Nitrate of potash	—	—	0·426
Nitrate of magnesia	—	—	0·858
Water	—	2·000	1·993
Insoluble matters	—	—	0·203
	100·000	100·000	100·000

It is evident that nitrate of soda can be formed artificially by saturating nitric acid with soda or its carbonate, and evaporating the solution until the salt crystallises.

Nitrate of soda is extensively and economically employed as a source of nitric acid. It is also used for the purpose of being converted by double decomposition with chloride of potassium into nitrate of potash. See NITRATE OF POTASH. It is employed in great quantities as a manure.

In analysing a sample of the salt, it should be dissolved in boiling distilled water; any insoluble matters are to be removed by the filter, and after being washed and dried, may be weighed. To the clear filtrate acidulated with pure nitric acid, nitrate of silver is to be added; the precipitate of chloride of silver when weighed with proper precautions will enable the amount of chloride of sodium to be calculated. For this purpose we say; as one equivalent of chloride of silver is to one equivalent of chloride of sodium, so is the quantity of chloride of silver obtained to the quantity of chloride of sodium in the specimen taken. In another portion of the salt, the solution being prepared as before, the sulphuric acid may be determined by precipitation with chloride of barium; and, in a third, the lime and magnesia are to be determined by precipitation, the first with oxalate of ammonia, and the latter in the filtrate from the oxalate of lime, by means of phosphate of soda and ammonia. The water may be determined by drying a known weight of the salt in the water bath until it ceases to diminish in weight.

A good sample of nitrate of soda should not contain more than two per cent. of chloride of sodium. The nitric acid may be determined by the process described under NITRATE OF POTASH.

Nitrate of soda is not applicable for the preparation of gunpowder or fireworks, partly in consequence of its tendency to attract moisture from the air, and partly owing to the fact that mixtures made in imitation of gunpowder, but having nitrate of soda in place of nitrate of potash, explode far less powerfully than gunpowder itself.

Solubility of Nitrate of Soda in Water.

One part of the salt dissolves in—

1·58 at a temperature of 21°2 Fahr.
1·25 „ „ 32·0

1·36 at a temperature of			66°·0
1·12	„	„	82·4
0·77	„	„	116·6
0·46	„	„	246·2

The above table is not perfectly satisfactory, and the solubility of nitrate of soda in water at different temperatures requires reinvestigation.

The term cubic nitre applied to this salt is incorrect; the crystals, it is true, appear cubic at a rough glance, but they are in fact, rhombohedra, of which the angles are not very far removed from those of a cube.—C. G. W.

SODA, NITRITE OF. (NaO,NO^3.) This salt is not unfrequently employed as a source of nitrous acid, especially in researches on the volatile organic bases. Nitrite of soda possesses some advantages over nitrite of potash, owing to the comparative ease with which it is prepared. In the process for preparing nitrite of potash a considerable quantity of the salt is entirely decomposed into the caustic state, the resulting product being strongly alkaline, and therefore deliquescent. But with the soda salt it is easy to produce a very pure nitrite by mere fusion, without any particular dexterity in controlling the temperature. The fused salt, like the corresponding potash compound, gives a rich and brilliant apple-green coloration when dropped into a solution of a salt of copper. Messrs. Perkin and Church have ascertained that nitrite of soda, as prepared by simple fusion of nitrate of soda at a low red heat decomposes acetate of aniline with extreme facility, yielding (probably among other products) a crystalline body to which at present they have not assigned any formula, but which evidently contains an oxide of nitrogen in the place of one of the atoms of hydrogen previously existing in the parent alkaloid. Nitrosonaphthaline may also be prepared by an analogous process from the hydrochlorate of naphthylamine.

These bodies, despite their extreme difference in properties, still belong in the most unmistakable manner to the ammonia type. The product from naphthylamine may therefore be written

$$\left.\begin{matrix} C^{20}H^7 \\ H \\ NO^2 \end{matrix}\right\} N$$

The nitrite of soda is especially adapted for the preparation of nitrite of silver. For this purpose it is only necessary to add to the soda salt dissolved in distilled water, nitrate of silver, when the nitrite of silver is immediately precipitated. In order to obtain the salt chemically pure, it is merely requisite, after slight washing, to recrystallise the salt from boiling distilled water.—C. G. W.

SODA, SULPHATE OF. ($Na,SO^4, + 10HO$.) This salt is obtained as a residue in several chemical processes, as in the manufacture of hydrochloric and nitric acids, &c., but owing to the enormous quantity used in the manufacture of carbonate of soda, it is made purposely as described above. It is generally known as *Glauber's salt*, and has been found native near Madrid, nearly pure, deposited at the bottom of some saline lakes, in anhydrous octohedra, called *Thenardite*, and also combined with sulphate of lime, as glauberite.

It crystallises in oblique rhombic prisms, which belong to the oblique prismatic system (*Pereira*). Its taste is saline, and bitterish. It is very efflorescent, and loses the whole of its ten equivalents of water by mere exposure to the atmosphere, at common temperatures (*Miller*).

There is a peculiarity in the solubility of this salt in water; its solubility gradually increases with rise of temperature, as most other salts, till at 91° F. water takes up about half its weight of the anhydrous salt. Beyond 91° F. by raising the temperature to the boiling point, one-sixth of the salt previously dissolved is deposited in the form of anhydrous acute rhombic prisms, which are again dissolved as the liquid cools to 91° F.

Another peculiarity of this salt is, that a boiling saturated solution of it, if closed hermetically, may be kept for months without crystallising, but the moment air is admitted, the whole becomes a semi-solid mass, and the temperature rises.

Sulphate of soda is used sometimes in medicine and for forming freezing mixtures, which see.—H. K. B.

SODA, SULPHITE. ($Na,SO^3 + 10HO$). This salt is prepared largely for removing the last traces of chlorine from the bleached pulp obtained in the manufacture of paper, and is hence called *antichlore*.

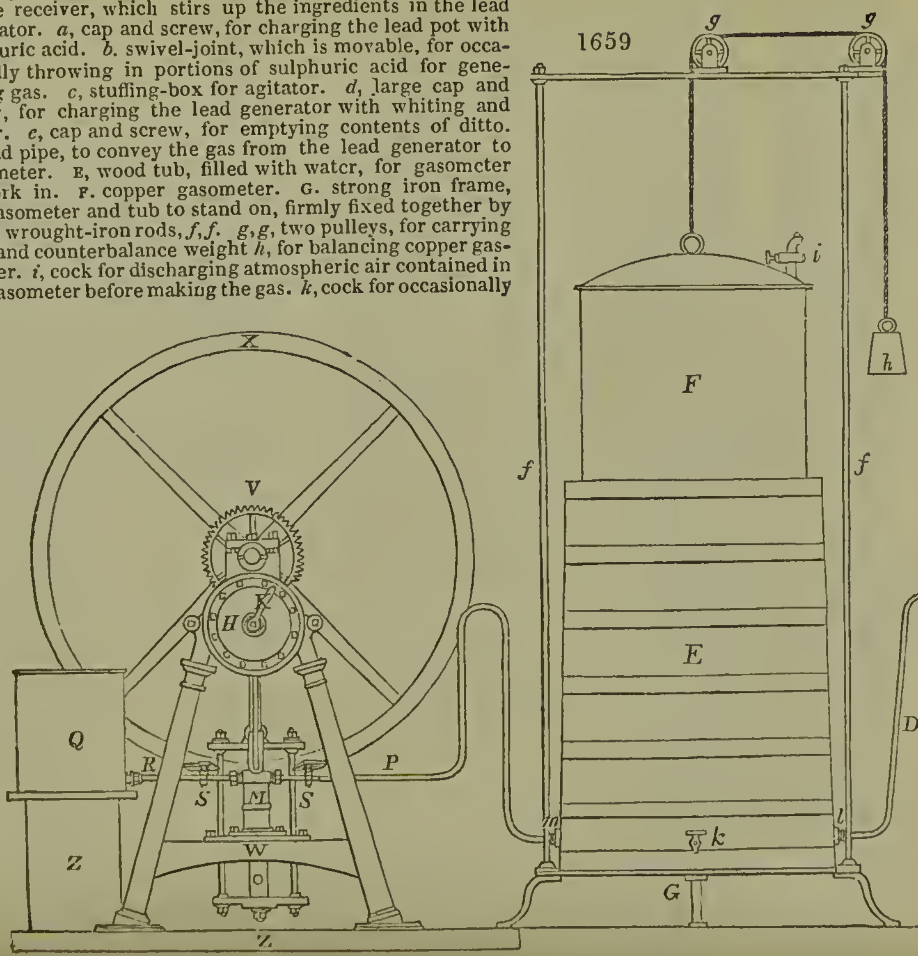
It is prepared by passing sulphurous acid gas through a solution of carbonate of soda, or on the large scale, by passing sulphurous acid gas, obtained by burning sulphur in the air, over crystals of carbonate of soda. It crystallises in oblique prisms, and is efflorescent like the sulphate of soda, which it much resembles. Its taste is sulphurous, and it possesses a slight alkaline reaction.

A bisulphite of soda also exists, which forms irregular opaque crystals.—H. K. B.

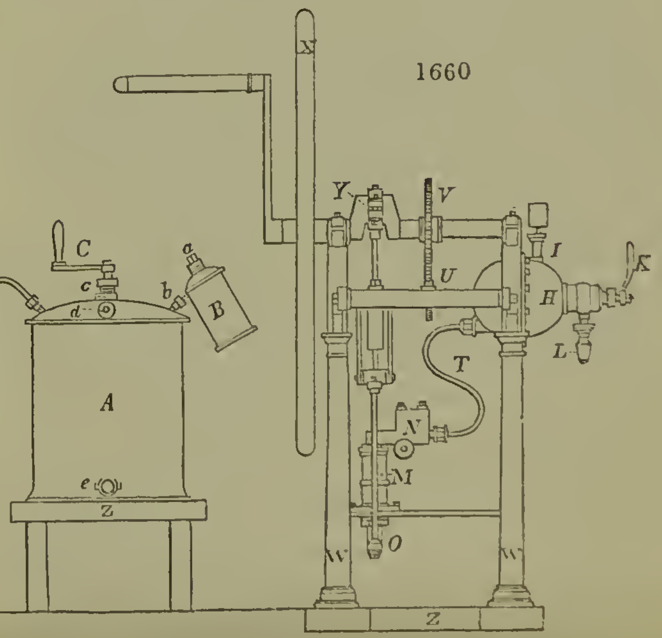
SODA WATER. A solution of soda charged with carbonic acid: for this purpose the following improved apparatus by J. Tyler & Sons, has been introduced. *Fig.* 1659, front view of the soda-water machine. *Fig.* 1660, end view of the same.

A, lead generator, for making the gas. B, lead pot, for holding sulphuric acid. C, handle for moving the agitator of the receiver, which stirs up the ingredients in the lead generator. *a*, cap and screw, for charging the lead pot with sulphuric acid. *b*. swivel-joint, which is movable, for occasionally throwing in portions of sulphuric acid for generating gas. *c*, stuffing-box for agitator. *d*, large cap and screw, for charging the lead generator with whiting and water. *e*, cap and screw, for emptying contents of ditto. D, lead pipe, to convey the gas from the lead generator to gasometer. E, wood tub, filled with water, for gasometer to work in. F. copper gasometer. G. strong iron frame, for gasometer and tub to stand on, firmly fixed together by three wrought-iron rods, *f*, *f*. *g*, *g*, two pulleys, for carrying rope and counterbalance weight *h*, for balancing copper gasometer. *i*, cock for discharging atmospheric air contained in the gasometer before making the gas. *k*, cock for occasionally emptying the water out of the tub. *l*, union joint, to which is fixed a copper pipe, passing through the water in the tub, to deliver the gas as generated into the copper gasometer. *m*, another union joint, with a similar copper pipe, passing through the water in the tub, and projecting two or three inches above the surface of the water, to convey the gas from the copper gasometer to the soda-water machine. H, H, condenser for aerating the soda-water. I, safety valve. K, K, bottling valve. L. bottling nipple. M, M, soda-water pump. N, valve-piece. O, O, piston of the pump. P, pipe for conducting gas from the gasometer to pump. Q, copper pan for holding the solution of soda. R, copper pipe for conducting the solution of soda to the force pump. S, S, two cocks for regulating the admission of the solution and gas to the pump. T, copper pipe through which the soda-water is forced to the condenser. U, pinion wheel, to give motion to the agitator revolving inside the condenser. V, V, wheel for driving ditto. W, W, cast-iron frame for carrying machinery. X, X, cast-iron fly-wheel. Y, wrought-iron crank Z, Z, Z, wood stools and curb, upon which the whole of the machinery is fixed.

1659



1660



SODIUM. (Na.) This metal was discovered by Sir H. Davy, almost immediately after potassium, and by the same means, viz., by exposing a piece of moistened hydrate of soda to the action of a powerful voltaic battery, the alkali being placed between a pair of platinum plates connected with the battery.

By this process only very small quantities could be obtained, and processes have since been devised which provide it in almost any quantity, and since the demand for sodium in the manufacture of aluminium by Wöhler's process, principally by the exertions of M. St. Clair Deville, the cost of it has been considerably diminished. The process now adopted is the same as that for obtaining potassium; an intimate, mixture of carbonate of soda and charcoal is made by igniting in a covered crucible a salt of soda containing an organic acid, as the acetate of soda, &c., or by melting ordinary carbonate of soda in its water of crystallisation and mixing with it, while liquid, finely divided charcoal, and evaporating to dryness; this mixture is mixed with some lumps of charcoal and placed in a retort, which is generally made of malleable iron, but owing to the difficulty of getting these sufficiently large, earthenware or fire-clay retorts have been used with success, and sometimes these are lined with or contain a trough of malleable iron. These retorts are so placed in a furnace that they are uniformly kept at a heat approaching to whiteness.

Mr. Beatson (*Pharmaceutical Journal*, vol. xv. p. 226), made an improvement in the process by which it can be carried on continuously for a week or fortnight. If the proportion of charcoal and soda be well regulated, the retort becomes nearly empty at the end of the process. In Mr. Beatson's process, as soon as one charge is worked off the receiver is removed, and a fresh charge is introduced through the same tube as serves to convey the sodium to the receiver, by means of a semicircular scoop, so that the retort is kept at a constant temperature, and hence little loss of time. The receiver contains rock-naphtha, and is surrounded by cold water. The manufacture of sodium, when properly conducted, is much easier and more certain than that of potassium; one advantage is, that the sodium does not unite with carbonic oxide to form the explosive compound, and the conducting tube is not so likely to be choked. The sodium which comes over is, however, mixed with some impurities, croconates, &c., and in order to separate the metal from these, Mr. Beatson melted the sodium under mineral naphtha, in a cylinder, into which is fitted a piston, worked by a screw or hydraulic press, and when this is forced down the metal forms in a mass above it, while the impurities remain at the bottom of the cylinder.

The principal reaction which takes place in the retort, is the reduction of the soda by the charcoal, which is thus converted into carbonic oxide, which escapes through an aperture in the receiver made on purpose.

$$\underbrace{NaO}_{\text{Soda.}} + \underbrace{C}_{\text{Charcoal.}} = \underbrace{Na}_{\text{Sodium.}} + \underbrace{CO.}_{\text{Carbonic oxide.}}$$

Sodium is a silver-white metal, very much resembling potassium in every respect; it is so soft at ordinary temperatures that it may be easily cut with a knife or pressed between the finger and thumb; it melts at 194° F., and oxidises rapidly in the air, though not so rapidly as potassium. Its sp. gr. is 0·972. When placed upon the surface of cold water it decomposes it with violence, but does not ignite the hydrogen which is liberated, unless the motion of the sodium be restrained, when the cooling effect is much less. When a few drops of water are added to sodium the hydrogen liberated immediately inflames, and such is also the case if it be put on hot water; when burning it produces a yellow flame, and yields a solution of soda. The equivalent of sodium is 23.

When sodium is burnt in oxygen gas or in air, two different oxides are produced, viz. the protoxide (NaO), and another whose composition is uncertain, perhaps binoxide (NaO^2) or teroxide (NaO^3). These oxides also very much resemble the corresponding oxide of potassium. The principal use of sodium is, as before stated, in the manufacture of aluminium, which is now carried on to a considerable extent. See ALUMINIUM. — H. K. B.

SODIUM, CHLORIDE OF. See SALT.

SOLANINE. A poisonous alkaloid of doubtful constitution, contained in various plants of the species *Solanum*, as *S. nigrum*, *S. dulcamara*, and in the potato (*S. tuberosum*). It is remarkable that in the shoots of potatoes which have sprouted in dark cellars the quantity of solanine is greater than in the shoots which have germinated normally. Solanine requires reinvestigation.

SOLAZZI JUICE. A name given to the best kind of Spanish liquorice, Solazzi being the maker's name. See LIQUORICE.

SOLDERING. The process of uniting together pieces of metal, by the interposition of a fusible alloy, which is called either soft or hard solder, accordingly as its fusing point is low or high. One process is called by its inventor, M. de Richemont, *autogenous*, because it takes place by the fusion of the two edges of the metals themselves, without interposing another metallic alloy, as a bond of union. See AUTOGENOUS SOLDERING.

SOLDERS. Alloys which are employed for the purpose of joining together metals are so called. They are of various kinds, being generally distinguished into hard and soft. Upon the authority of Holtzappfel, the following receipts for solder are given, and these have been adopted, because, after a long and particular inquiry in the workshops, we learn that these are regarded as very superior to any others recommended.

Pewterers' Solder. (*a*) 2 Bismuth, 4 lead, 3 tin. (*b*) 1 Bismuth, 1 lead, 2 tin.

Soft Spelter Solder. Equal parts of copper and zinc.

Coarse Plumbers' Solder. (*a*) 1 tin, 3 lead, melts at about 500 F. (*b*) 2 tin, 1 lead, melts at about 360 F.

Spelter Solder. 12 oz. of zinc, to 16 oz. of copper.

(For brass work the metals are generally mixed in equal proportions as above. For copper and iron the last given are usually employed).

The following table of solders has been constructed by the late Mr. Holtzappfel, from a table of a much more extended character, published by Mons. H. Gaulthier de Claubry.

	Alloys and their Melting Heats.				Fluxes.
1	1 Tin	25 Lead		558° Fahr.	A Borax
2	1 ,,	10 ,,		541	B Sal ammoniac
3	1 ,,	5 ,,		511	C Chloride of zinc
4	1 ,,	3 ,,		482	D Common resin
5*	1 ,,	2 ,,		441	E Venice turpentine
6	1 ,,	1 ,,		370	F Tallow
7	1½ ,,	1 ,,		334	G Gallipoli oil
8	2 ,,	1 ,,		340	
					MODES OF APPLYING HEAT.
9	3 ,,	1 ,,		356	*a* Naked fire
10	4 ,,	1 ,,		365	*b* Hollow furnace or muffle
11	5 ,,	1 ,,		378	*c* Immersion in melted solder
12	6 ,,	1 ,,		381	*d* Melted solder poured on
13	4 Lead	4 Tin	1 Bismuth	320	*e* Heated iron not tinned
14	3 ,,	3 ,,	1 ,,	310	*f* Heated copper tool tinned
15	2 ,,	2 ,,	1 ,,	292	*g* Blowpipe flame
16	1 ,,	1 ,,	1 ,,	254	*h* Flame alone, generally alcohol
17	2 ,,	1 ,,	2 ,,	236	*i* Stream of heated air
18	3 ,,	5 ,,	3 ,,	202	

SOOT (*Noir de fumée, Suie*, Fr.; *Russ, Flatterrus*, Germ.) is the pulverulent charcoal condensed from the smoke of wood or coal fuel. A watery infusion of the former is said to be antiseptic, probably from its containing some creosote.

The soot of coal contains some sulphate and carbonate of ammonia, along with bituminous matter.

SORBIC ACID is the same with malic acid. See MALIC ACID.

SOVEREIGN. The sovereign is the standard of value in Great Britain, and its weight is determined by the law that twenty pounds troy weight of standard gold shall be coined into 934½ sovereigns. To obtain the exact weight of one sovereign, reduce the pounds to grains and divide by the number of coins. A sovereign is thus found to weigh 123·274478330658 1059 grains, and as it is usual to deliver the coin to the bank in journey weights of 701 sovereigns, each journey should weigh if it be standard work 180·03210272873194 2215 ounces, and a million sovereigns should weigh 256821·8298555377 troy ounces, in round numbers about 7·8618 tons.—G. F. A.

SOY is a liquid condiment, or sauce, imported chiefly from China. It is prepared with a species of white haricots, wheat flour, common salt, and water; in the proportions respectively of 50, 60, 50, and 250 pounds. The haricots are washed, and boiled in water till they become so soft as to yield to the fingers. They are then laid in a flat dish to cool, and kneaded along with the flour, a little of the hot-water of the decoction being added from time to time. This dough is next spread an inch or an inch and a half thick upon the flat vessels (made of thin staves of bamboo), and when it becomes hot and mouldy, in two or three days, the cover is raised upon bits of stick,

* No. 5, is the *Plumbers' sealed solder*, which is assayed and then stamped by an officer of the Plumber's Company.

to give free access of air. If a rancid odour is exhaled, and the mass grows green, the process goes on well; but if it grows black, it must be more freely exposed to the air. As soon as all the surface is covered with green mouldiness, which usually happens in eight or ten days, the cover is removed, and the matter is placed in the sunshine for several days. When it has become as hard as a stone, it is cut into small fragments, thrown into an earthen vessel, and covered with the 250 pounds of water having the salt dissolved in it. The whole is stirred together, and the height at which the water stands is noted. The vessel being placed in the sun, its contents are stirred up every morning and evening; and a cover is applied at night to keep it warm and exclude rain. The more powerful the sun the sooner the soy will be completed; but it generally requires two or three of the hottest summer months. As the mass diminishes by evaporation, well water is added; and the digestion is continued till the salt water has dissolved the whole of the flour and the haricots; after which the vessel is left in the sun for a few days, as the good quality of the soy depends on the completeness of the solution, which is promoted by regular stirring. When it has at length assumed an oily appearance, it is poured into bags, and strained. The clear black liquid is the soy, ready for use. It is not boiled, but it is put up into bottles, which must be carefully corked. Genuine soy was made in this way at Canton, by Michael de Grubbens. See *Memoirs of Academy of Sciences of Stockholm* for 1803.

SPANISH BLACK. A black obtained by the charring of cork.

SPAR, HEAVY or PONDEROUS. Sulphate of baryta. See BARYTA.

SPARRY IRON ORE, or SPATHIC IRON. (Syn. *Chalybite*, *Siderite*, *Siderose*, *Brown Spar*, &c.) Spathose iron ore has been largely worked on the Brendon Hills, in Somersetshire, and it is also found on Exmoor, and in small quantities at the iron mines on the north coast of Cornwall. There are numerous other localities in which very fine specimens occur. It is found to be a very valuable ore in the manufacture of iron for steel. See IRON.

SPARTEINE. An organic base discovered by Stenhouse in common broom, *Spartium scoparium*. Its formula is probably $C^{16}H^{13}N$.—C. G. W.

SPECIFIC GRAVITY designates the relative weight of different bodies under the same bulk; thus a cubic foot of water weighs 1000 ounces of avoirdupois; a cubic foot of coal, 1350; a cubic foot of cast iron, 7280; a cubic foot of silver, 10,400; and a cubic foot of pure gold, 19,200; numbers which represent the specific gravities of the respective substances, compared to water, = 1·000. See GRAVITY, SPECIFIC.

SPECULUM METAL. The metal employed in the mirrors of reflecting telescopes. The Earl of Rosse, who has been eminently successful in the production and publishing of large specula, says, in his paper published in the *Transactions of the Royal Society*, "Tin and copper, the materials employed by Newton in the first reflecting telescope, are preferable to any other with which I am acquainted, the best proportions being 4 atoms of copper to 1 of tin (Turner's numbers), in fact 126·4 parts of copper to 58·9 of tin."

Mr. Ross remarks that when the alloy for speculum metal is perfect, it should be white, glassy and flaky. Copper in excess imparts a reddish tinge, and when tin is in excess the fracture is granulated and less white. Mr. Ross pours the melted tin into the copper when it is at the lowest temperature at which a mixture by stirring can be effected; then he pours the metal into an ingot, and, to complete the combination, remelts it in the most gradual manner, by putting the metal into the furnace almost as soon as the fire is lighted. Trial is made of a small portion taken from the pot immediately prior to pouring.

SPEISS. A compound of nickel, arsenic, and sulphur, containing small quantities of cobalt, copper, and antimony; it is found at the bottom of crucibles in which smalt is manufactured. See COBALT and SMALT.

SPELTER or SPELTRUM. See ZINC.

SPERMACETI; the *Cetine* of Chevreul. In certain species of the *cachelot* whale, as the *Physeter macrocephalus*, *tursio*, *microps*, and *orthodon*, as also the *Delphinus edentulus*, the fat of some parts of their bodies contains a peculiar substance, called spermaceti. The head is the principal part from whence it is obtained. In the right side of the nose and upper surface of the head of the whale, is a triangular-shaped cavity, called by the whalers, "the case." Into this the whalers make an opening, and take out the liquid contents (oil and spermaceti) by a bucket.

The dense mass of cellular tissue beneath the case and nostril, and which is technically called the "junk," also contains spermaceti, with which and oil its tissue is infiltrated. The spermaceti from the *case* is carefully boiled alone and placed in separate casks, when it is called "head matter." This "head matter," consists of spermaceti and oil. For the purpose of separating the spermaceti from the oil, it is cooled, when the spermaceti congeals, and is separated by being thrown into large filter bags, when the oil filters through, leaving the spermaceti behind; the solid thus obtained is subjected to compression in hair bags, placed in an hydraulic press. It is then melted in water, and the impurities skimmed off. Then it is remelted in a weak solution of potash to remove the last particles of oil, washed in water, and fused in a tub by the agency of steam, laded into tin pans, and allowed slowly to cool, when it forms a white semi-transparent brittle lamellar crystalline mass. Commercial spermaceti usually contains a minute portion of sperm oil, which may be removed by boiling with alcohol; the spermaceti dissolves and again separates on cooling; in order to obtain it perfectly pure, this process must be repeated until the alcohol separates no more oil.

When absolutely pure, spermaceti is a white laminated substance, without taste, and almost odourless, and in this state it is called *cetine.* By the addition of a few drops of alcohol or almond oil, it may be powdered. At 60° its sp. gr. is 0·943. It melts at 120° and at 670°, may be sublimed unchanged. It is insoluble in water, slightly soluble in alcohol, and much more so in ether; it is also soluble in the fatty and volatile oils, and if the solution be saturated when hot, the greater part of the spermaceti separates on cooling.

Spermaceti is only saponified with difficulty, in which process it is separated into two distinct substances, one, $C^{32}H^{34}O^{2}$, belonging to the series of alcohols, is called *cetylic* (*ethalic*) *alcohol*, and the other *cetylic* (*ethalic*) *acid*, $C^{32}H^{32}O^{4}$; the first is a crystallisable fat, whose melting point is nearly the same as that of spermaceti itself, but it is much more soluble in alcohol; it is readily sublimed without decomposition. Cetylic acid stands to cetylic alcohol in the same relation as acetic acid to ordinary alcohol, and may be actually procured from it by oxidation. It resembles in many respects margaric acid. By oxidation by nitric acid spermaceti yields a large quantity of succinic acid.

Spermaceti is composed of $C^{64}H^{64}O^{4} = C^{32}H^{33}O, C^{32}H^{31}O^{3}$. It is cetylate of oxide of cetyl, and represents in the cetyl series the acetic ether of the common alcohol series. —H. K. B.

SPHENE. A compound of titanate and silicate of lime. See TITANIUM.

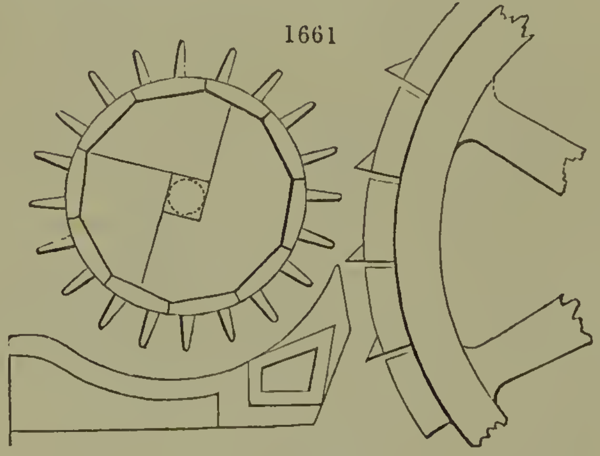
SPHEROIDAL STATE. The name given by Boutigny to the condition assumed by water when projected into red hot vessels. Under this condition the temperature never rises to the boiling point. See *Boutigny's Memoirs* on this curious subject.

SPINDLE-TREE OIL. See OILS.

SPINEL or SPINELLE. See RUBY.

SPINNING. The greatest improvement hitherto made in forming textile fabries, since the era of Arkwright, is due to Mr. G. Bodmer of Manchester. By his patent inventions the several organs of a spinning factory are united in one self-acting and self supplying body—a system most truly *automatic*. His most comprehensive patent was obtained in 1824, and was prolonged by the Judicial Committee of the Privy Council, for 7 years after the period of 14 years was expired. It contained the first development of a plan by which fibres of cotton, flax, &c., were lapped and unlapped through all the operations of cleaning and blowing, carding, drawing, roving, and spinning; in the latter, however, only as far as the operation of feeding is concerned. The patent of 1824 was the beginning; the result of which was the several patents for improvements in 1835, 1837, 1838, and 1842.

1661



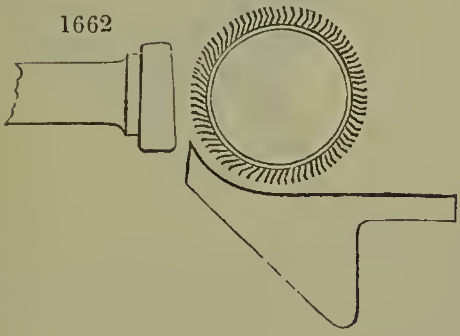
Patent of 1835.

By a machine generally called a Devil or Opener (" Wolf," in German), which consists of a feeding-plate set with teeth and a roller covered with spikes (see *fig.*

1661), the cotton is cleared from its heaviest dirt and opened. This machine delivers the cotton into a room or on to a travelling cloth, from which it is taken, weighed in certain portions, and spread upon cloth in equal portions; this is then rolled up, and placed behind the first blower.

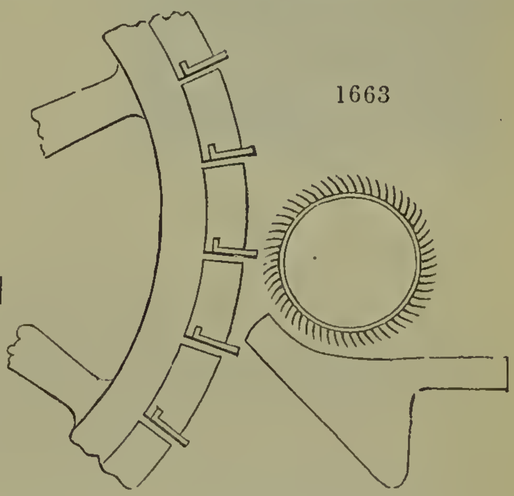
The first blower has a feeding-plate like *fig.* 1662 without teeth, and over this plate the cotton is delivered to the operation of the common beaters, from which it is received into a narrow compartment of 4½ or 5 inches broad, and wound, by means of his lap-machines, upon rollers in beautifully level and well-cleaned laps. Eight of these narrow laps are then placed behind a second blower, of a similar construction to the first. Instead of the common beater, however, a drum with toothed straight edges

1662



Patent of 1835.

1663



Patents of 1824 *and* 1835.

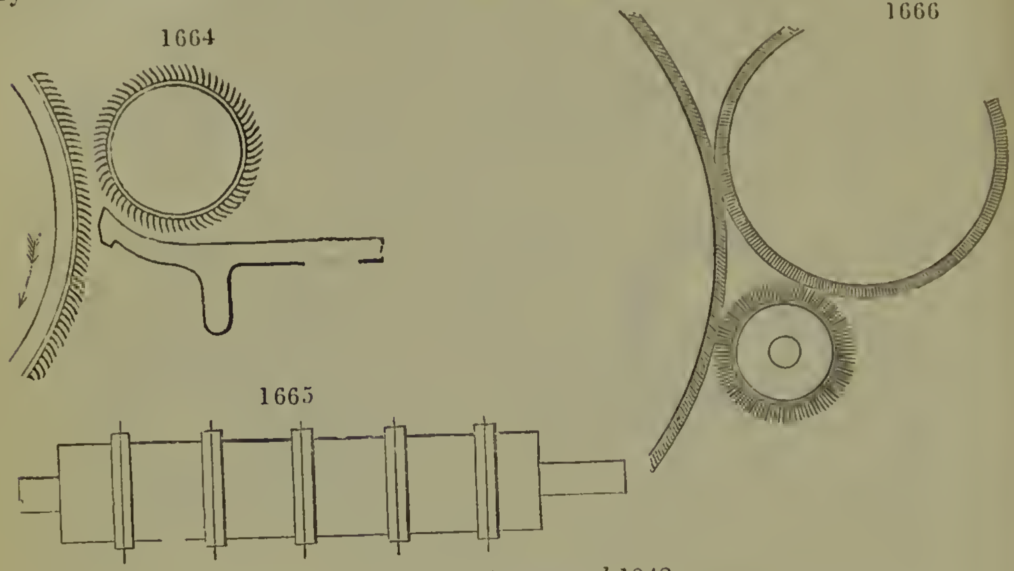
is used (see *fig.* 1663), which opens the cotton still more, and separates the fibres from one another. The cotton is again formed into similar narrow laps, which are still more equal than the preceding ones, and eight of these laps are then placed behind the carding engines. It was only by applying his lap-machine, patented in 1842, that he succeeded in forming small laps on the blower; without this he could not perform the doffing of the laps without stopping the wire-cloth, and in doing this, an irregular lap would be formed because of the accumulating of the falling cotton in one place while the wire-cloth was standing.

Carding Engine.—The patent of 1824 showed a mode of coupling a number of carding engines, the product of which was delivered upon an endless belt or a trough, and at the end of this trough was wound upon a roller.

When a set of cards work together, any interruption or stoppage of a single carding engine causes a defect in the produce of the whole lap. Interruptions occurred several times a day by the stripping of the main cylinder, and during this operation the missing band or sliver was supplied out of a can, being the produce of a single carding engine working into cans (a spare card). The more objectionable defect was, however, the difference of the product of the carding engine after the main cylinder had been stripped; the band or sliver from it will be thin and light, until the cards of the main cylinder are again sufficiently filled with cotton, when the band will again assume its proper thickness. Another irregularity was caused by the stripping of the flats or top cards, but was not so fatal as the first one. These defects were, of course, a serious drawback in his system of working, the latter of which he provided against in his first patent by stripping the top cards by mechanism; the former, however, was only conquered by his invention of the self-strippers for the main cylinders; thus the carding engine may now work from Monday morning till Saturday night without interruption, the cylinders requiring only to be brushed out every evening; the consequence is, that much time is gained, and a very equal, clean, and clear product is obtained. Old carding engines to which he applied his feeders (see *fig.* 1664) and main cylinder-clearers produce much superior work, and increase the production from 18 to 24 per cent.

The main cylinder clearer consists of a very light cast iron cylinder, upon which five, six, or more sets of wire brushes are fixed, which are caused to travel to and fro across the main cylinder; the surface or periphery of the brushes overrunning the surface or periphery of the main cylinder by 8 or 10 per cent., the brushes thus lifting the cotton out of the teeth of the cards of the main cylinder, and causing the dirt and lumps to fall.

As the brushes are not above a quarter-inch in breadth and travel to and fro, it is clear that no irregularity can take place in the fleece which comes from the doffer; not more than 1-40th part of the breadth of the cylinder being acted upon at the same time. *Figs.* 1665, 1666, give an idea of the clearer: the mechanism within the clearer and by which the brushes, *a*, are caused to travel is simple and solid. The main cylinders for the carding engines are made of cast iron, the two sets of arms and rims



Patents of 1838 *and* 1842.

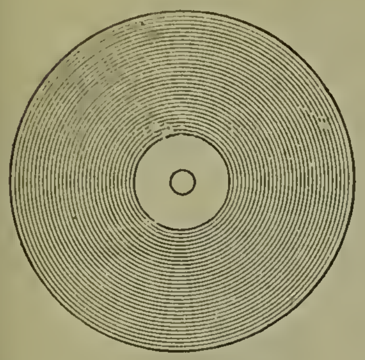
are cast in the same piece; when complete they weigh 50 lbs. less than those made of wood.

The new lap machine connected with these engines is almost self-acting; a girl has only to turn a crank when the lap is full; by this turn the full lap is removed and an empty roller put in its place, the band of cotton is cut, and no waste is made.

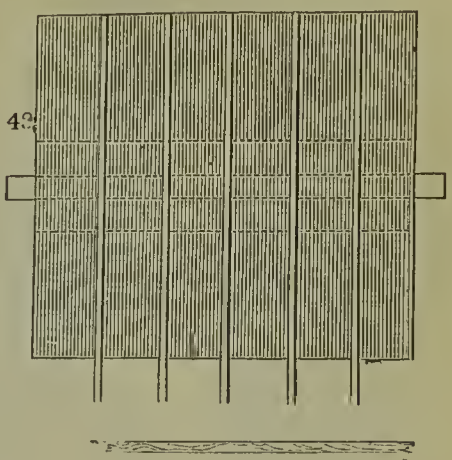
Drawing Frame.—The drawing frame of 1824 was improved, and the improvements patented in 1835, and others again in 1842. That of 1824 is known in Germany and France, and generally in use. The laps from the carding engine lap-machine are put upon delivering rollers, behind a set of drawing rollers, and from them delivered upon a belt or trough, and again formed into laps similar to those from the carding engines. The next operation formed the laps into untwisted rovings, and the next again into smaller untwisted rovings, or rovings with false twist in them, as infringed upon by Dyer. The false twist was rather objectionable, and in his patent of 1835 he put a number of rovings on the same bobbin, with left and right permanent twist in them. This does very well; there is, however, a little objection to that place in which the twist changes from right to left when it comes to the last operation before spinning. In his patent of 1838, and particularly in that of 1842, he confined the left and right-hand twist to the drawing frame, when he converts two laps into one roving, and forms a roller or bobbin of 14 inches diameter and 15 inches broad, with six separate and twisted rovings wound upon it. (See *figs.* 1667, and 1668.) The twist is given by tubes in two directions, so that it remains in it (see *fig.* 1668), the tube turns in the same direction, while the roving advances 4 or 5 inches, and then turns in the other direction. These laps or bobbins are then placed behind a machine, which he calls a coil-frame, the most important arrangement of which he claimed already in his patent of 1835. It consists of a slot with a travelling spout, without which the coils cannot be formed under pressure.

Coil Frame.—The bobbins (*fig.* 1667) are placed behind this machine, and two ends from the bobbin are passed through the drawing rollers and formed into one untwisted sliver or roving in the following manner:—When the cotton has passed through the drawing rollers (see *fig.* 1669) and calender rollers, A, it is passed through the tube, B, and the finger, C; the spindle with its disc, D, revolves in such a proportion as to take up the cotton which proceeds from the calendar rollers, A, and cause the rovings to be laid down in a spiral line closely one by one, and as the rollers, A, work at a regular speed, it is evident that the motion of the finger, C, and the speed of the tube, B, must vary accordingly. The coil, E, is stationary, and is pressed by the lid or top, F, which slides up the spindle, G, made of tin plate. The cotton enters through the slot, X, in *fig.* D. It is quite evident that the finger, C, and spindle, G, only perform one and the same varying motion, which is repeated at every fresh layer, and the coil is thus built from below; it is about 8 inches in diameter and 18 inches high when compressed, and contains 4½ lbs. of cotton. Mr. Bodmer has several modes of forming these coils, but one only is shown here. These coils are placed behind the twist coil frames in half cans or partly open ones or troughs, or behind a

1667



1668



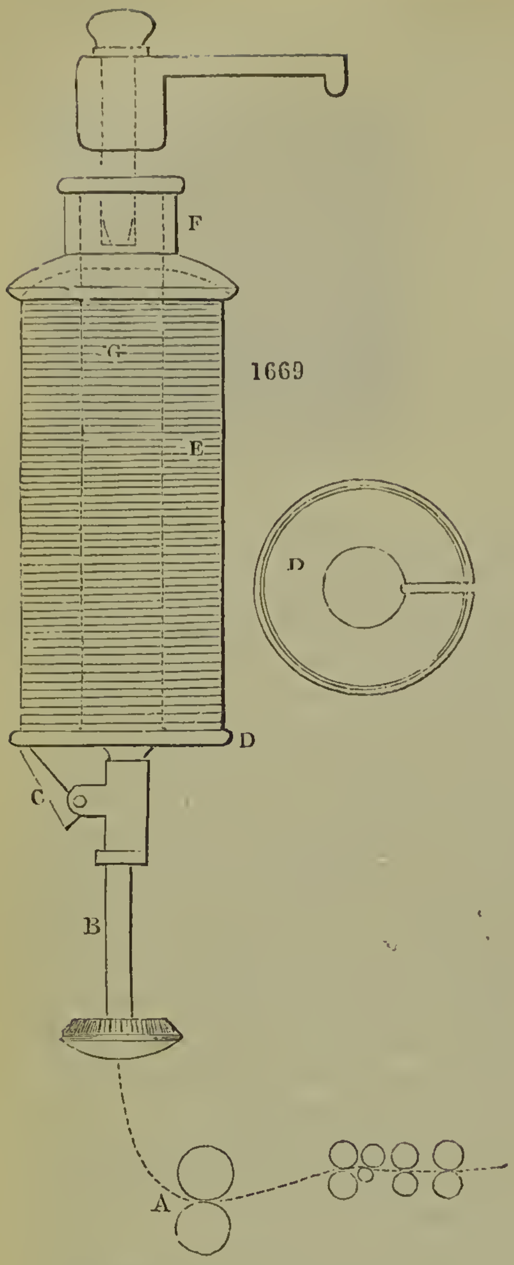
Patents of 1835, 1838, *and* 1842.

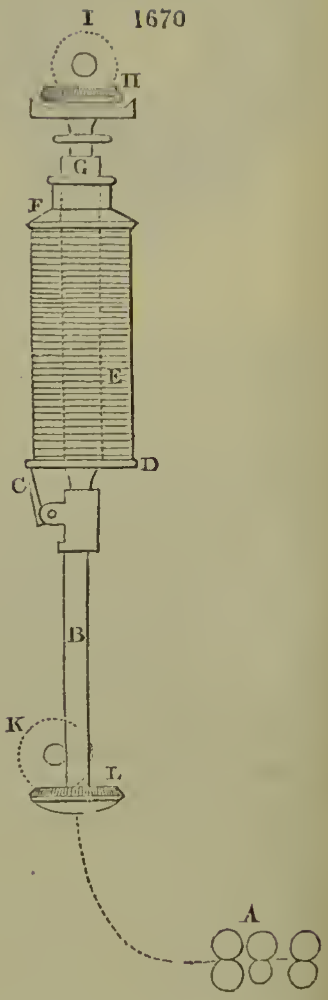
winding machine, where they are wound upon rollers side by side, like the lap or bobbin shown in the drawing frame, and placed behind the twist coil frame in this state.

Twist Coil Frame.—This frame forms rovings into coils similar to those above explained, with this difference, that the rovings are fine, say, from 1 to 10 hanks per pound, and regularly twisted; their diameter varies from 2½ to 5 inches. The same machines produce rovings more or less fine, but the diameter of the coils does not differ. The difference of this machine from that above described consists in the dimensions of their parts, and in its having the spindle, G, and the lid or top, F, revolving, as well as the tube, B. (See *fig.* 1670.) In this machine the motion of the spindle, B, is uniform: the spindle, G, however, is connected by the bevel wheels, H and I, with a differential motion at the end of the frame, with which the motion of the finger, C, corresponds. The skew wheels, K and L, are connected with the drawing rollers, A. The speed of the tube, B, and the spindle, G, are so proportioned, that while the spindle, G, performs one revolution, and therefore puts one twist into the roving, the tube, B, also performs one revolution, missing so much as will be required to pass through the slot in the cap or disc, D, and lay on it as much of the roving as proceeds from the rollers, A, and in which one twist is contained. Of course the twist of these rovings can be adapted to their fineness and varied; but it is evident that, on account of the regularity of the machine and its simplicity of movement, the rovings can never be stretched, and much less twist can be put into them than can be put in the common fly frames. These coils are put behind the spinning machines on shelves or in small cans, open in front; or they are wound from 24 to 72 ends upon bobbins, and placed upon unlap rollers behind the spinning frames.

Coiling Machine for Carding Engines and Drawing Frames.—These are simple machines, which may be applied to carding engines or drawing frames of any description. They form large coils, 9 inches in diameter and 22 inches long, when on the machine. There are two spindles (see *a*, *fig.* 1671) on each machine, for the purpose of doffing without stopping the drawing frame and carding engines. When one coil is filled, the finger, *b*, is just brought over to the other spindle, so that the full coil is stopped and the new one begins to be formed without the slightest interruption of the machine.

Mr. B. forms coils in various ways, also in cans; but this description is sufficient to show the application of this mode of winding up bands or rovings. Several of the above-described machines are adapted with equal success to wool and flax. In his patents of 1835, 1837, and 1838, he shows several modes of applying his system to cotton and other machinery. He winds directly from the carding engines the slivers separately upon long bobbins, and he gives them twist in two directions, for the purpose of uniting the fibres to some extent, so that they may not only come off the bobbins without sticking to one another, but also that they may draw smoother. He also showed a machine, by which several rovings, say 4 or more, are put upon the same bobbin with conical ends; these bobbins are placed behind the mules or throstles, and are unwound by a belt or strap running parallel with the fluted rollers of the spinning machine, as seen in *fig.* 1672. The belt or band, A, is worked in a similar way to that described in his former patent, and the bobbins, B, rest upon and revolve upon their surface, exactly according to the speed of the belt. It is quite evident that the whole



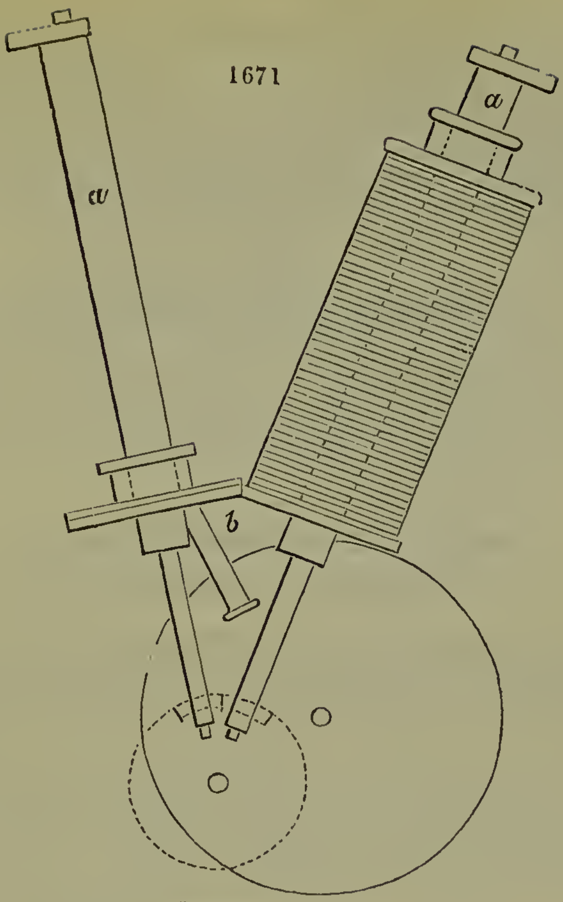


Patents of 1838 *and* 1842. *Patents of* 1838 *and* 1842.

set of rovings must be unwound exactly at the same speed, and that no stretching can take place. He can put real and reversed twist in these rovings as well as false twist only. The most important feature in the roving machine is a metal plate, in which a slot is formed through which the rovings pass ; this slot is seen in *figs.* 1673, 1674, and 1675. The cotton when coming from the drawing rollers is passed through the twisters, C, and through the slot in the plate, D. Thus he is enabled to put any convenient number of neatly formed and perfectly separate coils upon the wooden barrel or bobbin. The bobbin formed upon these machines is represented in *fig.* 1676, and the conical ends are formed by a mechanism, by which the twisters, C, are caused to approach a little more to one another, after each layer of rovings has been coiled round the barrel : the section of the bobbin is, therefore, like that shown in *fig.* 1676. He makes use of exactly the same arrangement, viz. a finger travelling along a slot in a plate, for the purpose of forming the coils, which has been already described.

Rovings wound upon bobbins by means of tubes revolving in one direction are certainly not so fit for spinning as rovings into which a small degree of twist is put. The tube by which a twist is put in on one side and taken out at the other curls or ruffles the cotton, and causes it to spread out as it passes between the rollers, while rovings with a little permanent twist in them are held together in the process of

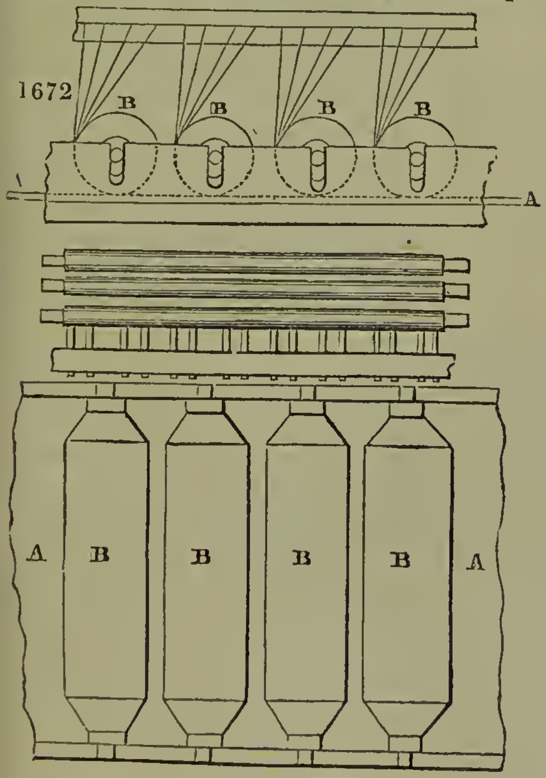
1671



Patents of 1842.

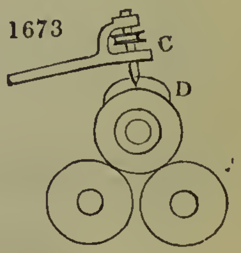
drawing, and thus produce smooth yarn. To remedy the evil above described, when untwisted rovings are used, he causes the spouts or guides, through which the rovings

1672

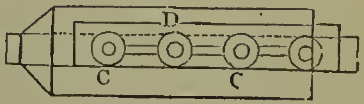


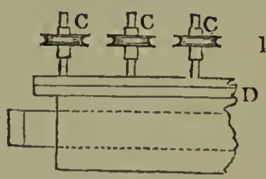
Patent of 1835

1673



1674





1675

1676

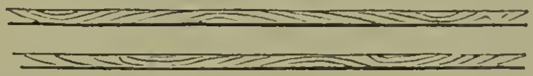
pass into or between the drawing rollers, to revolve slowly first in one, and then in the other direction, and thus puts a certain quantity of twist into the rovings while they are being prepared for spinning. Two modes of performing this operation are clearly described in his patent of 1835.

There is a little defect in the working of the rovings with reversed twist when too much or too little twist is put in them, or when the winding machine is not kept in good order. This defect proceeds from the change in the twist of the roving seen at A, *fig.* 1677; in this place the twist is not like that at B, and it would, in some parts

1677

of the yarn, be detected under circumstances just described. In cases where double rovings are used, the twisters are so arranged as to put the twist in the rovings, as shown in *fig.* 1678; in this case the reversing place of one roving meets the twisted place of the other, and the fault is completely rectified.

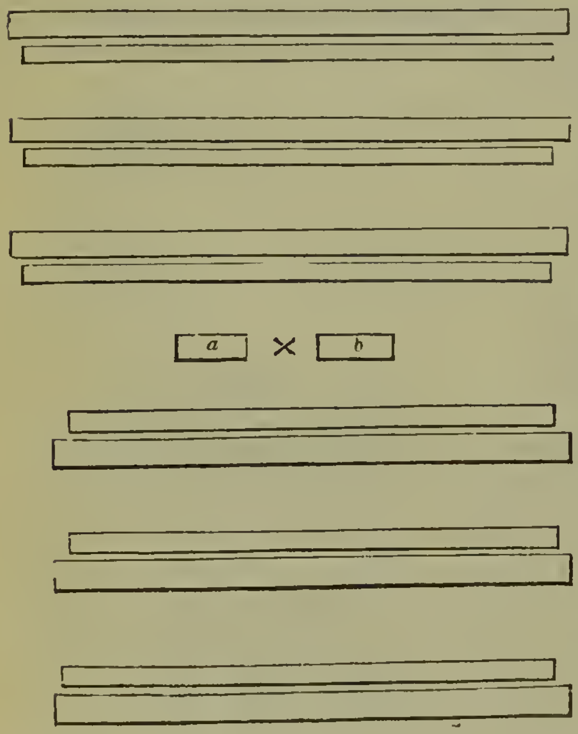
1678



The preceding description gives an idea of Mr. Bodmer's admirable system of preparing and spinning cotton, wool, flax, &c., and of the several processes; it would be superfluous to describe the several machines, or the details of the same, as exhibited in his patents.

In his patent of 1838, he specifies a self-actor, namely a machine in itself, which can be attached to 2, 3, or even 4 mules of almost any convenient number of spindles. The mules are previously stripped of all their mechanism, except the rollers and their wheels, the carriage and spindles; all the other movements ordinarily combined with the mule are contained in the machine, which is placed between a set of mules, as seen in *fig.* 1679; *a* and *b*, the self-actors, to each of which 3 mules are yoked, and which are connected by bands and shafts with the self-actor, or rather partly self-actor. A girl of fifteen or sixteen years old stands at × between *a* and *b*, and never leaves her place except, perhaps, for aiding in doffing or in banding the spindles. The gearing of the room acts by means of straps upon the machines *a* and *b*, and from these machines all the movements are given to the six mules, namely, the motion of the rollers, the spindles, the drawing out of the carriage, the after draft, &c. When the carriages are to be put up, the girl takes hold of two levers of the machine *a*, and by moving them in certain proportions, acts upon two cones and pulleys, and thus causes, in the most easy and certain manner, the carriages to run in and the yarn to be wound on the spindles. The first machine Mr. B. made for this purpose was completely self-acting, but he found very soon that the mechanism was more complicated and apt to go out of order than that of the above-described machine; and as it is necessary to have a girl of a certain age to watch over the piecers for a certain number of mules, he preferred the simplified machine; placing the girl near these machines, from whence the whole set of mules attached to the same can be overlooked; as the creels behind the mules are not wanted in his system, this impediment to the sight of the girl would be removed. He schemed these machines for the purpose of

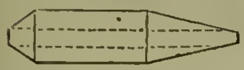
1679



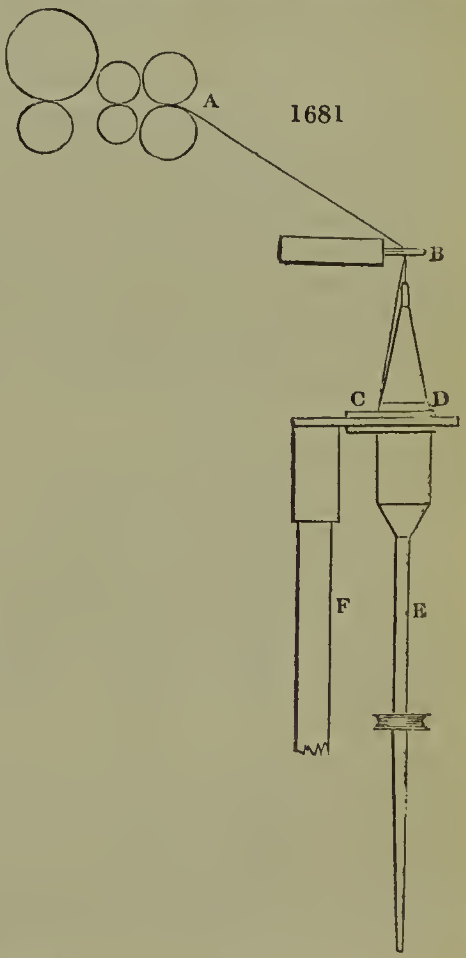
altering, at a trifling expense, the common mules into self-actors; they are equally good for any numbers of yarn.

Bastard Frame.—In his patent of 1838 and 1842, we find the description of a very simple bastard frame, namely, a throstle with mule spindles, forming cops, as seen in *fig.* 1680, and wound so hard that they can be handled about without any danger of spoiling them; in the same dimensions they contain one-third more yarn than the best cops of self-actors. The machine is extremely simple; but owing to some circumstances in the construction of the winders and plates, he has not been able to spin advantageously upon large machines above No. 20's. He has spun on it No. 56, and most beautiful yarn. The quantity this machinery produces is nearly one third more than the best self-actor, on an equal number of spindles, and

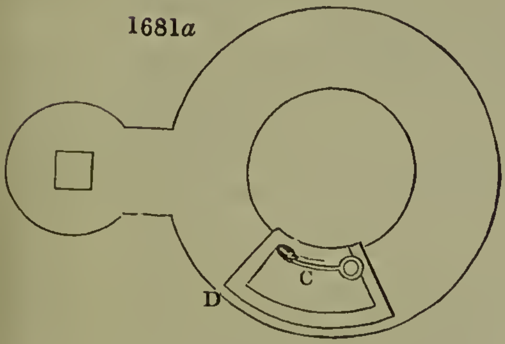
1680



1681



1681*a*



Patents of 1838 *and* 1842.

the yarn and cops are much superior. Of course there is a copping motion connected with the machine: the winding, however, is continuous, as well as the twisting, and *figs.* 1681, and 1681 *a* will give the reader an idea of the frame. The yarn coming from the rollers, A, goes through an eye, B, to the wire, C, fixed in the flyer, D, and from thence on to the mule spindle, E: as the spindle revolves, the flyer is dragged along, and by its centrifugal power winds the yarn tight upon the spindles.

SPIRIT OF AMMONIA. The name usually given to the solution of ammonia. It should, strictly speaking, be confined to the solution in spirit only.

SPIRIT OF SALTS. Hydrochloric or muriatic acid.

SPIRITS OF WINE. ALCOHOL (which see).

SPIRITS, VINOUS. See ALCOHOL, FERMENTATION, WINE, &c.

SPONGE. (*Eponge*, Fr.; *Schwamm*, Germ.) For a long time it was a disputed point whether the sponge of commerce belonged to the animal or the vegetable kingdom. Of late years the evidence has appeared to be conclusive as to its animal nature.

The sponge consists of a soft gelatinous mass, mostly supported by an internal skeleton composed of reticularly anastomosing horny fibres, in or among which are usually imbedded siliceous or calcareous spicula. Sponges are mostly marine — two or three species only being found in fresh water. They are fixed by a kind of root, by which they hold firmly any surface upon which they once fix themselves. Sponges may be propagated by division, but more usually by gemmules, which detach themselves from the parent body, and float about until they find a fitting resting-place, where they fix themselves and grow. The sponges of commerce are obtained from the Mediterranean—Smyrna being the principal mart. They are collected by divers, many of whom have been trained to the work from their infancy. Sponges are treated with muriatic (hydrochloric) acid to remove the lime.

SPOON MANUFACTURE. See Stamping of Metals.

SPRUCE BEER is prepared as follows:— Essence of spruce, half a pint; pimento and ginger bruised, of each 4 ounces; hops, from 4 to 5 ounces; water, 3 gallons. Boil for ten minutes, then strain and add 11 gallons of warm water, a pint of yeast, and 6 pints of molasses. Mix and allow the mixture to ferment for twenty hours.

SPRUCE, ESSENCE OF, is prepared by boiling the young tops of the *Abies nigra*, or black spruce, in water, and concentrating the decoction by evaporation.

STAINED GLASS. Under Glass, a general account of the processes for colouring glass has been given; for the manufacture, however, of stained glass for windows, some special details have been reserved for this place. When certain metallic oxides or chlorides, ground up with proper fluxes, are painted upon glass, their colours fuse into its surface at a moderate heat and make durable pictures, which are frequently employed in ornamenting the windows of churches, as well as of other public and private buildings. The colours of stained glass are all transparent, and are therefore to be viewed only by transmitted light. Many metallic pigments, which afford a fine effect when applied cold on canvas or paper, are so changed by vitreous fusion as to be quite inapplicable to painting in stained glass.

The glass proper for receiving these vitrifying pigments should be colourless, uniform, and difficult of fusion; for which reason crown glass, made with little alkali, or with kelp, is preferred. When the design is too large to be contained on a single pane, several are fitted together and fixed in a bed of soft cement while painting, and then taken asunder to be separately subjected to the fire. In arranging the glass pieces, care must be taken to distribute the joinings, so that the lead frame-work may interfere as little as with the effect.

A design must be drawn upon paper, and placed beneath the plate of glass; though the artist cannot regulate his tints directly by his pallet, but by specimens of the colours producible from his pallet pigments after they are fired. The upper side of the glass being sponged over with gum-water, affords, when dry, a surface proper for receiving the colours, without the risk of their running irregularly, as they would be apt to do, on the slippery glass. The artist first draws on the plate with a fine pencil all the traces which mark the great outlines and shades of the figures. This is usually done in black, or at least, some strong colour, such as brown, blue, green, or red. In laying on these the painter is guided by the same principles as the engraver, when he produces the effect of light and shade by dots, lines, or hatches; and he employs that colour to produce the shades, which will harmonise best with the colour which is to be afterwards applied; but for the deeper shades, black is in general used. When this is finished, the whole picture will be represented in lines or hatches similar to an engraving finished up to the highest effect possible; and afterwards, when it is dry, the vitrifying colours are laid on by means of larger hair pencils; their selection being regulated by the burnt specimen tints. When he finds it necessary to lay two colours adjoining, which are apt to run together in the kiln, he must apply one of them to the back of the glass. But the few principal colours to be presently mentioned, are all fast colours which do not run, except the yellow, which must therefore be laid on the opposite side. After colouring, the artist proceeds to bring out the lighter effects by taking off the colour in the proper place, with a goose quill cut like a pen without a slit. By working this upon the glass, he removes the colour from the parts where the lights should be the strongest; such as the hair, eyes, the reflection of bright surfaces, and light parts of draperies. The blank pen may be employed either to make the lights by lines, or hatches and dots, as is most suitable to the subject.

By the metallic preparations now laid upon it, the glass is made ready for being fired, in order to fix and bring out the proper colours. The furnace or kiln best adapted for this purpose, is similar to that used by enamellers. See Enamel, and the *Glaze-kiln*, under Pottery. It consists of a muffle or arch of fire-clay or pottery, so set over a fire-place, and so surrounded by flues, as to receive a very considerable heat within, in the most equable and regular manner; otherwise some parts of the glass will be melted; while, on others, the superficial film of colours will remain unvitrified. The mouth of the muffle, and the entry for introducing fuel to the fire, should be on opposite sides, to prevent as much as possible the admission of dust into the muffle, whose mouth should be closed with double folding-doors of iron, furnished with small peep-holes, to allow the artist to watch the progress of the staining, and to withdraw small trial slips of glass, painted with the principal tints used in the picture.

The muffle must be made of very refractory fire-clay, flat at its bottom, and only 5 or 6 inches high, with such an arched top as may make the roof strong, and so close on all sides as to exclude entirely the smoke and flame. On the bottom of the muffle a smooth bed of sifted lime, freed from water, about half an inch thick, must be prepared for receiving the pane of glass. Sometimes several plates of glass are laid over each other with a layer of dry pulverulent lime between each. The fire is now lighted, and most gradually raised, lest the glass should be broken; and after it has attained to its full heat, it must be kept for three or four hours, more or less, according to the indications of the trial slips; the yellow colour being principally watched, as it is found to be the best criterion of the state of the others. When the colours are properly burnt in, the fire is suffered to die away slowly, so as to anneal the glass.

Stained-glass Pigments.

Flesh colour. — Take an ounce of red lead, two ounces of red enamel (Venetian glass enamel, from alum and copperas calcined together), grind them to fine powder, and work this up with spirits (alcohol) upon a hard stone. When slightly baked, this produces a fine flesh colour.

Black colour. — Take 14½ ounces of smithy scales of iron, mix them with two ounces of white glass (crystal), an ounce of antimony, and half an ounce of manganese; pound aud grind these ingredients together with strong vinegar. A brilliant black may also be obtained by a mixture of cobalt blue with the oxides of manganese and iron. Another black is made from three parts of crystal glass, two parts of oxide of copper, and one of (glass of) antimony worked up together, as above.

Brown colour. — An ounce of white glass or enamel, half an ounce of good manganese; ground together.

Red, rose, and brown colours are made from peroxide of iron, prepared by nitric acid. The flux consists of borax, sand, and minium in small quantity.

Red colour may be likewise obtained from one ounce of red chalk pounded, mixed with two ounces of white hard enamel, and a little peroxide of copper.

A red may also be composed of rust of iron, glass of antimony, yellow glass of lead, such as is used by potters (or litharge), each in equal quantity; to which a little sulphuret of silver is added. This composition, well ground, produces a very fiue red colour on glass. When protoxide of copper is used to stain glass, it assumes a bright red or green colour, according as the glass is more or less heated in the furnace, the former corresponding to the orange protoxide, the latter having the copper in the state of peroxide.

Bistres and brown reds may be obtained by mixtures of manganese, orange oxide of copper, and the oxide of iron called umber, in different proportions. They must be previously fused with vitreous solvents.

Green colour. — Two ounces of brass calcined into an oxide, two ounces of minium, and eight ounces of white sand; reduce them to a fine powder, which is to be enclosed in a well luted crucible, and heated strongly in an air furnace for an hour. When the mixture is cold, grind it in a brass mortar. Green may, however, be advantageously produced by a yellow on one side, and a blue on the other. Oxide of chrome has been also employed to stain glass green.

A fine yellow colour. — Take fine silver laminated thin, dissolve in nitric acid, dilute with abundance of water, and precipitate with solution of sea salt. Mix this chloride of silver, in a dry powder, with three times its weight of pipe-clay well burnt and pounded. The back of the glass pane is to be painted with this powder, for when painted on the face, it is apt to run into the other colours.

Another yellow can be made by mixing sulphide of silver with glass of antimony, and yellow ochre previously calcined to a red-brown tint. Work all these powders together, and paint on the back of the glass. Or silver *laminæ* melted with sulphur and glass of antimony, thrown into cold water, and afterwards ground to powder, afford a yellow.

A pale yellow may be made with the powder resulting from brass, sulphur, and glass of antimony, calcined together in a crucible till they cease to smoke; and then mixed with a little burnt yellow ochre.

The fine yellow of M. Merand, is prepared from chloride of silver, oxide of zinc, white-clay, and rust of iron. This mixture, simply ground, is applied on the glass.

Orange colour. — Take 1 part of silver powder, as precipitated from the nitrate of that metal by plates of copper, and washed; mix it with one part of red ochre and 1 of yellow, by careful trituration; grind into a thin pap with oil of turpentine or lavender, and apply this with a brush, dry, and burn in.

In the *Philosophical Magazine*, of December, 1836, the anonymous author of an ingenious essay, "On the Art of Glass-painting," says, that if a large proportion of ochre has been employed with the silver, the stain is yellow; if a small proportion, it is orange-coloured; and by repeated exposure to the fire, without any additional colouring-matter, the orange may be converted into red: but this conversion requires a nice management of the heat. Artists often make use of panes coloured throughout their substance in the glass-house pots, because the perfect transparency of such glass gives a brilliancy of effect, which enamel painting, always more or less opaque, cannot rival. It was to a glass of this kind that the old glass-painters owed their splendid red. This is, in fact, the only point in which the modern and ancient processes differ; and this is the only part of the art which was ever really lost. Instead of blowing plates of solid red, the old glass-makers (like those of Bohemia for some time back), used to *flash* a thin layer of brilliant red over a substratum of colourless glass; by gathering a lump of the latter upon the end of their iron rod in one pot, covering with a layer of the former in another pot, then blowing out the two together into a globe or cylinder, to be opened into circular tables, or into rectangular plates. The elegant art of tinging glass red by protoxide of copper, and flashing it on common crown glass, has become general within these few years.

That gold melted with flint glass stains it purple was originally discovered and practised, as a profitable secret, by Kunckel. Gold has been recently used at Birmingham for giving a beautiful rose-colour to scent bottles. The proportion of gold should be very small, and the heat very great, to produce a good effect. The glass must contain either the oxide of lead, bismuth, zinc, or antimony; for crown glass will take no colour from gold. Glass combined with this metal, when removed from the crucible, is generally of a pale rose colour; nay, sometimes is as colourless as water, and does not assume its ruby colour till it has been exposed to a low red heat, either under a muffle, or at the lamp. This operation must be nicely regulated; because a slight excess of fire destroys the colour, leaving the glass of a dingy brown, but with a green transparency like that of gold leaf. It is metallic gold which gives the colour; and, indeed, the oxide is too easily reduced, not to be converted into the metal by the intense heat which is necessarily required.

Coloured transparent glass is applied as enamel in silver and gold *bijouterie* previously *bright-cut* in the metal with the graver or rose-engine. The cuts, reflecting the rays of light from their numerous surfaces, exhibit through the glass, richly stained with gold, silver, copper, cobalt, &c., a gorgeous play of prismatic colours, varied with every change of aspect. When the enamel is to be painted on, it should be made opalescent by oxide of arsenic, in order to produce the most agreeable effect.

The blues of vitrified colours are all obtained from the oxide of cobalt. Cobalt ore (sulphide) being well roasted at a dull red heat, to dissipate all the sulphur and arsenic is dissolved, in somewhat dilute nitric acid, and after the addition of much water to the saturated solution, the oxide is precipitated by carbonate of soda, then washed upon a filter and dried. The powder is to be mixed with thrice its weight of saltpetre; the mixture is to be deflagrated in a crucible, by applying a red hot cinder to it, then exposed to the heat of ignition, washed and dried. Three parts of this oxide are to be mixed with a flux, consisting of white sand, borax, nitre, and a little chalk, subjected to fusion for an hour, and then ground down into an enamel powder for use. Blues of any shade or intensity may be obtained from the above, by mixing it with more or less flux.

The beautiful greenish-yellow, of which colour so many ornamental glass vessels have been lately imported from Germany, is made in Bohemia by the following process. Ore of uranium, *Uran-ochre*, or *Uran-glimmer*, in fine powder, being roasted and dissolved in nitric acid, the filtered solution is to be freed from any lead present in it by the cautious addition of dilute sulphuric acid. The clear green solution is to be evaporated to dryness, and the mass ignited till it becomes yellow. One part of this oxide is to be mixed with 3 or more parts of a flux, consisting of 4 parts of red lead and 1 of ground flint; the whole fused together and then reduced to powder.

Chrome green.—Triturate together in a mortar equal parts of chromate of potash and flowers of sulphur: put the mixture into a crucible and fuse. Pour out the fluid mass; when cool, grind and wash well with water, to remove the sulphuret of potash and to leave the beautiful green oxide of chrome. This is to be collected upon a filter, dried, rubbed down along with thrice its weight of a flux, consisting of 4 parts of red lead and 1 part of ground flints fused into a transparent glass; the whole is now to be melted and afterwards reduced to a fine powder.

Violet.—One part of calcined black oxide of manganese, 1 of zaffre, 10 parts of white glass pounded, and 1 of red lead, mixed, fused, and ground. Or gold purple (Cassius's purple precipitate) with chlorsilver, previously fused with ten times its weight of a flux, consisting of ground quartz, borax, and red lead, all melted together.

Or solution of tin being dropped into a large quantity of water, solution of nitrate of silver may be first added, and then solution of gold in *aqua regia*, in proper proportions. The precipitate to be mixed with flux and fused.

STAMPING OF METALS. The following ingenious machine for manufacturing metal spoons, forks, and other articles, was made the subject of a patent by Jonathan Hayne, of Clerkenwell, in May 1833. He employs a stamping-machine with dies, in which the hammer is raised to a height between guides, and is let fall by a trigger. He prefers fixing the protuberant, or relief portion of the dye, to the stationary block, or bed of the stamping-machine, and the counterpart or intaglio, to the falling hammer or ram.

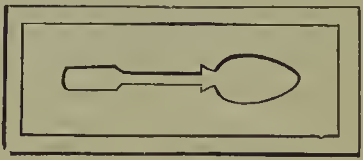
The peculiar feature of improvement in this manufacture consists in producing the opoon, ladle, or fork perfect at one blow in the stamping-machine, and requiring no further manipulation of shaping, by simply trimming off the barb or fin, and polishing the surface to render the article perfect and finished.

Heretofore, in employing a stamping-machine, or fly-press, for manufacturing spoons, ladles, and forks, it has been the practice to give the impression to the handles, and to the bowls or prongs, by distinct operations of different dies, and after having so partially produced the pattern upon the article, the handles had to be bent and formed by the operations of filling and hammering.

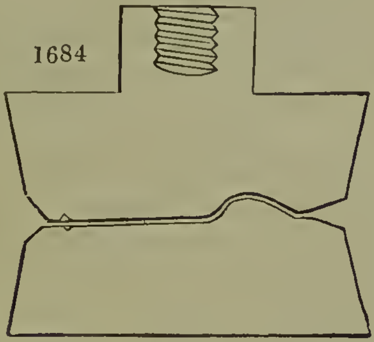
By his improved form of dies, which, having curved surfaces and bevelled edges, allow of no parts of the faces of the die and counter-die to come in contact, he is enabled to produce considerable elevations of pattern and form, and to bring up the article perfect at one blow, with only a slight barb, or fin, upon its edge.

In the accompanying drawings, *fig.* 1682 is the lower or bed die for producing a spoon, seen edgewise; *fig.* 1683 is the face of the upper, or counter-die, corresponding;

1683



1684



1682

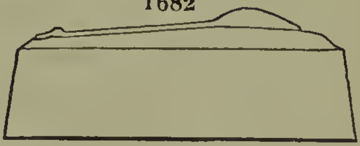


fig. 1684 is a section, taken through the middle of the pair of dies, showing the space in which the metal is pressed to form the spoon.

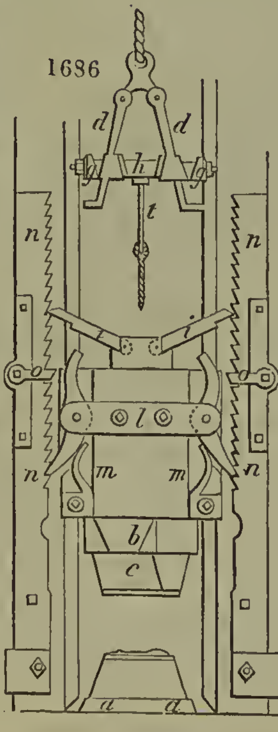
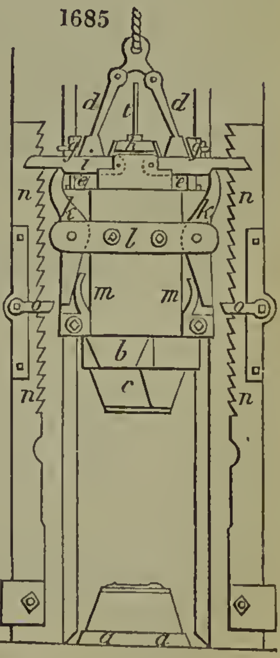
To manufacture spoons, ladles, or forks, according to his improved process, he first forges out the ingot into flat pieces, of the shape and dimensions of the die of the intended article; and if a spoon or ladle is to be made, gives a slight degree of concavity to the bowl part; but, if necessary, bends the back, in order that it may lie more steadily and bend more accurately, upon the lower die; if a fork, he cuts or otherwise removes portions of the metal at those parts which will intervene between the prongs; and, having thus produced the rude embryo of the intended article, scrapes its entire surface clean and free from oxidation-scale, or fire strain, when it is ready to be introduced into the stamping-machine.

1686



1685



He now fixes the lower die in the bed of the stamping-machine, shown at *a*, *a*, in the elevations *figs.* 1685 and 1686, and fixes, in the hammer *b*, the upper or counter-die, *c*, accurately adjusting them both, so that they may correspond exactly when brought together. He then places the rudely-formed article above described upon the lower die, and having drawn up the hammer to a sufficient elevation, by a windlass and rope, or other ordinary means, lets go the trigger, and allows the hammer, with the counter-die to fall upon the under die, on which the article is placed; when by the blow thus given to the metal, the true and perfect figure and pattern of the spoon, ladle, or fork is produced, and which, as before said, will only require the removal of the slight edging of barb, or fin, with polishing, to finish it.

On striking the blow, in the operation of stamping the article, the hammer will recoil and fly up some distance, and if allowed to fall again with reiterated blows, would injure both the article and the dies; therefore, to avoid this inconvenience, he causes the hammer on recoiling to be caught by a pair of palls locked into racks on the face of the standards, seen in the figures; the hammer *b*, of the stamping-machine, is seen raised and suspended by a rope attached to a pair of jointed hooks or holders, *d*, *d*, the lower ends of which pass into eyes, *e*, *e*, extending from the top of the hammer. When the lever or trigger, *t*, is drawn forward, as in *fig.* 1686, the two inclined planes, *g*, *g*, on the axle, *h*, press the two legs of the holders, *d*, *d*, inward, and cause their hooks or lower ends to be withdrawn from the eyes, *e*, *e*, when the hammer instantly falls, and brings the dies together: such is the ordinary construction of the stamping-machine.

On the hammer falling from a considerable elevation, the violence of the blow causes it to recoil and bound upwards, as before mentioned; it therefore becomes necessary to catch the hammer when it has rebounded, in order to prevent the dies coming again together; this is done by the following mechanism: —

Two latch levers, *i*, *i*, are connected by joints to the upper part of the hammer, and two pall levers, *k*, *k*, turning upon pins, are mounted in the bridge, *l*, affixed to the hammer. Two springs, *m*, *m*, act against the lower arms of these levers, and press them outwards, for the purpose of throwing the palls at the lower ends of the levers into the teeth of the ratchet racks, *n*, *n*, fixed on the sides of the upright standards.

Previously to raising the hammer, the upper ends of the pall levers, *k*, are drawn back, and the latches, *i*, being brought down upon them, as in *fig.* 1685, the levers, *k*, are confined, and their palls prevented from striking into the slide racks; but as the hammer falls, the ends of the latches, *i*, strike upon the fingers, *o*, *o*, fixing to the side standards, and liberate the palls, the lower ends of which, when the hammer rebounds, after stamping, catch into the teeth of the racks, as in *fig.* 1686, and thereby prevent the hammer from again descending.

STANNATE AND STANNITE OF POTASH AND SODA. Stannates and stannites of alkalies are valuable mordants in calico printing, and are prepared by the patented plan of Messrs. Greenwood, Church, and Barnes, as follows:— For the stannate of soda: 22 lbs. of caustic soda are first put into an iron crucible, heated to a low red heat, till the hydrate be produced; to which 8 lbs. of nitrate of soda and 4 lbs. of common salt are introduced. When the mixture is at a fluxing heat, 10 lbs. of feathered block tin are added, and it is stirred with an iron rod. The mass now becomes dark coloured and pasty, and ammonia is given off (the tin decomposing the water of the hydrated soda and part of the nitrate of soda). The stirring is continued, as well as the heat, till deflagration takes place, and the mass becomes red hot and pasty. This product is stannate of soda. It may be purified by solution and crystallisation.

Stannite of soda is made by putting 4 lbs. of common salt, 13½ lbs. of caustic soda, and 4 lbs. of feathered block tin into a hot iron crucible over a fire, and stirring and boiling to dryness, and as long as ammonia is given off. What remains is stannite of soda.

To produce the tin preparing liquor, 3 lbs. of stannate of soda are dissolved in 1 gallon of boiling water, and 3 gallons or more of cold water, to bring it to the required strength. The stannite of soda is treated in the same way.

The process of Mr. James Young is much more recent, and presents a very beautiful application of science. Instead of reducing metallic tin from the ore, and oxidating the metal again to form the stannic acid at the expense of nitric acid, Mr. Young takes the native peroxide of tin itself, and fuses it with soda. The iron and other foreign metals present in the ore are insoluble in the alkali, so that by solution of the fused mass in water, a pure stannate of soda is obtained at once. It is crystallised by evaporation, and obtained in efflorescent crystals containing nine equivalents of water.

STARCH (*Amidon*, *Fecule*, Fr.; *Stärke*, Germ.) is a white pulverulent substance, composed of microscopic spheroids, which are bags containing the amylaceous matter. It exists in a great many different plants, and varies in the form and size of its microscopic particles. As found in some plants, it consists of spherical particles $\frac{1}{1000}$ of an inch in diameter; and in others of ovoid particles, $\frac{1}{300}$ or $\frac{1}{400}$ of an inch. It occurs — 1. In the seeds of all the acotyledonous plants, among which are the several species of corn, and those of other *gramineæ*. 2. In the round perennial tap roots, which shoot up an annual stem; in the tuberose roots, such as potatoes, the *Convolvulus batatas* and *edulis*, the *Helianthus tuberosus*, the *Jatropha manihot*, &c., which contain a great quantity of it. 3. In the stems of several monocotyledonous plants, especially of the palm tribe, whence sago comes; but it is very rarely found in the stems and branches of the dicotyledonous plants; 4. It occurs in many species of lichen. Three kinds of starch have been distinguished by chemists; that of wheat, that called *inuline*, and lichen starch. These three agree in being insoluble in cold water, alcohol, ether, and oils, and in being converted into sugar by either dilute sulphuric acid or diastase. The main difference between them consists in their habitudes with water and iodine. The first forms with hot water a mucilaginous solution, which constitutes, when cold, the paste of the laundress, and is tinged blue by iodine; the second forms a granular precipitate, when its solution in boiling-hot water is suffered to cool, which is tinged yellow by iodine; the third affords, by cooling the concentrated solution, a gelatinous mass, with a clear liquid floating over it, that contains little starch. Its jelly becomes brown grey with iodine.

Ordinary starch. — This may be extracted from the following grains: — Wheat, rye, barley, oats, buckwheat, rice, maize, millet, spelt; from the siliquose seeds, as peas, beans, lentiles, &c.; from tuberous and tap roots, as those of the potato, the orchis, manioc, arrow-root, batata, &c. Different kinds of corn yield very variable quantities of starch. Wheat differs in this respect, according to the varieties of the plant, as well as the soil, manure, season, and climate. See BREAD.

Wheat partly damaged by long keeping in granaries, may be employed for the manufacture of starch, as this constituent suffers less injury than the gluten; and it may be used either in the ground or unground state.

With unground wheat. — The wheat being sifted clean, is to be put into cisterns, covered with soft water, and left to steep till it becomes swollen and so soft as to be easily crushed between the fingers. It is now to be taken out, and immersed in clear water of a temperature equal to that of malting-barley, whence it is to be transferred into bags, which are placed in a wooden chest containing some water, and exposed to strong pressure. The water rendered milky by the starch being drawn off by a tap, fresh water is poured in, and the pressure is repeated. Instead of putting the swollen grain into bags, some prefer to grind it under vertical edge-stones, or between a pair of horizontal rollers, and then to lay it in a cistern, and separate the starchy liquor by elutriation with successive quantities of water well stirred up with it. The residuary matter in the sacks or cisterns contain much vegetable albumen and gluten, along with the husks; when exposed to fermentation, this affords a small quantity of starch of rather inferior quality.

The above milky liquor, obtained by expression or elutriation, is run into large cisterns, where it deposits its starch in layers successively less and less dense; the uppermost containing a considerable proportion of gluten. The supernatant liquor being drawn off, and fresh water poured on it, the whole must be well stirred up, allowed again to settle, and the surface-liquor withdrawn. This washing should be repeated as long as the water takes any perceptible colour. As the first turbid liquor contains a mixture of gluten, sugar, gum, albumen, &c., it ferments readily, and produces a certain portion of vinegar, which helps to dissolve out the rest of the mingled gluten, and thus to bleach the starch. It is, in fact, by the action of this fermented or soured water, and repeated washing, that it is purified. After the last deposition and decantation, there appears on the surface of the starch a thin layer of a slimy mixture of gluten and albumen, which being scraped off, serves for feeding pigs or oxen; underneath will be found a starch of good quality. The layers of different sorts are then taken up with a wooden shovel, transferred into separate cisterns, where they are agitated with water, and passed through fine sieves. After this pap is once more well settled, the clear water is drawn off, the starchy mass is taken out, and laid on linen cloths in wicker baskets, to drain and become partially dry. When sufficiently firm, it is cut into pieces which are spread upon other cloths, and thoroughly desiccated in a proper drying-room, which in winter is heated by stoves. The upper surface of the starch is generally scraped, to remove any dusty matter, and the resulting powder is sold in that state. Wheat yields, upon an average, only from 35 to 40 per cent. of good starch. It should afford more by skilful management.

With crushed wheat. — In this country, wheat crushed between iron rollers is laid to steep in as much water as will wet it thoroughly; in four or five days the mixture ferments, soon afterwards settles, and is ready to be washed out with a quantity of water into the proper fermenting vats. The common time allowed for the steep is from 14 to 20 days. The next process consists in removing the stuff from the vats into a stout round basket set across a back below a pump. One or two men keep going round the basket, stirring up the stuff with strong wooden shovels, while another keeps pumping water, till all the *farina* is completely washed from the bran. Whenever the subjacent back is filled, the liquor is taken out and strained through hair sieves into square frames or cisterns, where it is allowed to settle for 24 hours; after which the water is run off from the deposited starch by plug traps at different levels in the side. The thin stuff, called *slimes*, upon the surface of the starch, is removed by a tray of a peculiar form. Fresh water is now introduced, and the whole being well mixed by proper agitation, is then poured upon fine silk sieves. What passed through is allowed to settle for 24 hours; the liquor being withdrawn, and then the slimes, as before, more water is again poured in, with agitation, when the mixture is again thrown upon the silk sieve. The milky liquor is now suffered to rest for several days,—4 or 5,—till the starch becomes settled pretty firmly at the bottom of the square cistern. If the starch is to have the blue tint, called Poland. fine smalt must be mixed in the liquor of the last sieve, in the proportion of 2 or 3 lbs. to the cwt. A considerable portion of these slimes may, by good management, be worked up into starch by elutriation and straining.

The starch is now fit for *boxing*, by shovelling the cleaned deposit into wooden chests, about 4 feet long, 12 inches broad, and 6 inches deep, perforated throughout, and lined with thin canvas. When it is drained and dried into a compact mass, it is turned out by inverting the chest upon a clean table, where it is broken into pieces 4 or 5 inches square, by laying a ruler underneath the cake, and giving its surface a cut with a knife, after which the slightest pressure with the hand will make the fracture. These pieces are set upon half-burned bricks, which by their porous capillarity imbibe the moisture of the starch, so that its under surface may not become hard and horny. When sufficiently dried upon the bricks, it is put into a stove (which resembles that of a sugar refinery), and left there till tolerably dry. It is now removed to a table, when all the sides are carefully scraped with a knife; it is next packed up in the papers in which it is sold; these packages are returned into the stove, and subjected to a gentle heat during some days; a point which requires to be skilfully regulated.

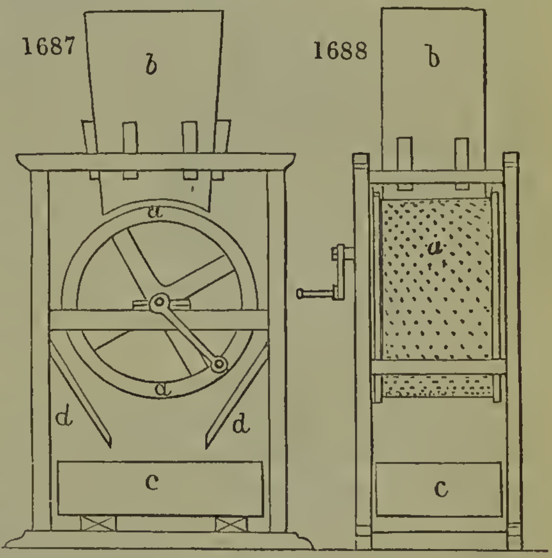
During the drying, starch splits into small prismatic columns, of considerable regularity. When kept dry, it remains unaltered for a very long period. When it is heated to a certain degree in water, the envelopes of its spheroidal particles burst, and the *farina* forms a mucilaginous emulsion, magma, or paste. When this apparent solution is evaporated to dryness, a brittle, horny-looking substance is obtained, quite different in aspect from starch, but similar in chemical habitudes. When the moist paste is exposed for two or three months to the air in summer, the starch is converted into sugar, to the amount of one third or one half of its weight, into gum and gelatinous starch, called *amidine* by De Saussure, with occasionally a resinous matter. This curious change goes on even in close vessels.

Starch from potatoes.—From the following table of analysis, it appears that potatoes contain from 24 to 30 per cent. of dry substance:—

	Starch.	Fibrous parenchyma.	Veg. Albumen.	Gum, Sugar, and Salts.	Water.
Red potato - -	15·0	7·0	1·4	9·2	75·0
Germinating potatoes	15·0	6·8	1·3	3·7	73·0
Kidney potatoes -	9·1	8·8	0·8	—	81·3
Large red potatoes -	12·9	6·0	0·7	—	78·0
Sweet potatoes -	15·1	8·2	0·8	—	74·3
Peruvian potatoes -	15·0	5·2	1·9	1·9	76·0
English potatoes -	12·9	6·8	1·1	1·7	77·5
Parisian potatoes -	13·3	6·8	0·9	4·8	73·1

The potatoes are first washed in a cylindrical cage formed of wooden spars, made to revolve upon a horizontal axis, in a trough filled with water to the level of the axis. They are then reduced to a pulp by a rasping machine, similar to that represented in *figs.* 1687, 1688, where *a* is a wooden drum covered with sheet-iron, roughened outside with numerous prominences, made from punching out holes from the opposite side. It is turned by a winch fixed upon each end of the shaft. The drum is enclosed in a square wooden box, to prevent the potato-mash from being scattered about. The hopper, *b*, is attached to the upper frame, has its bottom concentric with the rasp-drum, and nearly in contact with it. The pulp chest, *c*, is made to slide out, so as when full to be readily replaced by another. The two slanting boards, *d, d*, conduct the pulp into it. A moderate stream of water should be made to play into the hopper upon the potatoes, to prevent the surface of the rasp from getting foul with fibrous matter. Two men, with one for a relay, will rasp, with such a machine, from 2½ to 3 tons of potatoes in 12 hours.

The potato pulp must be now elutriated upon a fine wire or hair sieve, which is set upon a frame in the mouth of a large vat, while water is made to flow upon it from a spout with many jets. The pulp meanwhile must be stirred and kneaded by the hand, or by a mechanical brush-agitator, till almost nothing but fibrous particles are left upon the sieve. These, however, generally retain about 5 per cent. of starch, which cannot be separated in this way. This parenchyma should therefore be subjected to a separate rasping upon another cylinder. The water, turbid with starch, is allowed to settle for some time in a back; the supernatant liquor is then run by a cock into a second back, and after some time into a third, whereby the whole starch will be precipitated. The finest powder collects in the last vessel. The starch thus obtained, containing 33 per cent. of water, may be used either in the moist state, under the name of *green fecula*, for various purposes, as for the preparation of dextrine and starch syrup, or it may be preserved under a thin layer of water, which must be renewed from time to time, to prevent fermentation; or lastly, it may be taken out and dried.



Washing apparatus have been contrived by Lainé, Dailly, Huck, Vernies, Stolz, and St. Etienne. These are contrivances for working very large quantities of potatoes in a short time. Huck's machine is stated to work 30,000 lbs. of potatoes daily, and in trials made with St. Etienne's rasp and starch machinery, in Paris, which was driven by two horses, nearly 18 cwt. of potatoes were put through all the requisite operations in one hour, including the pumping of the water. The product in starch amounted to from 17 to 18 per cent. of the potatoes. The quicker the process of potato-starch making the better is its quality. Völker proposed a process of rotting the potato to separate the starch.

Mr. P. L. Simmons, in a communication to the Society of Arts, has directed attention to a great number of roots from which starch might be possibly obtained, especially the yams, eddoes, cocos (*Arum esculentum*). The same authority has collected from various sources the quantity of starch contained in different tropical roots. *Sweet cassava*, 27 per cent.; *bitter cassava*, 16 to 25 per cent.; *common yam*, 24½ per cent.; *arrow-root*, 17 to 21½ per cent.; *Barbadoes yam*, 18¾ per cent.; *tannia* (*Caladium sagitte folium*), 15½ to 17 per cent.; *the Guinea yam*, 17 per cent.; *buck yam*, 14 to 16 per cent.; *sweet potato*, 16½ per cent.; *Plantain meat*, 17 per cent.

Horse chestnuts have been largely used at Nanterre, near Paris, in the manufacture of starch.

In the manufacture of potato starch a considerable quantity of the product is lost, owing to the strong affinity which the starch has for the fibre of the potato. M. Anthon (*Chemisch Central Blatt*), states that the manufacturer obtains only two thirds of the starch, the remainder being left in the pulp. He suggests that this third may be utilised, by converting it into sugar by means of either malt or dilute sulphuric acid. By employing 10 per cent. of the acid to the dry fibre, the saccharification is complete in about two hours and a half; but if only 3 or 4 per cent. of acid is used the boiling must be continued for at least 5 hours. Ten per cent. of malt effected the conversion in 6 hours. Mr. Calvert has given the following analysis of the potato:—*Water*, 74; *starch*, 20; the remainder being fibrous, earthy, and alkaline matter.

Starch from certain foreign plants.—1. From the pith of the *sago palm*. See SAGO.

2. From the roots of the *Maranta arundinacea*, of Jamaica, the Bahamas, and other West India Islands, the powder called arrow-root is obtained, by a process analogous to that for making potato starch.

3. From the roots of the *manioc*, which also grows in the West Indies, as well as in Africa, the *cassava* is procured, by a similar process. The juice of this plant is poisonous, from which the wholesome starch is deposited. When dried with stirring upon hot iron plates, it agglomerates into small lumps, called *tapioca*; being a gummy fecula.

The characters of the different varieties of starch can be learnt only from microscopic observation; by which means also their sophistication or admixture may be readily ascertained.

Starch, from whatever source obtained, is a white soft powder, which feels crispy, like flowers of sulphur, when pressed between the fingers; it is destitute of taste and smell, unchangeable in the atmosphere, and has a specific gravity of 1·53.

For the saccharine changes which starch undergoes by the action of *diastase*, see FERMENTATION.

Lichenine, a species of starch obtained from Iceland moss (*Cetraria islandica*), as well as *inuline*, from elecampane (*Inula helenium*), are rather objects of chemical curiosity than of manufactures.

There is a kind of starch made in order to be converted into gum for the calico-printer. This conversion having been first made upon the great scale in this country, has occasioned the product to be called British gum. The following is the process pursued in a large and well-conducted establishment near Manchester: — A range of four wooden cisterns, each about 7 or 8 feet square, and 4 feet deep, is provided. Into each of them 2,000 gallons of water being introduced, 12½ loads of flour are stirred in. The mixture is set to ferment upon old leaven left at the bottom of the backs, during 2 or 3 days. The contents are then stirred up, and pumped off into 3 stone cisterns, 7 feet square and 4 feet deep; as much water being added, with agitation, as will fill the cisterns to the brim. In the course of 24 hours the starch forms a firm deposit at the bottom; and the water is then siphoned off. The gluten is next scraped from the surface, and the starch is transferred into wooden boxes pierced with holes, which may be lined with coarse cloth, or not, at the pleasure of the operator.

The starch, cut into cubical masses, is put into iron trays, and set to dry in a large apartment, two stories high, heated by a horizontal cylinder of cast-iron traversed by the flame of a furnace. The drying occupies two days. It is now ready for conversion into gum, for which purpose it is put into oblong trays of sheet iron, and heated to the temperature of 300° Fahr. in a cast-iron oven, which holds four of these trays. Here it concretes into irregular semi-transparent yellow-brown lumps, which are ground into fine flour between mill-stones, and in this state brought to the market. In this roasted starch, the vesicles being burst, their contents become soluble in cold water. British gum is not convertible into sugar, as starch is, by the action of dilute sulphuric acid; nor into mucic acid, by nitric acid; but into the oxalic; and it is tinged purple red by iodine. It is composed, in 100 parts, of 35·7 carbon, 6·2 hydrogen, and 58·1 oxygen; while starch is composed of, 43·5 carbon, 6·8 hydrogen, and 49·7 oxygen. See DEXTRINE.

Manufacture of starch from rice, &c. — Mr. Thomas Berger, of Hackney, soaks rice in caustic alkali, as Mr. Wickham did in 1824, at successive times, levigates it into a cream, adds one part of oil of turpentine to 2,000 gallons of the cold mash, stirs the mixture, filters or strains through fine lawn sieves, settles, neutralises with dilute sulphuric acid, and adding 8 oz. of sulphate of zinc to each cwt. of starch, stirs, boxes, and finishes as usual.

In June 1841, Mr. W. T. Berger obtained a patent for manufacturing starch by the agency of an alkaline salt upon rice. He prefers the carbonates of potash and soda.

Mr. Orlando Jones macerates 100 lbs. of ground rice in 100 gallons of a solution composed of 200 grains of caustic soda or potash to a gallon of water, stirs it gradually till the whole is well mixed; after 24 hours he draws off the supernatant liquid solution of gluten in alkali, treats the starchy deposit with a fresh quantity of weak caustic lye, and thus repeatedly, till the starch becomes white and pure. The rice, before being ground, is steeped for some time in a like caustic lye, drained, dried, and sent to the mill.

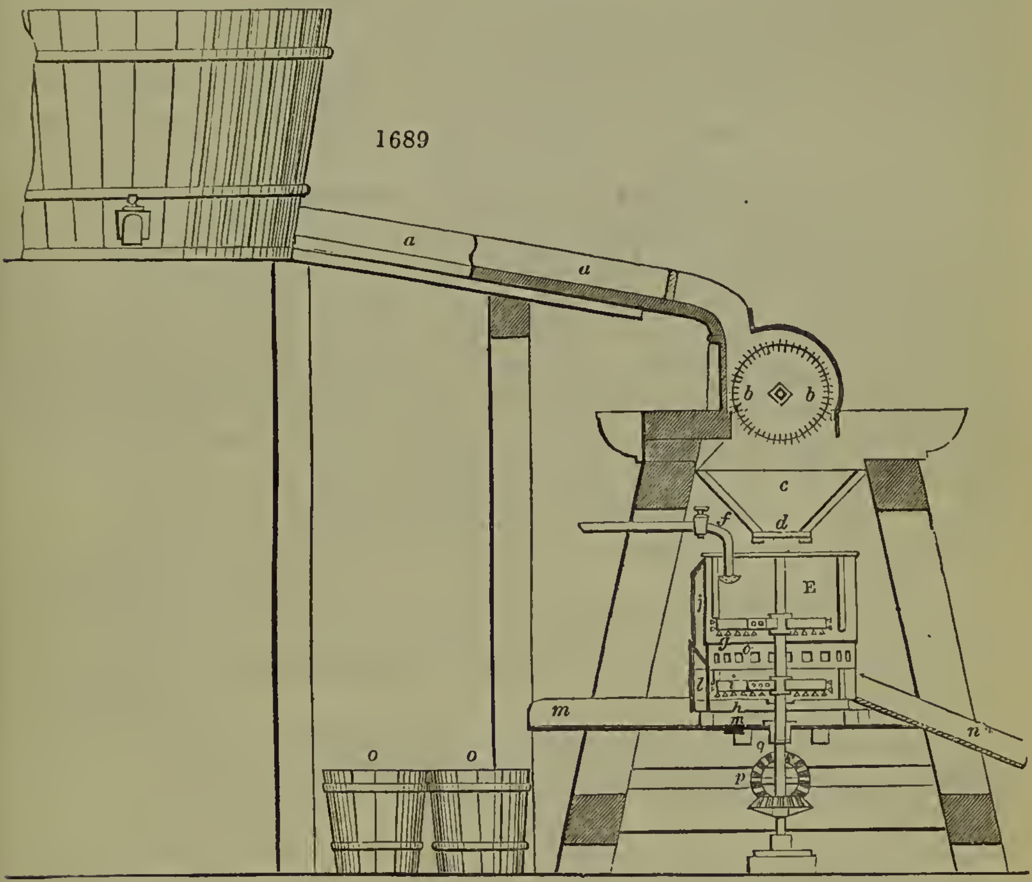
Mr. James Colman, by his patent of December 1841, makes starch from ground maize or Indian corn, by the agency either of the ordinary process of steeping and fermenting, or of caustic or carbonated alkaline lyes. He also proposes to employ dilute muriatic acid to purify the starchy matter from gluten, &c.

Starch prepared from rice or maize by alkali is said not to require boiling — a point of great importance in its use; and, being less hygrometric than wheat starch, retains a more permanent stiffness and glaze. The rough starch obtained in the process is valuable for feeding purposes, and for stiffening coarse fabrics.

Mr. John Hamilton, of Belfast, has a patent for submitting starch, after it has been deposited in the manufacturing process, to the action of a hydraulic press, in suitable boxes, so as to press all the water out of it, instead of evaporating all the moisture in artificially heated rooms, according to the usual practice; a great saving in fuel is thus effected.

Fig. 1689 represents in section the powerful and ingenious mechanical grater, or

1689



rasp (*râpe*), now used in France. *a a* is the canal, or spout, along which the previously well-washed potatoes descend; *b b* is the grater, composed of a wooden cylinder, on whose round surface circular saw rings of steel, with short sharp teeth, are planted pretty close together. The greater the velocity of the cylinder, the finer is the pulp. A cylinder 20 inches in diameter revolves at the rate of from 600 to 900 times a minute, and it will convert into pulp from 14 to 15 hectolitres (about 300 imperial gallons) of potatoes in an hour. Potatoes contain from 15 to 22 per cent. of dry fecula. The pulp, after leaving the rasp, passes directly into the apparatus for the preparation of the starch. *c* is a wooden hopper for receiving the falling pulp, with a trap door, *d*, at bottom. E, is the cylinder-sieve of M. Etienne; *f*, a pipe ending in a rose-spout, which delivers the water requisite for washing the pulp, and extracting the starch from it; *g g*, a diaphragm of wire cloth, with small meshes, on which the pulp is exposed to the action of the brushes, *i i*, moving with great speed, whereby it gives out its starchy matter, which is thrown out by a side aperture into the spout *n*. The fecula now falls upon a second web of fine wire cloth, and leaves upon it merely some fragments of the parenchyma or cellular matter of the potato, to be turned out by a side opening in the spout, *n*. The sifting or straining of the starch likewise takes place through the sides of the cylinder, which consists also of wire cloth; it is collected into a wooden spout, *m*, and is thence conducted into the tubs, *o*, *o*, to be deposited and washed. *p* is a mitre-toothed wheel-work, placed on the driving-shaft, and gives motion to the upright axis or spindle, *q q*, which turns the brushes, *i*, *i*.

Starch *exported* in 1858: — 17,925 cwts.; declared real value, 33,812*l*.

STARCHING AND STEAM-DRYING APPARATUS. For a full description of these processes, and of the machinery for accomplishing them, see BLEACHING and CALICO PRINTING.

STATUARY PORCELAIN. See POTTERY.

STEAM is water in its vaporiform state. The varied and important applications of steam as a mechanical power, would appear to render a consideration of its laws of the utmost importance. The circumstance that our spinning and weaving machinery, our pumping engines, our ships, our carriages, our hammers, our lathes, and our presses, are all moved by this power, seems to demand a full consideration of steam in a work devoted to *Arts, Manufactures, and Mines*, into each division of which it enters as an important element. But the limits assigned to the entire work renders it impossible to treat in any way commensurate with its importance this great mechanical power. It is, therefore, thought advisable to confine attention to a few general and well-established principles only. For especial information on the subject the reader is referred to W. J. Macquorn Rankine's *Manual of the Steam Engine;* Tredgold *on the Steam Engine;* De Pambour *on the Theory of the Steam Engine*, and *on the Locomotive Engine;* Arago *sur les Machines à Vapeur;* Regnault's papers in the *Memoires* and *Comptes Rendus* of the Academy of Sciences, &c.

Steam is a chemical compound of oxygen and hydrogen, in the proportion of 8 parts by weight of oxygen, to 1 of hydrogen. Its composition by volume is such, that the quantity of steam which, if it were a perfect gas, would occupy 1 cubic foot at a given pressure and temperature, contains as much oxygen as would, if uncombined, occupy half a cubic foot, and as much hydrogen as would, if uncombined, occupy 1 cubic foot, at the same pressure and temperature; so that steam, if it were a perfect gas, would occupy two thirds the space which its constituents occupy when uncombined. Hence is deduced the following composition of the weight of 1 cubic foot of steam would have at the temperature of 32° Fahr., and pressure of one atmosphere (or 14·7 lbs. on the square inch), if steam were a perfect gas, and if it could exist at the pressure and temperature stated.

Data from the Experiments of Regnault.

	lb.
Half a cubic foot of oxygen at the pressure of one atmosphere and temperature, 32° - - - - - - - -	0·044628
1 cubic foot of hydrogen - - - - - - -	0·005592
1 cubic foot of steam in the ideal state of perfect gas, at one atmosphere and 32° - - - - - - - -	0·050220

If steam were a perfect gas, the weight of a cubic foot could be calculated for any given pressure and temperature by the following formula.

Weight of a cubic foot = 0·05022 lbs. × pressure in atmosphere—

$$\times \frac{493\cdot{}^{\circ}2}{\text{Temp.} + 4\cdot 61\cdot{}^{\circ}2}$$

For example, at one atmosphere of pressure, and 212°, the weight of a cubic foot of steam would be:—

$$0\cdot 05022 \times \frac{493\cdot{}^{\circ}2}{673\cdot{}^{\circ}6} = 0\cdot 03679 \text{ lb.}$$

But steam is known not to be a perfect gas; and its actual density is greater than that which is given by the preceding formula, though to what extent is not yet known by direct experiment. The most probable method of indirectly determining the density of steam, is by computation from the latent heat of evaporation, from which it appears that at one atmosphere and 212°, the weight of a cubic foot of steam is probably 0·0379 lb. The greatest pressure under which steam can exist at a given temperature, is called the *pressure of saturation* for steam of a given temperature. The temperature is called the *boiling point* of water under the given temperature. The pressure of saturation is the only pressure at which steam and liquid water can exist together in the same vessel at a given temperature.

It becomes necessary to understand correctly the method of determiniug fixed temperatures by certain phenomena taking place at them. Thus ice begins to melt at a point, which we call the FREEZING POINT, marked 32° upon the scale devised by Fahrenheit (see THERMOMETER), and we determine the BOILING POINT of water to be 212° on the same scale, under the average atmospheric pressure of 14·7 lbs. on the square inch; 2116·4 lbs. on the square foot; 29·992 inches of the column of mercury. At this latter point water ceases to be *liquid*, and becomes vaporiform. From 32° to 212°, all the heat which has been poured into the water, has effected no change of physical condition, but the higher temperature being reached, a new condition is established, and steam is produced — this steam then beginning to act according to certain fixed laws.

A cubic inch of water evaporated under the ordinary atmospheric pressure is converted into a cubic foot of steam.

A cubic inch of water evaporated under the atmospheric pressure gives a mechanical force equal to what would raise a ton weight 1 foot high.

These are the effects produced at 212° under the above-named pressure.

Careful experiments have determined, within very small limits of error, the following facts: — Steam under pressure of 35 lbs. per square inch, and at the temperature of 261°, exerts a force equal to a ton weight raised one foot; under the pressure of 15 lbs. and at the temperature of 213°, it is 2,086 lbs., or about seven per cent. less; and under 70 lbs. and at 306° it is 2,382 lbs., or nearly six and a half per cent. more than a ton raised a foot. It is sufficient for all practical purposes to assume that each cubic inch evaporated, whatever be the pressure, develops a gross mechanical effort equivalent to a ton weight raised 1 foot.

As a given power is produced by a given rate of evaporation, to determine this the following rules are applicable: —

To produce the force expressed by one-horse power, the evaporation per minute must develop a mechanical force equal to 33,000 lbs., or about 15 tons raised 1 foot high. Fifteen cubic inches of water would accordingly produce this effect, which, without evaporation, would be equivalent to 900 cubic inches per hour. To find, therefore, the gross power developed by a boiler, it would be only necessary to divide the number of cubic inches of water evaporated per hour by 900. If, therefore, to 900 cubic inches be added the quantity of water per hour necessary to move the engine itself, independently of its load, we shall obtain the quantity of water per hour which must be supplied by the boiler to the engine for each horse power, and this will be the same whatever may be the magnitude or proportions of the cylinder.

An able memoir on the pressure and density of steam was laid before the Institute of Civil Engineers in June 1843, by Mr. Pole, C.E., which deserves confidence for its accuracy and usefulness. He proposed a new formula for the relation between these two mechanical quantities, applicable particularly to engines working with high pressure steam expansively.

The relations between the elasticity, temperature, and density of steam have long been interesting and important subjects of philosophical research. They are fully discussed, and represented in extensive tables in *Prechtl's Technological Encyclopædia*, article *Dämpfe.*

The connection of the two former, namely, pressure and temperature, with each other, has excited the greatest attention, numerous experiments having been undertaken to ascertain the values of them at all points of the scale, and many formulæ proposed by English and foreign mathematicians, to express approximately the relation between them.

The pressure and temperature being known, the density, or what answers the same purpose, the relative volume, compared with the water which has produced it, may be deduced by a combination of the laws of Boyle and Gay Lussac, and may be expressed algebraically in terms of the pressure and temperature combined; whence, by eliminating the latter, expressions can be arrived at which will connect at once the volume with the pressure.

But there are several difficulties in the way of this process, the equations which may be thus obtained being too complicated for practical use; and therefore, since it is important in calculations connected with steam and the steam engine, to find a tolerably accurate, and at the same time simple rule, which shall give the pressure and volume directly in terms of each other, the empirical method has been resorted to.

Three formulæ are given for this purpose by M. Navier and M. de Pambour, explaining the peculiar cases to which they are applicable, and those in which they fail; and Mr. Pole proposes a fourth expression, which is intended to meet a case not provided for by either of the others, namely, for "condensing engines working with high pressure steam expansively;" such as the Cornish, and Woulf's double, cylinder engine. The equation is,

$$P = \frac{24250}{V - 65}$$

$$\text{or reciprocally, } V = \frac{24250}{P} \times 65$$

P being the total pressure of the steam in lbs. per square inch, and V its relative volume, compared with that of its constituent, water.

These formulæ may be adopted without considerable error throughout the range generally required in such engines, viz. from about 5 lbs. to 65 lbs. per square inch.

Two tables are then given, showing the pressure and volumes, as calculated for every 5 lbs. pressure in this scale; they show a comparison of the results of the four formulæ with each other, and the respective amount of deviation from truth in each.

The greatest error is,—

	lbs.
By M. Navier's formula - - - -	1·31 per square inch.
M. de Pambour's first ditto - - -	4·12 ,,
,, ,, second ditto - - -	2·75 ,,
The new formula - - - - -	0·71 ,,

The mean error is,—

By M. Navier's formula - - - - -	0·245 per square inch.
M. de Pambour's first ditto - - -	1·42 ,,
,, ,, second ditto - - -	0·35 ,,
The new formula - - - - -	0·0062 ,,

The tables also show:—

1. That the new formula is nearer the truth than either of the others, taken separately, in three fourths of the scale.
2. That it is nearer than all three combined in half the scale.
3. That the greatest error of the new formula, with regard to the pressures, is only about half as great as that of the most correct of the other three.
4. That the mean error is only one-fortieth of either of the others, and equal to only about one-tenth of an ounce per square inch.
5. That the errors in the volumes are much less numerous and important with the new formula than with either of the others.
6. It is also added, that the new expression is simpler in algebraical form than the others; it is more easily calculated, the constants are easier to remember, and that no alteration of the constants in the other formulæ will make them coincide so nearly with the truth as the new one does.

In the application of steam power, the most economical means have been attained in the pumping engines of Cornwall, where the steam is employed expansively. The following tables will show the value of the Cornish engines.

General Table of the Action of the Cornish Steam-Engines.

		Month ending 20 July.	August.	Sept.	Oct.	Nov.	Dec.
Pumping-engines.	Number reported - - - -	23	24	24	24	24	24
	Average load per square inch on piston, in lbs. - - - -	11·9	11.4	11·5	11·8	12·5	12·7
	Average number of strokes per minute	4·8	4 8	5·3	5·2	5·3	5·6
	Gallons of water drawn per minute -	3,773	3,980	3,772	4,031	4,373	4,000
	Average duty — being million lbs. lifted 1 foot high by the consumption of 1 cwt. of coals - - -	61·1	59·5	67·2	63·4	64·9	63·9
	Actual horse-power employed - -	710·8	740·1	725·8	787·8	845·8	814 6

In an inquiry upon the incrustations of the boilers of steam vessels, by M. Couste, it is stated that 8 or 10 per cent. of the heat of fuel is lost after the first few days' work, at Bourdeax 15 per cent., and at Havre, after some days constant work and observation, 40 per cent.; in general practice it has been estimated that 40 per cent. of the heat of the fuel has been lost by the internal incrustations and deposits in the boilers of steam vessels.

The following results were obtained from French ocean steamers: —

Stations.	Sulphate of Lime.	Carbonate of Magnesia.	Free Magnesia.	Iron and Alumina.	Water.
Hamburg, deposit from the surface of boiler (partly crystallised) - -	85·20	2·25	5·95	—	6·5
Mediterranean, tubular boiler (amorphous) -	84·94	2·34	7·66	0·41	4·65
Mediterranean (amorphous deposit) - - -	80·90	3·19	10·35	6·50	4·56

* The average duty in fifth column gives the number of lbs. lifted one foot high by the consumption of a bushel of coal.

An essential character of the sea-water incrustations is that they are free from the deposit of calcareous carbonates.

STEAM BOILERS. Space does not allow of our entering on a consideration of this important subject. We desire however to refer our readers to Mr. W. Fairbairn's papers in the *Transactions of the Royal Society*.

STEARIC ACID. (*Talgsaure*, Germ.) What we have said on stearine explains the production of stearic acid. Chevreul's discovery of the constitution of fats, led to the present processes for the manufacture of stearic acid. The original experiments were published in 1823. And Gay-Lussac with Chevreul in 1825, took patents for the manufacture of fatty acids. Pure stearic acid is prepared, according to its discoverer, Chevreul, in the following way: — Make a soap by boiling a solution of potash and mutton-suet in the proper equivalent proportions, dissolve one part of that soap in six parts of hot water, then add to the solution 40 or 50 parts of cold water, and set the whole in a place whose temperature is about 52° Fahrenheit. A substance falls to the bottom, possessed of pearly lustre, consisting of the bi-stearate and bi-margarate of potash; which is to be drained and washed upon a filter. The filtered liquor is to be evaporated, and mixed with a small quantity of acid necessary to saturate the alkali left free by the precipitation of the above bi-salts. On adding water to it afterwards, the liquor affords a fresh quantity of bi-stearate and bi-margarate. By repeating this operation with precaution, we finally arrive at a point when the solution contains no more of these solid acids, but only the oleic. The precipitated bi-salts are to be washed and dissolved in hot alcohol, of specific gravity 0·820, of which they require about 24 times their weight. During the cooling of the solution, the bi-stearate falls down, while the greater part of the bi-margarate, and the remainder of the oleate, remain dissolved. By repeatedly dissolving in alcohol, and crystallising, the bi-stearate will be obtained alone; as may be proved by decomposing a little of it in water at a boiling heat, with muriatic acid, letting it cool, washing the stearic acid obtained, and exposing it to heat, when, if pure, it will not fuse in water under the 158th degree of Fahrenheit's scale. If it melts at a lower heat, it contains more or less margaric acid. The purified bi-stearate being decomposed by boiling in water along with any acid, as the muriatic, the disengaged stearic acid is to be washed by melting in water, then cooled and dried.

Stearic acid, prepared by the above process, contains combined water, from which it cannot be freed. It is insipid and inodorous. After being melted by heat, it solidifies at the temperature of 158° Fahrenheit, and affects the form of white brilliant needles grouped together. It is insoluble in water, but dissolves in all proportions in boiling anhydrous alcohol, and on cooling to 122°, crystallises therefrom in pearly plates; but if the concentrated solution be quickly cooled to 112°, it forms a crystalline mass. A dilute solution affords the acid crystallised in large white brilliant scales. It dissolves in its own weight of boiling ether of 0·727, and crystallises on cooling in beautiful scales, of changing colours. It distils over *in vacuo* without alteration; but if the retort contains a little atmospheric air, a small portion of the acid is decomposed during the distillation; while the greater part passes over unchanged, but slightly tinged brown, and mixed with traces of empyreumatic oil. When heated in the open air, and kindled, stearic acid burns like wax. By analysis it is found to contain in 100 parts, carbon 75·6, hydrogen 12·6, and oxygen 11·8, which agrees with the formula $C^{36}H^{36}O^4$, and makes the atomic weight of it 284, the formula of its neutral salts being $C^{36}H^{35}NO^4$. Stearic acid displaces, at a boiling heat in water, carbonic acid from its combinations with the bases; but in operating upon an alkaline carbonate, a portion of the stearic acid is dissolved in the liquor before the carbonic acid is expelled. The decomposition is founded upon the principle, that the stearic acid transforms the salt into a bicarbonate, which is decomposed by the ebullition.

Stearic acid put into a strong watery infusion of litmus has no action upon it in the cold; but when hot, the acid combines with the alkali of the litmus, and changes its blue colour to red; so that it has sufficient energy to abstract from the concentrated tincture all the alkali required for its neutralisation. If we dissolve bi-stearate of potash in weak alcohol, and pour litmus water, drop by drop, into the solution, this will become red, because the litmus will give up its alkali to a portion of the bi-stearate, and will convert it into neutral stearate. If we now add cold water, the reddened mixture will resume its blue tint, and will deposit bi-stearate of potash in small spangles. In order that the alcoholic solution of the bi-stearate may redden the litmus, the alcohol should not be very strong.

The margaric and oleic acids seem to have the same neutralising power, and the same atomic weight.

The preceding numbers will serve to regulate the manufacture of stearic acid for the purpose of making candles. Potash and soda were first prescribed for saponifying fat, as may be seen in M. Gay-Lussac's patent, under the article CANDLE; and were it not for the cost of these articles, they are undoubtedly preferable to all others in a chemical point of view. Of late years lime has been had recourse to, with perfect success, and has become subservient to a great improvement in candle-making. Lime was first successfully used by De Milley in 1831. The stearine block now made by many London houses, though containing not more than 2 or 3 per cent. of wax, is hardly to be distinguished from the purified produce of the bee. The first process is to boil the fat with quicklime and water in a large tub by means of perforated steam pipes distributed over its bottom. From the above statement we see that about 11 parts of dry lime are fully equivalent to 100 of stearine and oleine mixed: but as the lime is in the state of hydrate, 14 parts of it will be required when it is perfectly pure; in the ordinary state, however, as made from average good limestone, 16 parts may be allowed. After a vigorous ebullition of 3 or 4 hours, the combination is pretty complete. The stearate being allowed to cool to such a degree as to admit of its being handled, becomes a concrete mass, which must be dug out with a spade, and transferred into a contiguous tub, in order to be decomposed with the equivalent quantity of sulphuric acid diluted with water, and also heated with steam. Four parts of concentrated acid will be sufficient to neutralise three parts of slaked lime. The saponified fat now liberated from the lime, which is thrown down to the bottom of the tub in a state of sulphate, is skimmed off the surface of the watery menstruum into a third contiguous tub, where it is washed with water and steam.

The washed mixture of stearic, margaric, and oleic acids, is next cooled in tin pans; then shaved by large knives fixed on the face of a fly-wheel, called a tallow cutter, preparatory to its being subjected in canvas or caya bags to the action of a powerful hydraulic press. Here a large portion of the oleic acid is expelled, carrying with it a little of the margaric. The pressed cakes are now subjected to the action of water and steam once more, after which the supernatant stearic acid is run off, and cooled in moulds. The cakes are then ground by a rotatory rasping-machine to a sort of mealy powder, which is put into canvas bags, and subjected to the joint action of steam and pressure in a horizontal hydraulic press of a peculiar construction, somewhat similar to that which has been long used in London for pressing spermaceti. The cakes of stearic acid thus freed completely from the margaric and oleic acids, are subjected to a final cleansing in a tub with steam, and then melted into hemispherical masses called blocks. When these blocks are broken, they display a highly crystalline texture, which would render them unfit for making candles. This texture is therefore broken down or comminuted by fusing the stearine in a plated copper pan, along with one thousandth part of pulverised arsenious acid, after which it is ready to be cast into candles in appropriate moulds. See Candle.

Moinier and Boutigny introduced a process by which the production of stearic acid has been considerably increased. Their process is thus described in *Chemical Technology*, by Ronalds and Richardson: — Two tons of tallow and 900 gallons of water are introduced into a large rectangular vat of about 270 feet capacity. The tallow is melted by means of steam admitted through a pipe coiled round the bottom, and the whole kept at the boiling point for an hour, during which a current of sulphurous acid is forced in. At the end of this period 6 cwt. of lime, made into milk with 350 gallons of water, are added. The mixture soon acquires consistence, and becomes frothy and viscid. The whole is now agitated, in order to regulate the ebullitions and prevent the sudden swelling up of the soapy materials. The pasty appearance of the lime soap succeeds, and it then agglomerates into small nodular masses. The admission of sulphurous acid is now stopped; but the injection of the steam is continued until the small masses become hard and homogeneous. The whole period occupies eight hours, but the admission of sulphurous acid is discontinued at the end of about three hours. The water containing the glycerine is run off through a tube into cisterns prepared to receive it. The arrangements for producing sulphurous acid, are retorts, into which are put sulphuric acid and pieces of wood; upon the application of heat the sulphurous acid passes off, and is conveyed by leaden pipes into the vessel containing the tallow. The lime soap formed is then moistened with 12 cwt. of sulphuric acid, at 152° Fahr., diluted with 50 gallons of water. The whole is thoroughly agitated, and the steam cautiously admitted, so as not to dilute the acid too much until the decomposition is general at all points. This occupies about three hours, and in two or three hours more the sulphate of lime has collected at the bottom, while the fatty acids are floating on the surface of the solution of the bisulphate of lime. Several processes of washing with steam and water are necessary to ensure the removal of the sulphate of lime, &c., and after settling for four hours, the fatty acids are forced through a fixed siphon into a vat, wherethey are again washed with water; they are then siphoned at last into a trough lined with lead, on the bottom of which are placed leaden gutters, pierced below by long pegs of wood. The fatty acids are then placed in cloths, and subjected to pressure in the stearine cold press as described below.

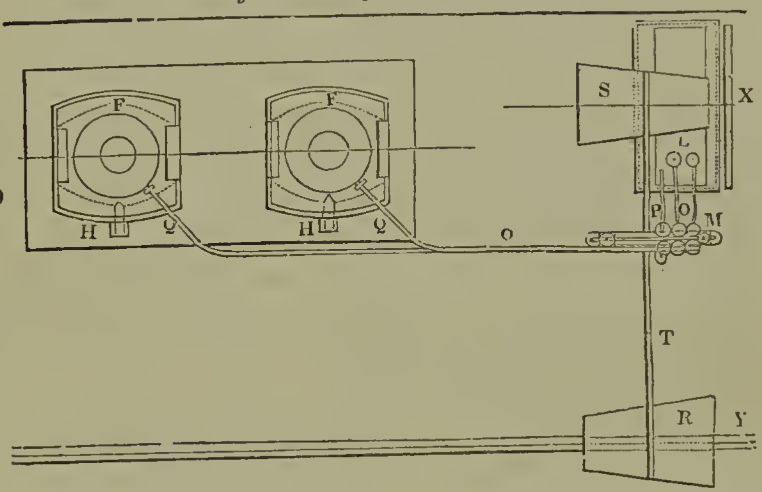
It is important for the fatty acids to cool slowly, as thus the confused crystallisation is prevented, and the expulsion of the oleic acid facilitated. When the cakes are solid they are placed between sacks of horsehair, and submitted to a second pressure at high temperature. The whole is covered with oilskin, and the temperature raised to 158°·5 Fahr., when pressure is applied. The heat slowly falls to 113° Fahr., and ultimately reaches 95° to 80° Fahr. This operation lasts about an hour. The cakes of stearic acid are sorted according to colour and transparency, and about 20 cwt. are then introduced into a vat constructed of wood lined with sheet iron. This is boiled by means of steam admitted through a leaden pipe, which is afterwards employed in heating a stove. Water acidulated is first employed, and afterwards pure water. When the materials are boiling, the whites of twenty-two eggs are introduced, and the albumen is intimately mixed by the violent ebullition. As soon as the albumen is coagulated, the whole is allowed to cool, and the stearic acid is removed to another apartment, where it is kept in a state of agitation to prevent the formation of crystals, and allow the cooling to be as gradual as possible. It is now fit for candles.

The cold hydraulic press, as mounted by Messrs. Maudslay and Field, for squeezing out the oleic acid from saponified fat, or the oleine from cocoa-nut lard, is represented in plan in *fig.* 1690, in side view of pump in *fig.* 1691, and in elevation, *fig.* 1692, where the same letters refer to like objects.

A, A, are two hydraulic presses; B, the frame; C, the cylinder; D, the piston or ram; E, the follower; F, the recess in the bottom to receive the oil; G, twilled woollen

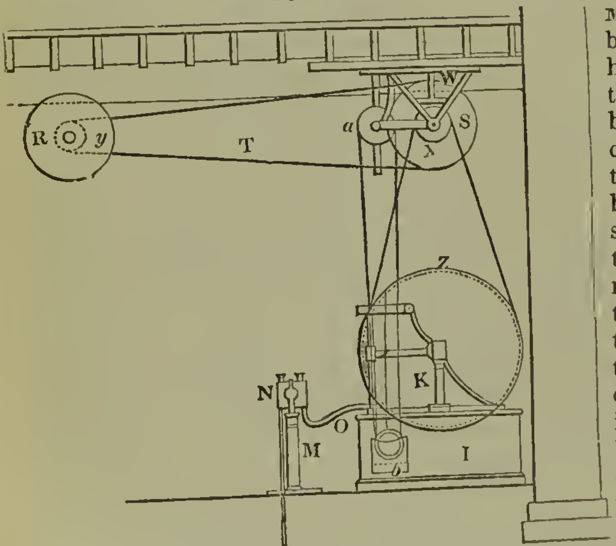
Scale of 3-20*ths of an inch to the foot.*

1690



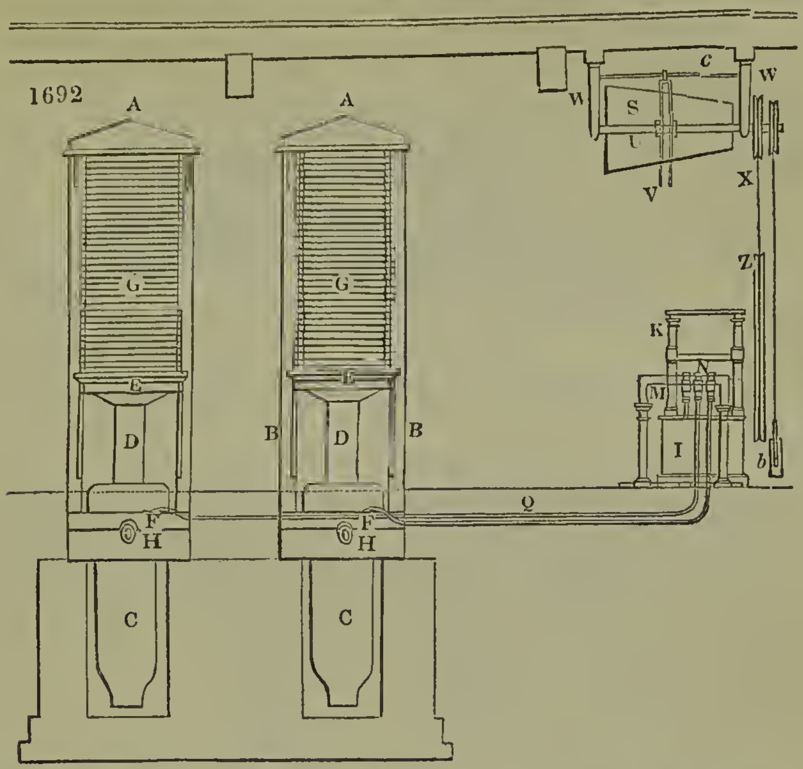
bags, with the material to be pressed, having a thin plate of wrought iron between each; H, apertures for the discharge of the oil; I, cistern in which the pumps are fixed; K, framing for machinery to work in; L, two pumps, large and small, to inject the water into the cylinders; M, a frame containing three double branches; N, three branches, each having two stops or plugs, by which the action of one of the pumps may be intercepted from, or communicated to, one or both of the presses; the large pump is worked at the beginning of the operation, and the small one towards the end; by these branches, one or both presses may be discharged when the operation is finished; O, two pipes from the pumps to the branches; P, pipe to return the water from the cylinders to the cisterns; Q, pipes leading from the pumps through the branches to the cylinders; R, conical drum, fixed upon the main shaft Y, driven by the steam-engine of the factory; S, a like conical drum to work the pumps; T, a narrow leather strap to communicate the motion from R to S; U, a long screw bearing a nut, which works along the whole length of the drum;

1691



V, the fork or guide for moving the strap T; W, W, two hanging bearings to carry the drum S; X, a pulley on the spindle of the drum S; Y, the main shaft; Z, fly-wheel

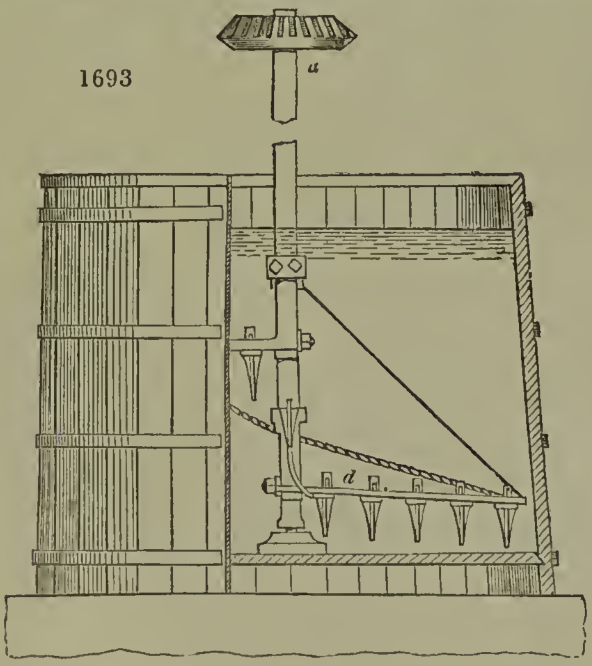
1692



with groove on the edge, driven by the pulley X; on the axis of S, is a double crank, which works the two pumps L. *a* is a pulley on the end of the long screw, U; an endless cord passes twice round this pulley, and under a pulley fixed in the weight, *b*; by laying hold of both sides of this cord, and raising or lowering it, the forked guide V, and the leather strap T, are moved backwards or forwards, by means of the nut fixed in the guide, so as to accelerate or retard at pleasure the speed of the working of the pumps; *c* is a piece of iron, with a long slit, in which a pin, attached to the fork V, travels, to keep it in the vertical position.

The accompanying *fig.* 1693, is a view both of the exterior and the interior

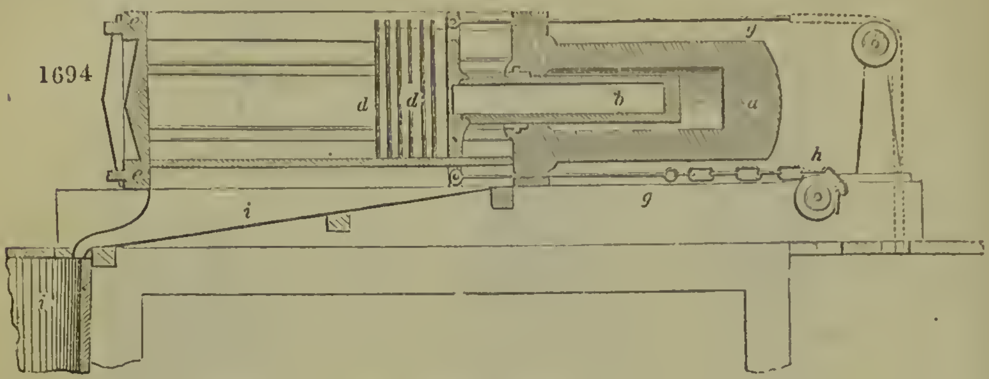
1693



of the saponifying tun of a stearine factory; where the constituents of the tallow are combined with quicklime, by the intervention of water and steam: *a* is the upright shaft of iron, turned by the bevel wheel above, in gear with another bevel wheel on the moving shaft, not shown in this figure. This upright shaft bears several arms, *d*, furnished with large teeth. The tun is bound with strong hoops of iron, and its contents are heated by means of a spiral tube laid on the bottom, perforated with numerous holes, and connected by a pipe with a high-pressure steam-boiler.

Fig. 1694 represents a longitudinal section of the horizontal hydraulic press for

1694



depriving stearic acid, as also spermaceti, of all their fluid oily impurities. *a* is the cylinder of the press; *b*, the ramor piston; *d d*, iron plates previously heated, inclosing hair and flannel bags and placed between every two cakes to facilitate the discharge of their oily matter; *e*, *e*, solid iron end of the press, made to resist great pressure; it is strongly bolted to the cylinder *a*, so as to resist the force of the ram; *g*, *g*, on rods for bringing back the ram *b* into its place after the pressure is over, by means of counter weights suspended to a chain, which passes over the pulleys *h*, *h*; *i*, *i*, a spout and a sheet-iron pan for receiving the oily fluid.

STEARINE (from στεαρ, tallow). The solid portions of fats are known by this term, the fluid portions being called *oleine* (from ἐλαιον, oleum, oil . If melted tallow be dissolved in about eight times its weight of ether, on cooling the oleine alone remains dissolved, the stearine crystallises, and can be rendered absolutely pure by washing with ether. Stearine is a solid transparent substance, easily reduced to powder. At one time stearine was an object of manufacture; but the production of stearic acid has superseded it. The process employed for the production of stearine was very simple. Tallow was melted, and by being kept quiet in the melted state all impurities subsided and were removed. Then the fluid and transparent tallow was allowed to cool as gradually as possible to the temperature of 100° Fahr. During the process of cooling the fluid mass is kept constantly agitated. At the above temperature, the stearine only becomes solid, separating from the oleine in a crystalline form, thickening the whole into a pasty mass. This is then placed in cloths and subjected to pressure in the hydraulic press. The oleine is absorbed by the cloths or drains off, and the stearine is eventually obtained in a solid cake, in many respects resembling spermaceti. Liebig and Pelouze consider stearine a salt of two bases. Water plays the part of one, while the other is the oxide of the radical *glyceryle* (C^6H^7) with 5 atoms of oxygen, which is contained in most fats, and is known in the form of a hydrate, $C^6H^7O^5 + HO$. See GLYCERINE.

STEATITE, or *Soapstone* (*Craie de Briancon*, Fr.; *Speckstein*, Germ.), is a mineral of the magnesian family, which has been grouped by Dana under the "Talc Section." It has a greyish-white or greenish-white colour, often marked with dendritic delineations, and occurs massive, as also in various supposititious crystalline forms; it has a dull or fatty lustre; a coarse splintery fracture, with translucent edges; a shining streak; it writes feebly; is soft, and easily cut with a knife; but somewhat tough; does not adhere to the tongue; feels very greasy; infusible before the blowpipe; specific gravity from 2·6 to 2·8. It is found frequently in small contemporaneous veins that traverse Serpentine in all directions, as at Portsoy, in Shetland, in the limestone of Icolmkiln, in the Serpentine of Cornwall, in Anglesey, in Saxony, Bavaria (at Bayreuth), Hungary, &c. It is used in the manufacture of porcelain. It makes the biscuit semi-transparent, but rather brittle, and apt to crack with slight changes of heat. It is employed for polishing serpentine, marble, gypseous alabaster, and mirror glass; as the basis of cosmetic powder; as an ingredient in anti-attrition pastes, sold under the name of FRENCH CHALK; the chemical composition is silica 62·14, magnesia 32·92, water 4·94, being sometimes contaminated with and coloured by a litttle iron, manganese, or chrome; it is dusted in powder upon the inside of boots, to make the feet glide easily into them; when rubbed upon grease-spots in silk and woollen clothes, it removes the stains by absorption; it enters into the composition of certain crayons, and is used itself for making traces upon glass, silk, &c. The spotted steatite, cut into cameos and calcined, assumes an onyx aspect. Soft steatite forms excellent stoppers for the chemical apparatus used in distilling or subliming corrosive vapours. Lamellar steatite is Talc. See Talc.

STEEL (*Acier*, Fr.; *Stahl*, Germ.) is a carburet of iron, more or less freed from foreign matter, and may be produced by two processes opposed to each other. First, by working pig iron, which contains 4 or 5 per cent. of carbon, in a suitable furnace, until such carbon is reduced to that quantity required for constituting steel, which is about 1 per cent; the second method is to heat iron bars in contact with charcoal, until they have absorbed that quantity of carbon which may be required.

Steel may be classed into three kinds.

1st. Natural steel which is manufactured from pig iron direct.

2nd. Cemented or converted steel, which is produced by the carbonisation of wrought iron.

3rd. Cast steel which is produced by the fusion of either natural or cemented steel, but principally from the latter.

The various kinds of iron which are used for the manufacture of steel are imported principally from Sweden, Norway, and Russia; but the high price of Swedish and other steel iron, has for the past few years compelled the consumers to look elsewhere for a supply of foreign made iron, whilst at the same time every encouragement has been offered to English manufacturers so to improve their steel irons as to render them at least suitable for the production of steel good enough for the manufacture of coach springs and such other purposes.

The following shows the importation of Swedish iron from 1845 to 1854:—

	Tons.		Tons.
1845 - - -	18,407	1850 - - -	28,096
1846 - - -	30,840	1851 - - -	35,467
1847 - - -	28,264	1852 - - -	23,817
1848 - - -	20,438	1853 - - -	23,540
1849 - - -	26,605	1854 - - -	24,436

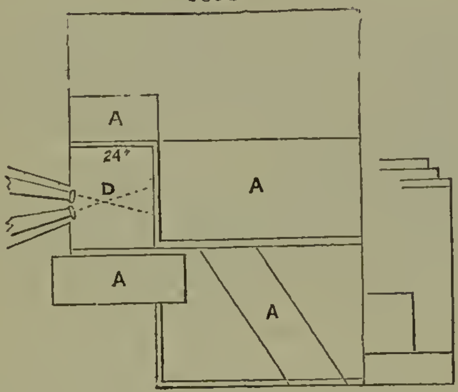
The above forms an average for ten years of 26,011 tons to which must be added 8 to 10,000 tons which comes from Russia and Norway, or 35,000 tons per annum.

England now furnishes a large quantity of iron suitable for steel purposes, which may be estimated at 20,000 tons per annum; this iron is manufactured with great care often with an admixture of charcoal pig iron, and various chemical reactives, which are added at the caprice of each manufacturer, but the object of which is to discharge the deleterious matters and to reduce the semi-metals.

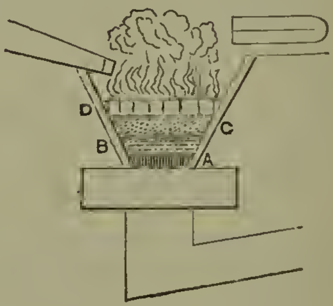
It is of the highest importance that the iron used for steel purposes should be as pure and free from foreign matters as possible; those irons which at present enjoy the highest reputation are those manufactured from the Dannemora ores in Sweden; the whole of the steel irons produced in that country are smelted from the black oxides, containing usually 60 per cent. of metal. The present price of the first marks of iron produced in Sweden are for ⓘ 33*l.*, G_L 32*l.*, GO 30*l.*; of the second marks, G_F 28*l.*, $\overset{3}{W}$ 26*l.*, B 26*l.*; there are others selling from 22*l.* to 16*l.* per ton, whilst the common Swedish steel iron may be estimated at 14*l.* per ton. The Russian iron marked K Ь and IOP3 is largely imported, and sells at 18*l.* per ton; it is produced in the Ural district of Russia. The price of English made steel iron is on an average 11*l.* per ton.

Natural or German steel is so called because it is produced direct from pig iron, the result of the fusion of the spathose iron ores alone, or in a small degree mixed with the brown oxide; these ores produce a highly crystalline metal called spiegle-eisen on account of the large crystals the metal presents. This crude iron contains 4 to 5 per cent. of carbon, and 4 to 5 per cent. of manganese. Karsten, Hassengratz, Marcher, and Reaumur, all advocate the use of grey pig iron for the production of steel; indeed they distinctly state that the best qualities cannot be produced without it; they state correctly that the object of working it in the furnace is to clear away all foreign matters, but there can be no advantage gained by retaining the carbon, and combining it with the iron. This theory is incorrect, although it is supported by such high authorities; grey iron contains the maximum quantity of carbon, and consequently remains for a longer time in a state of fluidity than iron containing less carbon; the metal is not only mixed up with the foreign matter it may itself contain, but also that with which it may become mixed in the furnace in which it is worked. This prolonged working, which is necessary in order to bring highly carbonised metal into a malleable state, increases the tendency to produce silicated oxides of iron; these mixing with the steel produced renders it red short, and destroys many good qualities which the pig iron may have originally possessed. The semi-metals produced tend also to prevent malleability; the use of highly carbonised *white pig iron* is equally inapplicable, and causes a large consumption of charcoal, as well as waste of metal. In Austria, where a large quantity of natural steel is produced, the fluid metal is tapped from the blast furnace into a round hole; water is sprinkled on the surface which chills it, and thus forms a cake about half an inch thick. This is taken from the surface, and the operation is again performed until the whole is formed into cakes, they are then piled edgewise in a furnace, and covered with charcoal, and heated a full red heat for about 48 hours; by this process much of the carbon is discharged. These cakes are then used for producing steel in the refinery. A much superior quality is thus obtained with greater economy. It appears that the most perfect plan for manufacturing the steel is to free the crude metal as much as possible from its impurities whilst in a fluid state. There is a process patented by Mr. Charles Sanderson of Sheffield, which fulfils all that is required. The crude metal is melted on the bed of a reverberatory furnace, and any chemical re-agent is added capable of disengaging oxygen during its decomposition. Carbonic acid or carbonic oxide gases are produced by the union of the oxygen with the carbon contained in the fluid iron which is thus eliminated; the gases so produced, being unable to re-enter the metal, either pass off in vapour, or act upon the silicates or other earthy compounds which the crude iron may contain, precipitating the metallic part and allowing the earthy matter to flow away as slag: a refined metal is thus produced of very great purity for the production of steel. The metal itself being to some extent decarbonised, the steel is more quickly produced, which secures economy in charcoal, time, and waste of metal, &c.; the purity of the metal also prevents the formation of those deleterious compounds, which, when they are incorporated with the steel seriously injure the quality. Natural steel manufactured from this purified iron has been found of very superior quality, and more uniform. The furnaces used for the production of natural steel are like the refineries in which charcoal iron is produced. In all countries their *general* construction is the same, but each has its own peculiar mode of working. We find therefore, the German, the Styrian, the Carinthian, and several other distinct methods, yet all producing steel from crude iron directly,

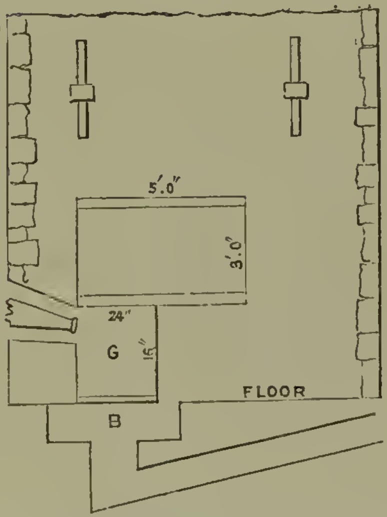
1695



1697



1696



although pursuing different modes of operation. These differences arise from the nature of the pig iron each country produces, and the peculiar habits of the workmen.

These modified processes do not affect the *theory* of the manufacture of the steel, but rather accommodate themselves to the peculiar character of the metal produced.

Fig. 1695 shows a ground-plan of the furnace; *fig.* 1696 an elevation; and *fig.* 1697 the form of the fire itself and the position of the metal within it. The fire, D, is 24 inches long and 24 inches wide; A, A, A are metal plates, surrounding the furnace.

Fig. 1696 shows the elevation, usually built of stone, and braced with iron bars. The fire, G, is 16 inches deep and 24 inches wide; before the tuyère, at B, a space is left under the fire, to allow the damp to escape, and thus keep the bottom dry and hot.

In *fig.* 1695 there are two tuyères, but only one tuyère iron, which receives both the blast nozzles, which are so laid and directed that the currents of air cross each other, as shown by the dotted lines; the blast is kept as regular as possible, so that the fire may be of one uniform heat, whatever intensity may be required.

Fig. 1697 shows the fire itself, with the metal, charcoal, and blast. A is a bottom of charcoal, rammed down very close and hard. B is another bottom, but not so closely beaten down; this bed of charcoal protects the under one, and serves also to give out carbon to the loop of steel during its production. C is a thin stratum of metal, which is kept in the fire to surround the loop. D shows the loop itself in progress.

When the fire is hot, the first operation is to melt down a portion of pig iron, say 50 to 70 pounds according as the pig contains more or less carbon; the charcoal is pushed back from the upper part of the fire, and the blast, which is then reduced, is allowed to play upon the surface of the metal, adding from time to time some hammer slack, or rich cinder, the result of the previous loop. All these operations tend to *decarbonise* the metal to a certain extent; the mass begins to thicken, and at length becomes solid. The workman then draws together the charcoal and melts down another portion of metal upon the cake; this operation renders the face of the cake again fluid, but the operation of decarbonisation being repeated in the second charge, it also thickens, incorporates itself with the previous cake, and the whole becomes hard; metal is again added until the loop is completed. During these successive operations, the loop is never raised before the blast, as it is in making iron, but it is drawn from the fire and hammered into a large bloom, which is cut into several pieces, the ends being kept separated from the middle or more solid parts, which are the best.

This operation, apparently so simple in itself, requires both skill and care; the workman has to judge, as the operation proceeds, of the amount of carbon which he has retained from the pig iron; if too much, the result is a very raw, crude, untreatable steel; if too little, he obtains only a steelified iron; he has also to keep the cinder at a proper degree of fluidity, which is modified from time to time by the addition of quartz, old slags, &c. It is usual to keep from two to three inches of cinder on the face of the metal, to protect it from the direct action of the blast. The fire itself is formed of iron plates, and the two charcoal bottoms rise to within nine inches of the tuyère, which is laid flatter than when iron is being made. This position of the tuyère causes the fire to work more slowly, but it insures a better result.

The quantity of blast required is about 180 cubic feet per minute. Good workmen make 7 cwt. of steel in 17 hours. The waste of the pig iron is from 20 to 25 per cent., and the quantity of charcoal consumed is 240 bushels per ton. The inclination of the tuyère is 12 to 15 degrees. The flame of the fire is the best guide for the workmen. During its working it should be a red bluish colour. When it becomes white the fire is working too hot.

From this description of the process, it will be evident that pig iron will require a much longer time to decarbonise than the cakes of metal which have been roasted, as already described; and, again, it must be evident, that a *purified* and *decarbonised* metal, must be the best to secure a good and equal quality to the steel, since the purified metal is more homogeneous than the crude iron.

When, therefore, care has been taken in melting down each portion of metal, and a complete and perfect layer of steel has been obtained after each successive melting, when the cinder has had due attention, so that it has been neither too thick nor too thin, and the heat of the fire regulated and modified during the progressive stages of the process, then a good result is obtained; a fine-grained steel is produced, which draws under the hammer, and hardens well. However good it may be, it possesses one great defect; it is this. During its manufacture, *iron* is produced along with the steel, and becomes so intimately mixed up with it, that it injures the otherwise good qualities of the steel; the iron becomes, as it were, interlaced throughout the mass, and thus destroys its hardening quality. When any tool or instrument is made from natural steel, without it has been well refined, it will not receive a *permanent* cutting edge; the iron part of the mass, of course, not being hard, the tool cuts only upon the steel portion, the edge, therefore, very soon becomes destroyed. There is another defect in natural steel, but it is of less importance. When too much carbon has been left, the steel is raw and coarse, and it draws very imperfectly under the hammer; the articles manufactured from such steel often break in hardening; thus it is evident, that in producing this kind of steel, every care, skill, and attention is required at the hands of the workman. These defects very materially affect the commercial value of the steel; the irregular quality secures no guarantee to the consumer that the tools shall be perfect, and, consequently, it is not used for the most important purposes; yet, when the raw steel is refined, it becomes a very useful metal, and is largely used in Westphalia for the manufacture of hardware, scythes, and even swords. It possesses a peculiarity of retaining its steel quality after repeated heating. This property renders it very useful for mining and many other purposes.

The raw steel, being so imperfect, is not considered so much an article of commerce with the manufacturer, but it is sold to the steel refiners, who submit it to a process of welding. The raw steel bloom is drawn into bars, one or two inches wide and half an inch thick, or less; a number of these are put together and welded; these bars are then thrown into water, and they are broken in smaller pieces to examine the fracture; those bars which are equally steelified are mixed together. In manufacturing refined steel, the degree of hardness is selected to suit the kind of article which it is intended to make. A bar, two to three feet long, forms the top and bottom of the bundle, but the inside of the packet is filled with the small pieces of selected steel. This packet is then placed in a hollow fire, and carefully covered from time to time with pounded clay, to form a coat over the metal, and preserve it from the oxidising influence of the blast. When it is at a full welding heat it is placed under a hammer, and made as sound and homogeneous as possible; it is again cut, doubled together, and again welded. For very fine articles, the refining is increased by several doublings, but this is not carried at present to so great an extent as formerly, since cast steel is substituted, being in many cases cheaper. Although the refined natural steel is very largely consumed in Germany, and also in Austria, yet a considerable quantity is exported to South America, the United States, and to Mexico. The Levant trade takes a large portion, and is supplied from the Styrian and Carinthian forges. This is shipped from Trieste; it is sold in boxes and bundles. That in boxes is marked No. 00, up to 4. The 00 is the smallest, being about $\frac{1}{4}$ in. square; number 4 is about $\frac{1}{2}$ in.; 0, 1, 2 and 3, being the intermediate sizes. It is broken in small pieces, about 3 to 7 inches long. In bundles of 100 lbs. the steel is drawn to various sizes, and is so packed. A large portion is sent to the East Indies, and also to the United States.

The average price of that sold in boxes is 20*l.* to 24*l.* per ton; in bundles, 17*l.* to 20*l.*; and the raw steel, as sold to the refiners, 15*l.* to 18*l.* per ton; whilst the refined steel increases in price according to the number of times it has been refined.

Natural steel being expensive many attempts were made in Westphalia to produce a kind of steel by puddling pig iron in a peculiar manner; a patent was taken out in England by Mr. Riepe, and a considerable quantity of this steel is produced. In Mr. Riepe's description of this process he says:—

"I employ the puddling furnace in the same way as for making wrought iron. I introduce a charge of about 280 lbs. of pig iron, and raise the temperature to redness. As soon as the metal begins to fuse and trickle down in a fluid state, the damper is to be partially closed in order to temper the heat. From 12 to 16 shovelfuls of iron cinder discharged from the rolls or squeezing machine are added, and the whole is to be uniformly melted down. The mass is then to be puddled with the addition of a little black oxide of manganese, common salt, and dry clay, previously ground together. After this mixture has acted for some minutes, the damper is to be fully opened, when about forty pounds of pig iron is to be put into the furnace, near the fire bridge, upon elevated beds of cinder prepared for that purpose. When this pig iron begins to trickle down, and the mass on the bottom of the surface begins to boil and throw out from the surface the well-known blue jets of flame, the said pig iron is raked into the boiling mass, and the whole is then well mixed together. The mass soon begins to swell up, and the small grains begin to form in it and break through the melted cinder on the surface. As soon as these grains appear, the damper is to be three-quarters shut, and the process closely inspected while the mass is being puddled to and fro beneath the covering layer of cinder. During the whole of this process the heat should not be raised above cherry redness, or the welding heat of shear steel. The blue jets of flame gradually disappear, while the formation of grains continues, which grains very soon begin to fuse together, so that the mass becomes waxy, and has the above mentioned cherry redness. If these precautions are not observed, the mass would pass more or less into iron, and no uniform steel product could be obtained. As soon as the mass is finished so far, the fire is stirred to keep the necessary heat for the succeeding operation—the damper is to be entirely shut, and part of the mass is collected into a ball, the remainder always being kept covered with cinder slack. This ball is brought under the hammer, and then worked into bars. The same process is continued until the whole is worked into bars. When I use pig iron made from sparry iron ore, or mixtures of it with other pig iron, I add only about 20 lbs. of the former pig iron at the later period of the process, instead of about 40 lbs. When I employ Welsh or pig iron of that description, I throw 10 lbs. of best plastic clay, in a dry granulated state, before the beginning of the process, on the bottom of the furnace. I add at the later period of the process, about 40 lbs. of pig iron as before described, but strew over it clay in the same proportion as just mentioned."

This steel is very useful for ships' plates, being very strong and rigid, and thus requiring less weight of metal; it may also eventually be used for rails and a great variety of purposes, for which at present strong charcoal or scrap iron is used. Its present price is about 25*l.* in plates, and 16*l.* in bars.

The Paal process may be considered as an improvement upon natural steel, the object being as far as possible to carbonise the iron fibres which this kind of steel always contains. The process is based upon the old one of Vanaccio; it consists in plunging iron into a bath of melted metal. The carbon of the metal combines with the iron, and in a very short time converts it into steel. This process was carried further by Vanaccio, who contrived to add wrought iron to the metal until he had decarbonised it sufficiently; this was found to produce a steel, but unfit for general use. That produced by plunging iron into metal was found to be very hard steel on the outside, but iron within; while that produced by adding iron to the metal was found too brittle to be drawn. The Paal method, however, is a decided improvement in the manufacture of refined natural steel. The packets, as already described in the refinement of natural steel, are welded and drawn to a bar; whilst hot they are plunged into a bath of metal for a few minutes, by which the iron contained in the raw steel becomes carbonised, and thus a more regular steel is obtained than that produced by the common process. The operation requires great care, for if the bars of steel be left in the metal too long they are more or less destroyed, or perhaps entirely melted. It commands a little higher price in the market, and is chiefly consumed by the home manufacturers, excepting a portion which is exported to Russia.

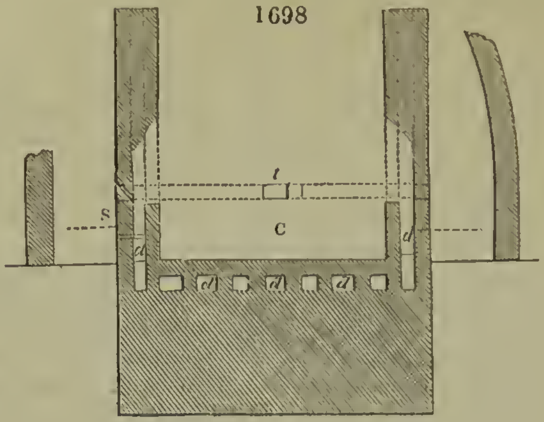
The foregoing kinds of steel may be classed under the first head of natural steel, being manufactured from the *crude iron direct.*

The next process is the production of steel by introducing carbon into malleable iron which is the reverse of the process already described. The iron to be converted is placed in a furnace, stratified with carbonaceous matter, and on heat being applied the iron absorbs the carbon, and a new compound is thus formed.

When this process was discovered is not known; at a very early period charcoal was found to harden iron, and to give it a better and more permanent cutting edge. It seems probable that from hardening small objects, bars of iron were afterwards submitted to the same process. To Reaumur certainly belongs the merit of first bringing the process of conversion to any degree of perfection. His work contains a vast amount of information upon the the theory of cementation; and although his investigations are not borne out by the practice of the present day, yet the first principles laid down by him are now the guide of the converter. Our furnaces are much larger than those used by Reaumur, and they are built so as to produce a more uniform and economical result. The furnace of cementation in which bar iron is converted into blistered steel is represented in *figs.* 1698, 1699, 1700.

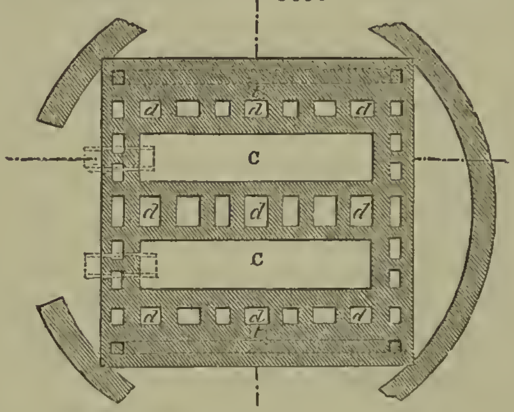
It is rectangular, and covered in by a semicircular arch, in the centre of which there is a circular hole left, 12 inches diameter, which is opened when the furnace is cooling. It contains two chests called "pots," C, C, made either of fire-stone or fire-bricks; each "pot" is 3 feet wide, 3 feet deep, and 12 feet long. One is placed on one side, and the other, on the contrary side of the fire-grate, A B, which occupies the whole length of the furnace, and is 13 to 14 feet long; the grate is 15 to 16 inches broad, and the bars rest from 10 to 12 inches below the inferior plane or bottom level of the "pots;" the height of the arch at the centre is 5½ feet above the top of the "pots," the bottoms of which are nearly level with the ground, so that the bars of iron do not need lifting so high when charging them into the furnace. The flame rises between the two "pots;" it passes also below and around them, through the horizontal and vertical flues, *d*, and issues from the furnace through the six small chimneys, H, into a large conical space which is built around the whole furnace, 30 to 40 feet high, open at the top. This cone increases the draft of the furnace, and carries away the smoke. There are three openings in the front of the arch; two, T, *fig.* 1700, above the pots serve to admit and remove the bars; they are about 8 inches square; in each a piece of iron is placed upon which the bars slide in and out of the furnace. The workman enters by the middle opening, P, to arrange the bars, which he lays flat in the pots and spread as layer of charcoal, ground small, between each layer; the bars are laid near each other, excepting those next to the side of the pot, which are placed an inch from it; the last stratum of iron is covered with a thick layer of charcoal, and the whole is carefully covered with loamy earth 4 to 5 inches thick. The iron is gradually heated, in about 4 days has become fully heated through, and the furnace

1698



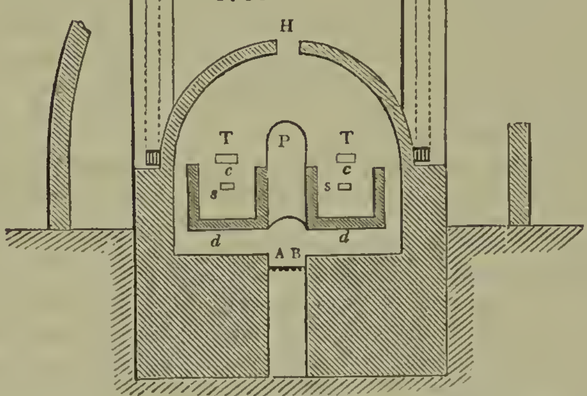
has then attained its maximum heat, which is maintained for 2 or 3 days until the first test bar is drawn out; the heat is afterwards regulated, according to the degree

1699



of hardness which may be required. The iron is converted in 8 days if for soft steel, and in 9 to 11 days if for harder purposes.

1700



Conversion usually commences in 60 to 70 hours after the furnace is lighted. The pores of the iron being opened by heat, the carbon is gradually absorbed by the mass of the bar, but the *carbonisation* or conversion is effected, as it were, in layers. To explain the theory in the clearest manner, suppose a bar to be composed of a number of laminæ—the combination of the carbon with the iron is first effected on the surface, and gradually extends from one lamina to another, until the whole is carbonised. To effect this complete carbonisation the iron requires to be kept at a considerable uniform heat for a length of time. Thin bars of iron are much sooner converted than thick ones. Reaumur states, in his experiments, that if a bar of iron 3-16ths of an inch thick is converted in 6 hours, a bar 7-16ths of an inch would require 36 hours to attain the same degree of hardness. The carbon introduces itself *successively*, the first lamina or surface of a bar combining with a portion of the carbon with which it is in contact, gives a portion of the carbon to the second lamina, at the same time taking up a fresh quantity of carbon from the charcoal; these successive combinations are continued until the whole thickness is converted; from which theory it is evident that from the exterior to the centre the dose of carbon becomes proportionately less. Steel so produced cannot be said to be perfect; it possesses in some degree the defect of natural steel, being more carbonised on the surface than at the centre of the bar. From this theory we perceive that steel made by cementation is different in its character from that produced directly from crude metal. In conversion the carbon is made successively to penetrate to the centre of the bar, whilst in the production of natural steel, the molecules of metal which compose the mass are *per se* charged with a certain percentage of carbon necessary for their steelification; not imbibed, but obtained by the decarbonisation of the crude iron down to a point requisite to produce steel.

During the process of cementation, the introduction of the carbon disintegrates the molecules of the metal, and in the harder steel produces a distinct crystallisation of a white silvery colour. Wherever the iron is unsound or imperfectly manufactured, the surface of the steel becomes covered with blisters thrown up by the dilation of the metal and introduction of carbon between those laminæ which are imperfectly welded. Reaumur and others have attributed this phenomena to the presence of sulphur, various salts, or zinc, which dilate the metal; but this is incorrect, because we find that a bar of cast steel which is homogeneous and perfectly free from internal imperfections never blisters, for although it receives the highest dose of carbon in the furnace, yet the surface is perfectly smooth. From this it is evident that the blisters are occasioned by imperfections in the iron. Iron increases, both in length and weight, during conversion. Hard iron increases *less* than soft. The augmentation in weight may be said to be $\frac{1}{200}$, and in length $\frac{1}{120}$, on an average.

The operation of conversion is extremely simple in its manipulation, nevertheless, it requires great care, and a long as well as a varied experience, to enable a manager to produce every kind or temper required by consumers. Considerable knowledge is required to ascertain the nature of the irons to be converted, because all irons do not convert equally well under the same circumstances; some require a different treatment from others, and, again, one iron may require to be converted at a different degree of heat from another. The furnace must have continual care, and be kept air-tight, so that the steel, when carbonised, may not again become oxidised. It is known amongst steel-makers, that if iron be brought in contact with carbon, and if heat be applied, it will become steel. This is the knowledge gleaned up by workmen, and also by too many owners of converting furnaces. The inconvenience arising from a want of care and knowledge of the peculiar state of the iron *during* its conversion, sometimes occasions great disappointment and loss. The success usually attained by workmen may, however, be attributable to an everyday attention to one object, thus gaining their knowledge from experience alone. The conversion or carbonisation of the iron, is the foundation of steel making, and, as such, may be considered as the first step in its manufacture. Before bar steel is used for manufacturing purposes, it has to be heated, and hammered or rolled. Its principal uses are for files, agricultural implements, spades, shovels, wire, &c., and in very large quantities for coach-springs.

Bar steel is also used for manufacturing shear steel. It is heated, drawn to lengths 3 feet long, then subjected to a welding heat, and some six or eight bars are welded together, precisely as described in the refinement of natural steel; this is called single shear. It is further refined by doubling the bar, and submitting it to a second welding and hammering; the result is a clearer and more homogeneous steel. During the last seven years the manufacture of this steel has been limited, mechanics preferring a soft cast steel, which is much superior, when properly manufactured, and which can be very easily welded to iron.

The price of bar steel varies according to the price of the iron from which it is made, but, as a general average, its price in commerce may be taken at 5*l.* per ton beyond the price of the iron from which it is made. Bar steel produced from the better irons is usually dearer than the commoner kind, on account of their scarcity.

Shear steel in ordinary size sells at 60*l.* per ton net.
Coach-spring steel from foreign iron, 22*l.* ,,
Coach-spring steel from English iron, 18*l.* ,,

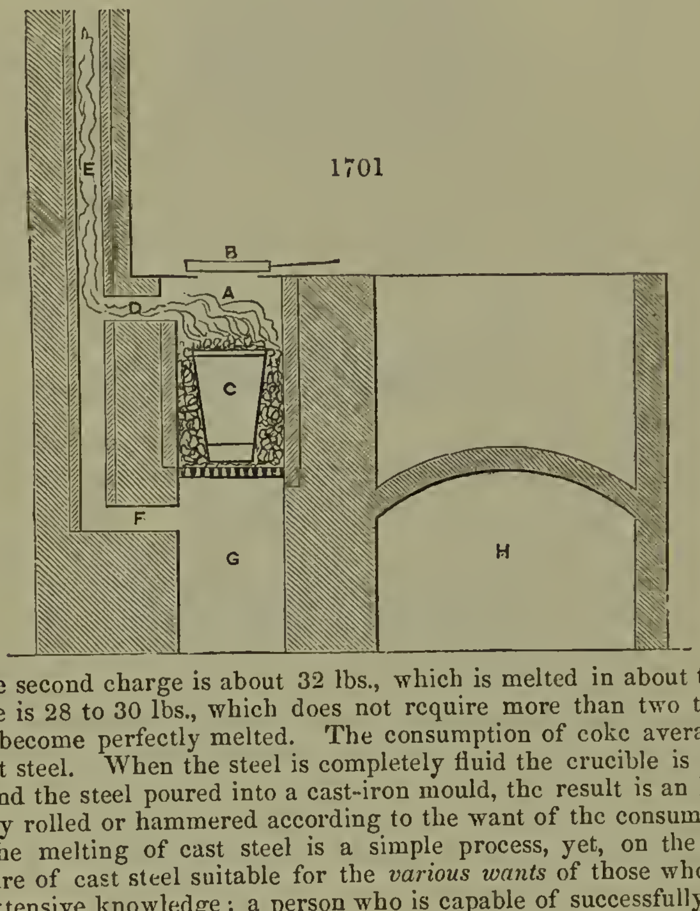
These may be taken as approximate prices in 1859-60.

Both natural, puddled, and converted steel have great defects in temper, clearness, and uniformity, and are unfit for most useful purposes. To obviate these defects, these steels are broken in pieces and melted in a crucible, thus freeing them from any deleterious matter they might contain; equality in texture and degree of hardness is thus obtained, whilst the steel is also capable of receiving a clear and beautiful polish.

The process of melting bar steel, and thus producing cast steel, was first practically carried on by Mr. Huntsman of Attercliffe; the process itself is very simple. *Fig.* 1701 shows a cross section of the furnace universally used.

The furnace A, is square, lined with fire-stone 12 inches by 22 wide, and 36 inches deep from the grate bar to the under side of the cover B. C is a crucible, of which two are placed in one "melting hole." D is the flue into the chimney, E, which is about 40 feet high, lined with fire-brick. There is an air flue which is used to regulate the draught at F. G is the ashpit, and H the cellar which is arched over.

The steel is broken in pieces and charged into the crucible, which is placed on a stand and provided with a cover; coke is used as a fuel, and an intense heat is obtained. The crucible is charged three times during the day, and is then burnt through; the first charge is usually 36 lbs., which requires from three to four hours



to melt it; the second charge is about 32 lbs., which is melted in about three hours; the last charge is 28 to 30 lbs., which does not require more than two to two and a half hours to become perfectly melted. The consumption of coke averages $3\frac{1}{2}$ tons per ton of cast steel. When the steel is completely fluid the crucible is drawn from the furnace, and the steel poured into a cast-iron mould, the result is an ingot, which is subsequently rolled or hammered according to the want of the consumer.

Although the melting of cast steel is a simple process, yet, on the other hand, the manufacture of cast steel suitable for the *various wants* of those who consume it requires an extensive knowledge; a person who is capable of successfully conducting a manufactory, must make himself master of the treatment to which the steel in manufactures will be submitted by every person who consumes it. Cast steel is not only made of many degrees of hardness, but it is also made of different qualities; a steel maker has, therefore, to combine a very intimate knowledge of the exact intrinsic quality of the iron he uses, or that produced by a mixture of two or three kinds together; he has to secure as complete and as equal a degree of carbonisation as possible, which can only be attained by possessing a perfect practical and theoretical knowledge of the process of converting; he has to know that the steel he uses is equal in hardness, in which without much practice he may easily be deceived; he must give his own instruction for its being carefully melted, and he must examine its fracture by breaking off the end of each ingot, and exercise his judgment whether or not proper care has been taken; besides all this knowledge and care, a steel maker has to adapt the *capabilities* of his steel to the *wants* and *requirements* of the consumer. There are a vast variety of defects in steel as usually manufactured; but there are a far greater number of instances in which steel is *not adapted* for the manufacture of the article for which it was expressly made. Cast steel may be manufactured for planing, boring, or turning tools; its defects may be, that the tools when made crack in the process of hardening, or that the tool whilst exceedingly strong in one part, will be found in another part utterly useless.

Cast steel may be wanted for the engraver. It may be produced apparently perfect, and with a clear surface, but may be so improperly manufactured, that when the plate has been engraved and has to be hardened, it is found covered with soft places. The trial is even greater when the engraving is transferred by pressure to another plate. It is, therefore, evident that a steel maker must not only attend to the intrinsic quality of his steel, but he has to use his judgment as regards the degree of hardness and tenacity which it should possess, so as to *adapt it to the peculiar requisites of its employment.*

The manufacture of cast steel is open to great temptations, which may be termed fraudulent. Swedish iron, as I have already stated, varies in price according to its usefulness for steel purposes; cast steel may, therefore, be manufactured from a metal selling at 20*l.* per ton, whilst the price charged for it to the consumer presumes it to have been made from a metal worth 30*l.* per ton. The exterior of the bar is perfect, the fracture appears to the eye satisfactory, and its intrinsic value is only discovered when it is put to the test; thus, whilst a steel maker has to exercise his knowledge, judgment, and care, he has a moral duty to perform, by giving to his customer a metal of the intrinsic value he professes it to be, and for which he makes his charge.

In manufacturing the commoner description of steel, particularly cast steel made from English iron, black oxide of manganese is added to the steel in the crucible, and acts as a detergent. The oxygen unites with a portion of the carbon in the steel, forming carbonic oxide gas, which acts upon the imperfectly metallic portions of the steel used, and liberates the metal whilst the deleterious matter is taken up and forms a slag with the manganese. There has been a great controversy regarding the invention which originated with Mr. Heath. This substance is not generally used when the Dannemora irons are melted, as they are very pure, and the addition of an oxide partially destroys the temper of the steel. The Indian steel, or wootz, is also a cast steel.

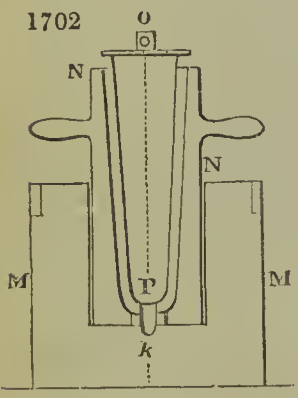
Indian steel, or wootz. — The wootz ore consists of the magnetic oxide of iron, united with quartz, in proportions which do not seem to differ much, being generally about 42 of quartz and 58 of magnetic oxide. Its grains are of various size, down to a sandy texture. The natives prepare it for smelting by pounding the ore. and winnowing away the stony matrix, a task at which the Hindoo females are very dexterous. The manner in which iron ore is smelted and converted into wootz or Indian steel, by the natives at the present day, is probably the very same that was practised by them at the time of the invasion of Alexander; and it is a uniform process, from the Himalaya mountains to Cape Comorin. The furnace or bloomery in which the ore is smelted is from 4 to 5 feet high; it is somewhat pear-shaped, being about 2 feet wide at bottom, and 1 foot at top; it is built entirely of clay, so that a couple of men can finish its erection in a few hours, and have it ready for use the next day. There is an opening in front about a foot or more in height, which is built up with clay at the commencement, and broken down at the end of each smelting operation. The bellows are usually made of a goat's skin, which has been stripped from the animal without ripping open the part covering the belly. The apertures at the legs are tied up, and a nozzle of bamboo is fastened in the opening formed by the neck. The orifice of the tail is enlarged and distended by two slips of bamboo. These are grasped in the hand, and kept close together in making the stroke for the blast; in the returning stroke they are separated to admit the air. By working a bellows of this kind with each hand, making alternate strokes, a pretty uniform blast is produced. The bamboo nozzles of the bellows are inserted into tubes of clay, which pass into the furnace at the bottom corners of the temporary wall in front. The furnace is filled with charcoal, and a lighted coal being introduced before the nozzles, the mass in the interior is soon kindled. As soon as this is accomplished, a small portion of the ore, previously moistened with water, to prevent it from running through the charcoal, but without any flux whatever, is laid on the top of the coals, and covered with charcoal to fill up the furnace.

In this manner ore and fuel are supplied; and the bellows are urged for 3 or 4 hours, when the process is stopped; and the temporary wall in front being broken down, the bloom is removed by a pair of tongs from the bottom of the furnace. It is then beaten with a wooden mallet, to separate as much of the scoriæ as possible from it, and, while still red hot, it is cut through the middle, but not separated, in order merely to show the quality of the interior of the mass. In this state it is sold to the blacksmiths, who make it into bar iron. The proportion of such iron made by the natives from 100 parts of ore is about 15 parts. In converting the iron into steel, the natives cut it into pieces, to enable it to pack better in the crucible, which is formed of refractory clay mixed with a large quantity of charred husk of rice. It is seldom charged with more than a pound of iron, which is put in with a proper weight of dried wood chopped small, and both are covered with one or two green leaves; the proportions being in general 10 parts of iron to 1 of wood and leaves. The mouth of the crucible is then stopped with a handful of tempered clay, rammed in very closely, to exclude the air. The wood preferred is the *Cassia auriculata*, and the leaf that of the *Asclepias gigantea*, or the *Convolvulus laurifolius.* As soon as the clay plugs of the crucibles are dry, from twenty to twenty-four of them are built up in the form of an arch, in a small blast furnace; they are kept covered with charcoal, and subjected to heat urged by a blast for about two hours and a half, when the process is considered to be complete. The crucibles being now taken out of the furnace and allowed to cool, are broken, and the steel is found in the form of a cake, rounded by the bottom of a crucible. When the fusion has been perfect, the top of the cake is covered with striæ, radiating from the centre, and is free from holes and rough projections; but if the fusion has been imperfect, the surface of the cake has a honeycomb appearance, with projecting lumps of malleable iron. On an average, four out of five cakes are more or less defective. These imperfections have been tried to be corrected in London by remelting the cakes, and running them into ingots; but it is obvious that when the cakes consist partially of malleable iron and of unreduced oxide, simple fusion cannot convert them into good steel. When care is taken, however, to select only such cakes as are perfect, to remelt them thoroughly, and tilt them carefully into rods, an article has been produced which possesses all the requisites of fine steel in an eminent degree. In the Supplement to the Encyclopædia Britannica, article *Cutlery*, the late Mr. Stoddart, of the Strand, a very competent judge, has declared "that for the purposes of fine cutlery, it is infinitely superior to the best English cast steel."

The natives prepare the cakes for being drawn into bars by annealing them for several hours in a small charcoal furnace, actuated by bellows; the current of air being made to play upon the cakes while turned over before it; whereby a portion of the combined carbon is probably dissipated, and the steel is softened; without which operation the cakes would break in the attempt to draw them. They are drawn by a hammer of a few pounds weight.

Fig. 1702 represents the mould for making the crucibles: each manufacturer makes his own; M, M, is a solid block of wood let into the floor, having a hole which admits a round piece of iron fixed in the centre of the plug P. The material of which the crucible is made consists of 22 lbs. of fire-clay got from Stannington near Sheffield, from the neighbourhood of Burton-on-Trent, or Stourbridge; 2 lbs. of the old crucible after it has been used, ground to powder, and about ½ lb. of ground coke. These quantities are sufficient for one crucible of the ordinary size. This composition is trodden for 8 or 10 hours on a metal floor; it is then cut into pieces of 26 to 28 lbs.; each piece is rolled round nearly to the size of the mould into which it is introduced, and the plug P is driven down with a mallet; the mould is furnished with a movable bottom: when the pot is made the mould is lifted up by the two handles, and fixing the bottom on a post, the mould falls, and leaves the crucible upon it. Converted bars, and also cast steel in ingots, are reduced to bars, rods, and sheets by hammering or rolling; when forged they are heated in a small furnace urged by blast, and drawn to bars under hammers of 7 to 9 cwt., giving 100 to 120 strokes per minute.

1702



When small rods are required they are "tilted," that is, they are heated and drawn under hammers of 3 or 4 cwt., striking 200 to 250 blows per minute. When steel is rolled the machinery used is of the same construction as that required for rolling iron, excepting that the rollers are usually hard on the surface. Hardening and tempering steel is a delicate operation; small articles of cutlery are usually hardened by first heating them to a red heat and plunging them in water, saws and such articles are when heated plunged into oil. All articles are tempered by carefully heating them when hardened, and the degree of temper is indicated by a change in the colour of the surface, which is first straw coloured, then blue, and deep blue: colour is thus made the most delicate test for the degree of temper given: after this operation steel is found to expand a little. Alloys of steel have been very carefully made by Messrs. Stoddart and Faraday, but no alloy has at present been found to give any addition to the intrinsic quality of steel; the empiric titles of "silver steel," "meteoric steel," &c., may be regarded simply as fanciful names to recommend the article, either as a raw material or in a manufactured state.

Those articles called "run steel" are made by melting pig-iron and pouring it into moulds of sand in which the required article has been moulded; they are then packed in round iron pots about 12 inches diameter, and 16 to 18 inches high, along with hæmatite iron ore crushed to powder; these pots are packed in a furnace, and heat is applied from 24 hours to several days; the oxygen abstracts the carbon from the metal of which the articles are made, and they become to a certain extent malleable, so much so, that pieces a quarter of an inch thick may be bent almost double, and can be drawn out under a hammer. Forks, table knives, scissors, and many other cheap articles are so made; also a vast variety of parts of cotton and flax machinery are so manufactured, especially those parts which are difficult to forge.

"Damascus" or Damasked "steel" is made by melting together iron and steel, or bars of steel of high and low degrees of carbonisation; it may also be produced by melting hard and soft steel in separate crucibles, mixing them together whilst fluid and immediately pouring the mixture into an ingot mould, the damask is shown by the application of dilute acid to the surface when brightened. The analysis of a genuine Damascus sword-blade has shown that it is not a homogeneous steel, but a mixture of steel and iron.

During the past few years a great many processes have been patented with a view of reducing the cost of cast steel; Mr. Bessemer, Mr. Marticu, Mr. Mushet, and several others have suggested modes of producing a serviceable steel from the common pig-iron. A full description of these proposed improvements would take up too much space, but can be examined in the "Repertory of Arts:" the whole of these processes are purposely omitted, because a description of them would necessarily demand some examination of their merits.

Statistical account of the manufacture of steel.— The manufacture of steel in England is chiefly confined to Sheffield, although it is also made at Newcastle and in Staffordshire. The importation of Swedish iron, combined with that furnished from English materials, amounts to from 40,000 to 50,000 tons per annum; of course this weight represents the quantity of steel manufactured of every description.

The number of furnaces in Sheffield and its neighbourhood are as follow:—

	Converting Furnaces.	Cast steel Furnaces. or holes.
1835	56	554
1842	97	774
1846	105	974
1853	160	1495

A converting furnace will produce 300 tons of steel per annum, but if each produce 250 tons, 160 converting furnaces would represent a make of 40,000 tons of steel a year in Sheffield alone. Again, there are 1495 melting holes; each furnace of 10 holes will melt 200 tons; this, therefore, shows a product annually of 29,900 tons, but as such furnaces may not all be in continual work from various causes, the quantity of cast steel manufactured in Sheffield may be estimated at 23,000 tons. The weight of coach-spring steel, estimated at 10,000 tons, leaving a remainder of 7000 tons of bar for the manufacture of German, faggot, single and double shear steel. As regards the price, I take cast steel at 45*l.* per ton; its commercial value varies from 35*l.* to 60*l.* per ton net, and as a large quantity of the cheaper steel is sold, 45*l.* per ton is an average. The price of bar steel is below the real value, since it includes all shear steel, the best of which sells at 60*l.* per ton, whilst, however, a portion of this 7000 tons sells only at 28*l.*, and some even lower. The price of coach springs is the price now paid for them.

The weight and value of the steel made in England may be estimated as follows:—

Tons.		£
23,000	of cast steel, all qualities, at 45*l* per ton	1,035,000
7,000	bar steel, including German, faggot, single and double shear steel, average 35*l.* per ton	245,000
10,000	coach-spring steel, 19*l.* per ton	190,000
40,000 Tons.		£1,470,000

The statistics of this metal give the following results:

	Tons.		£
France produces	14,954	average value of	443,850
Prussia "	5,453	"	170,824
Austria "	13,037	"	321,073
United States	10,000	"	212,500
England "	40,000	"	1,470,000

Such is the contrast of the manufacturing power of the steel-producing countries; it shows the eminent position of England, in both weight and value; this can only arise from the practical skill and scientific knowledge which we have brought to bear upon its manufacture; and the active energy which has enabled us to produce steel *suitable for every purpose in the arts.* This superiority not only enables our manufacturers to maintain the high position they now hold, but to increase it yet further; for we daily see our production expanding, not only to supply the wants of our home manufacturers, but also for the continent of Europe, as well as the United States of America and Canada.

Bessemer's malleable Iron and Steel.—In the article "Iron" will be found a statement of the process proposed by Mr. Bessemer for converting crude pig iron into malleable iron, which we believe to be a fair representation of all the facts up to the period when that paper was written. Since then the process has been tried in the manufacture of steel, and, certainly, it appears, with much more success than attended the early experiments made on iron. For the purpose of placing the matter, however, clearly before our readers, we extract a considerable portion of Mr. Henry Bessemer's paper "On the manufacture of malleable Iron and Steel," read before the Institution of Civil Engineers in May last.

"The want of success which attended some of the early experiments was erroneously attributed, by some persons, to the 'burning' of the metal, and by others, to the absence of cinder, and to the crystalline condition of cast metal. It was almost needless to say that neither of the causes assigned had anything to do with the failure of the process, in those cases where failure had occurred. Chemical investigation soon pointed out the real source of difficulty. It was found, that although the metal could be wholly decarbonised, and the silicium be removed, the quantity of sulphur and of phosphorus was but little affected; and as different samples were carefully analysed, it was ascertained that red-shortness was always produced by sulphur, when present to the extent of one tenth per cent., and that cold-shortness resulted from the presence of a like quantity of phosphorus; it, therefore, became necessary to remove those substances. Steam and pure hydrogen gas were tried, with more or less success, in the removal of sulphur, and various fluxes, composed chiefly of silicates of the oxide of iron and manganese, were brought in contact with the fluid metal during the process, and the quantity of phosphorus was thereby reduced. Thus, many months were consumed in laborious and expensive experiments; consecutive steps in advance were made, and many valuable facts were elicited. The successful working of some of the higher qualities of pig-iron caused a total change in the process, to which the efforts of Messrs. Bessemer and Longsdon were directed. It was determined to import some of the best Swedish pig-iron, from which steel of excellent quality was made, and tried for almost all the uses for which steel of the highest class was employed. It was then decided to discontinue, for a time, all further experiments, and to erect steel works at Sheffield for the express purpose of fully developing and working the new process commercially, and thus to remove the erroneous impressions so generally entertained in reference to the Bessemer process.

"In manufacturing tool steel of the highest quality, it was found preferable, for several reasons, to use the best Swedish pig-iron, and, when converted into steel by the Bessemer process, to pour the fluid steel into water, and afterwards to re-melt the shotted metal in a crucible, as at present practised in making blister-steel, whereby the small ingots required for this particular article were more perfectly and more readily made.

"It was satisfactory to know that there existed in this country vast, and apparently inexhaustible, beds of the purest ores fitted for the process. Of the hematite alone, 970,000 tons were raised annually, and this quantity might be doubled or trebled, whenever a demand arose. It was from the hematite pig-iron made at the Workington Iron Works, that most of the iron and steel was made. About 1 ton 13 cwts. of ore, costing 10*s.* per ton, would yield 1 ton of pig metal, with 60 per cent. less lime, and 20 per cent. less fuel, than were generally consumed when working inferior ores; while the furnaces using this ore alone yielded from 220 tons to 240 tons per week, instead of, say, 160 tons to 180 tons per week, when working with common ironstone. The Cleator Moor, the Weardale, and the Forest of Dean Iron Works also produced an excellent metal for this purpose.

"The form of converting vessel which had been found most suitable somewhat resembled the glass retort used by chemists for distillation. It was mounted on axes, and was lined with 'ganister' or road drift, which lasted during the conversion of thirty or forty charges of steel, and was then quickly and cheaply repaired, or renewed. The vessel was brought into an inclined position, to receive the charge of crude iron, during which time the tuyères were above the surface of the metal. As soon as the whole charge was run in, the vessel was moved on its axes, so as to bring the tuyères below the level of the metal, when the process was at once brought into full activity, and twenty small, though powerful, jets of air sprang upwards through the fluid mass; the air, expanding in volume, divided itself into globules, or burst violently upwards, carrying with it a large quantity of the fluid metal, which again fell back into the boiling mass below. The oxygen of the air appeared, in this process, first to produce the combustion of the carbon contained in the iron, and at the same time to oxidise the silicium, producing silicic acid, which, uniting with the oxide of iron, obtained by the combustion of a small quantity of metallic iron, thus produced a fluid silicate of the oxide of iron, or 'cinder,' which was retained in the vessel and assisted in purifying the metal. The increase of temperature which the metal underwent, and which seemed so disproportionate to the quantity of carbon and iron consumed, was doubtless owing to the favourable circumstances under which combustion took place. There was no intercepting material to absorb the heat generated, and to prevent its being taken up by the metal, for heat was evolved at thousands of points, distributed throughout the fluid, and when the metal boiled, the whole mass rose far above its natural level, forming a sort of spongy froth, with an intensely vivid combustion going on in every one of its numberless, ever-changing cavities. Thus by the mere action of the blast, a temperature was attained, in the largest masses of metal, in ten or twelve minutes, that whole days of exposure in the most powerful furnace would fail to produce.

"The amount of decarbonisation of the metal was regulated, with great accuracy, by a meter, which indicated on a dial the number of cubic feet of air that had passed through the metal; so that steel of any quality or temper could be obtained with the greatest certainty. As soon as the metal had reached the desired point (as indicated by the dial), the workmen moved the vessel, so as to pour out the fluid malleable iron or steel into a founder's ladle, which was attached to the arm of a hydraulic crane, so as to be brought readily over the moulds. The ladle was provided with a fire-clay plug at the bottom, the raising of which, by a suitable lever, allowed the fluid metal to descend in a clear vertical stream into the moulds. When the first mould was filled, the plug valve was depressed, and the metal was prevented from flowing until the casting ladle was moved over the next mould, when the raising of the plug allowed this to be filled in a similar manner, and so on until all the moulds were filled.

"The casting of large masses of a perfectly homogeneous malleable metal into any desired form rendered unnecessary the tedious, expensive, and uncertain operation of welding now employed wherever large masses were required. The extreme toughness and extensibility of the Bessemer iron was proved by the bending of cold bars of iron 3 in. square, under the hammer, into a close fold, without the smallest perceptible rupture of the metal at any part; the bar being extended on the outside of the bend from 12 in. to 16¾ in., and being compressed on the inside from 12 in. to 7¼ in., making a difference in length of 9½ in., between what, before bending, were the two parallel sides of a bar 3 in. square. An iron cable, consisting of four strands of round iron 1½ in. diameter, was so closely twisted, while cold, as to cause the strands at the point of contact to be permanently imbedded into each other. Each of these strands had elongated 12½ in. in a length of 4 ft., and had dimiuished 1-10th of an inch in diameter, throughout their whole length. Steel bars, 2 in. square and 2 ft. 6 in. in length, were twisted cold into a spiral, the angles of which were about 45 degrees; and some round steel bars, 2 in. in diameter, were bent cold under the hammer, into the form of an ordinary horse-shoe magnet, the outside of the bend measuring 5 in. more than the inside.

"The steel and iron boiler plates, left without shearing, and with their ends bent over cold, afforded ample evidence of the extreme tenacity and toughness of the metal; while the clear, even surface of railway axles and pieces of malleable iron ordnance were examples of the perfect freedom from cracks, flaws, or hard veins which forms so distinguishing a characteristic of the new metal. The tensile strength of this metal was not less remarkable, as the several samples of steel tested in the proving machine at Woolwich arsenal bore, according to the reports of Colonel Eardley Wilmot, R.A., a strain varying from 150,000 lbs. to 160,900 lbs. on the square inch, and four samples of iron boiler plate from 68,314 lbs. to 73,100 lbs.; while according to the published experiments of Mr. W. Fairbairn, Staffordshire plates bore a mean strain of 45,000 lbs.; and Low Moor and Bowling plates a mean of 57,120 lbs. per square inch.

"There was also another fact of great importance in a commercial point of view. In the manufacture of plates for boilers and for ship-building, the cost of production increased considerably with the increase of weight in the plate; for instance, the Low Moor Iron Company demanded 22*l.* per ton for plates weighing 2½ cwt. each; but if the weight exceeded 5 cwt., then the price rose from 22*l.* to 37*l.* per ton. Now with cast ingots, such as the one exhibited, and from which the sample plates were made, it was less troublesome, less expensive, and less wasteful of material, to make plates weighing from 10 cwt. to 20 cwt., than to produce smaller ones; and indeed there could be but little doubt that large plates would eventually be made in preference, and that those who wanted small plates would have to cut them from the large ones. A moment's reflection would, therefore, show the great economy of the new process in this respect; and when it was remembered that every riveted joint in a plate reduced the ultimate strength of each 100 lb. to 70 lb., the great value of long plates for girders and for ship-building would be fully appreciated.

"It would be interesting to those who were watching the advancement of the new process, to know that it was already rapidly extending itself over Europe. The firm of Daniel Elfstrand and Co., of Edsken, who were the pioneers in Sweden, had now made several hundred tons of excellent steel by the Bessemer process. Another large manufactory had since been started in their immediate neighbourhood, and three other companies were also making arrangements to use the process. The authorities in Sweden had fully investigated the whole process, and had pronounced in favour of it. Large steel circular saw-plates were made by Mr. Göranson, of Gefle, in Sweden, the ingot being cast direct from the fluid metal within fifteen minutes of its leaving the blast furnace. In France the process had been for some time carried on by the old established firm of James Jackson and Son, at their steel-works near Bordeaux. This firm was about to manufacture puddled steel on a large scale. They had already got a puddling furnace erected and in active operation, when their attention was directed to the Bessemer process, the apparatus for which was put up at their works last year; and they were now extending their field of operations, by putting up more powerful apparatus at the blast furnaces in the Landes. There were also four other blast furnaces in the South of France in course of erection, for the express purpose of carrying out the new process.

"The irons of Algeria and Saxony had produced steel of the highest quality.

"Belgium was not much behind her neighbours; the process was now being carried into operation at Liège, where excellent steel had been made from the native coke iron; while in Sardinia preparations were also being made for working the system. Professor Müller, of Vienna, and M. Dumas, from Paris, had visited Sweden, to inspect and report on the working of the new system in that country.

"That the process admitted of further improvement, and of a vast extension beyond its present limits, the author had no doubt; but those steps in advance would, he imagined, result chiefly from the experience gained in the daily commercial working of the process, and would most probably be the contributions of the many practical men who might be engaged in carrying on the manufacture of iron and steel by this system."

STEMPLES. *A mining term.* Strong pieces of timber, driven betwixt the sides of a vein, at short distances apart, to support the walls.

STEREOTYPE PRINTING signifies printing by fixed types, or by a cast typographic plate. This plate was formerly always, and is still sometimes, made as follows:—The form composed in ordinary types, and containing one, two, three, or more pages, inversely as the size of the book, being laid flat upon a slab, with the letters looking upwards, the faces of the types are brushed over with oil, or, preferably, with plumbago (black lead). A heavy brass rectangular frame of three sides, with bevelled borders adapted exactly to the size of the pages, is then laid down upon the chase*, to circumscribe three sides of its typography; but the fourth side, which is one end of the rectangle, is formed by placing near the types, and over the hollows of the chase, a single brass bar, having the same inwards-sloping bevel as the other three sides. The complete frame resembles that of a picture, and serves to define the area and thickness of the cast, which is made by pouring the pap of Paris plaster into its interior space, up to a given line on its edges. The plaster mould, which soon sets, or becomes concrete, is lifted gently off the types, and immediately placed upright on its edge in one of the cells of a sheet-iron rack mounted within the cast-iron oven. The moulds are here exposed to air heated to fully 400° Fahr., and become perfectly dry in the course of two hours. As they are now friable and porous, they require to be delicately handled. Each mould, containing generally two pages octavo, is laid, with the impression downwards, upon a flat cast-iron plate, called the floating-plate; this plate being itself laid on the bottom of the dipping-pan, which is a cast-iron square tray, with its upright edges sloping outwards. A cast-iron lid is applied to the dipping-pan and secured in its place by a screw. The pan having been heated to 400° in a cell of the oven, under the mould-rack, previous to receiving the hot mould, is ready to be plunged into the bath of melted alloy contained in an iron pot placed over a furnace, and it is dipped with a slight deviation from the horizontal plane, in order to facilitate the escape of the air. As there is a minute space between the back or top surface of the mould and the lid of the dipping-pan, the liquid metal, on entering into the pan through the orifices in its corners, floats up the plaster along with the iron plate on which it had been laid, thence called the floating-plate, whereby it flows freely into every line of the mould, through notches cut in its edge, and forms a layer or lamina upon its face, of a thickness corresponding to the depth of the border. Only a thin metal film is left upon the back of the mould. The dipping pan is suspended, plunged, and removed, by means of a powerful crane, susceptible of vertical and horizontal motions in all directions. When lifted out of the bath, it is set in a water-cistern, upon bearers so placed as to allow its bottom only to touch the surface. Thus the metal first concretes below, while by remaining fluid above, it continues to impart hydrostatic pressure during the shrinkage attendant on refrigeration. As it thus progressively contracts in volume, more metal is fed into the corners of the pan, in order to keep up the pressure upon the mould, and to secure a perfect impression, as well as a solid cast.

The whole process is greatly improved by the employment of a prepared bibulous paper, instead of the plaster of Paris. The paper employed is of French manufacture, and it is impregnated with some wax-like composition, the preparation of which is kept a profound secret by the inventor. The form of type being prepared, a sheet of this prepared paper is placed upon it, and the whole is subjected to considerable pressure. On removing the paper it is found to have received a most perfect impression of the type. This impressed paper mould is then placed in an iron box, which is fixed in a nearly vertical position, and the heavy cover being carefully closed, there only remains between it and the mould exactly the space which is necessary to ensure a proper thickness to the type metal. All being prepared, the melted metal is poured into the mould. It flows, of course, at once to the bottom of the mould, and as the liquid is rapidly supplied, the whole is filled, and, as in the case already given, some pressure is obtained by the lead of metal above the paper mould. The mass of metal (iron) forming the casting box, in comparison with the thin plate of type metal, ensures a rapid chilling of the latter, so that the plate can be removed in a very short time. The impression thus obtained is exceedingly perfect; and the whole process is one of great simplicity and exactness, and is capable of being executed with great rapidity.

The Times newspaper is regularly printed from stereotype plates made in the manner described. The advantages of a solid block over a form of loose type will be sufficiently obvious to all; and but for the security which is afforded by the use of the solid plate, there would be great risk in driving the printing machinery at such high rates of speed as are employed in *The Times* office, and other offices, where they re-

* Chase (*chassis*, frame, Fr.), quoin (*coin*, wedge, Fr.), are terms which show that the art of printing is indebted to our French neighbours for many of its improvements.

quire to throw off a very large impression within a very limited time. See PRINTING and PRINTING MACHINERY.

STEREOSCOPE (from στερεος, solid, and σκοπειν, to see). An instrument invented by Professor Wheatstone, and modified by Sir David Brewster, by means of which two images of the same object, depicted on paper, — as those images would be depicted upon the retina of each eye — are resolved into an apparent solid of three dimensions. The reflecting stereoscope of Professor Wheatstone was constructed by means of two mirrors, set at right angles to each other, so that while the right eye observed a reflected image of a picture placed on the right-hand side of the instrument, the left eye saw a reflected image of that on the left, and, as a result, saw — not two plane pictures, but one solid image. The refracting stereoscope, which is generally used, consists of two semi-lenses. This is a lens which is divided in the middle, and the two halves, with the edges towards each other, placed in a frame, at a distance from each other corresponding with the distances of the eyes apart. For the best result, two pictures are obtained by photography, as nearly as possible of the same character as the pictures impressed respectively upon the retina of each eye. These pictures, being placed below the lenses, are resolved into one image, and that image realises all the conditions of solidity, as in natural vision. See *Hunt's Manual of Photography.*

STILL. See DISTILLATION.

STIPPLE ENGRAVING is a process which was practised by Bartolozzi, Ryland, and others, in imitation of chalk drawings of the human figure. Stipple is performed with the graver, which is so managed as to produce the tints by small dots, rather than by lines, as in the ordinary method. It is very soft in its effect, but inferior to the more legitimate mode of engraving. See ENGRAVING.

STOCKING MANUFACTURE. See HOSIERY.

STONE is earthy matter, condensed into so hard a state as to yield only to the blows of a hammer, and therefore well adapted to the purposes of building. Such was the care of the ancients to provide strong and durable materials for their public edifices, that but for the desolating hands of modern barbarians, in peace and in war, most of the temples and other public monuments of Greece and of Rome would have remained perfect at the present day, uninjured by the elements during 2000 years. The contrast, in this respect, of the works of modern architects, especially in Great Britain, is very humiliating to those who boast so loudly of social advancement; for there is scarcely a public building of recent date which will be in existence one thousand years hence. Many of the most splendid works of modern architecture are hastening to decay, in what may be justly called the very infancy of their existence. This is remarkably the case with the bridges of Westminster and Blackfriars; the foundations of which began to perish most visibly in the very lifetime of their constructors.

Stones for building, it is stated, may be proved as to their power of resisting the action of frost, by the method, first practised by M. Brard, and afterwards by MM. Vicat, Billaudel, and Coarad, engineers of the bridges and highways in France. The operation of water in congealing within the pores of a stone may be imitated by the action of a salt, which can increase in bulk by a cause easily produced; such as efflorescence or crystallisation, for example. Sulphate of soda, or Glauber's salt, answers the purpose perfectly, and it is applied as follows: —

Average samples of the stones in their sound state, free from shakes, should be sawed into pieces 2 or 3 inches cube, and numbered with China ink or a graving tool. A large quantity of Glauber's salt should be dissolved in hot water, and the solution should be left to cool. The clear saturated solution being heated to the boiling point in a saucepan, the several pieces of stone are to be suspended by a thread in the liquid for exactly one half-hour. They are then removed and hung up each by itself over a vessel containing some of the above cold saturated solution. In the course of 24 hours, if the air be not very damp or cold, a white efflorescence will appear upon the stones. Each piece must be then immersed in the liquor in the subjacent vessel, so as to cause the crystals to disappear, be once more hung up; and dipped again whenever the dry efflorescence forms. The temperature of the apartment should be kept as uniform as possible during the progress of the trials. According to their tendency to exfoliate by frost, the several stones will show, even in the course of the first day, alterations on the edges and angles of the cubes; and in 5 days after efflorescence begins, the results will be manifest, and may be estimated by the weight of disintegrated fragments, compared to the known weight of the piece in its original state, both taken equally dry. In opposition to this, Mr. C. H. Smith, one of the commissioners for selecting the stone for the Houses of Parliament, states — "Such treatment, compared with that of nature, will be found to vary materially, both in detail and result. If Glauber's salt expands in changing from a fluid to a crystalline state, it is so little as to be inappreciable; whereas water increases considerably in bulk while freezing." Many experiments selected from the

Report on Stone for the New Houses of Parliament (March 1839), show that in M. Brard's treatment the effect is in most instances opposite to that of the action of the weather on stones which have been exposed to its influence many years. Some of the specimens well known to decay rapidly in a building disintegrated least of all by Brard's process; others of the most durable quality disintegrated more than all the rest, under similar treatment; consequently Brard's method of testing is not to be depended upon, and is liable to lead to erroneous conclusions.

The most important building stones of the United Kingdom are the following :—

Granites — produced chiefly in Cornwall, Devonshire, Leicestershire, Aberdeenshire, and in Wickow and Carlow.

Porphyries, Syenites, Elvans —obtained from Cornwall, Devonshire, Leicestershire, and many parts of Scotland and Ireland.

Sandstones — the chief quarries of which are in Yorkshire, Derbyshire, Shropshire, Surrey, &c., and in several of the Scottish counties. The Portland, Cragleith, and other celebrated stones, belong to this class.

Millstone Grit is found largely in Derbyshire, in Yorkshire, and indeed in most of the coal-producing districts.

Dolomites, or Magnesian Limestones. Yorkshire, Durham, and Northumberland, Derbyshire, Nottinghamshire, produce these stones abundantly.

Oolites. The Bath Stone is a well-known example of this stone; the stone from the quarries of Ancaster and of Ketton being fine specimens of the class.

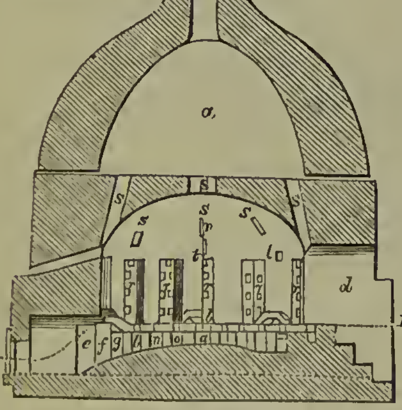
Limestones. These are very varied. The Purbeck marble, the Derbyshire marbles, the Lias bed, the Devonian Limestone, and the well-known mountain limestone being examples.

Slates. These are obtained in very great abundance in North Wales, in Devonshire, and in Cornwall; in some parts of Scotland and of Ireland.

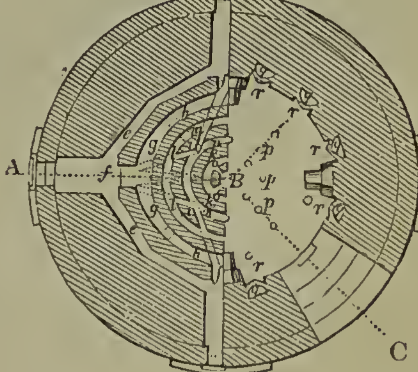
Such are the principal varieties, although many others exist which are exceedingly useful. Most of the above will be found described under their respective heads.

STONE, ARTIFICIAL, for statuary and other decorations of architecture, has been made for several years with singular success at Berlin, by Mr. Feilner. His materials are nearly the same with those of English pottery; and the plastic mass is fashioned either in moulds or by hand, being in fact a Terra-Cotta, which see. His kilns, which are peculiar in form, and economical in fuel, deserve to be generally known. *Figs.* 1703 and 1704 represent his round kiln; *fig.* 1703 being an oblique section in the line A, B, C, of *fig.* 1704, which is a ground plan in the line D, *a*, *b*, E, of *fig.* 1703. The inner circular space *c*, covered with the elliptical arch, is filled with the figures to be baked, set upon brick supports. The hearth is a few feet above the ground; and there are steps before the door *d*, for the workmen to mount by in charging the kiln. The fire is applied on the four sides under the hearth. The flame of each passes along the straight flues *f i*, *f i*, and *f k*. In the second annular flue *g*, *g*, as also in the third *l*, *l*, the flame of each fire is kept apart, being separated from the adjoining by the stones *h* and *m*. In the fourth flue *n*, the flames again come together, as also in *o*, and ascend by the middle opening. Besides this large orifice, there are several small holes, *p*, *p*, in the hearth over the above flues, to lead the flames from the other points into contact with the various articles. There are also channels *q*, *q*, in the sides, enclosed by thin walls *r*, to promote the equable distribution of the heat; and these are placed right over the first fire-flues *e*. The partitions *r*, are perforated with many holes, through which, as well as from their

1703



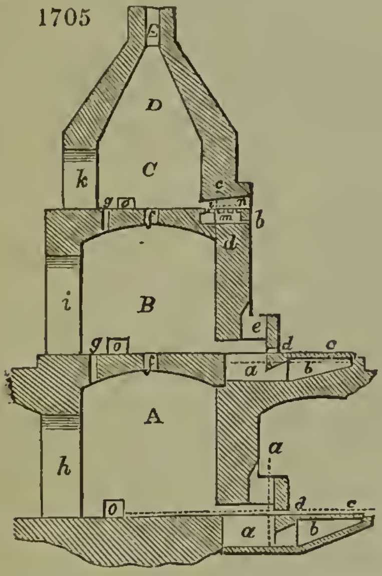
1704



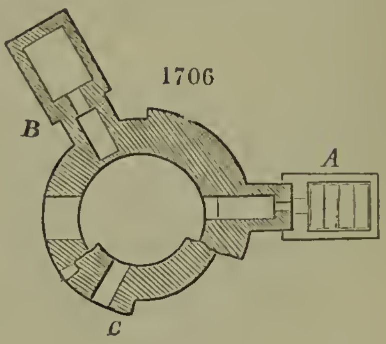
tops, the flame may be directed inwards and downwards; *s* are the vents for carrying off the flames into the upper space *u*, which is usually left empty. These vents can be closed by iron damper-plates, pushed in through the slide-slits of the dome. *t*, *t*, are peep-holes, for observing the state of ignition in the furnace; but they are most commonly bricked up. *Fig.* 1705 is a vertical section, and *fig.* 1706 a plan of an excellent kiln for baking clay to a stony consistence, for the above purpose, or for burning fire-bricks. A, is the lower; B, the middle; C, the upper kiln; and D, the hood, terminating in the chimney E. *a*, *a*, is the ash-pit; *b*, *b*, the vault for raking out the ashes; it is covered with an iron door *c*. *d*, is the peep-hole, filled with a clay stopper; *e*, is the fire-place; *f*, *f*, a vent in the middle of each arch; *g*, *g*, flues at the sides of the arches, situated between the two fireplaces; *h*, *i*, *k*, are apertures for introducing the articles to be baked; *l*, a grate for the fire in the uppermost kiln; *m*, the ash-pit; *n*, the fire-door; *o*, openings through which the flames of a second fire are thrown in. At first only the ground kiln A is fired, with cleft billets of pine-wood, introduced at the opening *e*; when this is finished, the second is fired, and then the third in like manner.

Many ingenious arrangements have been made for the construction of artificial stone. We might, of course, group under this head many varieties of clay wares and cements. See BRICKS, MORTARS, and HYDRAULIC CEMENTS.

1705



1706



Amongst all the numerous plans which have been devised, few of them have altogether succeeded; they have either proved too expensive in the manufacture, or they have not endured the test of time.

Mr. Buckwell proposed the following plans for the construction of artificial stone. Taking fragments of stone sufficiently large to go freely into his mould, he fills up the interstices with stones of various sizes, and then pours in a mixture of chalk and Thames mud or Mersey mud burnt together. This cement being poured into the mould, the whole is rammed together by falling hammers, and as the mould is perforated the water is forced out, and the resulting stone is so hard, when removed from the mould, that it rings when struck. It will be evident to those acquainted with hydraulic mortars and the application of concrete that this is only an improved concrete. The cost of production has been too great to admit of the general introduction of this artificial stone.

Ransome's patent siliceous stone, being one of the most successful attempts to produce a permanent stone artificially, requires a little further attention.

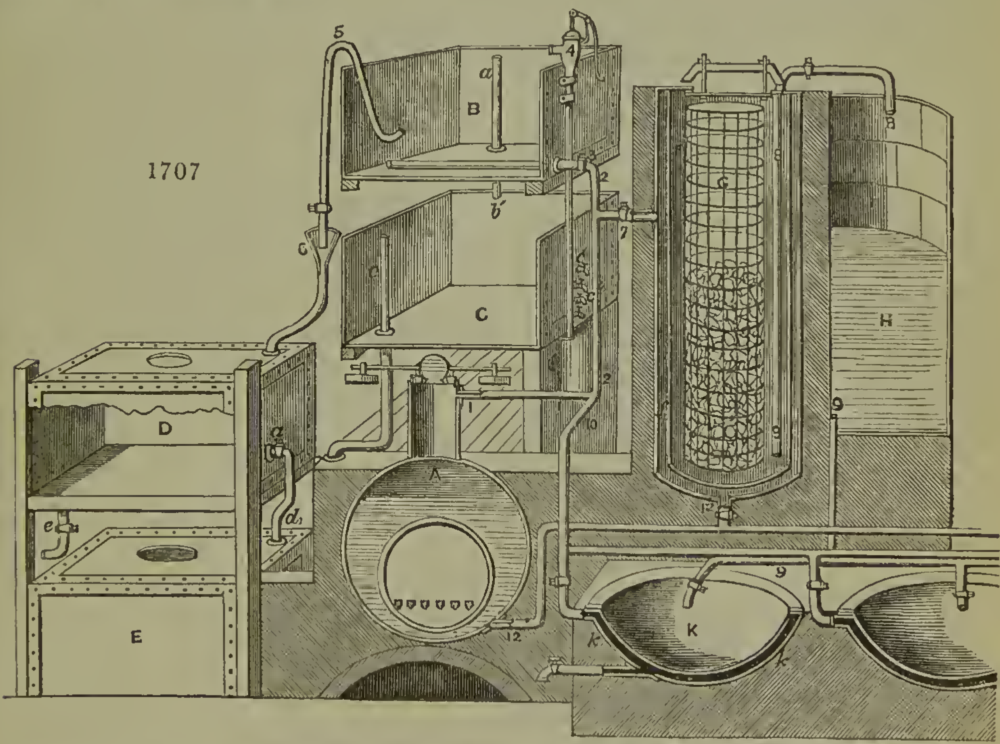
Mr. Ransome's attention was directed to the subject of artificial stone in 1844, while engaged as manager in the establishment of his relatives, the Messrs. Ransome, of the Orwell Works, Ipswich. At that time the above-named firm happened to have a considerable order for flour mills for the colonies; and, from the difficulty experienced in refacing the French burr stones, usually employed for the purpose, in situations where skilled labour was not attainable, it was proposed to obviate this difficulty by substituting for the stones surfaces of chilled cast iron. It was found, however, that after a while the grinding surfaces so constructed became glazed, and consequently unfit for the purpose for which they were intended. While overlooking the proceedings of a workman engaged in renewing, on one occasion, the worn-out ridges on a burr-stone, Mr. Ransome was struck by the apparent absurdity of having to chip away not only the soft parts of the stone, but also the hard siliceous prominences which constitute the real efficient portion of the surface. From the unequal and heterogeneous character of the burrs usually employed, one side was apt to wear away sooner than the other; and to bring the grinding surface to anything like a true bearing, the harder portions of the stone had to be cut away to the level of the lower and softer parts; thereby occasioning not only great labour in renewing the surface, but also a very rapid destruction of the whole material.

It at once occurred to Mr. Ransome that if he could procure a stone of perfect homogeneous texture, the surface would wear down equally, and this objectionable system of levelling the whole to the depth of the softer and most worn parts would be completely obviated. Unfortunately, however, all natural stones were, from their very nature, of unequal texture, even within the limits of the small segments usually employed in the construction of mill-stones. Gathering up a handful of the chips struck off by the tools of the workmen and pressing them together, the idea flashed across his mind that if he could discover any means of cementing those particles together he would be able to produce a stone of nearly uniform hardness throughout. The most convenient material for this purpose that first suggested itself was plaster of Paris. This idea was immediately put in execution; and, although the results at first offered some slight prospect of success, a little subsequent experience showed the utter fallaciousness of the hopes he had entertained concerning them. But from the first moment that the scheme of cementing together the loose and disintegrated fragments of the mill-stone entered his mind, he comprehended by anticipation the whole of the results, which, after twelve years of assiduous application, he has succeeded in carrying to a triumphant conclusion.

After numerous failures, it occurred to Mr. Ransome that a solution of silica as a cementing material would be superior to any other, and he accordingly started on the inquiry after an easy method of producing a solution of flints. Experiment proved to the inventor that flints subjected to heat, under pressure in a boiler with a solution of soda or potash, were dissolved.

The accompanying illustration gives a sectional view of the apparatus employed in preparing the siliceous cement.

1707



A is a steam boiler, capable of generating a sufficiency of steam for heating the dissolving and evaporative vessels, and usually worked at a pressure of about 70 lb. to the square inch. B is the upper ley-tank for dissolving the carbonate of soda. It is supplied with steam by the pipes 1, 2, 3, communicating with the boiler.

The first operation is to reduce the ordinary soda ash of commerce to the condition of caustic soda. For this purpose the ash is first dissolved in the tank B, the water in which is heated by means of the perforated steam-pipe *b*. A quantity of quick lime is then added, and the mixture well stirred. The soda is by this means deprived of the carbonic acid which it contains, by the quick lime forming with it a carbonate of lime. To ascertain when the ley is quite caustic, a small portion is taken out in a test tube, and a few drops of hydrochloric acid added. If there is no effervescence it may be assumed that the soda is entirely deprived of its carbonic acid, and is consequently caustic. When the lime, now converted into chalk, has subsided to the bottom of the tank, the clear supernatant ley is drawn off by the siphon 5, into the funnel 6, leading into a closed vessel D, to prevent the carbonic acid of the atmosphere combining with it, and destroying its causticity. When the ley has been drawn off from B, the sediment remaining at the bottom of the tank is allowed to fall into the lower tank C, by withdrawing the plug *a*, from the pipe b^1. Any undissolved crystals of the carbonate of soda which have been entangled among the particles of the lime are now washed out and pumped back to the upper tank B, where it forms a portion of the next charge.

The clear caustic being contained in the closed tank D, has a further process of depuration to undergo before it is ready to be used as a solvent for the flints. The ordinary soda ash of commerce is always more or less adulterated with a sulphate of soda, which although an inert substance in itself, if allowed to remain in the cement subsequently makes its appearance in an ugly efflorescence on the surface of the finished stone. To get rid of the sulphate, the caustic solution of soda has added to it, in the tank D, a quantity of caustic baryta, obtained by burning the commercial carbonate of baryta with wood charcoal. The caustic baryta seizes upon the sulphuric acid contained in the sulphate of soda, and forms with it an insoluble sulphate of baryta, which is precipitated on the bottom of the tank. The depurated ley is then drawn off by the pipe *d*, into the lower closed tank E, and the sulphate of baryta sediment passes off by the cock at the bottom. From E, the prepared solution of the caustic soda is pumped into the vertical boiler or digester F. This digester, in which the process of dissolving the flints is effected, is a cylindrical vessel, having a steam jacket *f*, into which steam from the boiler A is supplied by the pipes 1, 2, *y*. The inner cylinder F, is provided with a wire basket G, reaching the whole length of the vessel, and serving to hold a collection of nodules of common flint. When F has been filled with the caustic ley, and the basket with flints, the manhole at the top is closed and well screwed down, so as to be able to resist a pressure of at least 60 lb. on the square inch. The cock at *y* is then opened, and the full pressure of steam from the boiler passes into the jacket *f*, and causes the ley in F to rise to the same temperature. The condensed steam in the jacket *f* returns to the boiler by the pipe 12, which it enters below the water line. The pressure maintained in the digester is generally about 60 lb., and this is continued about 36 hours; at the end of which time the strength of the solution is tested. The workmen employed to superintend this part of the process generally use the tongue as the most delicate test. If the solution has a decidedly caustic alkaline taste they conclude that there is still too much free soda in the cement, and the boiling is allowed to continue until the cement has a slightly sweetish taste, which occurs when the alkali has been nearly neutralised by combination with the silicic acid of the flints. A more scientific mode of testing the strength of the solution is to take a wine-glassful and drop a little hydrochloric acid into it; by this means the whole of the silica in the solution is thrown down by the acid combining with the soda, so as to form chloride of sodium. The precipitated silica presents an appearance resembling half dissolved snow, and its comparative volume gives a good idea of the strength of the solution of the alkaline silicate.

When it is judged that the alkali has taken up as much of the silica as it is capable of doing, at the temperature to which it is subjected in the digester, the stop cock *y*, in the steam pipe communicating with the jacket, is shut, and a cock in the pipe 8 is opened. The pressure of the steam in F then forces the fluid silicate through the pipe 8 into the vessel H, where it is allowed to stand for a short time to deposit any sediment which it may contain. From H it is then conveyed by the pipe 9 to the evaporating pan, K, which has a steam jacket, *k*, supplied with steam by the pipe 10. The cement is then boiled in the evaporating pan until it becomes of the consistency of treacle, when it is taken out. The specific gravity of the cement when ready for use is about 1·600. The general proportions of the materials used in making up the artificial stone is about the following:—

10 pints of sand, 1 pint of powdered flint, 1 pint of clay, and 1 pint of the alkaline solution of flint.

These ingredients are first well mixed in a pug-mill, and kneaded until they are thoroughly incorporated and the whole mass becomes of a perfectly uniform consistency. When worked up with clean raw materials, the compound possesses a putty-like consistence which can be moulded into any required form, and is capable of receiving very sharp and delicate impressions.

The peculiarity which distinguishes this from other artificial stones consists in the employment of silica both as the base and the combining material. Most of the varieties of artificial stone hitherto produced are compounds, of which lime, or its carbonate, or sulphate, forms the base, and in some instances they consist in part of organic matters as the cement, and having inorganic matters as the base.

To produce different kinds of artificial stone, adapted to the various purposes to which natural stones are usually applied, both the proportions and the character of the ingredients are varied as circumstances require. By using the coarser description of grits, grinding stones of all kinds can be formed, and that with an uniformity of texture never met with in the best natural stones. Any degree of hardness or porosity may also be given, by varying the quantity of silicate employed and subjecting it to a greater or less degree of heat.

For some descriptions of goods a portion of clay is mixed with the sand and other ingredients, for the double purpose of enabling the material to stand up during the process of firing in the kiln and to prevent its getting too much glazed on the surface.

The plastic nature of the compound allows of the most complex and undercut patterns being moulded with greater ease than by almost any other material we are acquainted with, if we except gutta percha, which, however, has the drawback of being affected by common temperatures.

The moulds employed are generally of plaster of Paris, and are so divided as to allow of the different pieces which cannot be withdrawn together being separately removed from the putty-like substance with which it has been filled. In filling the moulds the workmen use a short stick, with which they ram in the material, much in the way in which green sand is forced into contact with the pattern in an iron foundry, only with the difference, that the sand in this case is mixed with glutinous cement, which enables it to retain the form impressed upon it with much greater persistency and sharpness than is practicable with dry sand, or even loam. The casts, after being taken from the mould, are first washed over with a diluted mixture of the silicate, technically called "floating." The whole surface is then carefully examined, and any broken or rough portions are sleeked with a tool. It should have been mentioned that the plaster of Paris moulds, before being filled, are first painted over with oil and then dusted with finely powdered glass to prevent them adhering to the cast.

In attempting, however, to carry out his plan, two difficulties of a rather formidable character presented themselves. It was found that, in the process of desiccation, the surface of the stone parted with the moisture contained in the soluble silicate, and became hardened into a tough impervious coating, which prevented the moisture escaping from the interior of the mass. Any attempt to dislodge the water retained in combination with the silicate in the interior of the stone, by raising the temperature of the whole above 212 degrees, had merely the effect of breaking this outer skin of desiccated silicate, and rendering the surface cracked and uneven.

Instead therefore of allowing the stones to be dried in an open kiln they were placed in a closed chamber or boiler, surrounded with a steam-jacket, by which the temperature of the interior chamber could be regulated. In order that no superficial evaporation should take place while the stones were being raised to the temperature of the steam in the jacket, a small jet of steam was allowed to flow into the chamber, and condense among and on the surface of the goods; until, as the temperature of the interior of the stones rose to 212° and upwards, they became enveloped in an atmosphere of steam, which effectually prevented any hardening of the surface. The minute vents or spiracles formed by the steam as it was generated in the interior of the masses, remained open, when the vapour contained in the closed chamber was allowed slowly to escape, and afforded a means of egress to any moisture which might still be retained among the particles of sand and cement. The whole of the moisture contained in the silicate of soda having been thus vaporised before it left the stone, an opportunity was afforded it by opening a communication with the external atmosphere, to pass off, leaving the interior of the stone perfectly dry. Simple as this arrangement may seem, we will venture to say that not one of our readers has hit upon the expedient through his own cogitations on the subject.

The process, in effect, consists in stewing the stones in a closed vessel, and when all the moisture which they contain is converted into vapour, allowing it to escape, so that no one part of the mass can be dried before another. By this means Mr. Ransome was enabled to desiccate his artificial stone without any risk of the cracking or warping which had hitherto been the result of his attempts to harden them by exposure in an open stove.

After being thoroughly dried they are taken to the kiln, but, instead of being placed in *seggars* or boxes of clay, as is usually done in the potter's kiln, the goods are first bedded up with dry sand, to prevent any risk of their bending or losing their shape while burning. Flat slabs of fire clay are then used to separate the various pieces laterally, and similar slabs are placed over them to form a shelf, on which another tier of goods is placed. The temperature of the kiln is very gradually raised for the first twenty-four hours; the intensity is then augmented until at the end of forty-eight hours a bright red heat is attained, when the kiln is allowed to cool gradually for four or five days, when the goods are ready to be taken out.

The purposes to which this artificial stone is now applied are of the most miscellaneous description, comprising groundstones, whetstones for sharpening scythes, gothic foliage and mouldings for ecclesiastical decorations, tombstones and monumental tablets, chimneypieces, fountains, garden stands for flowers, statuary, &c.

From being composed almost entirely of pure siliceous matter, it is not acted upon by acids, and is apparently quite insoluble, even in boiling water.

By proportioning the amount of cement, and varying the character of the sand which enters into the composition of the stone, it can be made porous or non-porous, as may be desired. The average absorbent power is less than that of the Bolsover Moor Dolomite used in the erection of the Houses of Parliament, and a little more than that of the Cragleight Sandstone.

Dippenhall Silica Works, Farnham, Surrey.

The manufactory which bears this name was built for the production of artificial stone, from a material only recently discovered, and never before employed for this purpose: *soluble silica*. By this term is meant that kind of silica which is found to be readily dissolved by boiling in open vessels with solutions of caustic potash or soda; thus distinguished from the silica of flint, which is only soluble in such solutions at a temperature of about 300° Fahr. in a steam-tight boiler; and from that of quartz or sand, which is altogether insoluble. Up to the period when this discovery was made, silica had been only known to exist naturally in the two latter forms, and the former was merely a chemical product, derived from one of them by artificial means. This was at any rate the case in England; but it is right to state that a somewhat similar deposit was mentioned by M. Sauvage, a French chemist, before the researches were made to which this paper relates, as existing in the Département des Ardennes. This information, however, has not been turned to any practical account; and therefore a short history of the English discovery may not be uninteresting, as the latter has introduced to the world a new material applicable to a great variety of purposes.

About ten years ago the late Mr. Paine, of Farnham, proposed to the Chemical Committee of the Royal Agricultural Society of England that a complete analysis should be made of all the soils of the kingdom, for the purpose of ascertaining their value as natural manures. He undertook, for his own share, the strata of the chalk formation; and his thorough geological knowledge, aided by the chemical science of Professor Way, then consulting chemist to the Royal Agricultural Society, enabled him fully to complete the inquiry.

Some of the results of this joint investigation were communicated to the public by Messrs. Paine and Way, in the 12th volume of the Journal of the Royal Agricultural Society, in a paper entitled "On the Strata of the Chalk Formation." The soluble silica deposit is thus described: — "Immediately above the gault, with the upper member of which it insensibly intermingles, lies a soft white-brown rock, having the appearance of a rich limestone. It is very remarkable on account of its low specific gravity, and still more so considering its position, by reason of the very small quantity of carbonate of lime which it contains. It is one of the richest subsoils of the whole chalk series, being admirably adapted for the growth of hops, wheat, beans, &c.

"The section of rock at Farnham is about 40 feet in thickness. The analysis gives as follows: —

	Per cent.
Combined water and a little organic matter	4·15
Soluble in dilute acids, 57·10	
Silicic acid (silica)	46·28
Carbonic acid	none.
Sulphuric acid	trace.
Phosphoric acid	ditto.
Chlorine	none.
Lime	0·26
Magnesia	·07
Potash	·79
Soda	·43
Protoxide and peroxide of iron	6·12
Alumina	3·15
Insoluble in acids, 38·75	
Lime	2·91
Magnesia	traces.
Potash	1·51
Soda	·60
Alumina with a little oxide of iron	14·20
Silicic acid and sand	19·53
	100·00"

At the end of the paper it is remarked that a careful study of this rock may throw light upon the composition of soils.

The same authors contributed another article to the 14th volume of the "Journal," on "the Silica Strata of the Lower Chalk," in which they state that "when the former paper was published, they were not unaware that this stratum contained a large proportion of silica in the form which chemists call "soluble;" but that they wished, before making public their discovery, to ascertain whether it existed in sufficient quantity to render it available for agricultural use." They then detail the result of their researches during the intervening two years, as far as they concern agriculture, mentioning all the localities in which this stratum may be found in England, and the various ways of employing it beneficially as a manure. They allude to the fact that it will be found useful in its application to the arts, and conclude with these remarks on its probable formation: "It is not infusorial, for with the exception of a few foraminifera, no traces of animal life can be observed in the rock by microscopical examination. It cannot have been subjected to heat of any intensity, or it would have been rendered insoluble in alkalies. It is plainly the result of aqueous decomposition; and it seems very reasonable to suppose that silicate of lime in solution derived from the older rocks may have met with carbonic acid produced either by vegetable and animal decay, or by volcanic agency, and at one and the same time carbonate of lime and gelatinous or soluble silica would have been formed. It should be remembered that we find these beds in immediate contact with the chalk; we find chalk without silica, silica without chalk, and in other cases, both intimately blended. There is therefore good reason for supposing that these productions have been in some way connected."

While these investigations were going on, it was also found that the new material was useful in a variety of ways quite distinct from agriculture. Mr. Way's experiments led to the conviction that it would be serviceable in sugar refining, in soap-making, in making animal charcoal, as a deodoriser, and above all, in the production of artificial stone.

The two investigators chiefly turned their attention to this latter branch of the subject; and in 1852 they took out a patent for "Improvements in the Manufacture of Burned and Fired Ware." In their specification they lay claim to the production of a superior class of burned goods by using the "soluble silica," with such admixtures of ordinary clay or lime as may be required. By these means they propose to make any kind of artificial stone, more or less resembling natural stone; blocks or slabs, excellent building bricks of any colour, and good fire bricks. They do not claim any novelty in moulding or burning, except that they consider that in some cases, articles might be burned to a slight degree of hardness, then finished up by the use of tools, and afterwards reburned to any hardness that might be required.

Mr. Paine's many other duties for some time prevented his carrying this patent into effect; but at last, feeling it to be incumbent on him to make public so important a discovery, in spite of failing health and arduous occupation he commenced building the "Dippenhall Silica Factory" in 1856. Unhappily he was not able to give his personal attention to the manufacture, so that it never had the benefit of his experience and scientific knowledge, and his death in 1858 put an end to his discoveries.

The factory has therefore been carried on from the first under serious disadvantages; but enough has been done to prove that its founder was not mistaken in the importance which he attributed to the invention. It is at present managed in a very simple manner. The material is carefully ground, either wet or dry, according to the purpose for which it is required, and mixed with clays or chalk when necessary. The bricks, vases, and other articles are moulded in the ordinary way, and burned in round kilns. The building bricks, vases, and terra-cotta wares of all descriptions are generally acknowledged to be superior to anything of the same kind hitherto produced, both in appearance, finish, and durability. There are at present practical difficulties in the manufacture of large blocks of stone, which do not seem to have been contemplated by the projectors; and the fire bricks cannot yet be called superior to the Stourbridge manufacture, as was confidently expected. They are perfectly infusible under any amount of heat, but they are friable, and cannot bear a sudden change of temperature. Still, when it is remembered that the works have been carried on without any assistance from without, these difficulties only serve as incentives to further endeavours; and the present proprietor is convinced that all that is required to overcome them, and to raise the reputation of the "Dippenhall Silica Works" to the height to which their originator expected it to attain, is a man of equal scientific attainment, to resume the labours which were so prematurely arrested. — C. P.

STONE COAL. Anthracite, which see.

STONE, PRESERVATION OF. The attention of the scientific world has for some time past been directed to the importance of providing a means for protecting the stone of our public buildings from the ravages of time and the injurious effects of the polluted atmospheres of our manufacturing and populous districts.

The principal cause of the ruinous decay which is so apparent in the national edifices, churches, mansions, &c., of this country, is generally admitted to be the absorption of water charged with carbonic or other acid gases, which by its chemical action either decomposes the lime or argillaceous matter forming the combining medium uniting the several siliceous or other particles of which the stone is composed, or mechanically disintegrates those particles by the alternate expansion and contraction caused by variations of temperature.

Many processes have from time to time been suggested, and several patents secured, for filling up the pores of the stone, and thus preventing the admission of these deleterious agents, but they have been mostly if not entirely composed of oleaginous or gummy substances or compounds, which, although possessing for a time certain preservative properties, become decomposed themselves upon exposure, and constantly require to be renewed; whilst from the nature of these applications the discoloration necessarily produced is highly objectionable.

A little reflection will be sufficient to satisfy a thoughtful mind, that in seeking for a means of preserving the stone of our national buildings, &c., we ought not to rest satisfied simply with the application *of any organic substances*, however great may be their apparent preservative qualities for a time, but should endeavour to supply the defects of nature with an *indestructible mineral* incapable of change by any atmospheric iufluences.

The process of silicatisation introduced by Kuhlmann has the disadvantage of requiring some considerable time before the atmosphere can do its work of effecting the necessary combination between the silica applied in solution to the stone, and the lime contained in it, and therefore when it is applied to the external parts of any building it is liable to be washed out before solidification has been secured. Mr. Frederick Ransome, advancing from his siliceous stone process a step further, meets the condition by effecting a chemical change at once within the stone. Mr. Ransome thus describes his process :—

"Haviug been led to consider the importance of preserving the stonework of our public and private edifices from the decay resulting from the variable condition of our climate, and other causes, I directed my attention to the existing processes proposed for effecting such an object, and more especially to that which has been for some time in use on the continent, in which a soluble silicate is employed, and I found that this process, though having for its base so important and indestructible a mineral as silica, was nevertheless very imperfect in its results. It appeared to me that one great cause of failure arose from the fact that the silicate, being applied in a soluble form, was liable to be removed from the surface by rain, or even the humidity of the atmosphere, before the alkali in the silicate could absorb sufficient carbonic acid to precipitate the silicate in an insoluble form. But another great and serious defect in this process still existed, viz., that even were it possible to effect the precipitation of the silicate, still it would be simply in the form of an impalpable powder possessing no cohesive properties in itself, and therefore able to afford but little, if any, real protection to the stone. It seemed to me, therefore, necessary not only to adopt a process which should insure an insoluble precipitate being produced, independently of the partial and uncertaiu action of the atmosphere, but that, to render such means efficient, a much more tenacious substance than merely precipitated silica must be introduced; and in the course of my experiments I discovered that, by the application of a second solution, composed of chloride of calcium, a silicate of lime would be produced, possessing the strongest cohesive properties, and perfectly indestructible by atmospheric influences. The mode of operation is simply this:—The stone or other material, of which a building may be composed, should be first cleaned by the removal of any extraneous matter on the surface, and then brushed over with a solution of silicate of soda or potash (the specific gravity of which may be raised to suit the nature of the stone or other material); this should be followed by a solution of chloride of calcium, applied also with a brush; the lime immediately combines with the silica, forming silicate of lime in the pores of stone; whilst the chloride combines with the soda, forming chloride of sodium, or common salt, which is removed at once by an excess of water. From the foregoing description it will be apparent that this invention has not only rendered the operation totally independent of any condition of the atmosphere in completing the process, but the work executed is unaffected by any weather, even the most excessive rains. Experience has shown that where once applied to the stone it is impossible to remove it, unless with the surface of the stone itself. I do not confine myself solely to the solutions above referred to; in some cases I prefer to use, first a solution of sulphate of alumina, and then a solution of caustic baryta, when a precipitate of sulphate of baryta and alumina is formed, the main object being to obtain by two or more solutions, which upon being brought into contact mutually decompose each other and produce an indestructible mineral precipitate in the structure and upon the surface of the stone.

The application is one of extreme simplicity, and the material used perfectly indestructible. The rationale of the process is thus explained: a liquid will enter any porous body to saturation, whilst a solid cannot go any further than the first interstices next the surface. Take, then, two liquids capable of producing, by mutual decomposition, a solid, and by the introduction of these liquids into the cells of any porous body, a solid is produced by their mutual decomposition internally; *ergo*, if a solid could not go in as a solid it cannot come out as a solid, and chemical decomposition having destroyed the solvents, they will never again be in a state of solution. The patentee has secured to himself the application of this important principle, and whilst we name silicate of soda and chloride of calcium as the agent under mutual decomposition by contact for producing the chloride of sodium, and the imperishable silicate of lime, there are many other ingredients that are capable of producing like results.

Several large buildings in London — the Baptist chapel in Bloomsbury, amongst others — Glasgow, and other cities, have been treated by Mr. Ransome's process; a portion of the Houses of Parliament have been experimented on, and the result, so far as the time which has passed can test its merits, leaves nothing to be desired.

STONEWARE. (*Fayence*, Fr.; *Steingut*, Germ.) See POTTERY.

STORAX, STYRAX. *Liquid storax* is obtained from the storax plant, *Styrax officinalis*. The finest is a pellucid liquid, having the consistency and tenacity of Venice turpentine, a brownish colour and a vanilla-like odour. The common, which is imported from Trieste in casks, is opaque, of a grey colour, and of the consistence of bird-lime. This has been frequently confounded with liquid amber. See AMBAR — LIQUID.

Common storax. — *Styrax calamita*. This is imported in large round cakes, of a brown or reddish-brown colour. "It appears to consist of some liquid resin mixed with fine sawdust or bran."—*Pereira*.

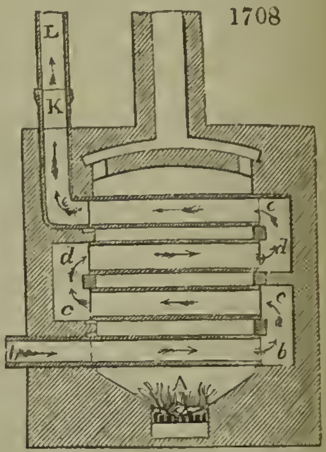
Storax in the tear. — This is imported in yellowish or reddish-white tears, about the size of peas. There are some other varieties, but these are not of sufficient importance to be noticed here. Storax has but little use, except as a pharmaceutical article.

STOVE (*Poele, Calorifère*, Fr.; *Ofen*, Germ.); is a fireplace, more or less close, for warming apartments. When it allows the burning coals to be seen, it is called a stove-grate. Hitherto stoves have rarely been had recourse to in this country for heating our sitting-rooms; the cheerful blaze and ventilation of an open fire being generally preferred. Some arrangements have been introduced for close stoves, in which charcoal or coke was burnt, and which required little or no chimney. When coke or charcoal is burned very slowly in an iron box, the carbonic acid gas which is generated, being half as heavy again as the atmospherical air, cannot ascend in the chimney at the temperature of 300° Fahr.; but regurgitates into the apartment through every pore of the stoves, and poisons the atmosphere. The large stoneware stoves of France and Germany are free from this vice; because, being fed with fuel from the outside, they cannot produce a reflux of carbonic acid into the apartment, when their draught becomes feeble, as inevitably results from the obscurely burning stoves which have the doors of the fireplace and ash-pit immediately above the hearth-stone.

Dr. Ure says:—"I have recently performed some careful experiments upon this subject, and find that when the fuel is burning so slowly in the stoves as not to heat the iron surface above the 250th or 300th degree of Fahr., there is a constant deflux of carbonic acid gas from the ash-pit into the room. This noxious emanation is most easily evinced by applying the beak of a matrass, containing a little Goulard's extract (solution of sub-acetate of lead), to a round hole in the door of the ash-pit of a stove in this languid state of combustion. In a few seconds the liquid will become milky, by the reception of carbonic acid gas. I shall be happy to afford ocular demonstration of this fact to any incredulous votary of the pseudo-economical, anti-ventilation stoves now so much in vogue. There is no mode in which the health and life of a person can be placed in more insidious jeopardy, than by sitting in a room with its chimney closed up with such a choke-damp-vomiting stove."

That fuel may be consumed by an obscure species of combustion, with the emission of very little heat, was clearly shown in Sir H. Davy's *Researches on Flame*. "The facts detailed on insensible combustion," says he, "explain why so much more heat is obtained from fuel when it is burned quickly, than slowly; and they show that, in all cases, the temperature of the acting bodies should be kept as high as possible; not only because the general increment of heat is greater, but likewise because those combinations are prevented, which, at lower temperatures, take place without any considerable production of heat. These facts likewise indicate the source of the great error into which experimenters have fallen, in estimating the heat given out in the combustion of charcoal; and they indicate methods by which the temperature may be increased, and the limits to certain methods." These conclusions are placed in a strong practical light by the following simple experiments:—I set upon the top orifice of a small cylindrical stove, a hemispherical copper pan, containing six pounds of water, at 60° Fahr., and burned briskly under it 3½ pounds of coke in an hour; at the end of which time, 4½ pounds of water were boiled off. On burning the same weight of coke *slowly* in the same furnace, surmounted by the same pan, in the course of 12 hours, little more than one-half the quantity of water was exhaled. Yet, in the first case, the aërial products of combustion swept so rapidly over the bottom of the pan, as to communicate to it not more than one-fourth of the effective heat which might have been obtained by one of the plans described in the article EVAPORATION; while, in the second case, these products moved at least 12 times more slowly across the bottom of the pan, and ought therefore to have been so much the more effective in evaporation, had they possessed the same power or quantity of heat.

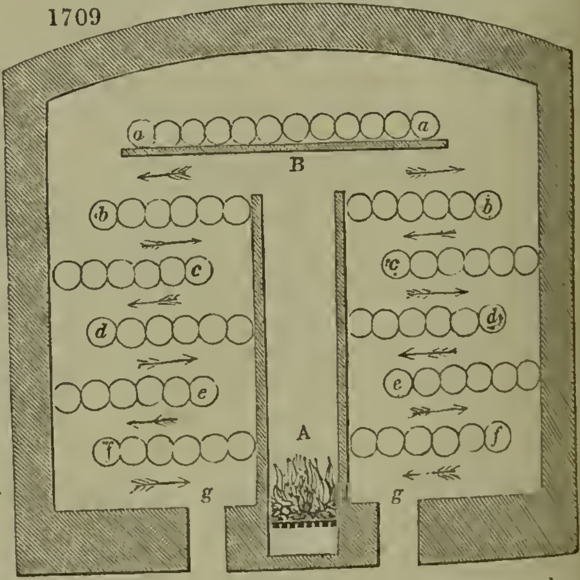
1708



Stoves when properly constructed may be employed both safely and advantageously to heat entrance-halls upon the ground story of a house; but care should be taken not to vitiate the air by passing it over ignited surfaces, as is the case with most of the patent stoves now foisted upon the public. *Fig.* 1708 exhibits a vertical section of a stove which has been recommended for power and economy; but it is highly objectionable as being apt to scorch the air. The flame of the fire A, circulates round the horizontal pipes of cast iron, *b b*, *c c*, *d d*, *e e*, which receive the external air at the orifice *b*, and conduct it up through the series, till it issues highly heated at K, L, and may be thence conducted wherever it is wanted. The smoke escapes through the chimney B. This stove has evidently two prominent faults; first, it heats the air-pipes very unequally, and the undermost far too much; secondly, the air, by the time it has ascended through the zigzag range to the pipe *e e*, will be nearly of the same temperature with it, and will therefore abstract none of its heat. Thus the upper pipes, if there be several in the range, will be quite inoperative, wasting their warmth upon the sooty air.

Fig. 1709 exhibits a transverse vertical section of a far more economical and powerful stove, in which the above evils are avoided. The products of combustion of the fire A, rise up between two brick walls, so as to play upon the bed of tiles B, where, after communicating a moderate heat to the series of slanting pipes whose areas are represented by the small circles *a*, *a*, they turn to the right and left, and circulate round the successive rows of pipes *b*, *b*, *c*, *c*, *d*, *d*, *e*, *e*, and finally escape at the bottom by the flues *g*, *g*, pursuing a somewhat similar path to that of the burned air among a bench of gaslight retorts. It is known that two-thirds of the fuel have been saved in the gas-works by this distribution of the furnace. For the purpose of heating apartments, the great object is to supply a vast body of genial air; and, therefore, merely such a moderate fire should be kept up in A, as will suffice to warm all the pipes pretty equally to the temperature of 220° Fahr.; and, indeed, as they are laid with a slight slope, are open to the air at their under ends, and terminate at the upper in a common main pipe or tunnel, they can hardly be rendered very hot by any intemperance of firing. I can safely recommend this stove to my readers. If the tubes be made of stoneware, its construction will cost very little;

1709



and they may be made of any size, and multiplied so as to carry off the whole effective heat of the fuel, leaving merely so much of it in the burned air as to waft it fairly up the chimney.

In connection with this subject Dr. Ure published in the last edition of this Dictionary some extracts from a paper communicated to the Royal Society on warming and ventilating apartments. A portion of this is still retained, as it exemplifies in a striking manner many of the evils resulting from the want of attention to this particular subject. Dr. Ure was engaged to inquire into the condition of the Long Room in the Custom-house, London, in which the air was so bad that illness continually prevailed. He thus describes the facts:—

"The symptoms of disorder experienced by the several gentlemen (about twenty in number), whom I examined, out of a great many who were indisposed, were of a very uniform character. The following is the result of my researches:—

"A sense of tension or fulness of the head, with occasional flushings of the countenance, throbbing of the temples, and vertigo, followed, not unfrequently, with a confusion of ideas, very disagreeable to officers occupied with important and sometimes intricate calculations. A few are affected with unpleasant perspiration on their sides. The whole of them complain of a remarkable coldness and languor in their extremities, more especially the legs and feet, which has become habitual, denoting languid circulation in these parts, which requires to be counteracted by the application of warm flannels on going to bed. The pulse is, in many instances, more feeble, frequent, sharp, and irritable than it ought to be, according to the natural constitution of the individuals. The sensations in the head occasionally rise to such a height, notwithstanding the most temperate regimen of life, as to require cupping, and at other times depletory remedies. Costiveness, though not a uniform, is yet a prevailing symptom.

"The sameness of the above ailments, in upwards of one hundred gentlemen, at very various periods of life, and of various temperaments, indicates clearly sameness in the cause.

"The temperature of the air in the Long Room ranged, in the three days of my experimental inquiry, from 62° to 64° of Fahrenheit's scale; and in the Examiner's Room it was about 60°, being kept somewhat lower by the occasional shutting of the hot-air valve, which is here placed under the control of the gentlemen; whereas that of the Long Room is designed to be regulated in the sunk story, by the fireman of the stove, who seems sufficiently careful to maintain an equable temperature amidst all the vicissitudes of our winter weather. Upon the 7th of January the temperature of the open air was 50°, and on the 11th it was only 35°; yet upon both days the thermometer in the Long Room indicated the same heat, of from 62° to 64°.

"The hot air discharged from the two cylindrical stove-tunnels into the Long Room was at 90° upon the 7th, and at 110° upon the 11th. This air is diluted, however, and disguised, by admixture with a column of cold air, before it is allowed to escape. The air, on the contrary, which heats the Examiners' Room, undergoes no such mollification, and comes forth at once in an ardent blast of fully 170°; not unlike the simoom of the desert, as described by travellers. Had a similar nuisance, on the greater scale, existed in the Long Room, it could not have been endured by the merchants and other visitors on business: but the disguise of an evil is a very different thing from its removal. The direct air of the stove, as it enters the Examiner's Room, possesses, in an eminent degree, the disagreeable smell and flavour imparted to air by the action of red-hot iron; and, in spite of every attention on the part of the fireman to sweep the stove apparatus from time to time, it carries along with it abundance of burned dusty particles.

"The leading characteristic of the air in these two rooms is its dryness and disagreeable smell. In the Long Room, upon the 11th, the air indicated, by Daniell's hygrometer, 70 per cent. of dryness, while the external atmosphere was nearly saturated with moisture. The thermometer connected with the dark bulb of that instrument stood at 30° when dew began to be deposited upon it; while the thermometer in the air stood at 64°. In the court behind the Custom-house, the external air being at 35°, dew was deposited on the dark bulb of the hygrometer by a depression of only 3°; whereas in the Long Room, on the same day, a depression of 34° was required to produce that deposition. Air, in such a dry state, would evaporate 0·44 inches depth of water from a cistern in the course of twenty-four hours; and its influence on the cutaneous exhalents must be proportionably great.

"As cast iron always contains, besides the metal itself, more or less carbon, sulphur, phosphorus, or even arsenic, it is possible that the smell of air passed over it in an incandescent state may be owing to some of these impregnations; for a quantity of noxious effluvia, inappreciably small, is capable of affecting not only the olfactory nerves, but the pulmonary organs

"The bell, or cockle, apparatus for heating the Long Room and the Examiner's apartment in the Custom-house consists of a series of inverted, hollow, flattened pyramids of cast-iron, with an oblong base, rather small in their dimensions, to do their work sufficiently in cold weather, when moderately heated. The inside of the pyramids is exposed to the flames of coke furnaces, which heat them frequently to incandescence, while currents of cold air are directed to their exterior surfaces by numerous sheet-iron channels. The incandescence of these pyramids, or bells, as they are vulgarly called, was proved by pieces of paper taking fire when I laid them on the summits.

"The fetid burned odour of the stove air, and its excessive avidity for moisture, are sufficient causes of the general indisposition produced among the gentlemen who are permanently exposed to it in the discharge of their public duties.

"From there being nearly a vacuum, as to aqueous vapour, in the said air, while there is nearly a plenum in the external atmosphere round about the Custom-house, the vicissitudes of feeling in those who have occasion to go out and in frequently must be highly detrimental to health.

"It may be admitted, as a general principle, that the comfort of sedentary individuals, occupying large apartments during the winter months, cannot be adequately secured by the mere influx of hot air from separate stove-rooms: it requires the genial influence of radiating surfaces in the apartments themselves, such as of open fires, of pipes, or other vessels filled with hot water or steam. The clothing of our bodies, exposed to such radiation in a pure, fresh, somewhat cool and bracing air, absorbs a much more agreeable warmth than it could acquire by being merely immersed in an atmosphere heated to 62° Fahr." Open fireplaces are, and probably will ever remain, favourites in this country. There is no doubt that the ordinary arrangement of our fireplaces is very defective. Much heat is lost — there is not an equal diffusion, and those sitting in the apartment are exposed to annoying drafts of cold air. Arranged as our buildings are, it is not easy to perceive how any very great improvement could be made so long as we desire the enjoyment of an open fire, and the luxury of light and air.

In the greater number of stoves proper, the objections mentioned by Dr. Ure are obvious to every one. In the more common kinds of stove the fire is surrounded directly by the surface to be heated, which, being placed unprotected in the room, radiates heat and warms the air by direct contact. All such are liable to become overheated, and then the unpleasant smell imparted to the air is highly objectionable. Such stoves also dry the air, and the result is that headaches and other annoying sensations are produced. The common stove need not be described. Dr. Arnott introduced, some years since, a stove in which the arrangements were very complete; and as the combustion was regulated with much facility, they were economical. The chief feature of Arnott's stove was a mode of adjusting the amount of air supplied to the fire. A regulating valve is fitted to the aperture of the ashpit, consisting of a frame nicely balanced, and turning with the slightest force upon a centre; to this is attached a steel yard, in which are several holes for the insertion of a weight. This determines exactly the size of the opening, and of course regulates the quantity of air admitted to the fire.

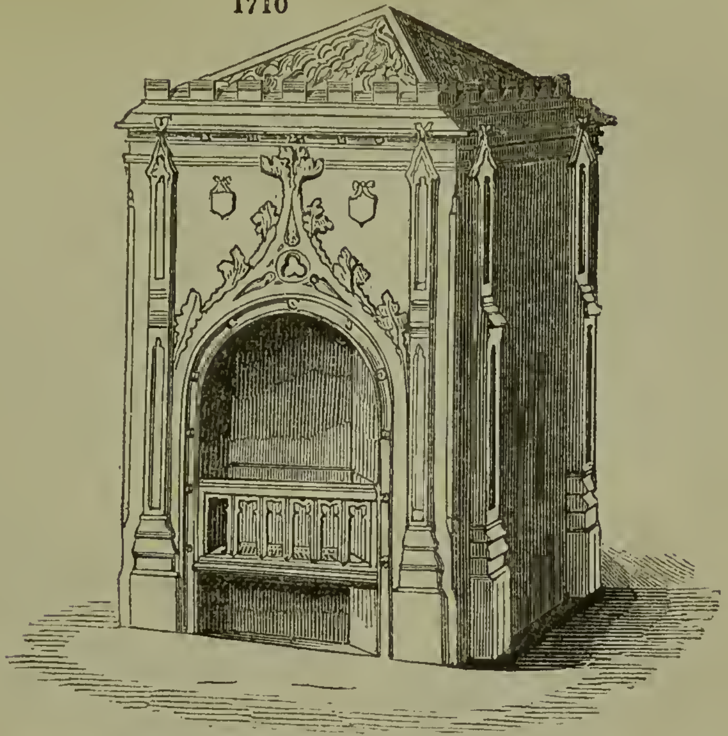
Dr. Ure states that in these stoves there is a tendency, when the stove is not heated above 250° or 300°, to the formation of considerable quantities of carbonic acid, which finds its way into the room from the ashpit door; and when the combustion is languid, carbonic oxide is often formed, which passes away by the chimney unconsumed, involving a loss of heat.

Space will not admit of our describing the Dutch or American stoves, which are mainly modifications of the ordinary forms, which are sufficiently well known. Pierce's pyro-pneumatic stove grate, shown *fig.* 1710, appears to meet the requirement of a stove, of an open fire, and good ventilation, in a remarkable manner.

In the annexed sketch is delineated the operation of the pyro-pneumatic stove, when employed in a large room *fig.* 1711. The channel B, serves to supply pure air from any source external to the building. The amount of the supply is regulated by the valve at B, and the direction of the currents is shown by the arrows. The fresh air is warmed in its course through the stove, and ascends to the ceiling, where it becomes diffused, and then descends, passing off by the smoke flue. A special tube, D, is provided for ventilating the gas lights, as exhibited in *fig.* 1711.

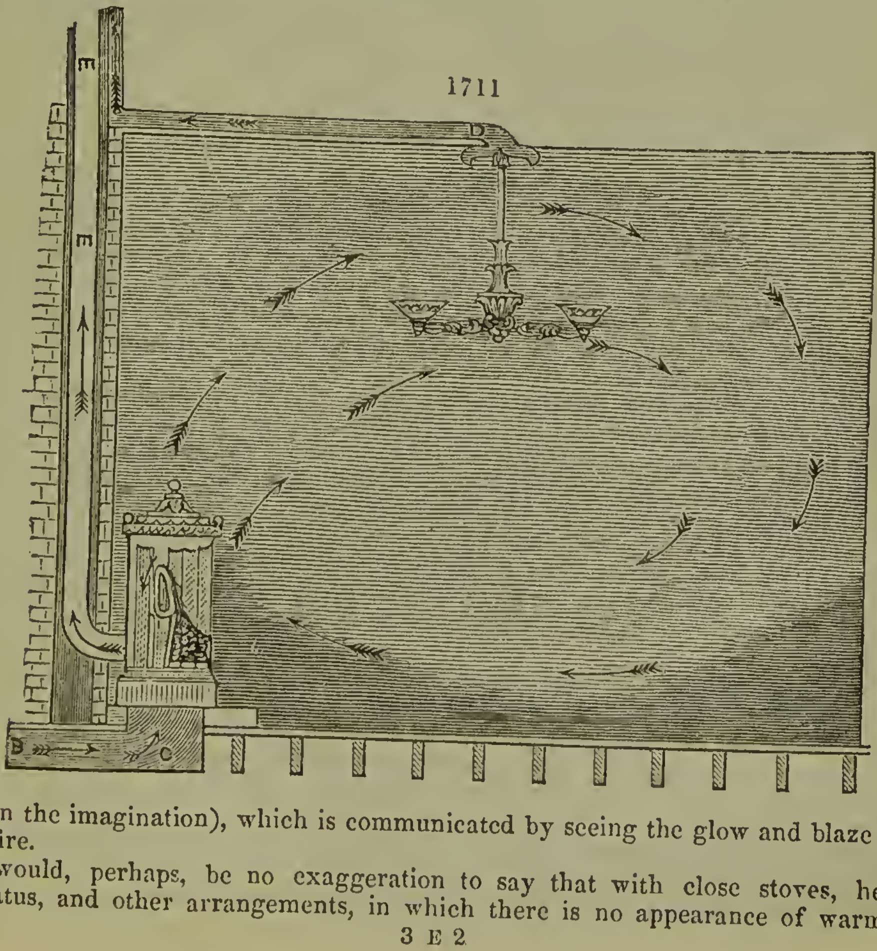
The application of the pyro-pneumatic stove to the warming of churches is extremely simple, and its effects are found highly satisfactory. It gives an abundant supply of fresh air, warmed to the desired temperature, and thereby prevents the influx of an impure atmosphere from vaults and other sources of pollution. It carries off the vitiated air by the smoke flue, or in cases where a more rapid ventilation may be desirable, the warmth which it imparts to the air is sufficient to create an ample current in any shaft or ventilator that may be provided in the roof or spire of the building.

1710



In all cases this apparatus is economical in a high degree, not only from the smallness of its first cost, but also from the fact that the full effect of the fuel consumed in it is secured to the uses of warming and ventilation. One element of economy cannot be too strongly insisted on, viz. the feeling of warmth and comfort (even if it only

1711



exist in the imagination), which is communicated by seeing the glow and blaze of an open fire.

It would, perhaps, be no exaggeration to say that with close stoves, heating apparatus, and other arrangements, in which there is no appearance of warmth, a *much higher temperature of the atmosphere is required to make it even feel* as warm as in that of an apartment heated by an open fire. Indeed it may be fairly asserted that most persons will tolerate inconvenience and submit to expense, provided they see the cheerful blaze of the open fire, which they are at liberty to approach at will, and in the ever varying embers of which they can conjure up visions of the past and fancies of the future.

One of the large pyro-pneumatic stove graves, when in full operation, is found to be capable of heating an apartment containing 50,000 cubic feet of air. In a very large church, containing upwards of 175,000 cubic feet of air, and capable of accommodating a congregation of 1,500 persons, four of these stoves of moderate size, arranged in convenient positions towards the angles of the building, so that every individual of the congregation may see the fire, are found to be sufficient in the coldest weather, and do not even require to be sustained in full action, except during a few hours in the morning. One of these stove-grates placed in the hall or lower part of a staircase, warms and tempers the internal climate of a large house, and gives the whole building a plentiful supply of pure fresh air. One of the smaller grates is capable of warming a large room. And whether in dwelling houses, schools, churches, or apartments, the arrangements can readily be brought into operation at a moderate cost, and without any (beyond the most trifling) interference with existing structural arrangements.

The same inventor has introduced what he calls the fresh air fire-lump stove grate, which may be thus described:—This grate is formed of the purest and best fire-clay, moulded in suitable forms, adapted to the varied arrangements that are found necessary, and consists of the open fire-grate bars in front, surrounded at the sides and back by the fire-clay lumps, around which lumps an air-chamber is formed, communicating with the external atmosphere, admitting air to a cavity in the lower part of the grate, which communicates with the mouths of the vertical channels in the earthen lumps that surround the fire. The warmth, which is communicated to the air through the body of these lumps, and which, from their small conducting power, rarely exceeds 90°, and can never be excessive, causes it to ascend through openings in the upper part of the casing into the apartment; its place being supplied by fresh accessions of air from below. The warm air thus admitted into the apartment floats above, and gradually descends as it cools, its place being supplied by warmer air from the stove-grate, and taking with it to the fire all the impurities of respiration, which is carried away by the flue, in which the heat maintains a constant upward current. Valves are provided for regulating the quantity and temperature of the fresh air admitted, and its distribution into the apartment when warmed.

STRASBURG TURPENTINE. See Abietine.

STRASS. See Pastes.

STRAW-HAT MANUFACTURE. The mode of preparing the Tuscany or Italian straw, is by pulling the bearded wheat while the ear is in a soft milky state, the corn having been sown very close, and of consequence produced in a thin, short, and dwindled condition. The straw, with its ears and roots, is spread out thinly upon the ground in fine hot weather, for 3 or 4 days or more, in order to dry the sap; it is then tied up in bundles and stacked, for the purpose of enabling the heat of the mow to drive off any remaining moisture. It is important to keep the ends of the straw air-tight, in order to retain the pith, and prevent its gummy particles from passing off by evaporation.

After the straw has been about a month in the mow, it is removed to a meadow and spread out, that the dew may act upon it, together with the sun and air, and promote the bleaching, it being necessary frequently to turn the straw while this process is going on. The first process of bleaching being complete, the lower joint and root is pulled from the straw, leaving the upper part fit for use, which is then sorted according to qualities; and after being submitted to the action of steam, for the purpose of extracting its colour, and then to a fumigation of sulphur, to complete the bleaching, the straws are in a condition to be platted or woven into hats and bonnets, and are in that state imported into England in bundles, the dried ears of the wheat being still on the straw.

Straw cannot be bleached by a solution of chloride of lime, as this preparation always turns the straw yellow. For this purpose, a cask open at both ends, with its seams papered, is to be set upright a few inches from the ground, having a hoop nailed to its inside, about six inches beneath the top, to support another hoop with a net stretched across it, upon which the straw is to be laid in successive handfuls loosely crossing each other. The cask having been covered with a tight overlapping lid, stuffed with lists of cloth, a brazier of burning charcoal is to be inserted within the bottom, and an iron dish containing pieces of brimstone is to be put upon the brazier. The brimstone soon takes fire, and fills the cask with sulphurous acid gas.

whereby the straw gets bleached in the course of three or four hours. Care should be taken to prevent such a violent combustion of the sulphur as might cause black burned spots, for these cannot be afterwards removed. The straw, after being aired and softened by spreading it upon the grass for a night, is ready to be split, preparatory to dyeing. Blue is given by a boiling-hot solution of indigo in sulphuric acid, called *Saxon blue*, diluted to the desired shade; yellow, by decoction of turmeric; red, by boiling hanks of coarse scarlet wool in a bath of weak alum water, containing the straw; or directly, by cochineal, salt of tin, and tartar. Brazil wood and archil are also employed for dyeing straw. For the other colours, see their respective titles in this Dictionary.

STREAM-WORKS. The name given by the Cornish miners to alluvial deposits of tin ore.

STRETCHING MACHINE. Cotton goods and other textile fabrics, either white or printed, are prepared for the market by being stretched in a proper machine, which lays all their warp and woof yarns in truly parallel positions. A very ingenious and effective mechanism of this kind was made the subject of a patent by Mr. Samuel Morand, of Manchester, in April, 1834, which serves to extend the width of calico pieces, or of other cloths woven of cotton, wool, silk, or flax, after they have become shrunk in the processes of bleaching, dyeing, &c. I regret that the limits of this volume will not admit of its description. The specification of the patent is published in *Newton's Journal* for December, 1835.

STRINGS (a *miner's term*). The name given by the Cornish miners to the small filamentous ramifications of a metallic vein.

STRIPPING LIQUID, SILVERSMITH'S, consists of 8 parts of sulphuric acid and 1 part of nitre.

STRONTIA (*oxide of strontium*), one of the alkaline earths, of which *strontium* is the metallic basis, occurs in a crystalline state, as a carbonate (*strontianite*), in the lead mines of Strontian, in Argyleshire — whence its name. The sulphate (*celestine*) is found crystallised near Bristol, in New Red marl, and in several other parts of the world; but strontian minerals are rather rare. The pure earth is prepared exactly like baryta, from either the carbonate or the sulphate. It is a greyish-white porous mass, infusible in the furnace, not volatile, of a specific gravity between 3·0 and 4·0 : 3·9321 (*Karsten*), having an alkaline reaction on vegetable colours, an acrid, burning taste, sharper than lime, but not so corrosive as baryta, potash, or soda. It becomes hot when moistened, and slakes into a white pulverulent hydrate, dissolves at 60° in 50 parts of water, and in much less at the boiling point, forming an alkaline solution, called *strontia* water, which deposits crystals in four-sided tables as it cools. These contain 60·9 per cent. of water, are soluble in 52 parts of water at 60°, and in 2·4 parts of boiling water; when heated they part with 50 per cent. of water, but retain the other parts, even at a red heat. The dry earth consists of 84·6 of base, and 15·4 of oxygen. It is readily distinguished from baryta, by its inferior solubility, and by its soluble salts giving a red tinge to flame, while those of baryta give a yellow tinge. Fluosilicic acid precipitates the salts of the latter earth, but not those of the former. The compounds of strontia are not poisonous, like those of baryta. The only preparation of strontia used in the arts is the NITRATE, which see.—H. W. B.

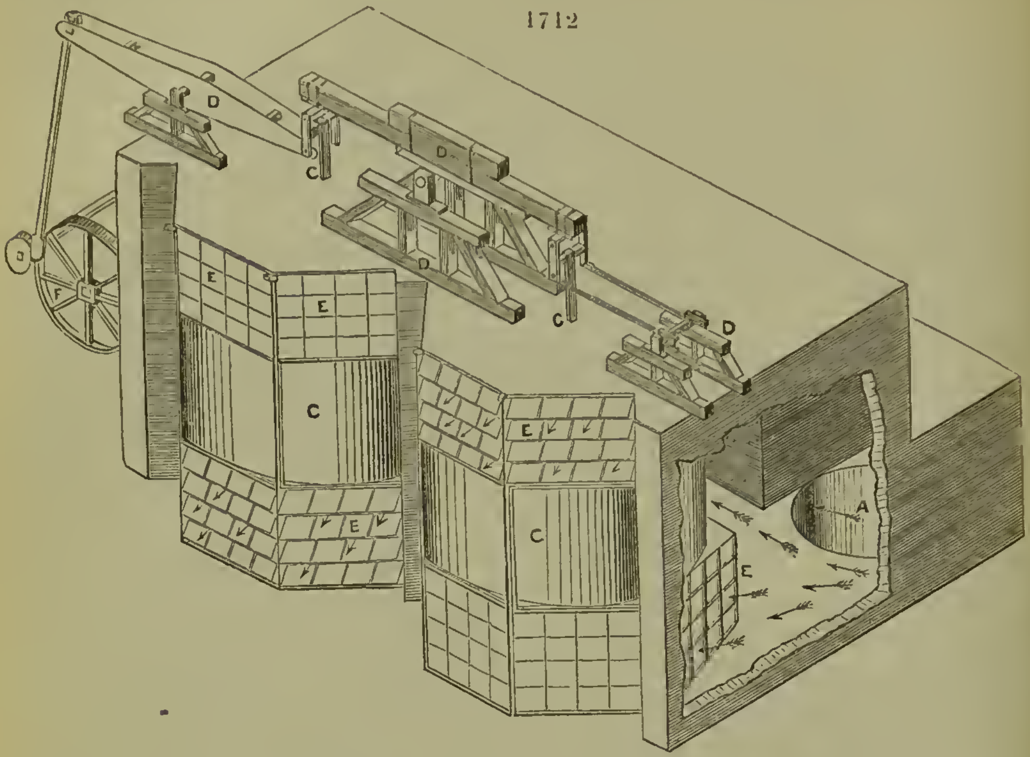
STRONTIA, NITRATE OF. (*Nitrate de strontiane*, Fr.; *Salpetersaürer strontian*, Germ.) This salt is usually prepared from the sulphide of strontium, obtained by decomposing sulphate of strontia with charcoal, by strong ignition of the mixed powders in a crucible. This sulphide being treated with water, and the solution being filtered, is to be neutralised with nitric acid, as indicated by the test of turmeric paper; care being taken to avoid breathing the noxious sulphuretted hydrogen gas, which is copiously disengaged. The neutral nitrate being properly evaporated and set aside, affords colourless, transparent, slender, octahedral crystals. It has a cooling, yet somewhat acrid taste; is soluble in 5 parts of cold, and in one half part of boiling water. Its principal use is the preparation of "red fire" for pyrotechnic works and theatrical effects. A very beautiful exhibition of red fire is obtained by preparing a gun-paper, by treating ordinary bibulous paper with nitric and sulphuric acids, and then well washing it; when quite free from acid, it is to be dried, and then saturated with a solution of the chloride of nitrate of strontia.—H. W. B.

STRONTIUM. The metallic base of the earth strontia; first obtained by Sir Humphry Davy, in 1808. It is prepared in the same way as barium. See BARIUM. —H. W. B.—See *Ure's Chemical Dictionary*.

STRUVE'S MINE VENTILATOR. The striking novelty of this ventilator is the gigantic scale upon which it has been constructed. Although in principle a pump of the simplest form, some of the pistons have been made 20 feet in diameter, and two pumps are about being constructed 21 feet in diameter. See *fig.* 1712.

In some mines to which the machine has been applied, the rarefaction and ventilation has proved so strong as to prevent single doors being opened, unless protected by supplemental doors. The circumstance of the air not being compressed in the

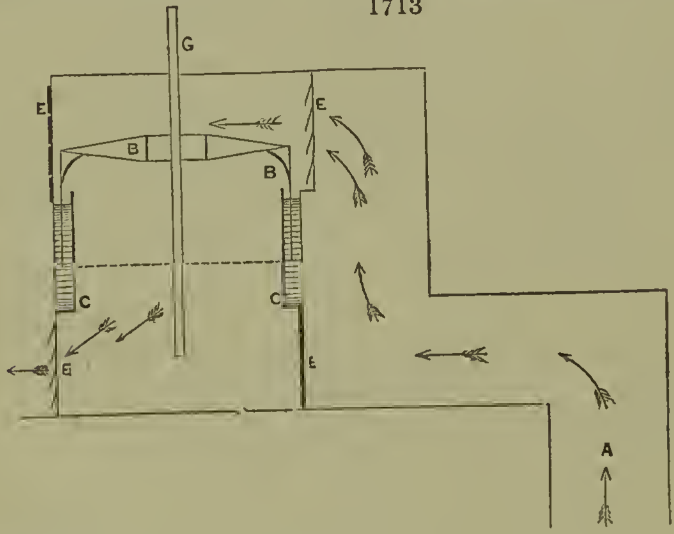
1712



machine, admits of large valve spaces, so that there is scarcely any appreciable resistance to the passage of the air through the machine.

The annexed drawing, *fig.* 1712, represents the machine in operation at the Go-

1713



A. The upcast pit.
B. Hollow pistons, made of wrought iron.
C. Wrought iron tanks, resting on two blocks of masonry, and on six iron pillars.
D. Beam work, resting on three blocks of masonry.
E. The valve work and framing, fastened to sixteen upright pieces of timber, 9 inches square.
F. Crank wheel of steam engine.
G. Piston rods.

vernor and Company's large collieries at Cwm Avon, Glamorganshire, and the following list of licences granted to several large colliery proprietors, is a convincing proof that this invention ranks high among the modern improvements of mining.

The sectional view explains the internal construction, the darts showing the air-currents ascending the upcast pit A, from the interior of the mine into the machine.

The piston B, is shown immersed in water, which forms an air-tight packing.

The front or outlet valves E, are shown in the external view of the ventilator The end of the machine is represented open in the drawing, for the convenience of showing the inlet valves E, and of explaining the internal construction.

Mine ventilators of this construction, and of capacities varying from 20,000 to 100,000 cubic feet of air per minute, have been erected at the following collieries:—

The Eaglesbush colliery: 2 of 12 feet in diameter.

The Westminster colliery, near Wrexham: 2 of 17 feet in diameter.

The Mynidd-Bach-y-Glo colliery, near Swansea: 2 of 16 feet in diameter.

The Bryndu colliery, near Bridgend: 2 of 17 feet in diameter.

The Millwood colliery, near Swansea: 1 of 12 feet in diameter.

The Middle Dyffryn colliery, Aberdare, T. Powell, Esq.: 2 of 20 feet in diameter.

Cwm Avon collieries, the English Copper Company: 2 of 18 feet in diameter.

The Neath Abbey Coal Company, Neath, now erecting: 2 of 16 feet diameter.

Rhimney Valley, near Cardiff, Thomas Powell, Esq.: 2 pumps, 20 feet diameter each.

The Risca Coal Company, Newport, Monmouthshire: 2 pumps of 20 feet diameter each.

The Lletti Schenheir colliery, Aberdare: 2 pumps of 21 feet diameter each.

The air-ports, or valve-work, can be made three-fourths of the area of the pistons, thus reducing the assistance of the air-current through the machine to a minimum.

These machines can be applied to winding shafts.

Cost of machines about 200*l.*, for capacities of 10,000 cubic feet of air per minute.

STRYCHNINE. $C^{42}H^{22}N^{2}O^{4}$. The bitter poisonous principle contained in the different varieties of *strychnos*. It is usually extracted for commercial purposes from the nux vomica bean, the seed of the *S. nux vomica*. It is a well-marked alkali, and yields a great number of crystalline salts with acids and metallic chlorides. Its true constitution has been fully made out by the researches of Messrs. Nicholson and Abel. Although a most valuable medicine in paralytic affections, when employed in very small doses, it is a dangerous remedy in unskilful hands, and has been the cause of numerous deaths arising from carelessness, without reckoning the many who have been destroyed by it at the hands of the poisoner. Some years ago a panic was occasioned by a rumour of its employment for the purpose of giving a bitter flavour to beer; this has been shown to be incorrect. Still the quantities of it produced annually by various manufacturers could not fail to excite attention and uneasiness. As much as 1000 ounces have been known to be purchased at one time. It has been proved, however, that the chief use is for the destruction of wild animals in Australia and other thinly peopled localities. A great number of processes have been devised for its preparation, but, after having been subjected to the extractive operations, the bean is generally found almost as bitter as before, indicating a want of economy in the methods. Probably the best method of extraction would be to disintegrate the beans with strong sulphuric acid (which is without action on strychnine), and then, after the addition of excess of alkali, to dissolve out the base with benzole or chloroform. The latter being distilled off would leave the strychnine nearly pure, and only requiring crystallisation. It has been shown by John Williams, that one bean will by this process yield a considerable quantity of crystals of pure strychnine.

The detection of strychnine has unhappily become a problem of only too frequent occurrence in chemical laboratories. It is, therefore, most important that ready and accurate methods should be known for the purpose. The following process may be relied on; it is founded on that adopted by Graham and Hofmann for the detection of it when present in beer. The stomach or other organic substance is to be cut small and boiled with dilute hydrochloric acid for a quarter of an hour. The acid fluid, after filtration, is to be carefully neutralised with potash, and then digested with recently ignited ivory black. The charcoal is to be separated by filtration, and, when well drained, is to be boiled with spirit of wine. The strychnine which will have been absorbed by the charcoal will be dissolved out by the spirit. The latter is then to be distilled off on the water bath. The contents of the retort being transferred to an evaporating basin are to be exposed on the water bath until dry. The residue is then to be tasted; if bitter, the process may be completed, but if no bitterness is observed it is scarcely worth while to proceed, as the merest trace of strychnine is capable of exciting the sense of extreme bitterness. The residue is to have a slight excess of potash added, and is to be shaken up with chloroform. The chloroform being separated is to be evaporated off. The operation must be repeated if the product be coloured. The substance thus obtained is to have a little strong oil of vitriol added, and a piece of bichromate of potash is to be rubbed on the parts where the strychnine is supposed to be; if present, rich deep purple streaks will become evident.—C. G. W.

STUCCO. See STONE, ARTIFICIAL.

SUBERIC ACID (from *Suber*, *bark*, Lat.; *korksaure*, Germ.) is prepared by digesting grated cork with nitric acid. It forms crystals, which sublime in white vapours when heated.

It may also be obtained by boiling nitric acid with stearic, margaric, or oleic acids. Its formula is $C^8H^6O^3,HO$.

SUBSALT. A salt in which the acid is insufficient to saturate the base. For a full examination of the theory of salts see *Ure's Dictionary of Chemistry*.

SUBLIMATE, is any solid matter resulting from condensed vapours. See CORROSIVE SUBLIMATE.

SUBLIMATION, the process by which volatile matter is vaporised by heat, and then condensed into a crystalline mass. For example, if gum benzoin is kept in a melted state, and even a cap of paper kept above it, the benzoic acid is first volatilised and then condensed on the paper. See AMMONIUM CHLORIDE, for an example of sublimation.

SUCCINIC ACID, *Acid of Amber* (*Acide Succinique*, Fr.; *Bernsteinsäure*, Germ.), was formerly obtained by the destructive distillation of amber, in which process it was accompanied by an essential oil, and a little acetic acid; it was purified by being precipitated as succinate of lead, which, after being well washed, was decomposed by the equivalent quantity of sulphuric acid; the solution of succinic acid, thus obtained, was evaporated, and allowed to cool, when the succinic acid crystallised out. It seems to exist ready formed in amber.

It is easily obtained artificially by acting on stearic or palmitic acid with nitric acid. It also occurs in the leaves of the wormwood, and in many of the resins of the pine tribe. It may likewise be obtained by fermentation from asparagin, and from malic acid, malate of lime yielding nearly one-third of its weight of it.

In order to produce it from malic acid, 3 lbs. of crude malate of lime are to be diffused through a gallon of warm water, and four ounces of decayed cheese added to the mixture, which is to be kept at the temperature of 100° for about a week. Carbonic acid is disengaged, whilst a mixture of crystallised carbonate and succinate of lime is deposited, and acetate of lime remains in solution.

$$\overbrace{3(2CaO,C^8H^4O^8)}^{\text{Malate of lime.}} = \overbrace{2(2CaO,C^8H^4O^6)}^{\text{Succinate of lime.}} + \overbrace{CaO,C^4H^3O}^{\text{Acetate of lime.}} + CaO,CO^2 + 3CO^2 + HO.$$

The succinate of lime is to be washed with cold water, and decomposed by hydrochloric acid, and the succinic acid purified by crystallisation. Sometimes there is in this process some lactic acid, and perhaps butyric acid formed; butyric acid by the action of nitric acid is converted into succinic acid.

$$\overbrace{HO,C^8H^7O^3}^{\text{Butyric acid.}} + O^6 = \overbrace{2HO,C^8H^4O^6}^{\text{Succinic acid.}} + 2HO.$$

Succinic acid crystallises in large, regular rhombic tables, soluble in five parts of cold and two of boiling water. It is freely soluble in alcohol, but only sparingly so in ether. It melts between 347° and 356°, but if suddenly heated to 455°, it melts and sublimes completely. It may be obtained anhydrous by distilling it with anhydrous phosphoric acid. Its principal use is for the precipitation of the persalts of iron from neutral solutions, when we wish to separate iron from nickel, cobalt, and magnanese; for this purpose it is used in the form of succinate of ammonia.—H. K. B.

SUET. See TALLOW.

SUGAR (*Sucre*, Fr.; *Zucker*, Germ.) is, with some slight exception, the sweet constituent of vegetable and animal products. It may be distinguished into three principal species. The first, which occurs in the sugar-cane, the beet-root, and the maple, crystallises in oblique four-sided prisms, terminated by two-sided summits; it has a sweetening power which may be represented by 100; and in circumpolarisation it bends the luminous rays to the right. The second occurs ready formed in ripe grapes and other fruits; it is also produced by treating starch with diastase or sulphuric acid. This species forms cauliflower concretions, but not true crystals; it has a sweetening power, which may be represented by 60, and in circumpolarisation it bends the rays to the left. Berthelot has lately shown that a moderately strong solution of glycerine, in contact with certain animal membranes, is found, after some weeks, to produce a substance with the properties of grape sugar. One pint of glycerine in 10 pints of water is added to the membrane, which may amount to $\frac{1}{20}$th of the weight of the glycerine. The time required is 10 to 12 weeks. If putrefaction begins it is destroyed. The third variety is found in fruits, and also in sugar which has been long boiled, or heated with acids; this is called fruit sugar. Besides these three principal kinds, the sugar of milk, and the sugar of manna, or *mannite*, are found closely allied, and may be called two other species. Allied to these is *sorbine*, extracted from the elderberry, and *mosite*, which occurs in the flesh of animals.

Sugar, extracted either from the cane, the beet, or the maple, is identical in its properties and composition, when refined to the same pitch of purity; that of the beet is said to surpass the other two in cohesive force, since larger and firmer crystals of it are obtained from a clarified solution of equal density; but this probably arises from the superiority of European over tropical manufacture. Sugar melts at 320° Fahr., and on cooling forms a transparent substance usually called *barley sugar*. When heated to between 400° and 410° Fahr. it loses two equivalents of water and becomes brown. Sugar thus fused is no longer capable of crystallisation, and is called caramel by the French. It is used for colouring liqueurs. Indeed, sugar is so susceptible of change by heat, that if a colourless solution of it be exposed for some time to the temperature of boiling water, it becomes brown and partially uncrystallisable. Acids exercise such an injurious influence upon sugar, that after remaining in contact with it for a little while, though they be rendered thoroughly neutral, a great part of the sugar will refuse to crystallise. Thus, if oxalic or tartaric acid be added to sugar in solution, and boiled, no crystals of sugar can be obtained by evaporation, even though the acids be neutralised by chalk or carbonate of lime. By boiling cane sugar with dilute sulphuric acid, and keeping it at least at 150° Fahr., it is changed into grape sugar, and then entirely into uncrystallisable sugar. Nitric acid converts sugar into oxalic acid. Alkaline matter is likewise most detrimental to the grain of sugar; as is always evinced by the large quantity of molasses formed when an excess of lime has been used in clarifying the juice of the cane or the beet.

Manufacturers of sugar should, therefore, be particularly watchful against the formation of acid from decomposition, or the introduction of any excess of alkali, or alkaline earth.

When one piece of lump sugar is rubbed against another in the dark, light is emitted.

Sugar is soluble in all proportions in water, but it takes four parts of spirits of wine, of spec. grav. 0·830, and 80 of absolute alcohol, to dissolve it, both being at a boiling temperature. As the alcohol cools, it deposits the sugar in crystals. Caramelised and uncrystallisable sugar dissolve readily in alcohol. Pure sugar is unchangeable in the air, even when dissolved in a good deal of water, if the solution be kept covered, at least in the dark; but with a very small addition of gluten, the solution soon begins to ferment, whereby the sugar is decomposed into alcohol and carbonic acid, by the action of the air; it then passes into acetic acid, when it may be still farther decomposed.

Sugar forms chemical compounds with the salifiable bases. It dissolves readily in caustic potash lye, whereby it loses its sweet taste, and affords on evaporation a mass which is insoluble in alcohol. When the lye is neutralised by sulphuric acid, the sugar recovers partially its sweet taste, and may be separated from the sulphate of potash by alcohol, but it will no longer crystallise.

That syrup possesses the property of dissolving the alkaline earths, lime, magnesia, strontia, baryta, &c., was demonstrated long ago by Mr. Ramsay, of Glasgow. He says that syrup is capable of dissolving half as much lime as it contains of sugar; and as much strontia as sugar.

If syrup be boiled with oxide of lead in excess, if the solution be filtered boiling hot, and if the phial be corked in which it is received, white bulky flocks will fall to the bottom in the course of 24 hours. This compound is best dried *in vacuo*. It is in both cases light, tasteless, and insoluble in cold and boiling water; it takes fire like German tinder (AMADOU), when touched at one point with an ignited body, and burns away, leaving small globules of lead. It dissolves in acids, and also in neutral acetate of lead, which forms with the oxide a subsalt, and sets the sugar free.

Carbonic acid gas passed through water in which the above saccharate is diffused, decomposes it, with precipitation of carbonate of lead. From the powerful action exercised upon sugar by acids and oxide of lead, we may see the fallacy and danger of using these chemical reagents in sugar-refining. Sugar possesses the remarkable property of dissolving the oxide, as well as the subacetate of copper (verdigris), and of counteracting their poisonous operation. Orfila found that a dose of verdigris, which would kill a dog in an hour or two, might be swallowed with impunity, provided it was mixed with a considerable quantity of sugar. When a solution of sugar is boiled with the acetate of copper, it causes an abundant precipitate of protoxide of copper; when boiled with the nitrates of mercury and silver, or the chloride of gold, it reduces the respective bases to the metallic state.

The following will show the composition of the various sugars, and their principal combinations with bases:—

Cane sugar, or sucrose - - -	$C^{12}H^{11}O^{11}$
Grape or starch sugar, or glucose -	$C^{12}H^{12}O^{12},2HO$
Fruit sugar, or fructose - - -	$C^{12}H^{12}O^{12}$ at 212° F.
Milk sugar, or lactose - - -	$C^{24}H^{19}O^{19},5HO$
Manna sugar, or mellitose - -	$C^{24}H^{24}O^{24},4HO$

Compounds of cane sugar called sugarates.

With soda - - - - -	$NaO,C^{12}H^{11}O^{11}$
With potash - - - - -	$KO,C^{12}H^{11}O^{11}$
With lime - - - - -	$CaO,C^{12}H^{11}O^{11}$
With baryta - - - - -	$BaO,C^{12}H^{11}O^{11}$
With lead - - - - -	$C^{24}\frac{H^{18}}{Pb^{4}}O^{22}$, or $2PbO,C^{12}H^{9}O^{9}$
With common salt - - - -	$NaCl,C^{24}H^{21}O^{21}$

Compounds of grape sugar, or glucose.

With baryta - - - - -	$C^{24}\frac{H^{22}}{Ba^{2}}O^{24},6HO$, or $3BaO,C^{24}H^{28}O^{28}$
With lime - - - - -	$C^{24}\frac{H^{22}}{Ca^{2}}O^{24},6HO$, or $3CaO,C^{24}H^{28}O^{28}$
With lead - - - - -	$C^{24}\frac{H^{18}}{Pb^{3}}O^{24},4HO$, or $6PbO,C^{24}H^{21}O^{21}$
With common salt - - - -	$C^{24}H^{24}O^{24},NaCl,2HO$

Cane sugar is soluble in all proportions in boiling water, and in ⅓ of cold. It is sparingly soluble in alcohol of 70 pc. and insoluble in absolute alcohol. The following table, by Payen shows the quantity of sugar contained in saccharine solutions of various specific gravity at 59° F. :—

Parts of sugar.		Parts of water.		Specific gravity.
100	dissolved in	50	give a syrup of	1·345
100	„	60	„	1·322

The specific gravity of crystallised cane sugar is 1·594. Crystallised cane sugar seems to be the most complete type of sugar known. Its crystals are the largest and most regular, and its taste the sweetest. These crystals are rhomboidal prisms, and appear largest in the form of sugar candy. When boiled much or heated with acids it would appear that a lower form of sugar resulted, namely, grape-sugar. This sugar crystallises with difficulty in tufts of small needles. When the same treatment is further continued the power to crystallise is entirely lost. It has been attempted, but without success, to reverse these processes. The solution of this problem would be of great value to the world, and already much time and talent have been expended upon it.

At 300° sugar loses 0·6 per cent., and remains uninjured after seven hours; it melts at 320°, and at this point it seems to have lost some of its sweetness, and probably a portion of water. The same result is obtained at a lower temperature if more time is allowed. The colour is changed to an orange-yellow at 410°: the sugar loses three equivalents of water, becomes gradually brown, has an empyreumatic taste, and is called *caramel*. With a heat approaching to a red heat, carburetted hydrogen, carbonic acid, acetic acid, and empyreumatic oils are produced, and carbon remains, amounting to 25 per cent. of the original mass. This disengagement of gases occurs with immense enlargement of volume, so that the carbonaceous residue is rendered exceedingly porous. If these gaseous products are inflamed, which may be done at 500°, the amount of heat disengaged is very great. It is believed generally that a perfectly pure solution of cane sugar in water will not decompose: this certainly is found to be the case in very dense solutions, at least after the lapse of several years; but when weak solutions are used, decomposition is effected in the course of a few months, even though the sugar is pure, the water distilled, and the vessel remain unopened.

Solutions of sugar are readily decomposed by acids as well as by acid salts of every kind. They are decomposed also almost as readily by caustic alkaline solutions, and by hot solutions of the carbonated fixed alkalies. Under the name alkaline solutions must be included both baryta and lime, if heat is to be long used, but both of these substances form compounds with sugar, the first of which will be treated of when beet-root sugar is under consideration. The compound of sugar and lime is very soluble in cold water, but is precipitated on heating. The amount dissolved is shown to be a true equivalent, by the inquiries of Peligot, who has proposed an ingenious method of ascertaining the amount of sugar in a solution by the estimation of the lime which it will dissolve. The lime in this process is estimated alkalimetrically by means of an acid. The following table has been constructed by M. Peligot for calculating the results:—

Quantity of sugar dissolved in 100 parts of water.	Density of syrup.	Density of syrup when saturated with lime.	100 parts of residue dried at 120° contain	
			Lime.	Sugar.
40·0	1·122	1·179	21·0	79·0

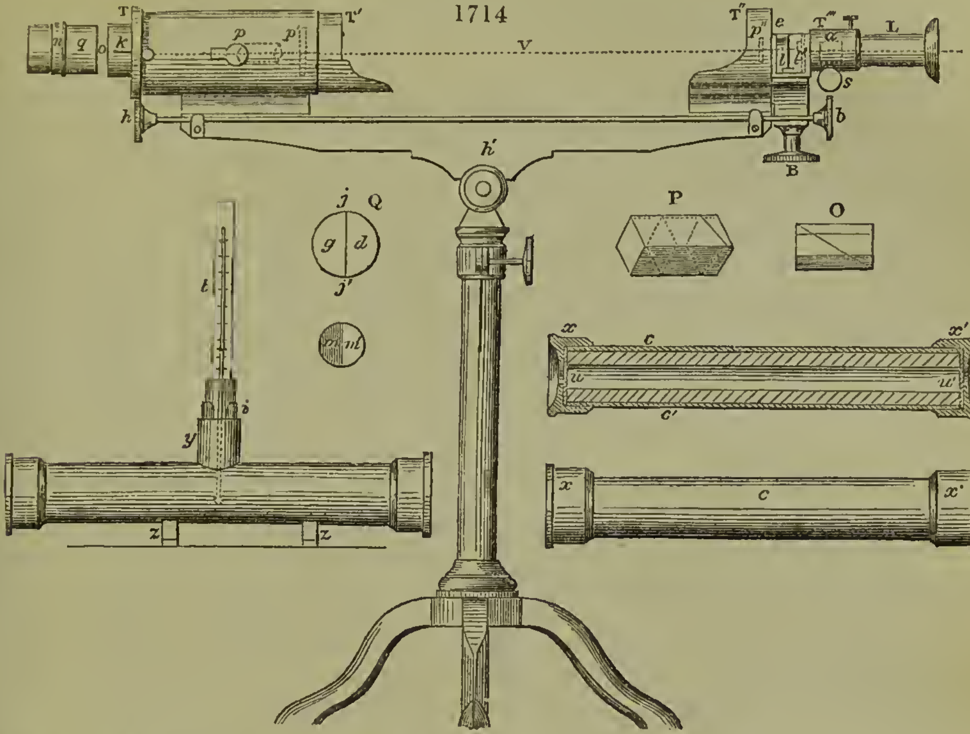
2·5	1·009	1·014	13·8	86·2

Sugar has the capacity of reducing many of the higher to lower oxides, and also of entirely reducing the oxides of some of the metals. At the same time it effects the oxidation of some of the commoner metals, and keeps the oxides in solution. As an example of these actions, the hydrated peroxide of iron is reduced to protoxide, and retained in solution, whilst the hydrated oxide of copper is reduced to the sub-oxide and precipitated in solutions both of grape sugar and uncrystallisable sugar. This action has been proposed as a mode of estimating the proportion of grape and uncrystallisable sugar in saccharine solutions, as will be shown. Iron is readily acted upon by grape and uncrystallisable sugar, and is retained in solution by sugar of every kind. Neither iron, zinc, nor lead are thrown down from sugar solutions by the usual alkaline reagents, bnt sulphide of ammonium separates them entirely.

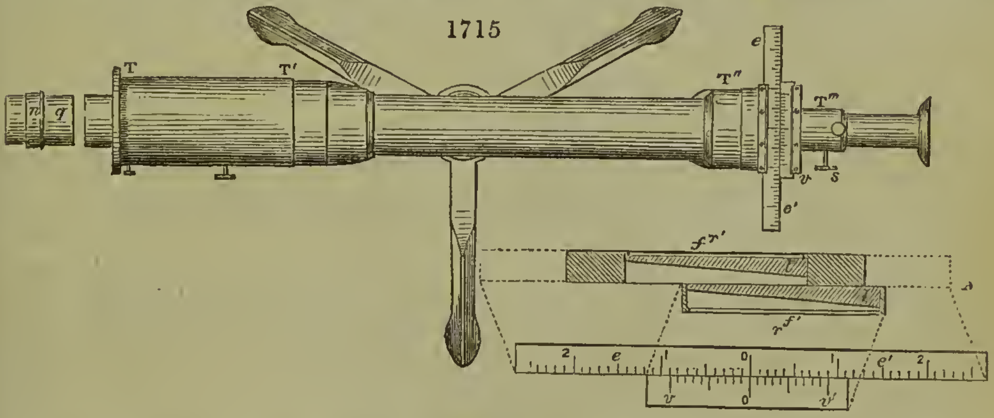
Saccharimetry.—We now come to the estimation of sugar, which is most simply performed by the hydrometer, when the solutions are pure and the kind of sugar known. But commercially it is required to ascertain the proportions of cane sugar, uncrystallisable sugar, water and impurities, and this is accomplished most successfully by means of the polarising saccharometer proposed by Biot and improved by Soleil. The following is a description of this beautiful instrument:— Two tubular parts, T T′, and T″ T‴, *figs.* 1714 and, 1715, constitute the principal part of the saccharometer. The light enters *n*, through a Nicol's prism *q*, shown separately, *fig.* 1714, at O, and passes first an achromatic polarising prism *p*, and shown separately at P and afterwards through a plate of quartz of double rotation at *p′*, which is also shown at Q. This plate is composed of two semi-discs cut perpendicularly to the axis of crystallisation, but though exactly of equal thickness and equal rotating power, the one turns the ray to the right, while the other turns it to the left. At *p″*, the ray passes a plate of quartz of single rotation, and at *l l′*, two wedges of quartz endued with the power of rotation, but in a contrary direction to the preceding plate. These two wedges are again represented in 1715 A, and are so made that by turning the milled head B, the sum of their thickness can be increased or diminished at pleasure, while the amount of thickness is shown by the ivory graduated scale *e e′*, and vernier *v v′*. Finally the ray traverses an analysing prism *a*, and an eye-piece L. If the instrument is directed to the light the observer will see a luminous disc, bisected by a central line (produced by the junction of the two semi-discs of quartz) of exactly the same tint, but which tint may be varied at pleasure, by rotating the Nicol's prism n, by means of the milled

1714



head b. If, however, we interpose between p' and p'', the tube c, *fig.* 1714, filled with a solution of cane sugar, and the ends closed with glass, the semi-discs will be

1715



differently coloured. Cane sugar, possessing the power of circular polarisation, combines with the rotating power of the half disc which turns the ray to the right, but tends to neutralise the half disc, whose direction is the reverse. By increasing or diminishing the thickness of the wedges of quartz $l l'$, to the extent required for counteracting their rotation to the right, and causing the semi-discs to reassume the same colours, we have a means by the graduated scale e e', v v', of measuring the rotating power, which is exactly proportional to the amount of cane sugar, temperatures being equal, and no foreign substance having the power of circular polarisation being present.

To apply this method, the deviation must be known which is produced by a solution of sugar of known strength. For this purpose a given weight, ϵ, of sugar is dissolved in such a quantity of distilled water that the solution occupies a given volume, V. Sufficient of this solution is taken to fill a tube of a certain length, and the deviation suffered by the plane of polarisation of the luminous ray passing through this tube is measured. Let this deviation be α. Let then other quantities of sugar be dissolved in sufficient water to give the same volume of solution, V; and let the deviations produced by these solutions in the same tube be α' α'', α''', &c.; then the quantities of sugar contained in the volume, V, of these liquids will be represented by the products $\epsilon\frac{\alpha'}{\alpha}$, $\epsilon\frac{\alpha''}{\alpha}$, $\epsilon\frac{\alpha'''}{\alpha}$, &c., respectively. If the sugar examined, instead of being pure, is mixed with other but inactive substances, it is evident that these same products express the absolute weights of pure sugar contained in the weights of substances employed in the formation of the liquids of the given volume, V. It is possible to employ proof tubes of different lengths; but it is then necessary to reduce by calculation the observed deflections to those which would have been produced in the same tube.

It often happens that solutions of sugar which have to be examined are turbid or strongly coloured. When this interferes with the examination, they must be clarified and rendered either quite colourless, or when this is not possible the colour must be at least reduced. This is often effected by precipitating the colouring matter of the syrups with subacetate of lead; but the most accurate method is by a filter of animal charcoal. The filtrates are then examined. When syrups contain, besides cane sugar, other constituents which exert an action upon the plane of polarisation, the amount of cane sugar present may be determined by inverting, by means of hydrochloric acid, the rotary power of the cane sugar. No other saccharine substance is, in fact, known which suffers a similar change under the same circumstances.

If, for instance, the liquid under examination contains besides cane sugar, glucose, whose rotary action on the plane of polarisation is in the same direction as that of cane sugar; if α' be the deviation observed to be produced by the liquid, then α' is evidently the sum of the separate deflections of the cane sugar x, and of the glucose, y. About one-tenth of its volume of hydrochloric acid is added to the syrup, and it is kept for ten minutes at a temperature of 140°—154°. The cane sugar is thereby completely transformed into noncrystallisable sugar, which turns the plane of polarisation to the left, while the rotary power of the glucose undergoes no alteration. When this change has been effected, the new deviation, α'', of the liquid is observed. It is now the difference between the deviation y of the glucose and that of the noncrystallisable sugar derived from the cane sugars. But the degree of dilution of the liquid having been changed by the addition of the hydrochloric acid, the deviation observed α'', must be replaced by the deviation, $\frac{10}{9}\alpha''$, which would have been observed if the inversion could have been produced without the addition of hydrochloric acid. Admitting therefore that a quantity of cane sugar which effects a deviation, x, gives rise to a quantity of noncrystallisable sugar which effects a deviation, $r\,x$, we have—

Before the inversion, $x+y=\alpha'$.

After the inversion, $y+r\,x=\frac{10}{9}\alpha''$.

From these two equations the quantities x and y may be determined. The coefficient of inversion, r, is determined once for all by a special experiment performed upon pure cane sugar at the temperature at which the experiments have afterwards to be made. According to Biot, this coefficient is 0·038 for hydrochloric acid at a temperature of 71·6°.

The process is the same when the cane sugar is mixed with noncrystallisable sugar, turning the plane of polarisation to the left. In this case the initial deviation, α', of the liquid is the difference between the deviation to the right, r, of the cane sugar, and the deviation, z, to the left of the noncrystallisable sugar. After treating with hydrochloric acid, the deviation, α'', is composed of the deviations of the original noncrystallisable sugar, and of that produced by the action of the hydrochloric acid. We then have—

Before inversion, $x - z = \alpha'$.

After inversion, $z + r\,x = \frac{10}{9}\alpha''$.

It is important in examining optically noncrystallisable sugar always to employ the same temperature, because a change of temperature materially affects the rotary power of this kind of sugar.

The table appended includes each degree of temperature from +10 to +35 centigrade, and for qualities increasiug in hundredths, this range being found sufficient for all practical purposes either in Europe or the colonies.

To note the temperature at which the observation is made, a tube $z\,z$, *fig.* 1714, provided with a vertical branch, is employed. In this branch a thermometer, t, is placed.

The following are two examples of the use of the table:

1. A solution of a saccharine substance prepared iu the normal proportions of weight and volume recommended, and giving before acidulation a notation on the left-hand part of the scale of - - - - 75 divisions.

And after the inversion (the temperature being +15°) a notation in the opposite direction of - - - - - - - - - 20 divisions.

Sum of the inversions - - - - - - 95 divisions.

TABLE FOR THE ANALYSIS OF SACCHARINE SUBSTANCES.

NOTE.—For liquids not submitted to acidulation the last two columns constitute a special table; in which case the figures in column A represent the number of degrees found, and those of column B the weight in grammes and centigrammes of sugar contained in a litre of liquid.

The numbers furnished by an analysis of solid sugars are necessarily comprised in the first hundred lines of the table; the thirty following lines have been added for the analysis of the principal natural saccharine fluids of high density. If liquors of a still greater density are presented, they will be comprised within the table by diluting them with a known quantity of water.

2. Another liquor similarly prepared, giving before the inversion a notation on the left of - - - - - - - - - - - 80 divisions.

And after the inversion, at the temperature of + 20°, another notation of the same direction, but only of - - - - - - - - 26 divisions.

Difference expressing the value of the inversion - 54 divisions.

The strength of the two solutions will be found thus; for the first, by seeing what is the figure of the column representing 15°, which is the nearest to the sum of the inversion, 95 divisions: it will be observed that this figure is 95·5, and that it corresponds to quality 70, shown on the same horizontal line in the last column but one, A; hence we conclude that the substance contained 70 per cent. of sugar.

As to the second solution, the figure nearest 54 is 53·6, in the column for the temperature of + 20°, and the strength sought will be 40% on the same line in the column of qualities. Finally, we shall find, besides, in the last column, B, of the table, the quantity in grammes and centigrammes of the sugar contained per litre in the solutions, which is 114 gr. 45 for the first, and 65 gr. 40 for the second.

Other methods for the estimation of sugar have been adopted. We have already described Peligot's method by means of lime. When sugar is formed from starch, its complete saccharification may be determined by the action of sulphuric acid, for if on a strong solution of imperfectly formed grape sugar, nearly boiling hot, one drop of strong sulphuric acid be added, no perceptible change will ensue, but if the acid be dropped into solutions of either cane or perfectly formed grape sugar, black carbonaceous particles will make their appearance.

The black oxide of copper is not affected by being boiled in solution of starch sugar.

"If a solution of grape sugar," says Trommer, "and potash, be treated with a solution of sulphate of copper, till the separated hydrate is re-dissolved, a precipitate of red oxide will soon take place, at common temperatures, but it immediately forms if the mixture is heated. A liquid containing $\frac{1}{100000}$ of grape sugar, even one-millionth part," says he, "gives a perceptible tinge (orange), if the light is let fall upon it." To obtain such an exact result, very great nicety must be used in the dose of alkali, which is found extremely difficult to hit. With a regulated alkaline mixture, however, an exceedingly small portion of starch sugar, is readily detected, even when mixed with Muscovado sugar.

Fehling has reduced this to a quantitative test, and makes a solution of copper that will keep permanently. This is seen by the following:—

40 grammes of sulphate of copper,
160 grammes of neutral tartrate of potassa, or 200 grammes of tartrate of soda, dissolved and added to
700—800 cub. c. (grammes) of caustic soda, specific gravity 1·12.

This is diluted with water to 1154·5 cub. c.

Of this solution 1 cub. c. = 0·0050 grape sugar, or
0·00475 cane sugar.

Grains may be used instead of grammes, and then 1 grain = 0·0050 grape sugar, without change of calculation.

100 parts of grape sugar, - - -		
95 ,, cane sugar, - - -	= 220·5 CuO, or 198 Cu^2O.	
90 ,, starch, - - - -		

Urine may be tested with this. It should be first diluted 10 to 20 times with water; when the test is added, it should be boiled a few seconds, when the suboxide of copper falls. Very constant results may be obtained.

Caramelin is the name given by E. Maumené to a brown substance, insoluble in acids and alkalies, which is produced by evaporating sugar with fifteen to thirty times its weight of chloride of tin, and heating it to about 220° Fahr. It is $C^{12}H^4O^4$, and being constant has been proposed by him to be used as a test of the presence and quantity of sugar.

Horsley detects minute quantities of sugar by means of chromate of potash.

Of the sugar cane, and the extraction of sugar from it.—Though we have no direct authority for believing that the sugar *cane* was known to the ancients, we find scattered through their writings notices of the occasional use of sweet substances different from honey.

The writers alluded to are these: Theophrastus, Dioscorides, Galen, Strabo, and Pliny: some of them speak distinctly of canes and reeds. Humboldt, after the most elaborate historical and botanical researches in the New World, has arrived at the conclusion that before America was discovered by the Spaniards the inhabitants of that continent and the adjacent islands were entirely unacquainted with the sugar canes, with any of our corn plants, and with rice. The progressive diffusion of the cane has been thus traced out by the partisans of its oriental origin. From the interior of Asia it was transplanted first into Cyprus, and thence into Sicily, or possibly by the Saracens directly into the latter island, in which a large quantity of sugar was manufactured in the year 1148. Lafitau relates the donation made by William the Second, King of Sicily, to the convent of St. Benoit, of a mill for crushing sugar canes, along with all its privileges, workmen, and dependencies: which remarkable gift bears the date of 1166. According to this author, the sugar cane must have been imported into Europe at the period of the Crusades. The monk Albertus Aquensis, in the description which he has given of the processes employed at Acre and at Tripoli to extract sugar, says that in the Holy Land the Christian soldiers being short of provisions, had recourse to sugar canes, which they chewed for subsistence. Towards the year 1420, Dom Henry, Regent of Portugal, caused the sugar cane to be imported into Madeira from Sicily. This plant succeeded perfectly in Madeira and the Canaries; and until the discovery of America, these islands supplied Europe with the greater portion of the sugar which it consumed.

The cane is said by some to have passed from the Canaries into the Brazils; but by others, from the coast of Angola in Africa, where the Portuguese had a sugar colony. It was transported in 1506, from the Brazils and the Canaries, into Hispaniola or Hayti, where several crushing-mills were constructed in a short time. It would appear, moreover, from the statement of Peter Martyr, in the third book of his first Decade, written during the second expedition of Christopher Columbus, which happened between 1493 and 1495, that even at this date the cultivation of the sugar cane was widely spread in St. Domingo.

Twenty-eight sugar works established by the Spaniards existed in St. Domingo in 1518. Sugar was first brought to England in 1563, by Admiral Hawkins, and a century later English planters were realising great wealth in Barbadoes.

It has been supposed to have been introduced into Hayti by Columbus himself, at his first voyage, along with other productions of Spain and the Canaries, and that therefore its cultivation had come into considerable activity at the period of his second expedition. Towards the middle of the 17th century, the sugar cane was imported into Barbadoes from Brazil, then into the other English West Indian possessions, into the Spanish Islands on the coast of America, into Mexico, Peru, Chili, and, last of all, into the French, Dutch, and Danish colonies.

The sugar cane, *Arundo saccharifera*, is a plant of the graminiferous family, which varies in height from 8 to 10, or even to 20 feet. Its diameter is about an inch and a half; its stem is dense, brittle, and of a green hue, which verges to yellow at the approach of maturity. It is divided by prominent annular joints of a whitish-yellow colour. These joints are placed about 3 inches apart; and send forth leaves, which fall off with the ripening of the plant. The leaves are 3 or 4 feet long, flat, straight, pointed, from 1 to 2 inches in breadth, of a sea-green tint, striated in their length, alternate, embracing the stem by their base. They are marked along their edges with almost imperceptible teeth. In the 11th or 12th month of their growth the canes push forth at their top a sprout 7 or 8 feet in height, nearly half an inch in diameter, smooth, and without joints, to which the name *arrow* is given. This is terminated by an ample panicle, about 2 feet long, divided into several knotty ramifications, composed of very numerous flowers, of a white colour, apetalous, and furnished with 3 stamens, the anthers of which are a little oblong. The roots of the sugar cane are jointed and nearly cylindrical; in diameter they are about one twelfth of an inch; in their utmost length 1 foot, presenting over their surface a few short radicles.

The stem of the cane in its ripe state is heavy, very smooth, brittle, of a yellowish-violet, reddish, or whitish colour, according to the variety. It is filled with a fibrous, spongy, dirty-white pith, which contains very abundant sweet juice. This juice is elaborated separately in each internodary portion, the functions of which are in this respect independent of the portions above and below. The cane is propagated by cuttings or joints of proper lengths, from 15 to 20 inches, in proportion to the nearness of the joints, which are generally taken from the tops of the canes, just below the leaves.

There are several varieties of the sugar cane. The longest known is the Creole, or common sugar cane, which was originally introduced at Madeira. It grows freely in every region within the tropics, on a moist soil, even at an elevation of 3000 feet above the level of the sea. In Mexico, among the mountains of Caudina-Masca, it is cultivated to a height of more than 5000 feet. The quantity a d quality of sugar which it yields, is proportional to the heat of the place where it grows, provided it be not too moist and marshy.

Another variety is the Otaheitan cane. It was introduced into the West Indies about the end of the 18th century. This variety, stronger, taller, with longer spaces between the joints, quicker in its growth, and much more productive in sugar, succeeds perfectly well in lands which seem too much impoverished to grow the ordinary cane. It sends forth shoots at temperatures which chill the growth and development of the creole plant. Its maturation does not take more than a year, and is accomplished sometimes in nine months. From the strength of its stem, and the woodiness of its fibres, it better resists the storms. It weighs a third more, affords a sixth more juice, and a fourth more sugar, than the common variety. It yields four crops in the same time that the creole cane yields only three. Its juice contains less feculency and mucilage, whence its sugar is more easily crystallised, and of a fairer colour.

Another variety, valuable chiefly from its hardiness, is the *purple violet* from Java. It grows from eight to ten feet high. This cane is covered with a resinous film which is difficult to grind; but as the sugar yielded is of excellent quality, this variety is of considerable value in bordering cane fields, protecting them from the inroads of cattle.

There is a caste in Ceylon, called *jaggeraros*, who make sugar from the produce of the *Caryota urens*, or Kitul tree; and the sugar is styled *jaggery*. Sugar is not usually made in Ceylon from the sugar cane; but either from the juice of the Kitul, from the *Cocos nucifera*, or the *Borassus flabelliformis* (the Palmyra tree).

1716

Several sorts of cane are cultivated in India.

The *cadjoolee* (*fig.* 1716) is a purple coloured cane; yields a sweeter and richer juice than the yellow or light coloured, but in less quantities, and is harder to press. It grows in dry lands. When eaten raw, it is somewhat dry and pithy in the mouth, but is esteemed very good for making sugar. It is not known to the West India planter. The leaves rise from a point 6 feet above the ground. An oblique and transverse section of the cane is represented by the parts near the bottom of the figure.

The *pooree* is a light-coloured cane, yellow, inclining to white, deeper yellow when ripe and on rich ground. West India planters consider it the same sort as one of theirs. It is softer and more juicy than the preceding, but the juice is less rich, and produces a weaker sugar. It requires seven parts of pooree juice to make as much goor as is produced from six of the cadjoolee. Much of this cane is brought to the Calcutta market, and eaten raw.

The *cullorah* thrives in swampy lands, is light-coloured, and grows to a great height. Its juice is more watery, and yields a weaker sugar also than the cadjoolee.

The manufacture of sugar in Bengal is conducted by the natives in the most primitive manner possible; the poverty and ignorance of the ryots or peasants being serious obstacles to the introduction of any system different from that practised by their forefathers. Early in June the soil is brought into a soft muddy state; slips of the cane, with one or two joints, are planted in rows about three feet six inches apart, and one foot six inches asunder in the rows; when about three inches above ground the earth is partially loosened, and in August trenches are cut, to drain off any superfluous moisture. From three to six canes spring from each slip. When about three feet high the lower leaves are wrapped round the canes and the whole from each slip supported by bamboos. The cutting commences in January or February, the canes being then eight or ten feet high, and one to one and a half inch thick, and are passed through a mill of the rudest construction, which will be fully described when sugar-mills are treated of.

The juice of the date tree is collected in pots by tapping the stem, and afterwards undergoes the same process as cane juice.

The cost of cultivating an acre of land in the neighbourhood of Calcutta may be estimated as follows:—

	C. Rupees and pice.			£	s.	d.	£	s.	d.
To ground rent	2	8	per biggah, equal per acre to about	0	17	6			
„ ploughing	1	0	„ „ „	0	7	0			
„ weeding	2	8	„ „ „	0	17	6			
„ watering	1	4	„ „ „	0	8	9			
„ seeds	4	8	„ „ „	1	11	6			
„ cutting	3	0	„ „ „	1	1	0			
„ crushing	15	0	„ „ „	5	5	0			

	C. Rupees and Pice.			£ s. d.	£ s. d.
To pots, bags, &c.	1	0	per biggah, equal per acre to about	0 7 0	
„ profit	14	14	„ „ „	1 9 9	
					£12 5 0
By Khaur, 9 Bengal maunds per biggah at C.R. 3.8, equal per acre to 23 cwts. 1 qr. 1lb. at 9*s.* 6*d.* - - -				11 1 0	
By Molasses, 7 Bengal maunds per biggah at C.R. 10, equal per acre to 17 cwts. 3qrs. 25 lbs. at 1*s.* 4*d.* - - -				1 4 0	£12 5 0

Such is the return from the rich plains of India under the wretched system carried on by the natives. In the West Indies similar land produces a much larger quantity, and greatly superior in quality. In the above calculations the expenses are those payable for contract work, but the ryot and his family being in many cases nearly the only labourers on their small patches of land, the wages may be considered as a portion of their profit. The climate and soil of India are all that can be desired for the cultivation of sugar, and land and labour being abundant and cheap, no country can hold out a better prospect of success for the prosecution of such a trade by the English capitalist, with improved machinery, if coupled with science and industry.

Some years ago returns were made to the Indian Government by the magistrates of the various districts of Bengal and North-Western Provinces, of the estimated product and local consumption of sugar throughout the country, which gave the following quantities:—

	Bengal Maunds.		Tons.
Production per annum - - - -	18,734,909	=	693,885
Local consumption - - - - -	11,778,356	=	436,223
	6,956,553		257,662
The largest quantity ever exported from Calcutta was about -			70,000
Which leaves unaccounted for about - - - - -			187,662

These returns were not considered very satisfactory; no great reliance can, therefore be placed on their correctness.

The China cane is said to be extremely hardy, standing both cold and drought, and, with abundant rain, giving out as many as thirty shoots. It resists the inroads of the white ants, which cannot penetrate its hard crust, whilst it is also proof against the teeth of the jackals. It requires, however, a stronger mill for grinding than the other varieties mentioned. Mr. Wray asserts that the Salangore cane is the finest in the Straits of Singapore, and perhaps in the world. He says that he has cut five from one stool, which were of a weight of from 17 lbs. to 25 lbs. They have been known to produce 7200 lbs. of undrained sugar per acre, equal to 5800 lbs. of dry sugar for shipping.

Dr. Livingstone says that sugar is cultivated in the Shire valley, as well as many parts of Africa near the Zambesi, and may be had for as little as one halfpenny per pound. There is field enough for great enterprise in that direction. The amount obtainable has not been investigated.

In all the colonies of the New World the sugar cane flowers, but it then sends forth a shoot (*arrow*), that is, its stem elongates, and the seed-vessels prove abortive. For this reason, the bud-joints must there be used for its propagation. It is said to grow to seed, however, in India. This circumstance occurs with some other plants, which, when propagated by their roots, cease to yield fertile seeds; such as the banana, the bread-fruit, the lily, and the tulip.

In the proper season for planting, the ground is marked out by a line into rows 4 or 6 feet asunder, in which rows the canes are planted from 2 to 5 feet apart The series of rows is divided into pieces of land 60 or 70 feet broad, leaving spaces of about 20 feet, for the convenience of passage, and for the admission of sun and air between the stems. Canes are usually planted in trenches, about 6 or 8 inches deep, made with the hand-hoe, the raised soil being heaped to one side, for covering-in the young cane; into the holes a negro drops the number of cuttings intended to be inserted, the digging being performed by other negroes. The earth is then drawn about the hillocks with the hoe. This labour has been, however, in many places better and more cheaply performed by the plough; a deep furrow being made, into which the cuttings are regularly planted, and the mould then properly turned in. If the ground is to be afterwards kept clear by the horse-hoe, the rows of canes should be 5 feet asunder, and the hillocks 2½ feet distant, with only one cane left in one hillock. After some shoots appear, the sooner the horse-hoe is used the more will the plants thrive, by keeping the weeds under, and stirring up the soil. Plant-canes of the first growth have been known to yield, on the brick-mould of Jamaica, in very fine seasons, 2½ tons of sugar per acre. The proper season for planting the cane-slips containing the buds, namely, the top part of the cane stripped of its leaves, and the two or three upper joints, is in the interval between August and the beginning of November. Favoured by the autumnal weather, the young plants become luxuriant enough to shade the ground before the dry season sets in; thereby keeping the roots cool and moderately moist. By this arrangement the creole canes are ripe for the mill in the beginning of the second year, so as to enable the manager to finish his crop early in June. It is a great error for the colonist to plant canes at an improper season of the year, whereby his whole system of operations becomes disturbed, and, in a certain degree, abortive.

The withering and fall of a leaf afford a good criterion of the maturity of the cane-joint to which it belonged; so that the last eight leafless joints of two canes, which are cut the same day, have exactly the same ripeness, though one of the canes be 15 and the other only 10 months old. Those, however, cut towards the end of the dry season, before the rains begin to fall, produce better sugar than those cut in the rainy season, as they are then somewhat diluted with watery juice, and require more evaporation to form sugar. It may be reckoned a fair average product, when one pound of sugar is obtained from one gallon (English) of juice.

Rattoons (a word corrupted from *rejettons*) are the sprouts or suckers that spring from the roots or stoles of the canes that have been previously cut for sugar. They are commonly ripe in 12 months; but canes of the first growth are called plant-canes, being the direct produce of the original cuttings or germs placed in the ground, and require a longer period to bring them to maturity. The first yearly return from the roots that are cut over, are called first rattoons; the second year's growth, second rattoons; and so on, according to their age. Instead of stocking up his rattoons, holing, and planting the land anew, the planter suffers the stoles to continue in the ground, and contents himself, as the cane-fields become thin and impoverished, with supplying the vacant places with fresh plants. By these means, and with the aid of manure, the produce of sugar per acre, if not apparently equal to that from plant-canes, gives perhaps in the long run as great returns to the owner, considering the relative proportion of the labour and expense attending the different systems.

When the planted canes are ripe, they are cut close above the ground by an oblique section, and the leaves and shoots being stripped off, they are transported in bundles to the mill-house. If the roots be then cut off a few inches below the surface of the soil, and covered up with fine mould, they will push forth more prolific offsets or rattoons than when left projecting in the common way.

The amount of sugar yielded per acre is very variously stated. In fact. the yield must vary with the different variety of canes cultivated, with the nature of the soil, the character of the season, and, more than all, with the more or less perfect apparatus used in manufacturing the sugar. The yield, from these causes, will vary from half a ton to two and a half tons of solid sugar per acre.

The following table by M. Duprez is given. The average amount of juice from 100 lbs. of canes was: —

1. By mills having horizontal rollers—motive power not stated—probably steam	61·2
2. By mills, motive power steam	60·9
3. By mills, motive power wind and steam	59·3
4. By mills having vertical rollers	59·2
5. By mills, motive power cattle	58·5
6. By mills, motive power wind	56·4

Dr. Evans gives the products of an acre of canes in Barbadoes as: —

Weight of canes.	Weight of juice.	Extract.	Extract per 100 lbs. of juice.	Extract per 100 lbs. of canes.
30 tons	60,480 lbs.	10,886 lbs.	18·0	16·20
30 „	47,040 „	8,467 „	18·0	12·6
30 „	33,600 „	3,500 „	10·0	5·0
30 „	33,600 „	7,280 „	21·6	10·8

An acre may be said to yield 30 tons of canes. The following table gives the produce in juice and sugar in such a case according to Mr. Wray: —

Juice obtained per cent.	Juice in pounds.	Pounds of Sugar. At 18 per cent.	At 20 per cent.	At 22 per cent.
70	47,040	8,468	9,408	10,348
75	50,400	9,092	10,080	11,088
80	53,760	9,676	10,752	11,827

Juice obtained per cent.	Juice in pounds.	Subtract for Molasses and Skimmings, at 12 per cent. At 18 per cent.	At 20 per cent.	At 22 per cent.	Pounds of dry Sugar yielded by one Acre. At 18 per cent.	At 20 per cent.	At 22 per cent.
70	47,040	705	792	862	7,763	8,616	9,486
75	50,400	757	840	924	8,335	9,240	10,164
80	53,760	806	896	994	8,871	9,856	11,173

Matured cane is better shown in the annexed table by Payen:—

M. Casaseca has analysed the creole cane at Havana, and found:—

	Cane entire.	Cane peeled.	The rind.
Water - - - - -	77·0	77·8	69·5
Sugar and soluble substances -	12·0	16·2	11·5
Ligneous matter - - -	11·0	6·0	19·0

M. Casaseca states that the juice is richer in sugar at the base of the cane and becomes gradually poorer towards the top; the middle third of the cane being the average.

The specific gravity of cane juice varies from 1046 to 1110, but is generally found from 1070 to 1090, being from 10° to 13° Baumé. It is opaque, frothy, and of a yellowish-green colour. On boiling, a green scum rises, consisting of chlorophylle, cellulose, ligneous fibre, and albumen, and the liquid remains of a pale yellow colour. The green scum, as analysed by Avequin, consists of—

	Per cent.
Cerosie—a peculiar wax - - - - - -	50·0
Green matter - - - - - - - -	10·0

The ashes of the cane, according to Dr. Stenhouse, yield—

Silica	46·46	41·37	46·48	50·00
Phosphoric acid	8·23	4·59	8·16	6·56
Sulphuric acid	4·65	10·93	7·52	6·40
Lime	8·91	9·11	5·78	5·09
Magnesia	4·50	6·92	15·61	13·01
Potassa	10·63	15·99	11·93	13·69
Soda	—	—	0·57	1·33
Chloride of potassium	7·41	8·96	—	—
Chloride of sodium	9·21	2·13	3·95	3·92
	100·00	100·00	100·00	100·00

The following elaborate analysis of cane juice after being manufactured into sugar and molasses, and after having passed through various iron and copper vessels, is given by Dr. Richardson:—

	Sugar.	Molasses.
Potassa	19·42	36·23
Lime	14·67	12·72
Magnesia	10·72	11·14
Oxide of iron	6·55	2·62
Oxide of copper	0·71	trace of both
Protoxide of manganese	trace	
Chloride of potassium	8·03	1·58
Chloride of sodium	15·46	25·87
Sulphuric acid	10·85	7·91
Silica	13·59	1·93
Ashes	1·33	3·60

Molasses alone were analysed by Payen, and 12 kilogrammes were found to contain—

Sugar	7·561·00
Acetate of potash	0·209·30
Chloride of potassium	0·114·60
Sulphate of potash	0·085·50
Mucilaginous matter	0·076·30
Phosphate of lime	0·052·00
Nitrogenous substances	0·050·00
Silica	0·023·90
Acetate of lime	0·016·20
Phosphate of copper	0·000·20
Water	1·800·00
Glucose and uncrystallisable sugar	1·561·00

The proportion of salts varies considerably with the soil on which the canes are grown. It is highly important that soluble salts, especially of alkalies, should not be added to the ground in the form of manure, for if absorbed into the cane juice, they cannot be removed in the process of manufacture, but convert a proportion of cane sugar (many times their own weight) into the uncrystallisable form.

Of Sugar Mills.

The first machines employed to squeeze the canes were mills similar to those which serve to crush apples in some cider districts, or somewhat like tan-mills. In the centre of a circular area, of about 7 or 8 feet in diameter, a vertical heavy wheel was made to revolve on its edge, by attaching a horse to a cross beam projecting horizontally from it and making it move in a circular path. The cane pieces were strewed on the somewhat concave bed in the path of the wheel, and the juice expressed flowed away through a channel or gutter in the lowest part. This machine was tedious and unproductive. It was replaced by the vertical cylinder mill of Gonzales de Velosa; which has continued till modern times, with little variation of external form, but is now generally superseded by the sugar-mill with horizontal cylinders.

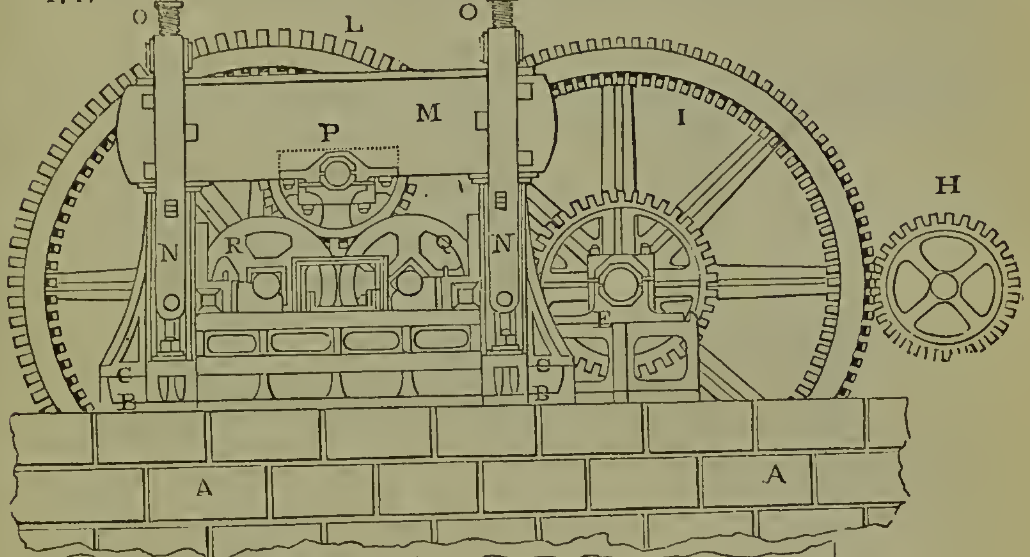
Specification of, and Observations on, the Construction and Use of the best Horizontal Sugar-mill.

Fig. 1719, front elevation of the entire mill. *Fig.* 1718, horizontal plan. *Fig.*

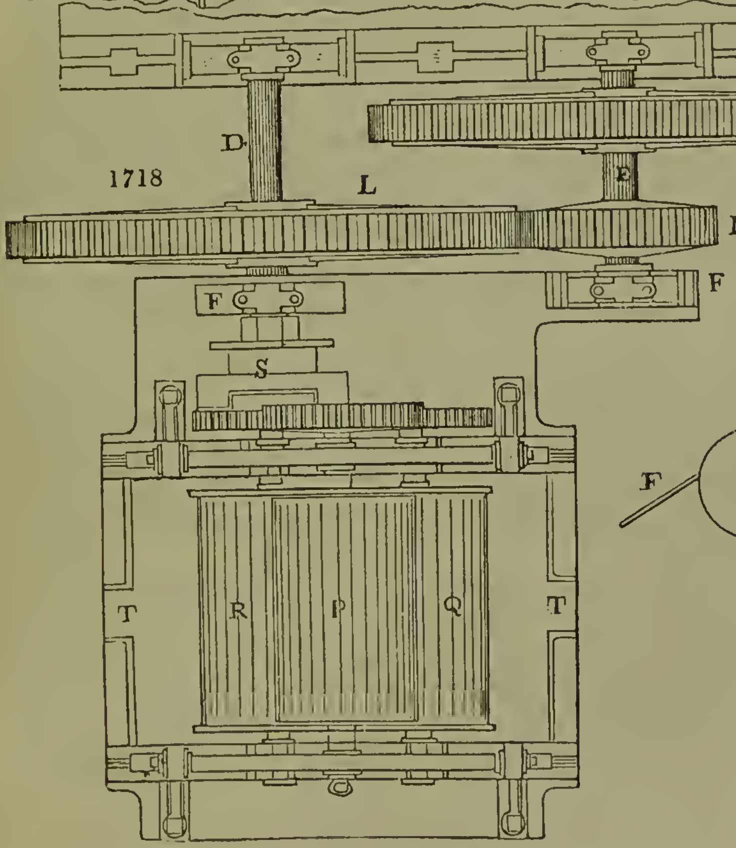
1717, end elevation. *Fig.* 1720, diagram, showing the dispositions of the feeding and delivering rollers, feeding board, returner, and delivering board.

Fig. 1717, A, A, solid foundation of masonry; B, B, bed plate; C, C, headstocks or standards; D, main shaft (seen only in *fig.* 1718); E, intermediate shaft; F, F, plummer-blocks of main shaft D (seen only in *fig.* 1718); H, driving pinion on the fly-wheel shaft of engine; I, first motion mortise wheel, driven by the pinion; K, second motion

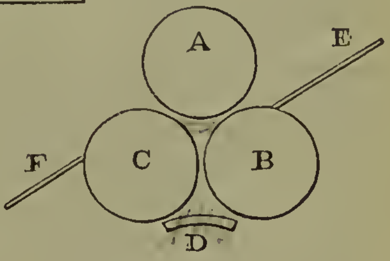
1717



1718



1720



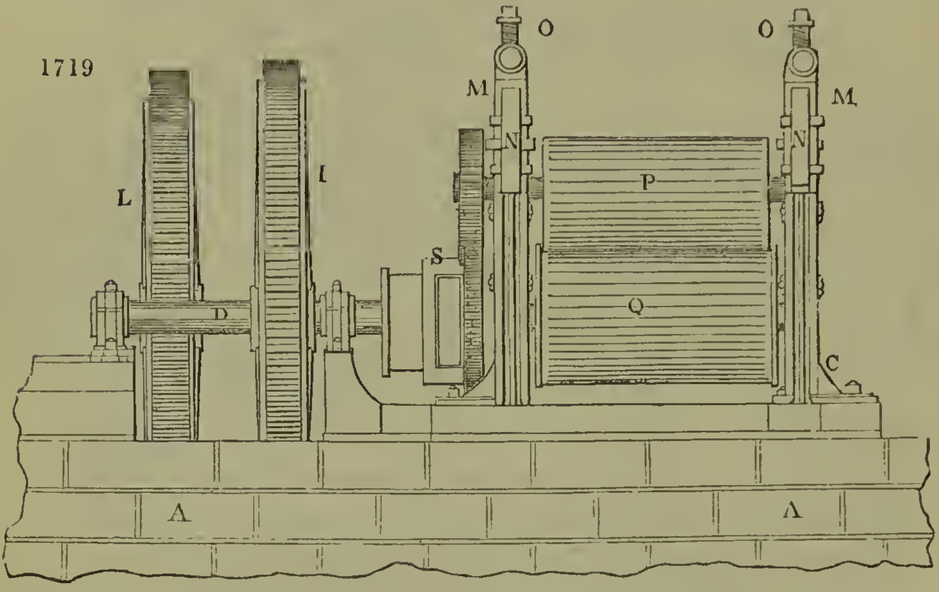
pinion, on the same shaft; L, second motion mortise-wheel, on the main shaft; M, brays of wood, holding the plummer-blocks for shaft D; N, wrought-iron straps connecting the brays to the standards C, C; O, O, regulating screws for the brays; P, top roller and gudgeons; Q and R, the lower or feeding and delivering rollers; S, clutch for the connexion of the side of lower rollers Q and R, to the main shaft (seen only in *fig.* 1718); T, T, the drain gutters of the mill-bed (seen only in *fig.* 1718).

The same letters of reference are placed respectively on the same parts of the mill in each of *figs.* 1717, 1718, and 1719.

The relative disposition of the rollers is shown in the diagram, *fig.* 1720, in which A is the top roller; B, the feeding roller; C, the delivering roller; D, the returner; E, the feed board; F, the delivering board.

The rollers are made $2\frac{1}{4}$ inches to $2\frac{1}{2}$ inches thick, and ribbed in the centre. The feeding and delivering rollers have small flanges at their ends (as shown in *fig.* 1717), between which the top roller is placed; these flanges prevent the pressed canes or

1719



megass from working into the mill-bed. The feeding and top rollers are generally fluted, and sometimes diagonally, enabling them the better to seize the canes from the feed-board. It is, however, on the whole, considered better to flute the feeding roller only, leaving the top and delivery rollers plane; when the top roller is fluted, it should be very slightly, for, after the work of a few weeks, its surface becomes sufficiently rough to bite the canes effectively. The practical disadvantage of fluting the delivering rollers, is in the grooves carrying round a portion of liquor, which is speedily absorbed by the spongy megass, as well as in breaking the megass itself, and thus causing great waste.

The feed plate is now generally made of cast iron, and is placed at a considerable inclination, to allow the canes to slip the more easily down to the rollers. The returner is also of cast iron, serrated on the edge, to admit the free flowing of the liquor to the mill-bed. The concave returner, formerly used, was pierced with holes to drain off the liquor, but it had the serious disadvantage of the holes choking up with the splinters of the cane, and has therefore been discarded. The delivering plate is of cast iron, fitted close to the roller, to detach any megass that may adhere to it and otherwise mix with the liquor.

In some cases a liquor pump, with two barrels and three adjustments of stroke, is attached to the mill. This is worked from the gudgeon of the top roller. In action, the liquor from the gutter of the mill-bed runs into the cistern of the pump, and is raised by the pump to the gutter which leads to the clarifier or coppers. Such pumps have brass barrels and copper discharging pipes, are worked with a very slow motion, and require to be carefully adjusted to the quantity of liquor to be raised, which, without such precaution, is either not drawn off sufficiently quick, or is agitated with air in the barrels, and delivered to the gutter in a state of fermentation.

In working this mill, the feeding roller is kept about half an inch distant from the upper roller, but the delivering roller is placed about $\frac{1}{8}$th of an inch from it.

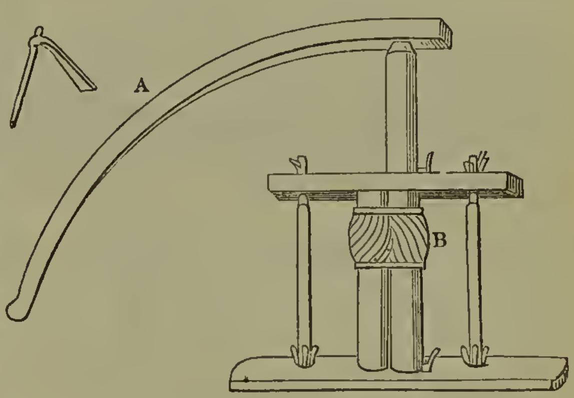
The canes are thrown upon the feed board, and spread so that they may cross each other as little as possible. They are taken in by the feed rollers, which split and slightly press them; the liquor flows down, and, the returner guiding the canes between the top and delivering rollers, they receive the final pressure, and are turned out on the mill-floor, while the liquor runs back and falls into the mill-bed. The megass, then in the state of *pith*, adhering to the skin of the cane, is tied up in bundles, and after being exposed a short time to the sun, is finally stored in the megass house for fuel. By an improvement in this stage of the process, the megass is carried to the megass-house by a carrier chain, worked by the engine.

The relative merits of horizontal and vertical sugar-mills on this construction may be thus stated:—The horizontal mill is cheaper in construction, and is more easily fixed; the process of feeding is performed at about one-half of the labour, and in a much superior manner; the returner guides the canes to receive the last pressure more perfectly; and the megass is not so much broken as in the vertical mill; but left tolerably entire, so as to be tied, dried, and stored, with less trouble and waste.

The vertical mill has a considerable advantage, in being more easily washed; and it can be readily and cheaply mounted in wooden framing; but the great labour of feeding the vertical mill renders it nearly inapplicable to any higher power than that of about ten horses. In situations where the moving power is a windmill, or a cattle gin, the vertical mill may require to be adopted.

The sugar-mill at Chica Ballapura is worked by a single pair of buffaloes or oxen, *fig.* 1721, going round with the lever A, which is fixed on the top of the right-hand roller. The two rollers have endless screw heads B, which are formed of four spiral grooves and four spiral ridges, cut in opposite directions, which turn into one another when the mill is working. These rollers and their heads are of one piece, made of the toughest and hardest wood that can be got, and such as will not impart any bad taste to the juice. They are supported in a thick strong wooden frame, and their distance from each other is regulated by means of wedges, which pass through mortises in the frame planks, and a groove made in a bit of some sort of hard wood, and press upon the axis of one of the rollers. The axis of the other presses against the left-hand side of the hole in the frame boards. The cane juice runs down the rollers, and through a hole in the lower frame-board, into a wooden conductor, which carries it into an earthen pot. Two long-pointed stakes or piles are driven into the earth, to keep the mill steady, which is all the fixing it requires. The under part of the lowermost plank of the frame rests upon the surface of the ground, which is chosen level and very firm, that the piles may hold the faster. A hole is dug in the earth, immediately below the spout of the conductor, to receive the pot.

1721

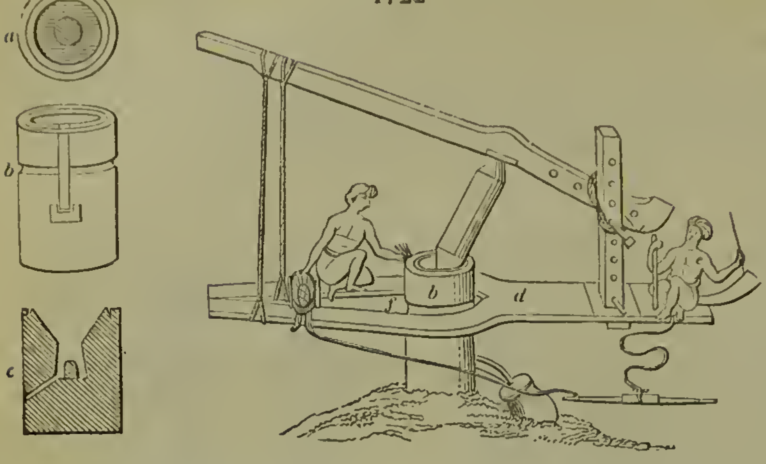


The mill used in Burdwan and near Calcutta is simply two small wooden cylinders, grooved, placed horizontally, close to each other, and turned by two men, one at each end. This simple engine is said completely, but slowly, to express the juice. It is very cheap, the prime cost not being two rupees; and being easily moved from field to field, it saves much labour in the carriage of the cane. Notwithstanding this advantage, so rude a machine must leave a large proportion of the richest juice in the cane-trash.

It is curious to find in the ancient arts of Hindostan exact prototypes of the sugar-rollers, horizontal and upright, of relatively modern invention in the New World.

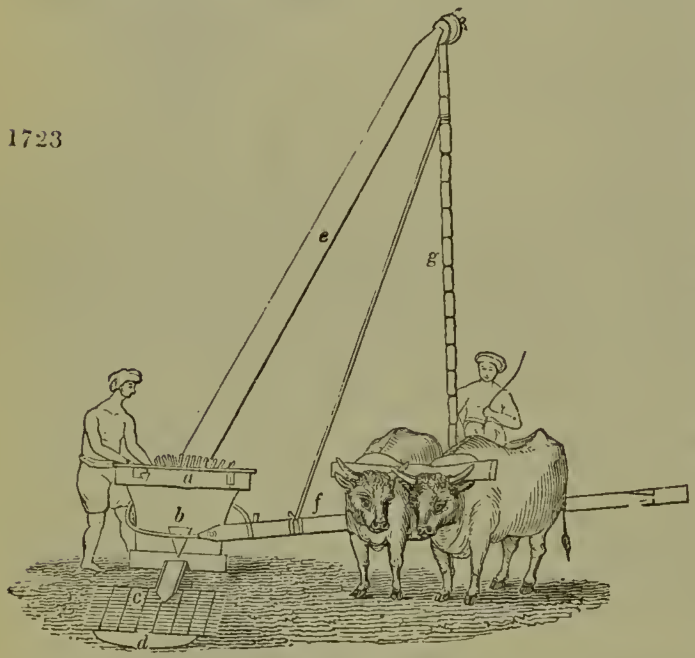
The sugar-mill of Chinapatam, *fig.* 1722, consists of a mortar, lever, pestle, and regulator. The mortar is a tree about 10 feet in length, and 14 inches in diameter: *a* is a plan of its upper end; *b* is an outside view; and *c* is a vertical section. It is sunk perpendicularly into the earth, leaving one end 2 feet above the surface. The hollow is conical, truncated downwards, and then becomes cylindrical, with a hemispherical projection in its bottom, to allow the juice to run freely to the small opening that conveys it to a spout, from which it falls into an earthen pot. Round the upper mouth of the cone is a circular cavity, which collects any of the juice that may run over from the upper ends of the pieces of cane; and thence a canal conveys this juice down the outside of the mortar, to the spout. The beam *d*, is about 16 feet in length, and 6 inches in thickness, being cut out from a large tree that is divided by a fork into two arms. In the fork an excavation is made for the mortar *b*, round which the beam turns horizontally. The surface of this excavation is secured by a semicircle of strong wood. The end towards the fork is quite open for changing the beam without trouble. On the undivided end of the beam sits the bullock-driver *e*, whose cattle are yoked by a rope which comes from the end of the beam; and they are prevented from dragging out of the circle by another rope, which passes from the yoke to the forked end of the beam. On the arms *f*, a basket is placed, to hold the cuttings of cane; and between this and the mortar sits the man who feeds the mill. Just as the pestle comes round, he places the pieces of cane sloping down into the cavity of the mortar; and after the pestle has passed, he removes those away that have been squeezed.

1722



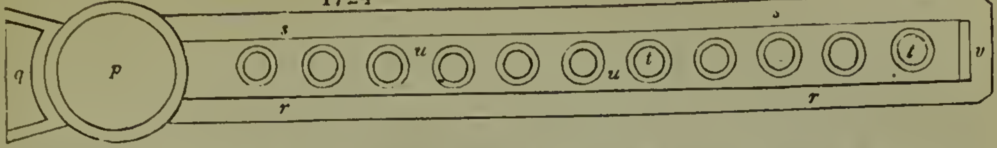
The following describes the primitive rude mill and boiler used in preparing the extract of sugar cane, and which are usually let to the ryots by the day. The mill in Dinajpur, *fig.* 1723, is on the principle of a pestle and mortar. The pestle, however, does not beat the canes, but is rubbed against them, as is done in many chemical triturations; and the moving force is two oxen. The mortar is generally a tamarind tree, one end of which is sunk deep in the ground, to give it firmness. The part projecting *a*, may be about 2 feet high, and a foot and a half in diameter; and in the upper end a hollow is cut, like the small segment of a sphere. In the centre of this, a channel descends a little way perpendicularly, and then obliquely to one side of the mortar, so that the juice as squeezed from the cane, runs off by means of a spout *b*, into a strainer *c*, through which it falls into an earthen pot that stands in a hole *d*, under the spout. The pestle *e*, is a tree about 18 feet in length, and 1 foot in diameter, rounded at its bottom, which rubs against the mortar, and which is secured in its place by a button or knob that goes into the channel of the mortar. The moving force is applied to a horizontal beam *f*, about 16 feet in length, which turns round about the mortar, and is fastened to it by a bent bamboo, *b*. It is suspended from the upper end of the pestle by a bamboo *g*, which has been cut with part of the root, in which is formed a pivot that hangs on the upper point of the pestle. The cattle are yoked to the horizontal beam, at about 10 feet from the mortar, move round it in a circle, and are driven by a man who sits on the beam to increase the weight of the triturating power. Scarcely any machine more miserable can be conceived; and it would be totally ineffectual, were not the cane cut into thin slices. This is a troublesome part of the operation. The grinder sits on the ground, having before him a bamboo stake, which is driven into the earth with a deep notch formed in its upper end. He passes the canes gradually through this notch, and at the same time cuts off the slices with a kind of rude chopper.

1723



The *boiling apparatus* is somewhat better contrived, and is placed under a shed, though the mill is without shelter. The fireplace is a considerable cavity dug in the ground, and covered with an iron boiler *p*, *fig.* 1724. At one side of this is an

1724



opening *q*, for throwing in fuel; and opposite to this is another opening, which communicates with the horizontal flue. This is formed by two parallel mud walls, *r*, *r*, *s*, *s*, about 20 feet long, 2 feet high, and 18 inches distant from each other. A row of eleven earthen boilers, *t*, is placed on these walls, and the interstices *u*, are filled with clay, which completes the furnace-flue, an opening *v*, being left at the end, for giving vent to the smoke.

The juice, as it comes from the mill, is first put into the earthen boiler that is most distant from the fire, and is gradually removed from one boiler to another, until it reaches the iron one, where the process is completed. The fireplace is manifestly on the same model as the boiler-range in the West Indies, and may possibly have suggested it, since the Hindostan furnace is, no doubt, of immemorial usage. The execution of its parts is very rude and imperfect. The inspissated juice that can be prepared in twenty-four hours by such a mill, with sixteen men and twenty oxen, amounts to no more than 476 lbs.; and it is only in the southern parts of the district, where the people work night and day, that the sugar-works are so productive. In the northern districts, the people work only during the day, and inspissate about one-half the quantity of juice. The average daily make of a West India sugar-house is from 2 to 3 hogsheads, of 16 cwts. each.

The Indian manufacturers of sugar purchase the above inspissated juice or goor from the farmers, and generally prefer that of a granular honey consistence, which is offered for sale in pots. As this, however, cannot conveniently be brought from a distance, some of the cake kind is also employed. The boilers are of two sizes: one adapted for making at each operation about 10 cwt.; the other about 8½. The latter is the segment of a sphere, 9 feet diameter at the mouth; the former is larger. The boiler is sunk into a cylindrical cavity in the ground, which serves as a fireplace, so that its edge is just above the floor of the boiling-house. The fuel is thrown in by an aperture close to one side of the boiler, and the smoke escapes by a horizontal chimney that passes out on the opposite side of the hut, and has a small round aperture, about 10 feet distant from the wall, in order to lessen the danger from fire. Some manufacturers have only one boiler; others as many as four; but each boiler has a separate hut, in one end of which is some spare fuel; and in the other some bamboo stages, which support cloth strainers, that are used in the operation. This hut is about 24 cubits long, and 10 broad; has mud walls 6 cubits high; and is raised about 1 cubit above the ground.

For each boiler, two other houses are required; one, in which the cane extract is separated by straining from the molasses, is about 20 cubits long by 10 wide; another, about 30 cubits long by 8 wide, is that in which, after the extract has been strained, boiled, and clarified, the treacle is separated from the sugar by an operation analogous to claying.

Each sugar manufacturer has a warehouse besides, of a size proportional to the number of his boilers.

About 960 pounds of pot extract being divided into four parts, each is put into a bag of coarse sackcloth, hung over an equal number of wide-mouthed earthen vessels, and is besprinkled with a little water. These drain from the bags about 240 lbs. of a substance analogous to West Indian molasses. The remainder in the bags is a kind of coarse muscovado sugar; but it is far from being so well drained and freed from molasses as that of the Antilles. The 720 lbs. of this substance are then put into a boiler with 270 pounds of water, and the mixture is boiled briskly for 144 minutes, when 180 additional pounds of water are added, and the boiling is continued for 48 minutes more. An alkaline solution is prepared from the ashes of the plantain tree, strewed over straw placed in the bottom of an earthen pot perforated with holes. Ninety pounds of water are passed through; and 6 pounds of the clear lixivium are added to the boiling syrup, whereby a thick scum is raised, which is removed. After 24 minutes, four and a half pounds of alkaline solution, and about two-fifths of a pound of raw milk, are added; after which the boiling and skimming are continued 24 minutes. This must be repeated from five to seven times, until no more scum appears. 240 pounds of water being now added, the liquor is to be poured into a number of strainers. These are bags of coarse cotton cloth in the form of inverted quandrangular pyramids, each of which is suspended from a frame of wood, about 2 feet square. The operation of straining occupies about 96 minutes. The strained liquor is divided into three parts: one of these is put into a boiler, with from half a pound to a pound and a half of alkaline solution, one-twelfth of a pound of milk, and 12 pounds of water. After having boiled for between 48 and 72 minutes, three quarters of a pound of milk are added, and the liquor is poured, in equal portions, into four refining pots. These are wide at the mouth, and pointed at the bottom; but are not conical, for the sides are curved. The bottom is perforated, and the stem of a plantain leaf forms a plug for closing the aperture. The two remaining portions of the strained liquor are managed in exactly the same manner; so that each refining pot has its share of each portion. When they have cooled a little, the refining pots are removed to the curing-house, and placed on the ground for 24 hours; next day they are placed on a frame, which supports them at some distance from the ground. A wide-mouthed vessel is placed under each, to receive the viscid liquor that drains from them. In order to draw off this more completely, moist leaves of the *Valisneria spiralis* are placed over the mouth of the pot, to the thickness of two inches; after 10 or 12 days these are removed, when a crust of sugar, about half an inch in thickness, is found on the surface of the boiled liquor. The crust being broken and removed, fresh leaves are repeatedly added, until the whole sugar has formed; this requires from 75 to 90 days. When cake extract is used, it does not require to be strained before it be put into the boiler.

In every part of the Behar and Putna districts, several of the confectioners prepare the coarse article called *shukkur*, which is entirely similar in appearance to the inferior Jamaica sugars. They prepare it by putting some of the thin extract of sugar cane into coarse sackcloth bags, and by laying weights on them, they squeeze out the molasses; a process perfectly analogous to that contemplated in several English pateuts.

Of the Manufacture of Sugar in the West Indies.

Cane-juice varies exceedingly in richness, with the nature of the soil, the culture, the season, and variety of the plant.

When left to itself in the colonial climates, the juice runs rapidly into the acetous fermentation; twenty minutes being, in many cases, sufficient to bring on this destructive change. Hence arises the necessity of subjecting it immediately to clarifying processes, speedy in their action. When deprived of its green fecula and glutinous extractive, it is still subject to fermentation; but this is now of the vinous kind. The juice flows from the mill through a wooden gutter lined with lead, and being conducted into the sugar-house, is received in a set of large pans or cauldrons, called clarifiers. On estates which make on an average, during crop time, from 15 to 20 hogsheads of sugar a week, three clarifiers, of 400 gallons' capacity each, are sufficient. With pans of this dimension, the liquor may be drawn off at once by a stopcock or siphon, without disturbing the feculencies after they subside. The clarifiers are sometimes placed at one end, and sometimes in the middle of the house, particularly if it possesses a double set of evaporating pans.

Whenever the stream from the mill cistern has filled the clarifier with fresh juice, the fire is lighted, and the *temper*, or dose of slaked lime, diffused uniformly through a little juice, is added. If an albuminous emulsion be used to promote the clarifying, very little lime will be required; for recent cane-liquor contains no appreciable portion of acid to be saturated. In fact, the lime and alkalies in general, when used in small quantity, seem to coagulate the glutinous extractive matter of the juice, and thus tend to brighten it up. But if an excess of temper be used, the gluten is taken up again by the strong affinity which is known to exist between sugar and lime. Excess of lime may always be corrected by a little alum-water. Where canes grow on a calcareous marly soil, in a favourable season the saccharine matter gets so thoroughly elaborated, and the glutinous mucilage so completely condensed, that a clear juice and a fine sugar may be obtained without the use of lime.

As the liquor grows hot in the clarifier, a scum is thrown up, consisting of the coagulated feculencies of the cane-juice. The fire is now gradually urged till the temperature approaches the boiling point; to which, however, it must not be suffered to rise. It is known to be sufficiently heated, when the scum rises in blisters, which break into white froth; an appearance observable in about forty minutes after kindling the fire. The damper being shut down, the fire dies out; and after an hour's repose, the clarified liquor is ready to be drawn off into the last and largest in the series of evaporating pans. In the British colonies, these are merely numbered 1, 2, 3, 4. 5, beginning at the smallest, which hangs right over the fire, and is called the *teache*; because in it the trial of the syrup, by *touch*, is made. The flame and smoke proceed in a straight line along a flue to the chimney-stalk at the other end of the furnace.

The area of this flue proceeds, with a slight ascent from the fire, to the aperture at the bottom of the chimney; so that between the surface of the grate and the bottom of the teache, there is a distance of 28 inches; while between the bottom of the flue and that of the *grand*, No. 5, at the other end of the range, there are barely 18 inches.

In some sugar-houses there is planted, in the angular space between each boiler, a basin, one foot wide and a few inches deep, for the purpose of receiving the scum which thence flows off into the *grand copper*, along a gutter scooped out on the margin of the brickwork. The skimmings of the *grand* are thrown into a separate pan, placed at its side. A large cylindrical *cooler*, about 6 feet wide and 2 feet deep, has been placed in certain sugar-works near the teache, for receiving successive charges of its inspissated syrup. Each finished charge is called a skipping, because it is skipped or laded out. The term *striking* is also applied to the act of emptying the *teache*. When upon one skipping of syrup in a state of incipient granulation in the cooler, a second skipping is poured, this second congeries of saccharine particles agglomerates round the first as *nuclei* of crystallisation, and produces a larger grain; a result improved by each successive skipping. This principle has been long known to the chemist, but does not seem to have been always properly considered or appreciated by the sugar-planter.

From the above described *cooler*, the syrup is transferred into wooden chests or boxes, open at top, and of a rectangular shape; also called *coolers*, but which are more properly crystallisers or granulators. These are commonly six in number; each being about 1 foot deep, 7 feet long, and 5 or 6 feet wide. When filled, such a mass is collected as to favour slow cooling, and consequent large-grained crystallisation. If these boxes be too shallow, the grain is exceedingly injured, as may be easily shown by pouring some of the same syrup on a small tray; when, on cooling, the sugar will appear like a muddy soft sand.

The due concentration of the syrup in the teache is known by the boiler, by the appearance of a drop of the syrup pressed and then drawn into a thread between the thumb and fore-finger. The thread eventually breaks at a certain limit of extension, shrinking from the thumb to the suspended finger, in lengths somewhat proportional to the inspissation of the syrup. But the appearance of granulation in the thread must also be considered; for a viscid and damaged syrup may give a long enough thread, and yet yield almost no crystalline grains when cooled. Tenacity and granular aspect must therefore be both taken into the account, and will continue to constitute the practical guides to the negro boiler, till a less barbarous mode of concentrating cane-juice be substituted for the present *naked teache*, or *sugar frying-pan*.

A viscous syrup containing much gluten and sugar, altered by lime, requires a higher temperature to enable it to granulate than a pure saccharine syrup; and therefore the thermometer, though a useful aid, can by no means be regarded as a sure guide, in determining the proper instant for *striking* the *teache*.

The colonial *curing-house* is a capacious building, of which the earthen floor is excavated to form the molasses reservoir. This is lined with sheet lead, boards, tarras, or other retentive cement; its bottom slopes a little, and it is partially covered by an open massive frame of joist-work, on which the potting casks are set upright. These are merely empty sugar hogsheads, without headings, having 8 or 10 holes bored in their bottoms, through each of which the stalk of a plantain leaf is stuck, so as to protrude downwards 6 or 8 inches below the level of the joists, and to rise above the top of the cask. The act of transferring the crude concrete sugar from the crystallisers into these hogsheads, is called potting. The bottom holes, and the spongy stalks stuck in them, allow the molasses to drain slowly downwards into the sunk cistern. In the common mode of procedure, sugar of average quality is kept from 3 to 4 weeks in the curing-house; that which is soft grained and glutinous must remain 5 or 6 weeks. The curing-house should be close and warm, to favour the liquefaction and drainage of the viscid molasses.

Out of 120 millions of pounds of raw sugar which used to be annually shipped by the St. Domingo planters, only 96 millions were landed in France, according to the authority of Dutrone, constituting a loss by drainage in the ships of 20 per cent. The average transport waste at present in the sugars of the British colonies cannot be estimated at less than 12 per cent., or altogether upwards of 27,000 tons! What a tremendous sacrifice of property!

Some years ago a very considerable quantity of sugar was imported into Great Britain in the state of concentrated cane-juice, containing nearly half its weight of granular sugar, along with more or less molasses, according to the care taken in the boiling operations. Among more than a hundred samples analysed for the custom-house, Dr. Ure did not perceive any traces of fermentation. Since sugar softens in its grain at each successive solution, whatever portion of the crop may be destined for the refiner should upon no account be granulated in the colonies, but should be transported to Europe in the state of a rich cane-syrup, or still better of concrete. If the process is carefully performed, the syrup may be transferred at once into the blowing-up cistern, and subjected to the process of refining. Were this means generally adopted, probably 30 per cent. would be added to the amount of home-made sugar loaves corresponding to a given quantity of average cane-juice; while 30 per cent. would be taken from the amount of molasses. The saccharine matter now lost by drainage from the hogsheads in the ships, amounting to from 10 to 15 per cent., would also be saved. The produce of the cane would, on this plan, require less labour in the colonies, and might be exported 5 or 6 weeks earlier than at present, because the period of drainage in the curing-house would be spared.

It does not appear that our sugar colonists have availed themselves of the proper chemical method of counteracting that incipient fermentation of the cane-juice which sometimes supervenes, and proves so injurious to their products. It is known that grape-must, feebly impregnated with sulphurous acid, by running it slowly into a cask in which a few sulphur matches have been burned, will keep without alteration for a year; and if boiled into a syrup within a week or ten days, it retains no sulphurous odour. A very slight treatment would suffice for the most fermentable cane juice; and it could be easily adopted by the use of suitable apparatus, or still better by the use of bi-sulphite of lime, which is specially prepared for this purpose by Alexander M'Dougall, of Manchester. Thus the acidity so prejudicial to the saccharine granulation would be certainly prevented.

Syrup intended for forming clayed sugar must be somewhat more concentrated in the teache, and run off into a copper cooler, capable of receiving three or four successive skippings. Here it is stirred to ensure uniformity of product, and is then transferred by ladles into conical moulds, made of coarse pottery or of sheet iron, having a small orifice at the apex, which is stopped with a plug of wood wrapped in a leaf of maize. These conical pots stand with the base upwards. As their capacity, when largest, is considerably less than that of the smallest potting-casks, and as the process lasts several weeks, the claying-house requires to have very considerable dimensions. Whenever the syrup is properly granulated, which happens usually in about 18 or 20 hours, the plugs are removed from the apices of the cones, and each is set on an earthen pot to receive the drainings. At the end of 24 hours the cones are transferred over empty pots, and the molasses contained in the former ones is either sent to the fermenting-house or sold. The claying now begins, which consists in applying to the smoothed surface of the sugar at the base of the cone a plaster of argillaceous earth, or tolerably tenacious loam in a pasty state. The water diffused among the clay escapes from it by slow infiltration, and descending with like slowness through the body of the sugar, carries along with it the residuary viscid syrup, which is more readily soluble than the granulated particles. Whenever the first magma of clay has become dry, it is replaced by a second; and this occasionally in its turn by a third, whereby the sugar cone gets tolerably white and clean. It is then dried in a stove, cut transversely into *frusta*, crushed into a coarse powder on wooden trays, and shipped off for Europe. Clayed sugars are sorted into different shades of colour according to the part of the cone from which they were cut. The clayed sugar of Cuba, which is sun-dried, is called Havannah sugar, from the name of the shipping port.

Clayed sugar can be made only from the ripest cane juice, for that which contains much gluten would be apt to get too much burned by the ordinary process of boiling to bear the claying operation. The syrups that run off from the second, third, and fourth application of the clay-paste, are concentrated afresh in a small building apart, called the refinery, and yield tolerable sugars. Their drainings go to the molasses cistern. The cones remain for 20 days in the claying-house before the sugar is taken out of them.

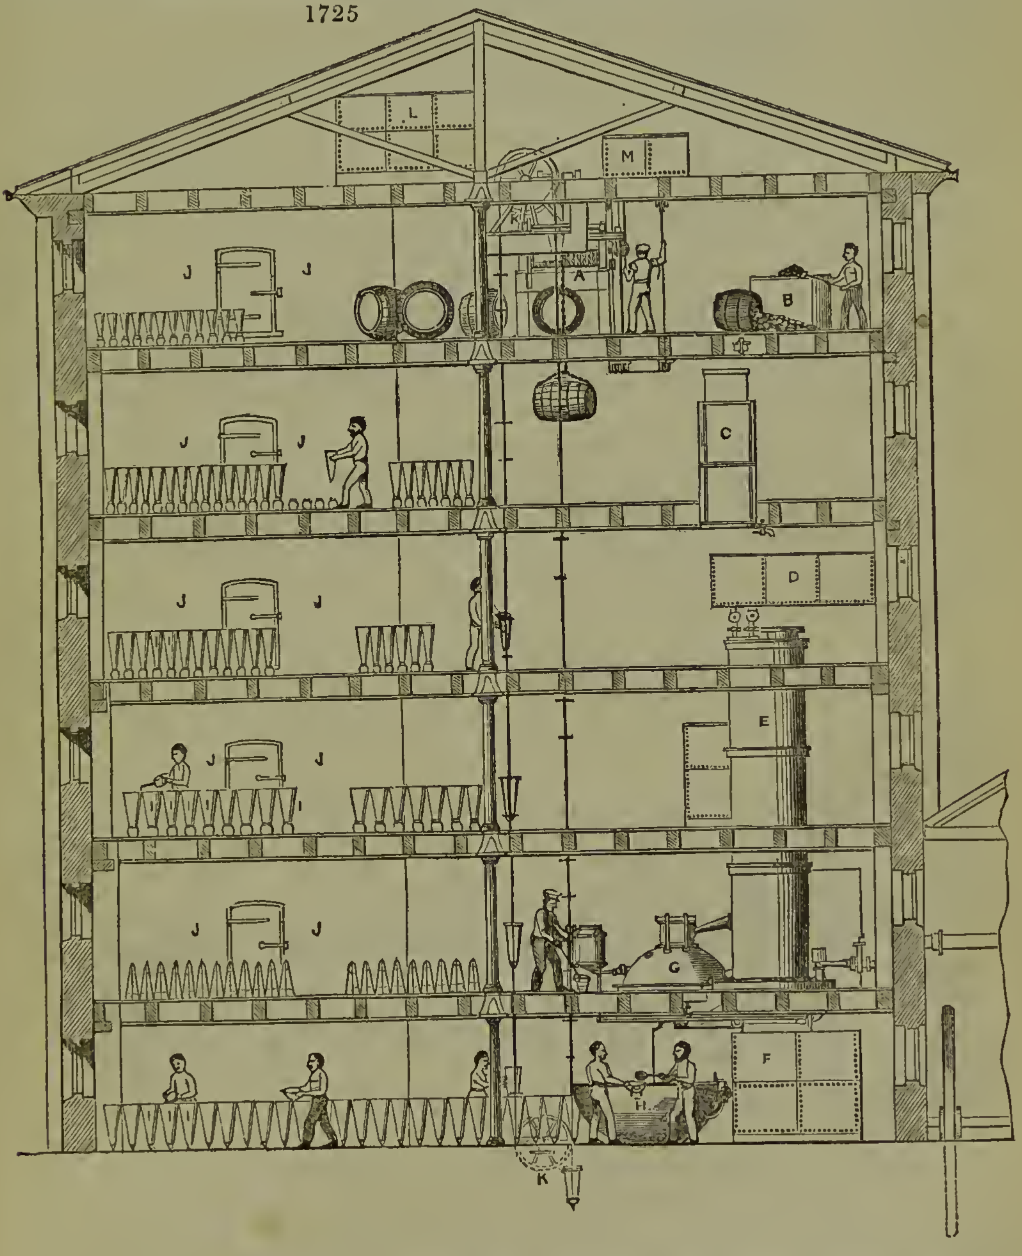
Claying is seldom had recourse to in the British plantations, on account of the increase of labour, and diminution of weight in the produce, for which the improvement in quality yields no adequate compensation. Such, however, was the esteem in which the French consumers held clayed sugar, that it was prepared in 400 plantations of St. Domingo alone.

Sugar Refining. — The raw or Muscovado sugar, as usually imported, is not in a state of sufficient purity for use. The sugar is blended with more or less of fruit and grape sugars, with sand and clay, with albuminous and colouring matter, chiefly caramel. To separate the pure sugar, the plan formerly adopted was to add blood, eggs, and lime-water to a solution of the raw sugar, and after applying heat, to remove the thick scum of coagulated albumen, which also removed a considerable portion of colouring matter. The clear liquid was concentrated, and the semi-crystalline mass being placed in conical moulds, as much of the molasses as would drain by gravitation was allowed to escape from the points of the moulds, and the remainder was expelled by allowing water or a solution of pure sugar to trickle through the mass of crystals. The loaves, being trimmed into shape and dried, were fit for sale.

By this process only a small proportion of the sugar was made into loaf. The method of removing the colouring matter was crude, imperfect, and expensive, and the high temperature requisite for the fermentation of the syrup not only injured its colour, but converted a large proportion of the sugar into the uncrystallisable variety.

These defects were remedied, to a great extent, by the adoption of Howard's vacuum pan, for the concentration of syrups under diminished atmospheric pressure,

1725



and consequently at a low temperature, together with the use of filtering beds of animal charcoal for the removal of colouring matter.

There are three classes of sugar-refineries in this country, the chief productions of which are respectively:—

1st. Loaf sugar.

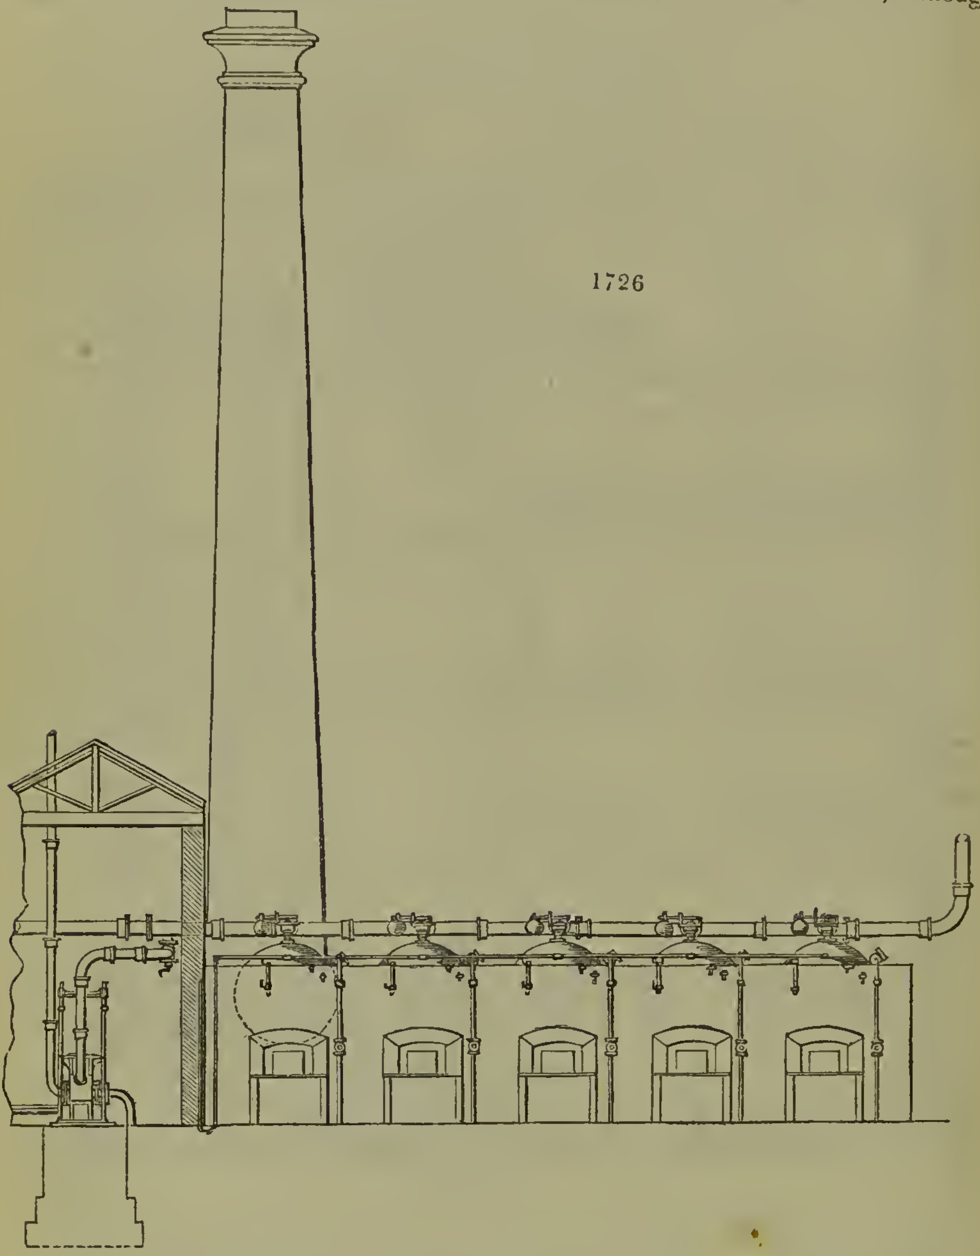
2nd. Crystals (*i. e.* large, well-formed, dry white crystals of sugar).

3rd. Crushed sugar.

In the former two, good West India, Havannah, Mauritius, or Java sugar are almost exclusively used. In the last, all classes of sugar are indiscriminately employed. The manufacture of loaf sugar is chiefly carried on in London; of crystals, in Bristol and Manchester; of crushed sugar, in Liverpool, Greenock, and Glasgow. Besides these places, which are the chief seats of the sugar-refining trades, this branch of industry is carried on more or less at Plymouth, Southampton, Goole, Sheffield, Newton (Lancashire), and Leith. The methods vary a little in different refineries, but the following description refers to the most modern and best conducted which are to be found in this country. The general arrangements of a sugar house are shown in *figs.* 1725 and 1726.

Loaf Sugar. — *Solution.* The raw sugar is emptied from the hogsheads, boxes, or mats, as the case may be, and discharged through a grating in the floor into a copper pan, about 8 feet in diameter. This dissolving pan is sometimes, although

1726



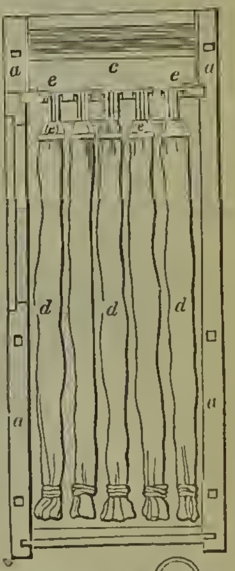
incorrectly, called a defecator, it was formerly called a blow-up, from the practice of blowing steam into it, but the practice and the name are now antiquated. Hot water is added, and the solution is facilitated by the action of an agitator, or stirrer, kept in motion by the steam-engine. The proportions of sugar and water are regulated so that the liquid attains a specific gravity of about 1·250 or 29° Baumé, as a higher density than this would interfere with subsequent processes. A copper coil or casing to the pan, heated by steam, furnishes the means of raising the liquid to a temperature of 165°. The plan of boiling the "liquor" is becoming gradually disused. If the solution is acid, sufficient lime-water is added to make it neutral. The use of blood, which was formerly added at this stage, is in most cases dispensed with;

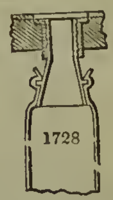
the advantage arising from its use is readily obtained from the employment of an increased amount of animal charcoal in a subsequent process, while the mischief arising from the introduction of nitrogenous matter so prone to decompose is avoided. Some machinery is used for crushing the hard lumps to facilitate solution.

Removal of insoluble matter. The liquor having been brought to the requisite density and temperature, and also being perfectly neutral, is passed through the bag filter.

The apparatus consists of an upright square iron or copper case, *a*, *a*, *fig.* 1727, about 6 or 8 feet high, furnished with doors; beneath is a cistern with a pipe for receiving and carrying off the filtered liquor; and above the case is another cistern *c*. Into the upper cistern the syrup is introduced, and passes thence into the mouths *e*, *e*, of the several filters, *d*, *d*. These consist each of a bag of thick twilled cotton cloth, about 2 feet in diameter, and 6 or 8 feet long, which is inserted into a narrow "sheath," or bottomless bag of canvas, about 5 inches in diameter, for the purpose of folding the filter-bag up into a small space, and thus enabling a great extent of filtering surfaces to be compressed into one box. The orifice of each compound bag is tied round a conical brass mouth-piece or nozzle *e*, which screws tight into a corresponding opening in the bottom of the upper cistern. From 40 to 400 bags are mounted in each filter case. The liquor which first passes is generally turbid, and must be pumped back into the upper cistern, for refiltration. The interior of the case is furnished with a pipe for injecting steam, which is occasionally used for warming the case. *Fig.* 1728, shows one mode of forming the funnel-shaped nozzles of the bags, in which they are fixed by a bayonet catch. *Fig.* 1729 shows the same made fast by means of a screwed cap, which is more secure.

1727





1728

1729

When the bags are fouled from the accumulation of clay and a slimy substance on their inner surfaces, the filter is unpacked, the bags withdrawn from the sheaths, and well washed in hot water. This washing is usually performed with a dash-wheel, or some one of the numerous kinds of washing machines now in use. Perhaps that of Manlove and Alliott, of Nottingham, is in greatest favour. The dirty water, with the addition of a little lime, is smartly boiled, and after some hours being allowed for subsidence, the supernatant, clear, weak solution of sugar is removed and used in the first process (solution), while the muddy residue is placed in canvas bags and subjected to pressure. The residue, technically called scum, is thrown away.

Removal of colour.—The liquor issuing from the bag-filters generally resembles in colour dark sherry wine. To render this colourless it is passed through deep filtering-beds of granulated burnt bones or animal charcoal. When this substance was first introduced, beds of a few inches in depth were considered sufficient, but the quantity of charcoal used per ton of sugar has steadily increased, and filters of no less a depth than 50 feet are now sometimes used.

Cylinders of wrought or cast iron, varying in diameter from 5 to 10 feet, and in height from 10 to 50, having a perforated false bottom, a couple of inches above the true one, are filled with granulated animal charcoal.

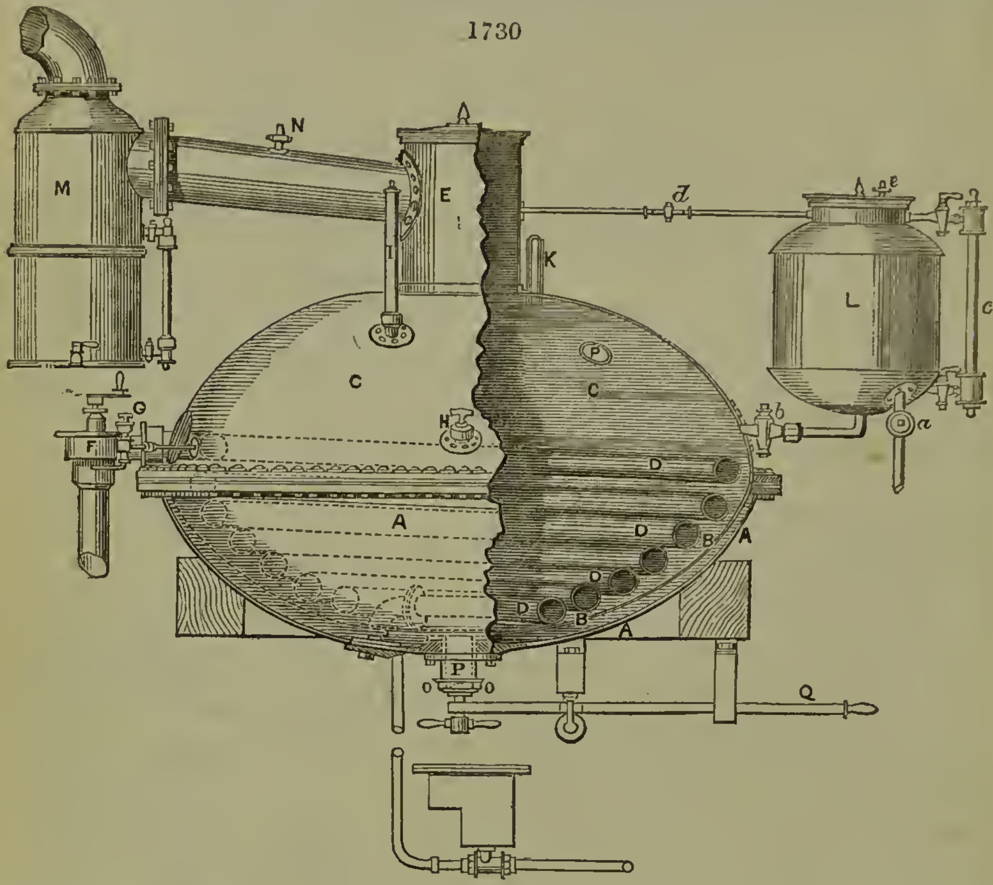
The grain varies from the size of turnip seed to that of peas, some refiners preferring it fine, and others coarse.

Liquor from the bag-filters is run on to the charcoal till the cylinder is perfectly filled, when the exit tap at the bottom is opened, and a stream of dense saccharine fluid, perfectly colourless, issues forth. The amount of sugar which the charcoal will discolour depends upon the age and composition of the charcoal, the degree of perfection with which the previous revivification has been performed, and the quality, colour, and density of the liquor to be operated upon. One ton of charcoal is sometimes used to purify two tons of sugar; and in at least one refinery, where inferior sugar is operated on, two tons of charcoal serve for one ton of sugar. In most provincial refineries about one ton of charcoal is used to one of sugar; but in London, from the dearness of fuel and other causes, a smaller proportion of charcoal is employed. The liquor from the charcoal filter, at first colourless, becomes slightly tinged, and in course of time, varying from 24 hours to 72, the power of the charcoal becomes exhausted, the partially decoloured syrup is passed through a fresh charcoal filter, and the sugar is washed out from the charcoal by means of hot water. The charcoal is ready to be removed for revivification, which process is treated of on page 827.

Concentration.—The next process in sugar-refining is the evaporation of the clarified syrup to the granulating or crystallising point. The more rapidly this is effected, and the less the heat to which it is subjected, the better and greater is the product in sugar-loaves. No apparatus answers the refiner's double purpose of safety and expedition so well as the vacuum-pan.

The vacuum-pan, invented by Howard, and patented in the year 1812, is an enclosed copper vessel, heated by steam, passing through one or more copper coils, and a steam jacket. The vapour arising from the boiling solution of sugar is condensed by an injection of cold water, the arrangement of which, and the maintenance

1730

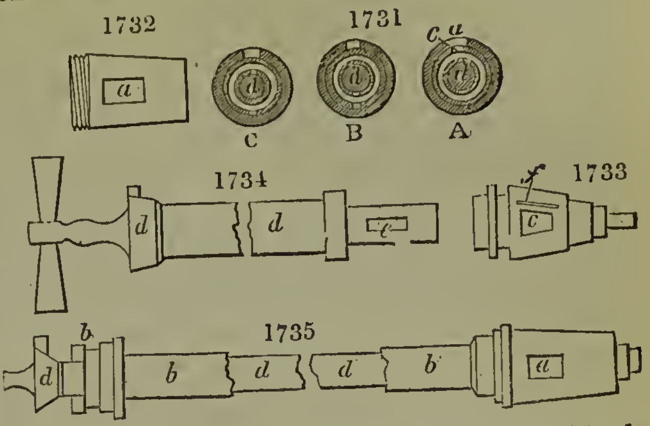


of a vacuum, closely resemble the condenser, injection, and air-pump of an ordinary condensing steam engine.

Fig. 1730, shows the structure of a single vacuum-pan. The horizontal diameter of the copper spheroid C C, is from 7 to 10 feet; the depth of the under hemisphere A, is at least 2 feet from the level of the flange; and the height of the dome-cover is from 3 to 5 feet. The two hemispheres (of which the inferior one is double, or has a steam-jacket), are put together by bolts and screws, to preserve the joints tight against atmospheric pressure.

The steam enters through the valve F, traversing the copper coil D, and filling the steam-jacket, the condensed water issuing from a small pipe below. C represents the dome of the vacuum-pan, the vapour from which passing in the direction of N, allows any particles of sugar carried over by the violence of the ebullition to be deposited in the receiver, M.

The vapour is condensed by jets of cold water issuing from a perforated pipe, and the water, uncondensed vapour, and air, are removed by the action of a powerful air-pump. L is the measure cistern, from which the successive charges are admitted into the pan; I and K represent respectively a thermometer and a barometer. the former being required to indicate the temperature of the boiling syrup, and the latter the diminished atmospheric pressure within the pan. P is the discharge cock, and H, the proof stick, is an apparatus inserted air-tight into the cover of the vacuum-pan, and which dips down into the syrup, serving to take out a sample of it, without allowing air to enter. It is shown in detail by figure 1735, which represents a cylindrical rod, capable of being screwed air-tight into the pan in an oblique direction downwards. The upper or exterior end is open; the under, which dips into the syrup, is closed, and has on one side a slit *a* (*figs.* 1732, 1735), or notch, about ½ in. wide. In this external tube, there is another shorter tube *b*, capable of moving round it, through an arca of 180°. An opening upon the under end *e*, corresponds with the slit in the outer tube, so that both may be made to coincide, *fig.* 1731, A. A plug *d*; is put in the interior tube, but so as not to shut it entirely. Upon the upper end there is a projection or pin, which catches in a slit of the inner tube, by which this may be turned round at pleasure. In the lower end of the plug there is a holc *e*, which can be placed in communication with the lateral openings in both tubes. Hence it is possiblc, when the plug and the inner tube are brought into the proper position, A, *fig.* 1731, to fill the cavity of the rod with the syrup, and to take it out without allowing any air to enter. In order to facilitate the turning of the inner tube within the outer, there is a groove in the under part, into which a little grease may be introduced.



Whenever a proof has been taken, thc plug must be placed in reference to the inner tube, as shown in *fig.* 1731, C, and then turned into the position A; when the cavity of the plug will again be filled with syrup. C must be now turned back to the former position, whereby all intercourse with the vacuum-pan is cut off; the plug being drawn out a little, and placed out of communication with the inner tube. The plug is then turned into the position B, drawn out, and the proof examined by the fingers.

The method of using the vacuum-pan varies with the character of the grain required to be produced. On commencing boiling, the syrup should be run in as quickly as possible, till the whole heating surface is covered, when the steam is turned on, and the evaporation conducted at a temperatnre of from 170° to 180° Fahr. As soon as the syrup begins to granulate, the temperature becomes reduced to 160°; and finally, just before the evaporation is completed, and the sugar ready to be discharged into the heater, it is further reduced, and approaches 145°, being the lowest temperature at which proof sugar boils, 3 inches from a perfect vacuum. When the sugar-boiler ascertains, by withdrawing a sample of the syrup by means of the proof-stick, and examining it against the light between his finger and thumb, that the crystals are in a sufficiently forward state for his purpose, he adds another measure full to that already in the pan, and the same process is repeated till the whole charge has been admitted. After each successive charge the crystals continue increasing in size to the end of the operation, those first formed acting as nuclei, a skip, as it is technically called, or a panful of the concentrated sugar, may be made in from two to four hours from the commencement of the boiling. If a fine grain sugar be required, greater quantities of syrup are admitted at each charge of the measure, and *vice versâ*.

Making of loaf sugar.—The proof sugar at a temperature not exceeding 145° is then let down through a cock or valve in the bottom of the pan into the heater. The sugar liquor consists at this stage of the process of a large number of small crystals floating in a medium of syrup.

The heater is an open copper pan of about the same capacity as the vacuum-pan, and is furnished with a steam-jacket and provided with an agitator,—in fact, it closely resembles the dissolving pan used for the first process. The object to be attained in the heater is to raise thc sugar to a temperature of 180°, which has been found by practice to be the point best adapted for hardening and completing the formation of the crystals, during which process the sugar is constantly stirred.

The sugar is then run out through a cock in the bottom of the heater into a ladle, from whence it is poured into moulds or cones of sheet iron strongly painted. The sizes of the moulds vary, from a capacity of 10 pound *loaves* to that of 56 pound *bastards* — a kind of soft brown sugar obtained by thc concentration of the inferior syrups. Thcse moulds have thc orifices at their tips closed with nails inserted through pieces of cloth or indiarubber, and are set up in rows close to each other, in an apartment adjoining the heaters. Here they are left several hours, commonly the whole night, after being filled, till their contents become solid, and they are lifted next morning into an upper floor, kept at a temperature of about 100° by means of steam pipes, and placed over gutters to receive the syrup drainings — the plugs being first removed, and a steel wire, called a piercer, being thrust up to clear away any concretion from the tip. The syrup which flows off spontaneously is called green syrup. It is kept separate. In the course of one or two days, when the drainage is nearly complete, some finely clarified syrup, made from a filtered solution of fine raw sugar is poured to the depth of about an inch upon the base of each cone, the surface having been previously rendered level and solid by an iron tool, called a bottoming trowel. The liquor, in percolating downwards, being already a saturated syrup, can dissolve none of the crystalline sugar, but only the coloured matter and molasses; whereby, at each successive liquoring, the loaf becomes whiter, from the base to the apex.

To economise the quantity of "fine liquor" used, it is usual to give a first and even a second liquor of an inferior quality before applying the finishing liquor, which is a dense and almost saturated solution of fine sugar absolutely free from colour. A few moulds, taken promiscuously, are emptied from time to time, to inspect the progress of the blanching operation; and when the loaves appear to have acquired as much *colour*, according to the language of refiners, as is wanted for the particular market, they are removed from the moulds, turned on a lathe at the tips, if necessary, set for a short time upon their bases, to diffuse their moisture equally through them, and then transferred into a stove heated to 130° or 140° by steam pipes, where they are allowed to remain for two or three days, till they are baked thoroughly dry. They are then taken out of the stove, and put up in paper for sale.

In the above description of sugar-refining, nothing is said of the process of claying loaves, because it is now nearly abandoned in all well-appointed sugar-houses.

The drainage of the last portion of the liquor from the moulds is sometimes accelerated by means of a vacuum. Centrifugal action has been also proposed for this purpose, but has not been found to succeed.

The drainings from the moulds which are collected in gutters and run into cisterns are boiled, and form an inferior quality of sugar. The drainings from this last sugar consist of treacle or syrup, which is always obtained as a final product.

Manufacture of crystals. — The use of centrifugal action for the separation of liquids and solids has been adopted in the arts for many years; its application for the separation of syrup and sugar occurred to several individuals, but it was best effected by means of the admirable hydro-extractor, invented and patented by Manlove and Alliott of Nottingham. Various modifications of this machine have been proposed and patented, but it is very doubtful whether anything that has been devised has improved upon the original machine. It would be tedious and unnecessary to detail the list of so-called improvements.

Considerable value, however, has been supposed to attach to the use of a blast of steam to free the meshes of the revolving cylinder from the semi-crystalline syrup. This plan was the subject of a patent granted to the late C. W. Finzel, but the opinion of those who consider that the injurious action of a blast of open steam upon the syrup far outweighs the advantage arising from a machine so easily cleansed, is gaining ground daily.

In the manufacture of "crystals," sometimes called centrifugal sugar, all the earlier processes previous to boiling are conducted as already described.

Concentration. — It is found more convenient to make use of vacuum-pans of large dimensions, and provided with extra heating surface by the introduction of several additional coils. The object sought to be obtained is the formation of large crystals, which is effected as follows: the pan is partially filled with liquor; this is concentrated until minute crystals appear; a further portion of liquor is added — the concentration continued — more liquor and further concentration again and again — until the pan is filled; the object being to keep the *mother-liquor* sufficiently fluid to prevent the formation of a second crop of crystals and yet sufficiently dense to feed the crystals already formed. One half the contents of the pan is discharged into the heater, while the remaining half is retained as a nucleus and the pan charged as before. This process is sometimes repeated several times.

Separation of crystals. — The semi-fluid mass is removed to the centrifugal machines with the least possible delay, and each machine barely attains its maximum speed before the syrup is discharged. To cleanse the surface of the crystals they are washed with liquor, sprinkled in the machine by means of a watering-can, a few pints of liquor being used to each cwt.

By this process the percentage of sugar obtained from the first and each separate crystallisation is considerably less than that obtained in the making of loaf-sugar or the ordinary method of making "crushed," though the *total* product does not vary materially, being rather more than that of the former where the product is stove dried and less than the latter, which is sold damp. The drainage is diluted, filtered through animal charcoal, boiled, and passed through the centrifugal machines, and results in a second quality of sugar, the crystals being smaller. The drainage from this is treated in a similar manner, and a third quality of crystals is the result. A fourth quality of crystals is also sometimes obtained, the drainage from which is again boiled and laid aside in large moulds to crystallise for about a week, when treacle and a low quality of "pieces" is the final result. The drainages are sometimes filtered along with inferior qualities of raw sugar.

The difficulty with which these large and beautiful crystals obtained by this process dissolve is an obstacle to their extensive consumption.

Crushed sugar. — This process closely resembles the manufacture of loaf sugar, but the raw sugar used is generally of an inferior quality. The filtration through the animal charcoal is in consequence not so perfect; the concentration resembles that of loaf sugar, but the use of a heater is dispensed with, and the process of liquoring is also dispensed with where practicable. The first crystallisation is called "crushed," and the second "pieces," the drainage from which goes by the name of "syrup." When this syrup is diluted, filtered through animal charcoal, and concentrated, it is called "golden syrup."

Treatment of molasses.—Foreign and colonial molasses, containing a large proportion of crystallisable sugar, are purchased by refiners. The Muscovado molasses from Cuba, from Porto Rico, Antigua, and Barbadoes, are esteemed the best, but the quality of molasses deteriorates as improvements in the manufacture of sugar are introduced on the plantations. The treatment of molasses formerly was simple; it was merely concentrated and allowed to stand for several weeks in large moulds to drain. The liquid was sold as treacle, and the impure soft, dark sugar, called bastards, found a market amongst the poorer classes, especially in Ireland.

The more recent and better plan, is to dilute the molasses, filter it through animal charcoal, and concentrate to the crystallising point, but without forming crystals. This readily crystallises in the moulds, and in place of the bastards and treacle a bright yellow sugar and a fair quality of syrup are the result. Good molasses yields 40 per cent. sugar, 40 per cent. syrup, the remaining 20 per cent. being water, dirt, and loss.

Palm or Date Sugar.—Many trees of the palm tribe yield a copious supply of sweet juice, which, when boiled down, gives a dark brown deliquescent raw sugar, called in India jaggery. The wild date palm and the gommuto palm yield the largest proportion of this kind of sugar, which is chemically identical with the sugar from the cane, though the crudeness of the manufacture is very injurious to it, and causes a large proportion to assume the uncrystallisable condition. One twenty-fourth of all the cane sugar extracted for useful purposes is obtained from the palm tree.

Beet root Sugar.—The extraction of sugar from beet root, which has become an important manufacture in several countries on the continent, especially in France and Germany, was developed in consequence of the difficulty of obtaining colonial sugar in France during the blockade in the time of Napoleon I. The high price of sugar (5*s.* per lb.) was not the only stimulus to invention, as a prize of a million of francs was offered by the government for the most successful method of manufacturing indigenous sugar. The beet is a biennial plant, native to the south of Europe. There are several varieties of this root, each fitted to its own climate and soil; but the white Silesian beet is most prized where it can be grown, on account of the large amount of sugar in the juice, and the comparative absence of salts; it is less prone to decay when stored previous to use. The average composition of the root of the sugar beet may be stated as follows:—

Sugar - - - - -	$10\frac{1}{2}$ per cent.
Gluten - - - - -	3
Woody fibre, &c. - - -	5
Water - - - - -	$81\frac{1}{2}$
	100

The proportion of sugar varies very much. First, it is greater in some varieties than others; second, it is greater in small beets than in large; third, in dry climates, especially when the climate is dry after the roots have begun to swell; fourth, in light than heavy soils; fifth, in the part above than under ground; sixth, when manure has not been directly applied to the crop. The average proportion of sugar extracted from beet is 6 per cent., though it is stated that $7\frac{1}{2}$ per cent. is obtained in some well conducted manufactories. In France and Belgium the average yield is 14 or 15 tons of beet to the acre, while about Magdeburg they do not exceed 10 to 12 tons, but the latter are richer in sugar.

During the first year of its life the root is developed to its full size, and secretes the whole amount of sugar which, in the natural life of the plant, furnishes the material for the growth and maturity of its upper part. It follows that when the plant is cultivated for its sugar, it is ripe for the sugar manufacturers when its first year's stage of development is complete. The time required for this depends upon that of the sowing, and upon the season. Its criterion is the commencement of death in the leaves. When ripe the beet roots are dug out, the mould gently shaken off, and the heads cut off, together with as much of the root as shows the presence of leaf buds. As the action of light is detrimental even to the exhumed roots, the latter must be covered quickly. If the quantity be small they may be covered with the leaves which have been cut off. It is more usual, however, to pile them in heaps on the ground, to hinder the evaporation of their water, and to protect them from light and frost by covering the heaps with a thin layer of earth. These mounds are sometimes sprinkled with water, which is taken up by the roots, restoring to them the plumpness and crispness which they have lost in a dry season.

Boussingault gave the following analyses of French beets:—

Where grown.	Time of taking from ground, &c.	Per cent. of dry matter.	Water.	Sugar.	Ligneous fibre and albumen.	Pectine?
Botanic school -	Aug. 2.—Roots small - - -	9 5	90·5	5·0	4·5	added to the lig. matter.

The physical characters which serve to show that a beet-root is of good quality, are its being firm, brittle, emitting a creaking noise when cut, and being perfectly sound within; the degree of sweetness is also a good indication. The 45th degree of latitude appears to be the southern limit of the successful growth of beet in reference to the extraction of sugar.

The first manipulations to which the beets are exposed, are intended to clear them from the adhering earth and stones, as well as the fibrous roots and portions of the neck. The roots are washed by a rotary movement upon a grating made like an Archimedes' screw, formed round the axis of a squirrel-cage cylinder, which is laid horizontally beneath the surface of water in an oblong trough. It is turned rapidly by means of a toothed wheel and pinion. The roots, after being sufficiently agitated in the water, are tossed out by the rotation at the opposite end of the cylinder.

The parenchyma of the beet is a spongy mass, whose cells are filled with juice. The cellular tissue itself, which forms usually only a twentieth or twenty-fifth of the whole weight, consists of ligneous fibre. Compression alone, however powerful, is inadequate to force out all the liquor which this tissue contains. To effect this object, the roots must be subjected to the action of an instrument which will tear and open up the greatest possible number of these cells. Experiments have, indeed, proved, that by the most considerable pressure, not more than 40 or 50 per cent. in juice can be obtained from the beet; whilst the pulp procured by the action of a grater produces from 75 to 80 per cent.

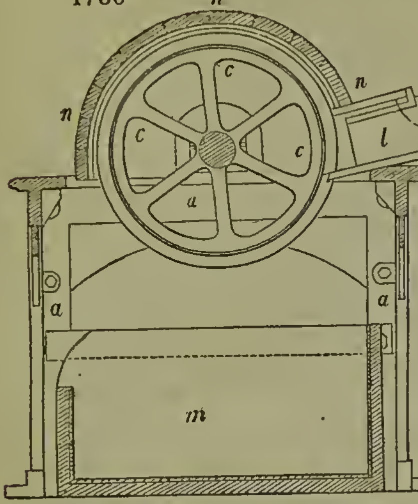
The beet-root rasp is represented in *figs.* 1736, 1737. *a*, *a* is the framework of the machine; *b* the feed-plate, made of cast iron, divided by a ridge into two parts; *c*, the hollow drum; *d*, its shaft, upon either side of whose periphery nuts are screwed

* Add 0·9 of nitre.

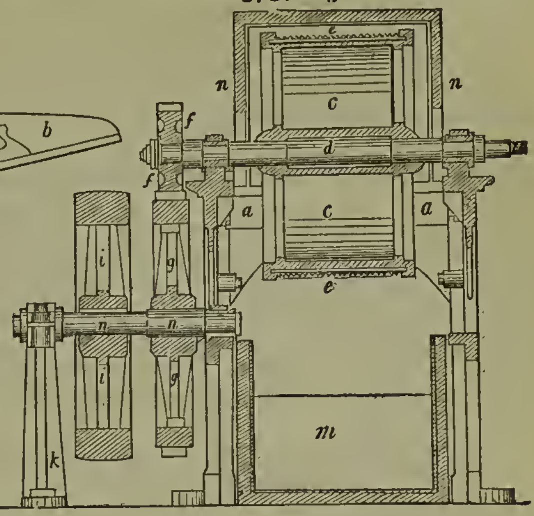
† Add 1·5 nitre; the albumen added to the sugar.

for securing the saw blades *e, e*, which are packed tight against each other by means of laths of wood; *f* is a pinion upon the shaft of the drum, into which the wheel *g*

1736



1737



works, and which is keyed upon the shaft *h*; *i* is the driving rigger; *k*, pillar of support; *l*, blocks of wood, with which the workman pushes the beet-roots against the revolving-rasp; *m*, the chest for receiving the beet-pap; *n*, the wooden cover of the drum, lined with sheet iron. The drum should make 500 or 600 turns in the minute.

A few years ago, M. Dombasle introduced a process of extracting the juice from the beet without either rasping or hydraulic pressure. The beets were cut into thin slices by a proper rotatory blade-machine; these slices were put into a macerating cistern, with about their own bulk of water, at a temperature of 212° Fahr. After half an hour's maceration, the liquor was said to have a density of 2° B., when it was run off into a second similar cistern, upon other beet-roots; from the second it was let into a third, and so on to a fifth; by which time, its density having risen to $5\frac{1}{2}$°, it was ready for the process of defecation. Juice produced in this way is transparent, and requires little lime for its purification; but it is apt to ferment, or to have its granulating power impaired by the watery dilution. A further obstacle to this process is presented by the cost of fuel required for concentrating so weak a solution, and the process has accordingly been abandoned.

By the process of M. Schutzenbach, the manufacture may be carried on during the whole year, instead of during a few winter months. At Waghäusel, near Carlsruhe, this system is adopted. The beets having been washed, are rapidly cut up into small pieces, and subjected to the drying heat of a coke fire for six hours. They lose from 80 to 84 per cent. of their weight; the dried root may be kept without injury for many months, and the sugar is extracted by infusion. At this colossal establishment, which in 1855 employed 3,000 people, and the buildings of which covered 12 acres of land, there were 20 infusing vessels 12 to 14 feet deep, and 7 wide. A cwt. of raw roots cost 7*d*., and the dried root contained 46 to 47 per cent. of sugar; the capital employed was eighty millions of francs.

Whether the juice is extracted from fresh or dried beets the subsequent processes are the same. The juice, having been extracted either by infusion or by submitting the rasped pulp to hydraulic pressure, is placed in a shallow vessel, and mixed with as much milk of lime as renders it strongly alkaline, it is then boiled, generally by means of a copper coil heated by high pressure steam. The excess of lime is removed by passing a stream of carbonic acid gas through the liquid. The gas is generally produced by forcing a stream of air through an enclosed coke fire. The liquid is next filtered through cloth concentrated to a specific gravity of 25° B., filtered through animal charcoal, and treated in all respects similarly to ordinary cane sugar in a refinery. Though the vacuum-pan is employed in most beet-root establishments, there are some manufacturers who continue to evaporate in open vessels.

The large amount of water which has to be removed in the concentration of beet-root syrups involves the use of so much fuel that to economise it an ingenious apparatus has been constructed by M. Cail of Paris. The principle adopted is to use the steam generated from the ebullition of liquid in one vessel for boiling another, the steam from which in like manner boils a third.

Maple Sugar.—The manufacture of sugar from the juice of a species of maple trees, which grow spontaneously in many of the uncultivated parts of North America, appears to have been first attempted about 1752, by some of the farmers of New England, as a branch of rural economy.

The sugar maple, the *Acer saccharinum* of Linnæus, thrives especially in the states of New York and Pennsylvania, and yields a larger proportion of sugar than that which grows upon the Ohio. It is found sometimes in thickets which cover five or six acres of land; but it is more usually interspersed among other trees. They are supposed to arrive at perfection in 40 years.

The extraction of maple sugar is a great resource to the inhabitants of districts far removed from the sea, and the process is very simple. After selecting a spot among surrounding maple trees, a shed is erected, called the *sugar-camp*, to protect the boilers and the operators from the vicissitudes of the weather. One or more augers, three-fourths of an inch in diameter; small troughs for receiving the sap; tubes of elder or sumach, 8 or 10 inches long, laid open through two-thirds of their length, and corresponding in size to the auger-bits; pails for emptying the troughs, and carrying the sap to the camp; boilers capable of boiling 15 or 16 gallons; moulds for receiving the syrup inspissated to the proper consistence for concreting into a loaf of sugar; and, lastly, hatchets to cut and cleave the fuel, are the principal utensils requisite for this manufacture. The whole of February and beginning of March are the sugar season.

The trees are bored obliquely from below upwards, at 18 or 20 inches above the ground, with two holes 4 or 5 inches asunder. Care must be taken that the auger penetrates no more than half an inch into the alburnum, or white bark; as experience has proved that a greater discharge of sap takes place at this depth than at any other. It is also advisable to perforate in the south face of the trunk.

The trough, which contains 2 to 3 gallons, and is made commonly of white pine, is set on the ground at the foot of each tree, to receive the sap which flows through the two tubes inserted into the holes made with the auger; it is collected together daily, and carried to the camp, where it is poured into casks, out of which the boilers are supplied. In every case it ought to be boiled within the course of two or three days from flowing out of the tree, as it is liable to run quickly into fermentation, if the weather become mild. The evaporation is urged by an active fire, with careful skimming during the boiling; and the pot is continually replenished with more sap, till a large body has assumed a syrupy consistence. It is then allowed to cool, and passed through a woollen cloth, to free it from impurities.

The syrup is transferred into a boiler to three-fourths of its capacity, and it is urged with a brisk fire, till it acquires the requisite consistence for being poured into the moulds or troughs prepared to receive it. This point is ascertained, as usual, by its exhibiting a granular aspect, when a few drops are drawn out into a thread between the finger and thumb. If in the course of the last boiling, the liquor froth up considerably, a small bit of butter or fat is thrown into it. After the molasses has been drained from the concreted loaves, the sugar is not at all deliquescent, like equally brown sugar from the cane. Maple sugar is in taste equally agreeable with cane sugar, and it sweetens as well. When refined it is equally fair with the loaf sugar of Europe.

The period during which the trees discharge their juices is limited to about six weeks. Towards the end of the flow, it is less abundant, less saccharine, and more difficult to be crystallised.

In spring, when plentiful, maple sugar sells as low as 3*d* per lb.; in winter it sometimes rises as high as 6*d*.

The total production of maple sugar has been estimated at 45 millions of pounds, or the one hundred and twenty-fifth part of the whole quantity of cane sugar extracted for the use of man. The manufacture of maple sugar diminishes yearly in proportion as the native American forests are cut down.

Potato Sugar.—The manufacture of sugar from starch derived from potatoes, from woody matter, and from rags, can be effected by treating them with sulphuric acid and heat; but the process, interesting though it is, is rarely if ever adopted at present, as the sugar is inferior in quality to that obtained from the cane, and dearer in price.

The process for making sugar from potato starch is to mix 100 gallons of boiling water with every 112 lbs. of the fecula, and 2 lbs. of the strongest sulphuric acid. This mixture is boiled about 12 hours in a large vat, made of white deal, having lead pipes laid along its bottom, which are connected with a high-pressure steam boiler. After being thus saccharified, the acid liquid is neutralised with chalk, filtered, and then evaporated to the density of about 1·300, at the boiling temperature, or exactly 1·342, when cooled to 60°. When syrup of this density is left in repose for some days, it concretes altogether into crystalline tufts, and forms an apparently dry solid of specific gravity 1·39. When this is exposed to the heat of 220° it fuses into a liquid nearly as thin as water; on cooling to 150° it takes the consistence of honey, and at 100° Fahr. it has that of viscid varnish. It must be left a considerable time at rest before it recovers its pristine state. When heated to 270° it boils briskly, gives off one-tenth of its weight of water, and concretes on cooling into a bright yellow, brittle, but deliquescent mass, like barley sugar. If the syrup be concentrated to a much greater density than 1·340, as to 1·362, or if it be left faintly acidulous, in either case it will not granulate, but will remain either a viscid magma, or become a concrete mass, which may indeed be pulverised, though it is so deliquescent as to be unfit for sale as sugar.

The following table exhibits several good analyses of the potato:—

Sort.	Fibrine.	Starch.	Veg. album.	Gum.	Acids and salts.	Water.	Analyst.
Red potatoes - -	7·0	15·0	1·4	4·1	5·1	75·0	Einhof.

Good muscovado sugar from Jamaica fuses only when heated to 280°, it turns immediately dark brown, and becomes, in fact, the substance called *caramel* by the French, which is used for colouring brandies, white wines, and liqueurs. Thus starch or grape sugar is well distinguished from cane sugar, by its fusibility at a moderate heat, and its unalterability at a pretty high heat. Its sweetening power is only two-fifths of that of ordinary sugar. A good criterion of incompletely formed grape sugar is its resisting the action of sulphuric acid, while perfectly saccharified starch or cane sugar is readily decomposed by it. If to a strong solution of imperfectly saccharified grape sugar, nearly boiling hot, one drop of sulphuric acid be let fall, no perceptible change will ensue; but if the acid be dropped into solutions of either of the other two sugars, black carbonaceous particles will make their appearance.

The specific gravity of cane and beet root is 1·577, not 1·6065 as given by Berzelius and others; that of starch sugar, in crystalline tufts, is 1·39, or perhaps 1·40, as it varies a little with its state of dryness. At 1·342 syrup of the cane contains seventy per cent. of sugar; at the same density syrup of starch sugar contains seventy-five and a half per cent. of concrete matter, dried at 260° (Fahr.), and, therefore, freed from the ten per cent. of water, which it contains in the granular state. Thus, another distinction is obtained between the two sugars in the relative densities of their solutions, at like saccharine contents, per cent.

Animal charcoal. One of the most important considerations for a sugar refiner is to furnish himself amply with bone charcoal of the best quality, and to devote unsparing attention to the process of revivification. The theory of the action of bone charcoal upon solutions of raw sugar and other coloured liquids need not be discussed here. It may, however, be observed, that but little is known upon the subject, and that the behaviour of bone charcoal with respect to metallic oxides and various salts is as remarkable as its action upon colouring matter.

After the *raw liquor* has been passed continuously through a filter of bone charcoal, the decolouring power of the charcoal becomes impaired, and finally lost. This power may be more or less restored by the following means:—

First. Washing with water.
Second. Fermentation.
Third. Washing with weak hydrochloric acid.
Fourth. Long exposure to air and moisture.
Fifth. Heating to redness.

The last plan being the only one which does not materially injure the charcoal, and most completely restores its power, is the course almost invariably adopted; it is however preceded by washing with water.

Various forms of apparatus for reburning charcoal have been proposed and adopted, but the four following methods are the chief at present used.

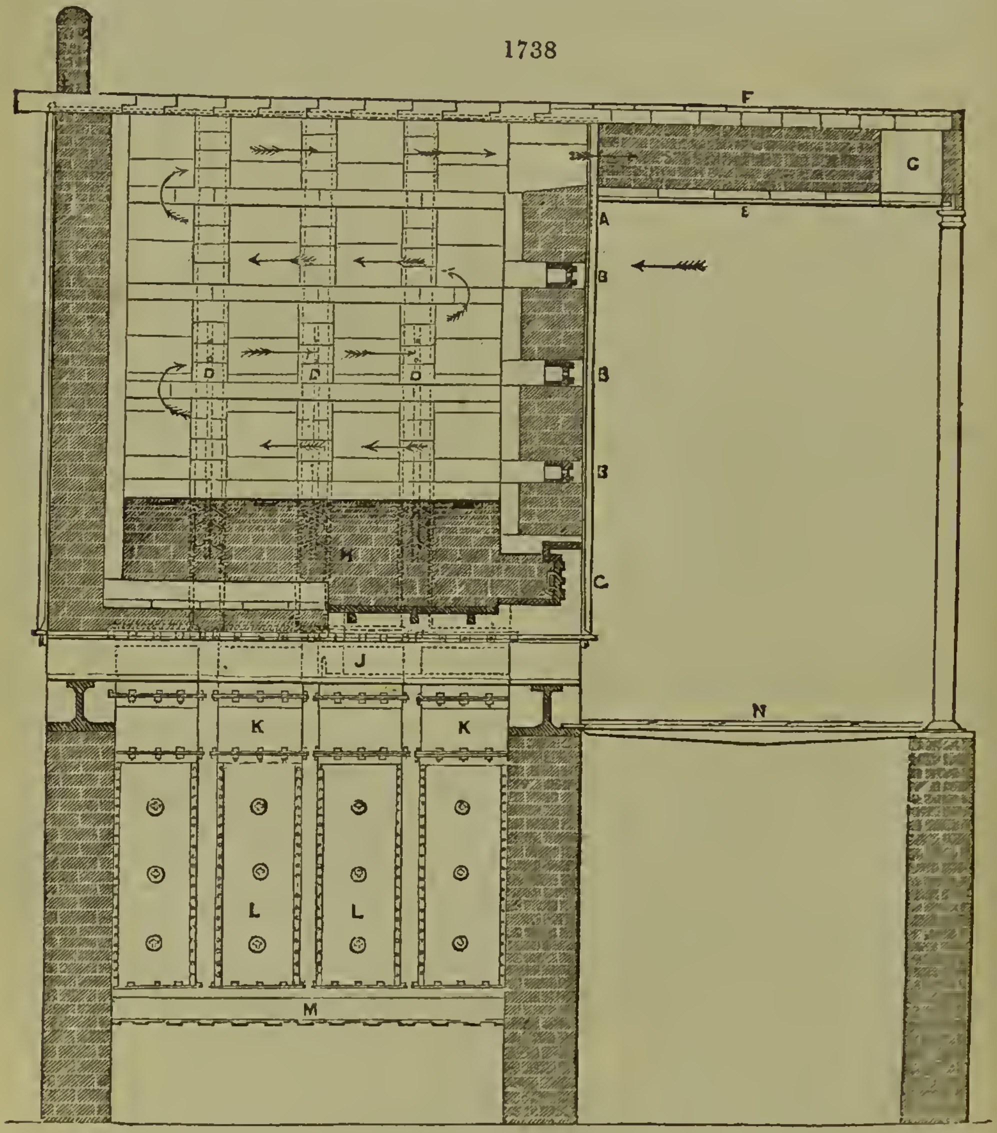
First. Burning in iron pipes.

A furnace about six feet in length, and eighteen inches wide is placed between two rectangular chambers with which it communicates; each chamber contains thirty-two cast-iron pipes of four inches diameter and nine feet in length, whose extremities pass through the top and bottom of each chamber; to the lower end of each pipe, a sheet iron cooler is suspended. When the charcoal kiln is in use, the pipes filled with charcoal are maintained at a dull red heat, and the charcoal is withdrawn from the coolers in measured quantities at such intervals of time as to allow it to be four hours under the action of the heat. The *advantages* of this plan are, cheapness of first cost and simplicity; its disadvantages are first, that the charcoal is unequally burnt, the pipes near the furnace being more heated than those further removed from it; second, the kilns require frequent repairs, some of the pipes being destroyed by the fire; third, the amount of fuel required is large; fourth, the pipes are apt to become choked.

Second. Burning in fire-clay chambers.

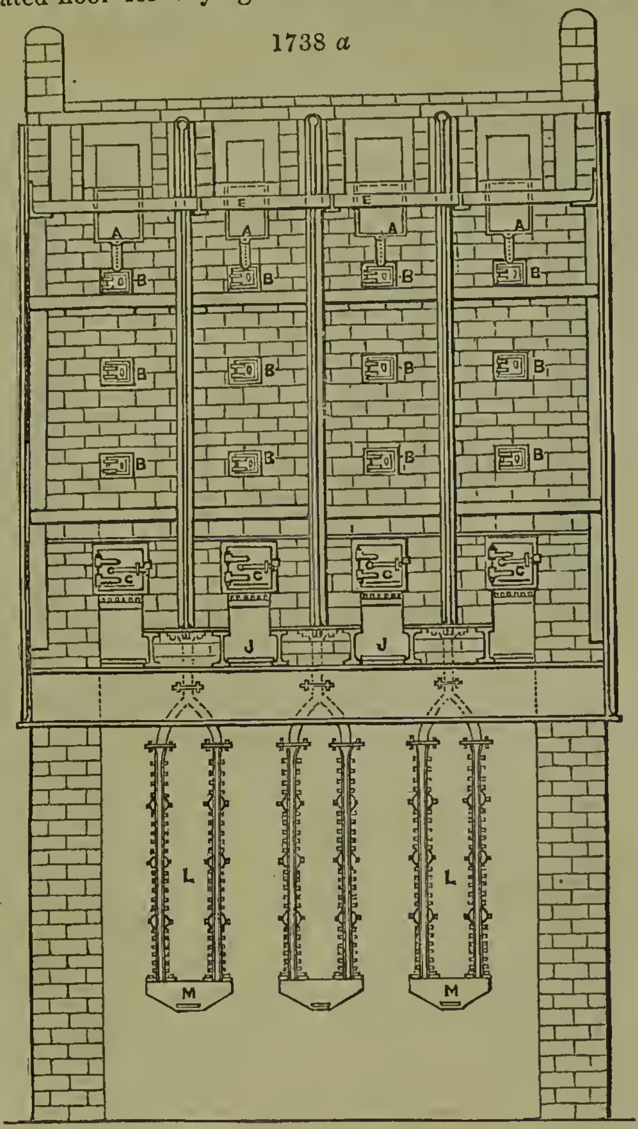
This plan, proposed by Mr. Parker, of London, and improved by Mr. G. F. Chantrell, of Liverpool, is becoming generally adopted. The plan consists in arranging narrow chambers, composed of fire-tiles, and containing charcoal, between small fur-

1738



naces. *Fig.* 1738 shows a section of Mr. Chantrell's kiln through one of the fire places; *figs.* 1738 *a*, 1738 *b*, two front views of the same. C, is the fire door; H, the furnace; the products of combustion issue through apertures in the arched roof of the furnace, and are compelled to take a zigzag course to the flue G, by means of horizontal floors of tiles, each floor being open at alternate ends. B, B, are apertures for cleaning the flues or inspecting the state of the kiln; L, L, the coolers; M, the measuring box or receiver; F, a heated floor for drying the charcoal previous to being reburned; N,

1738 *a*



the firing floor. The advantages of this system are, first, the charcoal is very equally burnt; second, the amount of fuel required is small, not reaching ten per cent. of the charcoal reburned ; third, non-liability to get out of order; the chief disadvantage is the amount of first cost.

Third. Reburning in rotating cylinders.

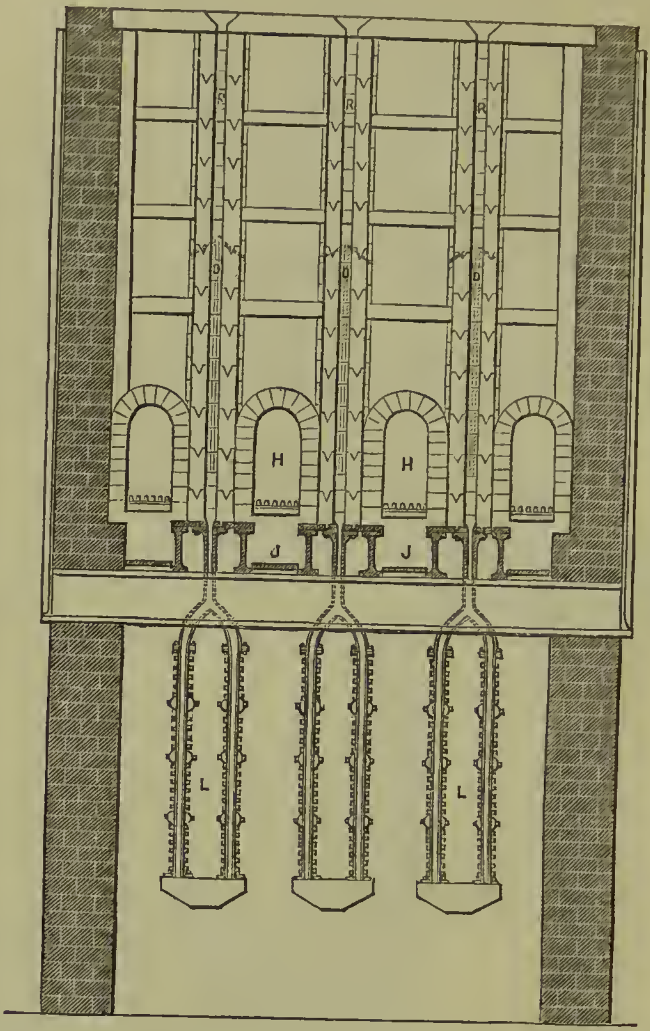
This plan like the former, the subject of a patent, is used at the extensive establishment of Mr. G. Torr, London, the regularity and the excellence of the result being considered by him a sufficient compensation for the costliness of the process.

Fourth. Reburning by means of superheated steam.

This ingenious method, were it not for the expense of the apparatus, and practical difficulties, would supersede the previous methods. The apparatus, is the invention of MM. Laurens and Thomas of Paris. A furnace is constructed, in the flues of which a number of cast-iron tubes connected together and ranged in order, are placed; the products of combustion, after maintaining the pipes at a high temperature, impart heat likewise to the vase-shaped vessel before entering the chimney. A jet of steam being passed through the pipes becomes sufficiently superheated to expel the moisture from the charcoal contained in the receiver, and subsequently to raise it to a temperature of 600° F. This is sufficient to effect destructive distillation of the colouring matter absorbed by the charcoal. The process takes about eight hours; the advantages of this method consist in the steam coming in absolute contact with every single grain of charcoal; the distillates are effectually removed, and there is little or no risk of the charcoal being subjected to too high a temperature; but the plan is expensive and inconvenient; and has not been adopted in England.

To reburn charcoal the best methods are those which most rapidly remove the water, raise the temperature of each grain of charcoal to a uniform temperature of 700° Fahr., and which admit of its being readily cooled without contact with the air.

1738 *b*



The influences of time and temperature, in the reburning process, are very marked; in the best regulated refineries the decolouring power of the charcoal is frequently examined and recorded, and an analysis of the charcoal is made each month.

The following table contains the average results of many analyses made by Dr. Wallace of Glasgow, of several kinds of raw sugar as imported into Greenock and Glasgow, and of the different products of a Greenock sugar house.

	West India.	Beet.	Date.	Lumps.	Pieces.	Bastards.	Green Syrup.	Golden Syrup.	Molasses.	Treacle.

A. F.

SUGAR OF LEAD, properly *Acetate of Lead* (*Acetate de plomb: Sel de Saturne*, Fr.; *Essigsaures Bleioxyd, Bleizucker*, Germ.), is prepared by dissolving pure litharge, with heat, in strong vinegar, made of malt, wood, or wine, till the aeid be saturated. A copper boiler, rendered negatively eleetrical by soldering a strap of lead within it, is the best adapted to this proeess on the great scale. 325 parts of finely ground and sifted oxide of lead require 575 parts of strong acetic aeid, of spec. grav. 7° Baumé, for neutralisation, and afford 960 parts of crystallised sugar of lead. The oxide should be gradually sprinkled into the moderately hot vinegar, with constant stirring, to prevent adhesion to the bottom; and when the proper quantity is dissolved, the solution may be weakened with some of the washings of a preceding process, to dilute the acetate, after which the whole should be heated to the boiling point, and allowed to cool slowly in order to settle. The limpid solution is to be drawn off by a siphon, eoncentrated by boiling to the density of 32° B., taking eare that there be always a faint excess of acid, to prevent the possibility of any basic salt being formed, whieh would interfere with the formation of regular crystals. Should the concentrated liquor be coloured, it may be whitened by filtration through granular bone black.

Stoneware vessels, with salt glaze, answer best for erystallisers. Their edges should be smeared with candle-grease, to prevent the salt creeping over them by *efflorescent vegetation.* The erystals are to be drained, and dried in a stove-room very slightly heated. It deserves remark, that linen, mats, wood, and paper, imbued with sugar of lead, and strongly dried, readily take fire, and burn away like tinder. When the mother waters cease to afford good crystals, they should be decomposed by carbonate of soda, or by lime skilfully applied, when a carbonate or an oxide will be obtained, fit for treating with fresh vinegar. The supernatant acetate of soda may be employed for the extraction of pure acetic acid.

A main point in the preparation of sugar of lead is to use a strong acid; otherwise much time and acid are wasted in concentrating the solution. This salt crystallises in colourless, transparent, four and six-sided prisms, from a moderately concentrated solution; but from a stronger solution, in small needles, which have a yellow cast if the acid has been slightly impure. It has no smell, a sweetish astringent metallic taste, a specific gravity of 2·345; it effloresces slightly in a dry atmosphere, and when heated above 212° F. it froths up and loses all its water of crystallisation, together with some acetic acid, falling into a powder which passes slowly in the air into carbonate of lead. If heated to 536° F. it is entirely liquid, and at a higher temperature is decomposed, disengaging acetic and carbonic acids, and some acetone; the residue consisting of very finely divided and very combustible metallic lead. The crystals of acetate of lead dissolve in $1\frac{1}{2}$ times their weight of water at 60° F., but in much less of boiling water, and in 8 parts of alcohol. The solution feebly reddens litmus paper, although it imparts a green colour to syrup of violets. The constituents of the salt are, 58·71 oxide of lead, 27·08 acetic acid, and 14·21 water, in 100, or $PbO, C^4H^3O^3 + 3HO$.

Acetate of lead is much used in calico-printing. It is poisonous, and ought to be prepared and handled with attention to this circumstance.

Four subacetates of lead are generally acknowledged to exist, viz.:—

	Oxide of lead.	Acetic acid.
Sesquibasic ditto	$1\frac{1}{2}$	1
Bibasic acetate	2	1
Tribasic ditto	3	1
Hexbasic ditto	6	1

Sesquibasic acetate. $3PbO, 2C^4H^3O^3 + Aq$. This is obtained by heating the neutral acetate in a capsule till the fused mass becomes white and porous; this is then dissolved in water and evaporated, when on cooling pearly lamina separate; they are soluble in water and alcohol, and the solution possesses an alkaline reaction.

Dibasic acetate. This salt, when in solution, is known as *Goulard's extract*, and is formed by boiling together a solution of the neutral acetate and an equivalent quantity of pure litharge (oxide of lead). In the solid state it is crystalline, and consists of $2PbO, C^4H^3O^3 + Aq$.

Tribasic acetate. $3PbO, C^4H^3O^3 + Aq$. This salt is the most stable of the subsalts. It is obtained in the crystalline state, by leaving to itself a cold saturated solution of the neutral acetate, to which one-fifth of its volume of caustic ammonia has been added. It may also be made by digesting 7 parts of pure litharge with a solution containing 6 parts of the crystallised neutral acetate. It forms long silky needles, which are very soluble in water, but insoluble in alcohol. Carbonic acid transmitted through the solution precipitates the excess of oxide of lead, in the state of carbonate; a process long since described by Thénard, for making white lead.

Hexbasic acetate. $6PbO, C^4H^3O^3 + Aq$. This subsalt is obtained by boiling any of the other acetates with an excess of litharge. It is a precipitate, which, when examined by the microscope, presents a crystalline aspect. It is slightly soluble in boiling water, from which, in cooling, white silky needles are deposited. This salt is frequently found in commercial white lead. The solutions of subacetates are rapidly decomposed by the carbonic acid of the atmosphere.

SULPHATE OF ALUMINA AND POTASSA is alum. See Alum.

SULPHATE OF BARYTA is the mineral called Heavy-Spar. See Baryta, Sulphate.

SULPHATE OF COPPER, *Roman or Blue Vitriol* (*Vitriol de Chypre*, Fr.; *Kupfervitriol*, Germ.), is a salt composed of sulphuric acid and oxide of copper, and may be formed by boiling the concentrated acid upon the metal, in an iron pot. It is, however, a natural product of many copper mines, from which it flows out in the form of a blue water, being the result of the infiltration of water over copper pyrites, which has become oxygenated by long exposure to the air in subterranean excavations. The liquid is concentrated by heat in copper vessels, then set aside to crystallise. The salt forms in oblique four-sided tables, of a fine blue colour; has a spec. gravity of 2·104; an acerb, disagreeable, metallic taste; and, when swallowed, it causes violent vomiting. It becomes of a pale dirty blue, and effloresces slightly, on long exposure to the air; when moderately heated, it loses 36 per cent. of water, and falls into a whitish powder. It dissolves in 4 parts of water at 60°, and in 2 of boiling water, but not in alcohol; the solution has an acid reaction upon litmus paper. When strongly ignited, the acid flies off, and the black oxide of copper remains. The constituents of crystallised sulphate of copper are—oxide, 31·80; acid, 32·14; and water, 36·06. Its chief employment in this country is in dyeing, and for preparing certain green pigments. See SCHEELE'S and SCHWEINFURTH GREEN. In France, as well as in England, the farmers sprinkle a weak solution of it upon their grains and seeds before sowing them, to prevent their being attacked by birds and insects. See COPPER.

SULPHATE OF IRON, *Green vitriol, Copperas* (*Couperose verte*, Fr.; *Eisen-vitriol, Schwefelsaures Eisenouxydl*, Germ.), is a crystalline compound of sulphuric acid and protoxide of iron; hence called, by chemists, the protosulphate; consisting of 26·10 of base, 29·90 of acid, and 44·00 of water in 100 parts; or of 1 prime equivalent of protoxide, 36, + 1 of acid, 40, + 7 of water, 63, = 139. It may be prepared by dissolving iron to saturation in dilute sulphuric acid, evaporating the solution till a pellicle forms upon its surface, and setting it aside to crystallise. The copperas of commerce is made in a much cheaper way, by stratifying the pyrites found in the coal measures (*Vitriolkies* and *Strahlkies* of the Germans), upon a sloping puddled platform of stone, leaving the sulphide exposed to the weather, till, by the absorption of oxygen, it effloresces, lixiviating with water the supersulphate of iron thus formed, saturating the excess of acid with plates of old iron, then evaporating and crystallising. The other pyrites, which occurs often crystallised, called by the Germans *Schwefelkies* or *Eisenkies*, must be deprived of a part of its sulphur by calcination before it acquires the property of absorbing oxygen from the atmosphere, and thereby passing from a bisulphide into a bisulphate. Alum schist very commonly contains vitriolkies, and affords, after being roasted and weather-worn, a considerable quantity of copperas, which must be carefully separated by crystallisation from the alum.

This liquor used formerly to be concentrated directly in leaden vessels; but the first stage of the operation is now carried on in stone canals of considerable length, vaulted over with bricks, into which the liquor is admitted, and subjected at the surface to the action of flame and heated air, from a furnace of the reverberatory kind, constructed at one end, and discharging its smoke by a high chimney raised at the other. See SODA MANUFACTURE. Into this oblong trough, resting on dense clay, and rendered tight in the joints by water-cement, old iron is mixed with the liquor, to neutralise the excess of acid generated from the pyrites, as also to correct the tendency to superoxidisement in copperas, which would injure the fine green colour of the crystals. After due concentration and saturation in this surface evaporator, the solution is run off into leaden boilers, where it is brought to the proper density for affording regular crystals, which it does by slow cooling, in stone cisterns.

Copperas forms sea-green, transparent, rhomboidal prisms, which are without smell, but have an astringent, acerb, inky taste; they speedily become yellowish-brown in the air, by peroxidisement of the iron, and effloresce in a warm atmosphere; they dissolve in 1·43 parts of water at 60°, in 0·27 at 190°, and in their own water of crystallisation at a higher heat. This salt is extensively used in dyeing black, especially hats, in making ink, and prussian blue, for reducing indigo in the blue vat, in the China blue dye, for making the German oil of vitriol, and in many chemical and medicinal preparations.

There is a persulphate and a subpersulphate of iron, but they belong to the domain of chemistry. The first may be formed, either by dissolving with heat one part of red oxide of iron (colcothar) in one and a half of concentrated sulphuric acid, or by adding some nitric acid to a boiling-hot solution of copperas, to which half as much sulphuric acid has been added as it already contained. It forms with galls and log-wood a very black ink, which is apt to become brown-black. When evaporated to dryness, it appears as a dirty white pulverulent substance, which is soluble in alcohol. It consists, in 100 parts, of 39·42 of red oxide of iron, and 60·58 sulphuric acid.

SULPHATE OF LIME. See GYPSUM.

SULPHATE OF MAGNESIA, *Epsom Salts* (*Sel amer*, Fr.; *Bittersalz*, Germ.). See MAGNESIA, SULPHATE.

SULPHATE OF MANGANESE is prepared on the great scale for the calico-printers, by exposing the peroxide of the metal and pitcoal ground together, and made into a paste with sulphuric acid, to a heat of 400° F. On lixiviating the calcined mass, a solution of the salt is obtained, which is to be evaporated and crystallised. It forms pale amethyst-coloured prisms, which have an astringent bitter taste, dissolve in 2½ parts of water, and consist of, protoxide of manganese, 31·93; sulphuric acid, 35·87; and water, 32·20, in 100 parts.

SULPHATE OF MERCURY. See MERCURY.

SULPHATE OF POTASH. See POTASH.

SULPHATE OF SODA is commonly called Glauber's salt, from the name of the chemist who first prepared it. See SODA.

SULPHATE OF ZINC, called also *White Vitriol*, is commonly prepared in the Harz, by washing the calcined and effloresced sulphide of zinc or blende, on the same principle as green and blue vitriol are obtained from the sulphides of iron and copper. Pure sulphate of zinc may be made most readily by dissolving zinc in dilute sulphuric acid, evaporating and crystallising the solution. It forms prismatic crystals, which have an astringent, disagreeable, metallic taste; they effloresce in a dry air, dissolve in 2·3 parts of water at 60°, and consist of—oxide of zinc, 28·29; acid, 28·18; water, 43·53. Sulphate of zinc is used for preparing drying oils for varnishes, and in the reserve or resist pastes of the calico-printer. See Zinc.

SULPHATES are saline compounds of sulphuric acid with oxidised bases. The minutest quantity of them present in any solution may be detected by the precipitate, insoluble in nitric or muriatic acid, which they afford with nitrate or chloride of barium. They are mostly insoluble in alcohol.

SULPHIDE OF CARBON. See Carbon, Bisulphide.

SULPHITES are a class of salts, consisting of sulphurous acid, combined in equivalent proportions with the oxidised bases.

SULPHOSELS is the name given by Berzelius to a class of salts which are now called sulphides.—H. K. B.

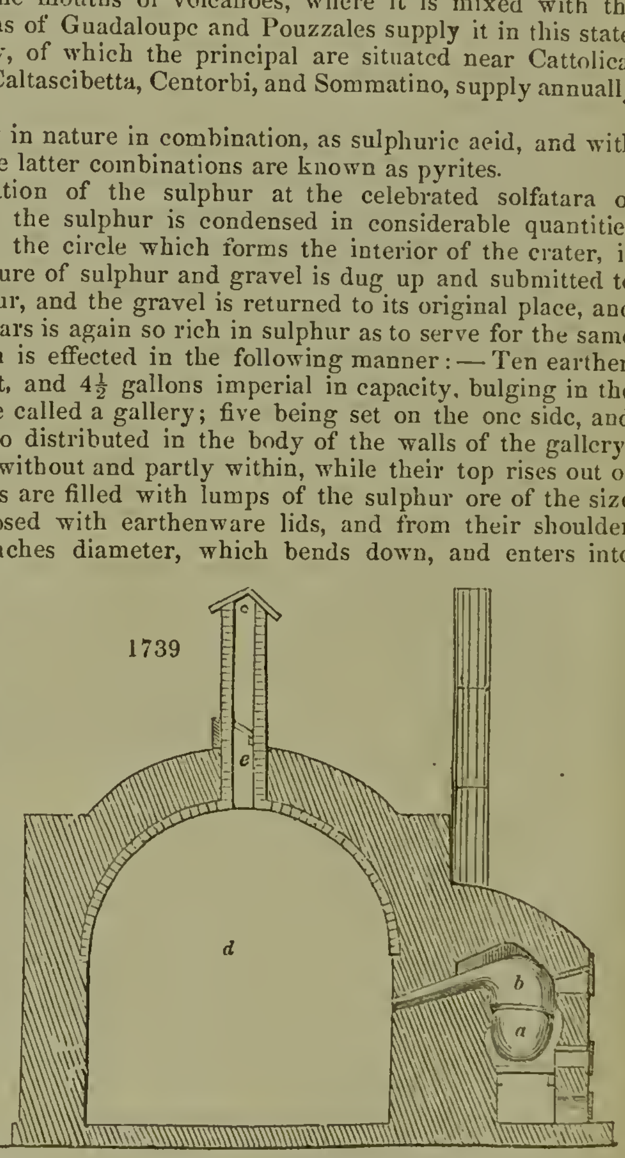
SULPHUR, *Brimstone* (*Saufre*, Fr.; *Schwefel*, Germ.), is an elementary substance of great importance. It is abundantly distributed in nature, either in the free state or in combination with other elements. In the free state it is found in three different forms; 1st, as kidney-shaped lumps disseminated through layers of tertiary and contemporaneous formations; 2nd, in irregular masses in chalky formations, associated with gypsum and rock salt. It is under these circumstances that it is principally found in the mines of Sicily, which supply nearly all the sulphur of commerce in Europe. 3rd, as sublimations around the mouths of volcanoes, where it is mixed with the ashes or gravel. The solfataras of Guadaloupe and Pouzzales supply it in this state.

The sulphur mines of Sicily, of which the principal are situated near Cattolica, Girgenti, Licata, Caltanisetta, Caltascibetta, Centorbi, and Sommatino, supply annually immense quantities of sulphur.

Sulphur is also found largely in nature in combination, as sulphuric acid, and with metals forming sulphides; these latter combinations are known as pyrites.

The process for the separation of the sulphur at the celebrated solfatara of Pouzzales, near Naples, where the sulphur is condensed in considerable quantities amongst the gravel collected in the circle which forms the interior of the crater, is conducted as follows; the mixture of sulphur and gravel is dug up and submitted to distillation to extract the sulphur, and the gravel is returned to its original place, and in the course of about thirty years is again so rich in sulphur as to serve for the same process again. The distillation is effected in the following manner: — Ten earthen pots, of about a yard in height, and 4½ gallons imperial in capacity, bulging in the middle, are ranged in a furnace called a gallery; five being set on the one side, and five on the other. These are so distributed in the body of the walls of the gallery, that their belly projects partly without and partly within, while their top rises out of the vault of the roof. The pots are filled with lumps of the sulphur ore of the size of the fist; their tops are closed with earthenware lids, and from their shoulder proceeds a pipe of about 2 inches diameter, which bends down, and enters into another covered pot, with a hole in its bottom, standing over a tub filled with water. On applying heat to the gallery, the sulphur melts, volatilises, and runs down in a liquid state into the tubs, where it congeals. When one operation is finished, the pots are re-charged, and the process is repeated.

1739



The sulphur thus obtained is still more or less impure, and in this state can only be used in the manufacture of sulphuric acid; it is therefore subjected to another process of purification, which will now be described: —

Fig. 1739 represents one of the cast-iron retorts used at Marseilles for refining sulphur, wherein it is melted and converted into vapours, which are led into a large chamber for condensation. The body, *a*, of the retort is an iron pot

3 feet in diameter outside, 22 inches deep, half an inch thick, which weighs 14 cwt., and receives a charge of 8 cwt. of crude sulphur. The grate is 8 inches under its bottom, whence the flame rises and plays round its sides. A cast iron capital, *b*, being luted to the top, and covered with sand, the opening in front is shut with an iron plate. The chamber, *d*, is 23 feet long, 11 feet wide, and 13 feet high, with walls 32 inches thick. In the roof, at each gable, valves or flap-doors, *e*, 10 inches square, are placed at the bottom of the chimney, *c*. The cords for opening the valves are led down to the side of the furnace. The entrance to the chamber is shut with an iron door. In the wall opposite to the retorts, there are two apertures near the floor, for taking out the sulphur. Each of the two retorts belonging to a chamber is charged with 7½ or 8 cwts. of sulphur; but one is fired first, and with a gentle heat, lest the brimstone froth should overflow; but when the fumes begin to rise copiously, with a stronger flame. The distillation commences within an hour of kindling the fire, and is completed in six hours. Three hours after putting fire to the first retort, the second is in like manner set in operation.

When the process of distillation is resumed, after having been some time suspended, explosions may be apprehended, from the presence of atmospheric air; to obviate the danger of which, the flap-doors must be opened every 10 minutes; but they should remain closed during the setting of the retorts, and the reflux of sulphurous fumes or acid should be carried off by a draught-hood over the retorts. The distillation is carried on without interruption during the week, the charges being repeated four times in the day. By the third day, the chamber acquires such a degree of heat as to preserve the sulphur in a liquid state; on the sixth, its temperature becoming nearly 300° F., gives the sulphur a dark hue, on which account the furnace is allowed to cool on the Sunday. The fittest distilling temperature is about 248°. The sulphur is drawn off through two iron pipes cast in the iron doors of the orifices on the side of the chamber opposite to the furnace. The iron stoppers being taken out of the mouths of the pipes, the sulphur is allowed to run along an iron spout placed over red-hot charcoal, into the appropriate wooden moulds.

In some places sulphur is obtained from the metallic sulphides (of iron and copper) which contain a large excess of sulphur.

In Saxony and Bohemia, the sulphides of iron and copper are introduced into large earthenware pipes, which traverse a furnace-gallery; and the sulphur exhaled flows into pipes filled with cold water on the outside of the furnace, 900 parts of sulphide afford from 100 to 150 parts of sulphur, and a residuum of protosulphide.

Pyrites as a bi-sulphide, consisting of 45·5 parts of iron, and 54·5 of sulphur, may, by proper chemical means, be made to give off one half of its sulphur, or about 27 per cent.; but great care must be taken not to generate sulphurous acid, as is done very wastefully by the Fahlun and the Goslar processes. By the latter, indeed, not more than 1 or 2 parts of sulphur are obtained, by roasting 100 parts of the pyritous ores of the Rammelsberg mines. In these cases, the sulphur is burned, instead of being sublimed. The residuum of the operation, when it is well conducted, is black sulphide of iron, which may be profitably employed for making copperas. The apparatus for extracting sulphur from pyrites should admit no more air than is barely necessary to promote the sublimation.

The great disadvantage in the sulphur prepared from pyrites is, that some of the pyrites contain a large quantity of arsenic, and the sulphur thus obtained from them generally contains sulphide of arsenic, hence the sulphuric acid made from it would contain arsenic, and thus be unfitted for many purposes of the arts; though a tolerably good sulphuric acid may be made directly from the combustion of pyrites, instead of sulphur, in the lead chambers.

The present high price of the Sicilian sulphur is a great encouragement to its extraction from pyrites. It is said that the common English brimstone, such as was extracted from the copper pyrites of the Parys mine in Anglesey, contained fully a fifteenth of residuum, insoluble in boiling oil of turpentine, which was chiefly orpiment; while the fine Sicilian sulphur, now imported in vast quantities by the manufacturers of oil of vitriol, contains not more than 3 per cent. of foreign matter, chiefly earthy, but not at all arsenical.

Sulphur occurs in commerce in two different forms, viz. solid, or in powder; the former is generally in sticks, and is called *lump*, *roll*, or *stick* sulphur; and the latter as *sublimed* or *flowers of sulphur;* and also the kind principally used in medicine, as *precipitated sulphur* or *milk of sulphur.* These different forms are caused by the different modes of preparation; if the sulphur be sublimed into large chambers, which are kept cool during the operation, the product will appear as a powder (*sublimed*, or *flowers of sulphur*); but if the chamber be allowed to get hot, the sulphur melts, and is run off into moulds, and forms the lump sulphur. The washing of the sublimed sulphur is to remove any sulphurous or sulphuric acid, which it generally contains when taken from the chamber. The *precipitated sulphur* is formed by boiling ordinary sulphur with lime and water, the sulphur enters into combination with the lime forming a sulphide of calcium and hyposulphite of lime, which dissolve in the water; to the filtered liquid hydrochloric acid is added, which unites with the lime and precipitates the sulphur. The sulphur thus precipitated is of a pale yellow colour, and when first precipitated will pass through a filter with the water, just as if it were in solution, from the fact of its being so finely divided. Some manufacturers use sulphuric acid instead of hydrochloric acid in this process, and therefore the milk of sulphur found in the shops is generally largely contaminated with sulphate of lime, feels gritty between the teeth, and sparkles when looked at in one direction.

Ordinary sulphur may be crystalline or amorphous; it is capable of crystallising in two different forms, and is hence said to be dimorphous. In acute rhombic octohedrons, belonging to the right prismatic system, which is the principal form assumed by native sulphur, and may be obtained artificially by the spontaneous evaporation of a solution of sulphur in bisulphide of carbon; the second form is that of acute rhombic prisms, belonging to the oblique prismatic system, which is obtained by fusing sulphur in a crucible, and, when partly cooled, breaking the crust which is formed on the top, and pouring out the part which still remains liquid, when the part which has become solid will remain in long crystals. These crystals differ not only in shape, but also in specific gravity; the octohedral crystals having a specific gravity of 2·045, and the prisms a specific gravity of 1·982. The red tint, so common in the crystals of Sicily, and of volcanic districts, has been ascribed by some mineralogists to the presence of realgar, and by others to iron; but Stromeyer has found the sublimed orange-red sulphur of Vulcano, one of the Lipari islands, to result from a natural combination of sulphur and selenium.

Sulphur also presents another peculiarity. At all ordinary temperatures it is solid, but it melts at 232° Fahr., and at this temperature it is as fluid as water; if the heat be now gradually raised, it will become thicker and thicker until between 430 and 480° Fahr. it is so tenacious that the vessel containing it may be inverted for a moment without losing any of its contents; if while in this state it is cooled suddenly, as by pouring it into cold water, it will remain for many hours perfectly soft and flexible, and may be drawn out into threads; it now presents none of the appearances of sulphur, and is called *amorphous sulphur*. After some time, however, it regains its former properties, becoming brittle and crystalline, and may be restored still more rapidly to its original state by melting and slow cooling. If the temperature be still raised above 480° Fahr., the sulphur between this and the boiling point 792° Fahr., becomes again perfectly liquid. When heated in contact with the air, sulphur ignites and burns with a pale blue flame, generating sulphurous acid gas, which is employed to bleach woollen and silken goods; to disinfect vitiated air, though for this purpose it is greatly inferior to chlorine; to kill mites, moths, and other destructive insects in collections of zoology; and to counteract too rapid fermentation in wine vats, &c.

As the same acid gas has the property of suddenly extinguishing flame, sulphur has been thrown into a chimney on fire, with the best effect; a handful of it being sometimes sufficient.

Sulphur has a slight odour, and scarcely any taste. It is a very bad conductor of heat, and a lump of sulphur, even by the heat of the hand, will produce a crackling sound and often break in pieces. It is a bad conductor of electricity, and by friction becomes strongly charged with electricity, which is of the negative kind. Sulphur is insoluble in water and alcohol; but is dissolved by oil of turpentine and the fatty oils, the best solvent of it, however, is bisulphide of carbon. In its chemical relations it is allied to oxygen, &c. It has been known from the most remote ages, and from its kindling at a moderate temperature is employed for readily procuring fire, and lighting by its flame other bodies less combustible. At Paris, the preparation of sulphur matches was once a considerable branch of industry, but they are now principally displaced by the matches which ignite by friction.

Sulphur is also employed for cementing iron bars into stones; for taking impressions from seals and cameos, for which purpose it is kept previously melted for some time to give the casts an appearance of bronze. Its principal uses, however, are for the manufactures of vermilion or cinnabar, gunpowder, and sulphuric acid.

There is another form in which sulphur is sometimes known, and this is what is termed *horse brimstone*, or *black sulphur*. It is the dregs of the subliming pot after the purification of sulphur, and often contains large quantities of arsenic.

The purity of sulphur may be known by its being completely volatilisable, and by being soluble in bisulphide of carbon; any earthy impurities would in either case remain behind. The presence of arsenic may be known by digestion in ammonia, when the sulphide of arsenic would be dissolved, and may be again precipitated as a yellow powder, by the addition of an acid. — H. K. B.

SULPHURATION, is the process by which woollen, silk, and cotton goods are exposed to the vapours of burning sulphur—sulphurous acid gas.

Sulphuring-rooms are sometimes constructed upon a great scale, in which blankets, shawls, and woollen clothes may be suspended freely upon poles or cords. The floor should be flagged with a sloping pavement, to favour the drainage of the water that drops down from the moistened cloth. The iron or stoneware vessels, in which the sulphur is burned are set in the corners of the apartment. They should be increased in number according to the dimensions of the place, and distributed uniformly over it. The windows and the entrance door must be made to shut hermetically close. In the lower part of the door there should be a small opening, with a sliding shutter, which may be raised or lowered by the mechanism of a cord passing over a pulley.

The aperture by which the sulphurous acid and azotic gases are let off, in order to carry on the combustion, should be somewhat larger than the opening at the bottom. A lofty chimney carries the noxious gases above the building, and diffuses them over a wide space, their ascension being promoted by means of a draught-pipe of iron, connected with an ordinary stove, provided with a valve to close its orifice when not kindled.

When the chamber is to be used, the goods are hung up, and a small fire is made in the draught-stove. The proper quantity of sulphur being next put into the shallow pan, it is kindled, the entrance door is closed, as well as its shutter, while a vent-hole near the ground is opened by drawing its cord, which passes over a pulley. After a few minutes, when the sulphur is fully kindled, that vent-hole must be almost entirely shut, by relaxing the cord; when the whole apparatus is to be let alone for a sufficient time.

The object of the preceding precautions is to prevent the sulphurous acid gas escaping from the chamber by the seams of the principal doorway. This is secured by closing it imperfectly, so that it may admit of the passage of somewhat more air than can enter by the upper seams, and the smallest quantity of fresh air that can support the combustion. The velocity of the current of air may be increased at pleasure, by enlarging the under vent-hole a little, and quickening the fire of the draught-stove.

Before opening the entrance door of the apartment, for the discharge of the goods, a small fire must be lighted in the draught furnace, the vent hole must be thrown entirely open, and the sliding shutter of the door must be slid up, gradually more and more every quarter of an hour, and finally left wide open for a proper time. By this means the air of the chamber will soon become respirable. See BLEACHING and STRAW HAT MANUFACTURE.

SULPHURETTED HYDROGEN, *Hydrosulphuric acid.* Sulphur does not unite directly with hydrogen when in the free state, but when the sulphides of those metals which dissolve in dilute acids with liberation of hydrogen, are treated with the same acids, they are dissolved, and the hydrogen, as soon as liberated, unites with the sulphur of the sulphide, and is evolved as sulphuretted hydrogen. Sulphide of iron is the most general substance that is used for this purpose; the action goes on without the application of heat. The following formula represents the decomposition.

$$FeS + HSO^4 = FeSO^4 + HS.$$

This substance does not yield the gas in the pure state, so, when its purity is an object, it is obtained by the action of hydrochloric acid on tersulphide of antimony; in this case the gas is only liberated by the application of heat.

$$SbS^3 + 3HCl = SbCl^3 + 3HS.$$

The sulphide of iron may easily be prepared by projecting into a red-hot crucible a mixture of 2½ parts of sulphur and 4 parts of iron filings, or borings of cast iron, and excluding the air as much as possible; another process is to raise a bar of iron to a white heat, and then rub it with a lump of sulphur, over a vessel of water, the drops of fused sulphide fall into the water.

Sulphuretted hydrogen, at ordinary temperatures, is a colourless gas, possessing a most disgusting odour. It is liberated by many vegetable and animal substances in a state of decay. Its density is 1·171, and it contains 1 part of hydrogen and 16 parts of sulphur by weight. It possesses the properties of an acid, and its solution in water reddens litmus paper.

At a temperature of 50°, and under a pressure of 17 atmospheres, it is condensed to a highly limpid colourless liquid, of specific gravity 0·9, and when cooled to −122 solidifies, and is then a white crystalline translucent substance, heavier than the liquid. In the undiluted state this gas is very suffocating: the best antidote is a little chlorine, which decomposes it immediately, liberating the sulphur:

$$HS + Cl = HCl + S.$$

It is very soluble in water, that liquid dissolving 2½ times its bulk of the gas; the solution quickly becomes milky from the deposition of sulphur, the oxygen of the air uniting with the hydrogen.

$$HS + O = HO + S.$$

The principal use of sulphuretted hydrogen is in the laboratory for the separation of certain metals from their solutions. Being much heavier than air, it can be poured from one vessel to another, and was used successfully by M. Thenard to destroy rats, by pouring into their holes; but I think it would be quite as disagreeable for the time as the rats themselves.—H. K. B.

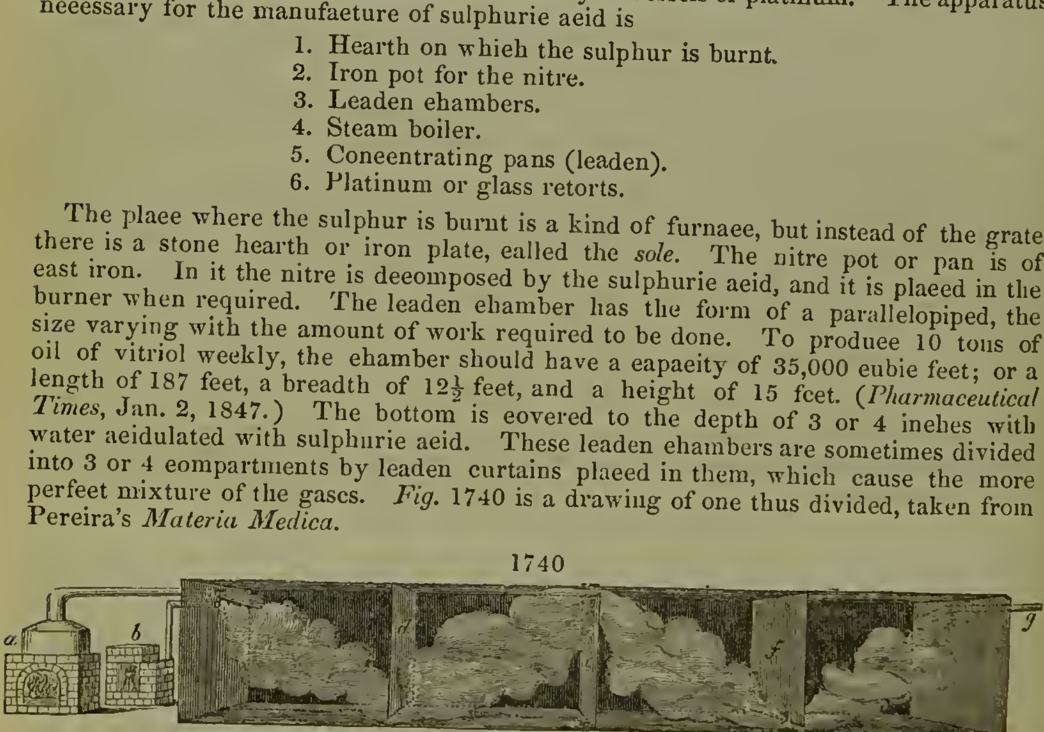
SULPHURIC ACID, *Vitriolic Acid*, or *Oil of Vitriol*. (*Acid sulfurique*, Fr.: *Schwefelsaüre*, Germ.) This important substance now forms an extensive article of manufacture. It appears to have been known several centuries back. It is found in large quantities in the mineral kingdom, combined with bases, in some rivers in the free state, and in such quantity as to render the water acid. It was previously prepared by the distillation of sulphate of iron or green vitriol, from which it received its name of *oil of vitriol* or *vitriolic acid*. This process is even now carried on in some parts of Germany to a certain extent, and the process will be more fully explained under Nordhausen Oil of Vitriol, hereafter. It was afterwards found that it might be produced by the combustion of sulphur, and the ultimate further oxidation of the sulphurous acid, thus obtained, by the means of nitric acid; and from time to time improvements have been made in the process, until it is now almost, perhaps entirely, perfect, and is the process most generally adopted. We shall proceed to describe the process more fully, as it is now carried on.

In the first place the sulphur is burnt on suitable hearths, and the sulphurous acid produced is carried by flues, together with some nitrous and nitric acids, generated in the same furnace from a mixture of nitre and sulphuric acid, into the large leaden chambers, into which steam and air are also admitted; here the different gases react on each other, and the sulphurous acid becomes converted into sulphuric acid, and falls into the dilute sulphuric acid which is placed in the bottom of the chamber, which thereby becomes stronger, and, when of sufficient strength, is drawn off, and concentrated first in leaden vessels, and finally in vessels of platinum. The apparatus necessary for the manufacture of sulphuric acid is

1. Hearth on which the sulphur is burnt.
2. Iron pot for the nitre.
3. Leaden chambers.
4. Steam boiler.
5. Concentrating pans (leaden).
6. Platinum or glass retorts.

The place where the sulphur is burnt is a kind of furnace, but instead of the grate there is a stone hearth or iron plate, called the *sole*. The nitre pot or pan is of cast iron. In it the nitre is decomposed by the sulphuric acid, and it is placed in the burner when required. The leaden chamber has the form of a parallelopiped, the size varying with the amount of work required to be done. To produce 10 tons of oil of vitriol weekly, the chamber should have a capacity of 35,000 cubic feet; or a length of 187 feet, a breadth of 12½ feet, and a height of 15 feet. (*Pharmaceutical Times*, Jan. 2, 1847.) The bottom is covered to the depth of 3 or 4 inches with water acidulated with sulphuric acid. These leaden chambers are sometimes divided into 3 or 4 compartments by leaden curtains placed in them, which cause the more perfect mixture of the gases. *Fig.* 1740 is a drawing of one thus divided, taken from Pereira's *Materia Medica*.

1740



Oil of Vitriol Chamber.

a. Steam boiler.
b. Section of furnace or burner.
d and *f*. Leaden curtains from the roof of the chamber to within six inches of the floor.
e. Leaden curtains rising from the floor to within six inches of the roof.
g. Leaden conduit or vent-tube for the discharge of uncondensible gases. It should communicate with a tall chimney to carry off these gases, and to occasion a slight draught through the chamber.

These curtains serve to detain the vapours, and cause them to advance in a gradual manner through the chamber, so that generally the whole of the sulphurous acid is converted into sulphuric acid and deposited in the water at the bottom before it reaches the discharge pipes; but as such is not always the case, there are sometimes smaller chambers, also containing water, appended to the larger, from which they receive the escaping gases before they are allowed to pass out into the air, and thus prevent loss. These smaller chambers are seen in *fig.* 1741 *c, d,* also taken from Pereira's *Materia Medica.*

Another method for preventing this loss has been contrived by M. Gay-Lussac, and made the subject of a patent in this country by his agent, M. Sautter. It consists in causing the waste gas of the vitriol chamber to ascend through the *chemical cascade* of M. Clement Desormes, and to encounter there a stream of sulphuric acid of specific gravity 1·750. The nitrous acid gas, which is in a well regulated chamber always slightly redundant, is perfectly absorbed by the said sulphuric acid; which, thus impregnated, is made to trickle down through another cascade, up through which passes a current of sulphurous acid, from the combustion of sulphur in a little adjoining chamber. The condensed nitrous acid gas is thereby immediately transformed into nitrous gas (deutoxide of azote), which is transmitted from this second cascade into the large vitriol chamber, and there exercises its well known reaction upon its aeriform contents. The economy thus effected in the sulphuric acid manufacture is such that for 100 parts of sulphur 3 of nitrate of soda will suffice, instead of 9 or 10 as usually consumed.

The flue or waste pipe serves to carry off the residual gas, which should contain nothing but the nitrogen of the atmosphere, which has been introduced.

Having now detailed, with sufficient minuteness, the construction of the chamber, we shall next describe the mode of operating with it. There are at least two plans at present in use for burning the sulphur continuously in the oven. In the one, the sulphur is laid on the hearth (or rather on the flat hearth in the separate oven, above described,) and is kindled by a slight fire placed under it; which fire, however, is allowed to go out after the first day, because the oven becomes by that time sufficiently heated by the sulphur flames to carry on the subsequent combustion. Upon the hearth, an iron tripod is set, supporting, a few inches above it, a hemispherical cast-iron bowl (basin) charged with nitre and its decomposing proportion of strong sulphuric acid. In the other plan, 12 parts of bruised sulphur, and 1 of nitre, are mixed in a leaden trough on the floor with 1 of strong sulphuric acid, and the mixture is shovelled

i. Pipe conveying the gas, not absorbed in the first and second chamber, into the third.
k. Flue or waste pipe.
l. Manhole, by which the workmen enter the chamber when the process is not going on.
m. Pipe for withdrawing a small portion of sulphuric acid from the chamber, in order to obtain its sp. gr. by the hydrometer.

through the sliding iron door upon the hot hearth. The successive charges of sulphur are proportioned, of course, to the size of the chamber. In one of the largest, which is 120 feet long, 20 broad, and 16 high, 12 cwt. are burned in the course of 24 hours, divided into 6 charges, every fourth hour, of 2 cwt. each. In chambers of one-sixth greater capacity, containing 1400 metres cube, 1 ton of sulphur is burned in 24 hours. This immense production was first introduced at Chaunay and Dieuze, under the management of M. Clement-Desormes. The bottom of the chamber should be covered at first with a thin stratum of sulphuric acid, of sp. gr. 1·07, which decomposes hyponitric acid into oxygen and binoxide of nitrogen; but not with mere water, which would absorb the hyponitric acid vapours, and withdraw them from their sphere of action. The crystalline compound, described below, is often formed, and is deposited, at low temperatures, in a crust of considerable thickness (from one-half to one inch) on the sides of the chamber, so as to render the process inoperative. A circumstance of this kind occurred, in a very striking manner, during winter, in a manufacture of oil of vitriol in Russia; and it has sometimes occurred, to a moderate extent, in Scotland. It is called, at Marseilles, the *maladie des chambres*. It may be certainly prevented, by maintaining the interior of the chamber, by a jet of steam, at a temperature of 100° Fahr. When these crystals fall into the dilute acid at the bottom, they are decomposed with a violent effervescence, and a hissing gurgling noise, somewhat like that of a tun of beer in brisk fermentation.

M. Clement-Desormes demonstrated the proposition relative to the influence of temperature by a decisive experiment. He took a glass globe, furnished with three tubulures, and put a bit of ice into it. Through the first opening he then introduced sulphurous acid gas; through the second, oxygen; and through the third binoxide of nitrogen. While the globe was kept cool by being plunged in iced water, no sulphuric acid was formed, though all the ingredients essential to its production were present. But on exposing the globe to a temperature of 100° Fahr., the four bodies began immediately to react on each other, and oil of vitriol was condensed in visible *striæ*.

The introduction of steam is a modern invention, which has vastly facilitated and increased the production of oil of vitriol. It serves, by powerful agitation, not only to mix the different gaseous molecules intimately together, but to impel them against each other, and thus bring them within the sphere of their mutual chemical attraction. This is its mechanical effect. Its chemical agency is still more important. By supplying moisture at every point of the immense included space, it determines the formation of hydrous sulphuric acid, from the compound of nitric, hypo-nitric, sulphurous, and dry sulphuric acids.

Besides the process here described, which is called the *continuous process*, there was another formerly adopted, called the *intermittent* process. This was also carried on in large leaden chambers, but instead of a continuous stream of air, as passes into the chambers, through the furnace by the continuous process, the chambers were opened now and then to introduce fresh atmospheric air. This process is, however, now generally abandoned, on account of the difficulties and delays attending it, though it afforded large products in skilful hands. The following is just an outline of the process: — On the intermittent plan, after the consumption of each charge, and condensation of the product, the chamber was opened and freely ventilated, so as to expel the residuary nitrogen, and replenish it with fresh atmospheric air. In this system there were four distinct stages or periods: — 1. Combustion for two hours; 2. Admission of steam, and settling for an hour and a half; 3. Conversion for three hours, during which interval the drops of strong acid were heard falling like heavy hailstones on the bottom; 4. Purging of the chamber for three-quarters of an hour.

By the continuous method, sulphuric acid may be currently obtained in the chambers, of the specific gravity 1·350, or 1·450 at most; for when stronger, it absorbs and retains permanently much nitrous acid gas; but by the intermittent, so dense as 1·550, or even 1·620; whence in a district where fuel is high priced, as near Paris, this method recommended itself by economy in the concentration of the acid. In Great Britain, and even in most parts of France, however, where time, workmen's wages, and interest of capital, are the paramount considerations, manufacturers do not find it for their interest in general to raise the density of the acid in the chambers above 1·400, or at most 1·500; as the further increase goes on at a retarded rate, and its concentration from 1·400 to 1·600, in leaden pans, costs very little.

For many purposes in the arts the acid, as it is taken from the leaden chambers, is quite strong enough, and is extensively employed under the name of "Chamber Acid."

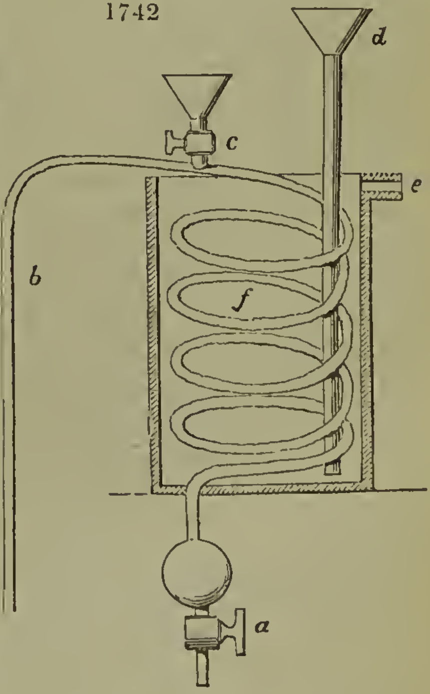
At about the specific gravity of 1·35, in Great Britain, the liquid of the chambers is run off by the siphon above described, into a leaden gutter or spout, which discharges it into a series of rectangular vessels made of large sheets of lead of 12 or 14 lbs. to the square foot, simply folded up at the angles into pans 8 or 10 inches deep, resting upon a grate made of a pretty close row of wrought-iron bars of considerable strength, under which the flame of a furnace plays. Where coals are very cheap, each pan may have a separate fire; but where they are somewhat dear, the flame, after passing under the lowest pan of the range, which contains the strongest acid (at about 1·600), proceeds upwards with a slight slope to heat the pans of weaker acid, which, as it concentrates, is gradually run down by siphons to replenish the lower pans, in proportion as their aqueous matter is dissipated. The three or four pans constituting the range are thus placed in a straight line, but each at a different level, terrace-like; *en gradins*, as the French say.

When the acid has thereby acquired the density of 1·650, or 1·700 at most, it must be removed from the leaden evaporators, because when of greater strength it would begin to corrode them; and it is transferred into leaden coolers, or run through a long refrigeratory worm-pipe, surrounded by cold water. In this state it is introduced into glass or platinum retorts, to undergo a final concentration, up to the specific gravity of 1·842, or even occasionally 1·845. When glass retorts are used, they are set in a long sand-bath over a gallery furnace, resting on fire-tiles, under which a powerful flame plays; and as the flue gradually ascends from the fireplace near to which it is most distant from the tiles, to the remoter end, the heat acts with tolerable equality on the first and last retort in the range. When platinum stills are employed, they are fitted into the inside of cast-iron pots, which protect the thin bottom and sides of the precious metal. The fire being applied directly to the iron, causes a safe, rapid, and economical concentration of the acid. The iron pots, with their platinum interior, filled with concentrated boiling-hot oil of vitriol, are lifted out of the fire-seat by tackle, and let down into a cistern of cold water, to effect the speedy refrigeration of the acid, and facilitate its transvasion into carboys packed in osier baskets lined with straw. Sometimes, however, the acid is cooled by running it slowly off through a long platinum siphon, surrounded by another pipe filled with cold water. *Fig.* 1742 shows a contrivance for this purpose.

The under stopcock *a* being shut, and the leg *b* being plunged to nearly the bottom of the still, the worm is to be filled with concentrated cold acid through the funnel *c*. If that stopcock is now shut, and *a* opened, the acid will flow out in such quantity as to rarefy the small portion of air in the upper part of the pipe *b*, sufficiently to make the hot acid rise up over the bend, and set the siphon in action. The flow of the fluid is to be so regulated by the stopcock *a*, that it may be greatly cooled in its passage by the surrounding cold water in the vessel *f*, which may be replenished by means of the tube and funnel *d*, and overflow at *e*.

A manufacturer of acid in Scotland, who burns in each chamber 210 pounds of sulphur in twenty-four hours, being at the rate of 420 pounds for 20,000 cubic feet (=nearly 2,000 metres cube), has a product of nearly 3 pounds of concentrated oil of vitriol for every pound of sulphur and twelfth of a pound of nitre. The advantage of this process results, from the lower concentration of the acid in the chambers, which favours its more rapid production.

1742



The platinum retort admits of from four to six operations in a day, when it is well mounted and managed. It has a platinum capital, furnished with a short neck, which conducts the disengaged vapours into a lead worm of condensation; and the liquid thus obtained is returned into the lead pans. Great care must be taken to prevent any particles of lead from getting into the platinum vessel, since at the temperature of boiling sulphuric acid, the lead unites with the precious metal, and thus causes holes in the retort. These must be repaired by soldering on a plate of platinum with gold.

Before the separate oven or hearth for burning the sulphur in contact with the nitre was adopted, this combustible mixture was introduced into the chamber itself, spread on iron trays or carthen pans, supported above the acid on iron stands. But this plan was very laborious and unproductive. It is no longer followed.

Sanitary motives alone induced the makers of soda to condense their waste hydrochloric acid in the first instance; though they now discover its worth as a means of manufacturing chloride of lime, and would not again return to the nuisance-creating system if they might. In time, no doubt, the copper smelter will also be compelled to arrest the poisonous fumes now so wantonly evolved; and then he too will find a profit in that which, at present, only injures his neighbour. It is with individual interests as with physical bodies, the largest are the most difficult to move from any established position. Not many years ago, all the sulphuric acid used in this country was made from sulphur alone; and, although scientific men had pointed out iron pyrites as an abundant indigenous source for the generation of this acid, yet no attention whatever was given to this seemingly valueless information. Folly, however, achieved that which wisdom could not reach; and the infatuated cupidity of a Sicilian king compelled our manufacturers to lend a willing ear to the voice of science, and seek at home that which a prohibitive export duty prevented them from obtaining abroad. Their eyes were at length opened, and, too late, the King of Sicily saw his error: for, though the excessive duty on sulphur has since been removed, it has not only failed to put down the use of iron pyrites, but the best informed authorities are decidedly of opinion, that this latter will eventually abolish the employment of sulphur, and that Ireland, and not Sicily, will furnish the essential element for the fabrication of nearly all our sulphuric acid. There is, however, one very serious drawback to the general use of iron pyrites for such a purpose, and that is the presence of arsenic in all the acid thus made. This objection is fatal at present, and the combined agency of mechanical and chemical genius alone can relieve this important manufacture from so great an obstacle. Means have indeed been devised for removing the arsenic from the acid after the formation of the latter; but those acquainted with the practical working of sulphuric acid well know that such a project is futile and impossible on the large scale. There are, in fact, but two modes of dealing with the difficulty, the one being to prevent the volatilisation of the arsenic at all, by mixing the pyrites with some suitable ingredient ere it is thrown into the furnace; and the other, to remove the arsenic from the sulphurous acid before it reaches the chamber of condensation. The first would be the simplest plan; but in the existing state of science, can scarcely be hoped for. The last, however, is not by any means beyond the scope of perseverance and ingenuity. It must be borne in mind, that, though the arsenic, being in the form of arsenious acid when it leaves the furnace with the sulphurous acid, is in the gaseous state, yet a very trifling reduction of temperature suffices to convert it into a solid powder; in which condition it is merely carried onwards, mechanically, by the current of sulphurous acid; and thus reaches the leaden chamber The mixture, therefore, resembles that of turbid water; and, bearing this analogy in mind, we shall now proceed to describe the pyritic process of making sulphuric acid,— adding, as we go on, a hint at the proper place for arresting the arsenious fumes, and thus producing a pure and satisfactory acid, equal to that obtained from Sicilian sulphur. The furnace employed for roasting iron pyrites is very peculiar, but essentially consists of an inverted cone, with, of course, a small area of fire-grate, in proportion to the cubical contents of the furnace, — the object of this being, to prevent the surplus passage of air through the furnace, and cause the sublimed sulphur to burn only at the upper part of the mass, where there are two or more holes for the supply of air, duly provided with stoppers, to regulate the combustion above with regard to that below. Thus, at starting, the principal effect of the lower heat is simply to decompose the bisulphide of iron, and expel one half of its sulphur; and at this stage, the upper openings of the furnace are all requisite, to ensure the combustion of this volatilised sulphur; but so soon as the bisulphide of iron has been converted into the proto-sulphide, then the upper openings are no longer useful, but must be closed, so as to compel the whole of the air to pass through the red-hot proto-sulphide, and thus form sulphurous acid and oxide of iron, — the latter of which is ultimately withdrawn as a waste product. An iron pan, containing nitrate of soda, is usually placed in the common flue of a number of these furnaces, to supply nitric oxide gas; and the whole of the volatile products are made to pass through a considerable length of tubing, subjected to the refrigerating effect of the air, so as to cool the gases prior to their introduction into the chamber of condensation.

The subsequent processes are the same whether we use sulphur or iron pyrites, the only difference being in the construction of the furnace for generating the sulphurous acid. We shall now, therefore, proceed to consider the question of removing from the volatile mixture the arsenical matters which it holds in suspension; for, during the passage of this mixture through the refrigerating tube, above described, the arsenious acid is really solidified; whilst the sulphurous acid, being a permanently elastic gas, suffers but a trifling contraction in its bulk. We requested attention to the case of turbid water as a simile from whence to acquire a correct notion of the kind of mixture passing into the condensing chamber; and this suggests also the means of purification. With turbid water filtration might indeed be resorted to, which is inapplicable to our difficulty; but there is another mode in which water is purified by nature on the large scale, and that is, by deposition, or attraction of gravitation. For this purpose absolute rest is not necessary; as may be seen on examining the water running into and out of a lake in spring or autumn. It enters foul and muddy; but, at its exit, is clear and pellucid as crystal. This is precisely the object desired with respect to the gaseous products given off from a pyrites furnace, and may be accomplished in precisely the same way. Let a gaseous lake, or large chamber in brickwork, be interposed between the refrigerating tube and the condensation-chamber, through which, of course, the contaminated sulphurous acid would flow, but so slowly as to deposit, like the water in the lake, the mechanical impurities suspended in it, and thus pass pure and undefiled into the leaden chamber, possessing now all the properties and uses of that obtained by the combustion of pure sulphur. The size of this gaseous lake or arsenical precipitator, as it might be termed, would require adjustment according to the area of the entrance tube and the velocity of the current, but need not, perhaps, be more than one half of the cubical contents of the leaden chamber, especially if the gas entered below and issued from the top.

The complicated changes which take place in the leaden chambers during the conversion of the sulphurous acid into sulphuric acid, were first traced by M. Clement Desormes. He showed that hyponitric acid and sulphurous acid gases when mixed, react on each other through the intervention of moisture; that there thence resulted a crystalline combination of sulphuric acid, binoxide of nitrogen, and water. That this crystalline compound was instantly destroyed by more water, with the separation of the sulphuric acid in a liquid state, and the disengagement of binoxide of nitrogen; that this gas re-constituted hyponitric acid at the expense of the atmospheric oxygen of the leaden chamber, and thus brought matters to their primary condition. From this point, starting again, the particles of sulphur in the sulphurous acid, through the agency of water, became fully oxygenated by the hyponitric acid, and fell down in heavy drops of sulphuric acid, while the binoxide of nitrogen derived from the hypo-nitric acid, had again recourse to the air for its lost dose of oxygen. This beautiful interchange of the oxygenous principle was found to go on, in their experiments, till either the sulphurous acid or oxygen in the air was exhausted.

They verified this proposition, with regard to what occurs in sulphuric acid chambers, by mixing in a crystal globe the three substances, binoxide of nitrogen, sulphurous acid, and atmospheric air. The immediate production of red vapours indicated the transformation of the binoxide into hyponitric acid gas; and now the introduction of a very little water caused the proper *reaction*, for opaque vapours arose, which deposited white star-form crystals on the surface of the glass. The gases were once more transparent and colourless; but another addition of water melted these crystals with effervescence, when ruddy vapours appeared. In this manner the phenomena were made to alternate, till the oxygen of the included air was expended, or all the sulphurous acid was converted into sulphuric. The residuary gases were found to be hyponitric acid gas, and nitrogen without sulphurous acid gas; while unctuous sulphuric acid bedewed the inner surface of the globe. Hence, they justly concluded their new theory of the manufacture of oil of vitriol to be demonstrated.

By a modification of this last process, the manufacture of sulphuric acid from sulphur and nitre may be elegantly illustrated. Take a glass globe with an orifice at its top large enough to take a lead stopper, through which are fixed five glass tubes; one in connection with a flask generating sulphurous acid from copper turnings and sulphuric acid; the second in connection with a gasometer supplying binoxide of nitrogen; the third in connection with a vessel, capable of supplying a tolerable current of steam; the fourth connected to another gasometer supplying atmospheric air; and the fifth which is left open, does not project far into the globe, and serves to carry off the residual nitrogen. By regulating the influx of the different gases and steam, the solid white crystalline compound may be alternately formed and again decomposed. The bottom of the glass globe is formed like a funnel, and the sulphuric acid, when formed, thus runs down the sides into a bottle placed beneath. Some difference of opinion exists about the composition of the crystalline compound thus formed sometimes in leaden chambers. It is probably a compound of sulphuric acid and binoxide of nitrogen $NO^2 + 2SO^3$, but it is not decided if it contains water or not.

Peligot (Ann. Chim. et Phys. 3me sér. xii. 1844) states that the sulphurous acid is oxidised *incessantly* and *exclusively* by nitric acid only, and he accounts for it in this way. The hypo-nitric acid (NO^4) by contact with water is converted into nitric acid, and nitrous acid ($2NO^4 + HO = HNO^6 + NO^3$), and the nitrous acid (NO^3) is again decomposed by more water into nitric acid and binoxide of nitrogen $3NO^3 + HO = HNO^6 + 2NO^2$. The binoxide of nitrogen by contact with atmospheric air is again converted into hypo-nitric acid ($NO^2 + O^2 = NO^4$), which goes through the same changes as before.

There are some points in the manufacture of sulphuric acid which require attention.

1st. If the heat in the sulphur furnace is too high, or when there is not a sufficient supply of air, some sulphur sublimes, and is condensed in the chamber, and at last falls into the sulphuric acid at the bottom of the chamber. By this means, not only is less sulphuric acid produced, but the sulphuric acid, when drawn from the chamber, contains some sulphur in suspension: in this case it must be allowed to stand, so as to deposit the sulphur, which may be collected, washed, dried, and again used. If the sulphur were not removed before concentrating, it would, at the temperature requisite for evaporation, decompose the sulphuric acid with the escape of sulphurous acid gas, and hence much sulphuric acid would be lost. The reaction that would take place is represented by the following equation:—

$$\underbrace{2HSO^4}_{\text{Sulphuric acid.}} + \underbrace{S}_{\text{Sulphur.}} = \underbrace{3SO^2}_{\text{Sulphurous acid gas.}} + \underbrace{2HO.}_{\text{Water.}}$$

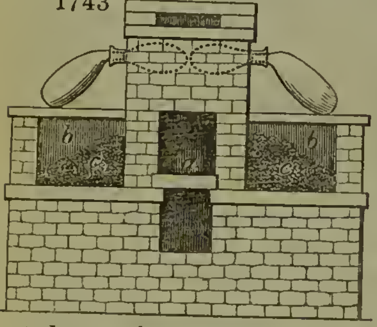
2nd. If there is not a sufficient quantity of steam admitted into the chamber, the solid compound of sulphuric acid and binoxide of nitrogen, above mentioned, would be formed on the sides of the chamber, and thus remove the oxidising agent from action, and hence a large quantity of sulphurous acid would escape by the waste-pipe unchanged.

3rd. A deficiency of nitric acid in the chamber also causes great loss; the sulphurous acid, as in the former case, escaping unoxidised.

The first of these three subjects was counteracted by M. Grovelle, who, taking advantage of an idea put forth by M. Clement Desormes, constructed a furnace for burning the sulphur, so as to have a double current of air. He substituted for the sole of the furnace some parallel bars of iron, on which were placed cast-iron pans or boxes, bound together, but leaving intervals for the entrance of air between each: these were filled with sulphur, which was then ignited, and thus a plentiful supply of air was constantly kept up.

Fuming, or Nordhausen sulphuric acid. At Nordhausen and other parts of Saxony, sulphuric acid continues to be made upon the old plan. This consists in first sub-

1743



jecting sulphate of iron or green vitriol to a gentle heat, by which it is deprived of its water of crystallisation; it is then distilled in earthenware, tubular, or pear-shaped retorts, of which a large number are placed in a gallery furnace. *Fig.* 1743 the fire-place; *a b b*, chamber on each side of the fire-place, for depriving the green vitriol (*c c*) of its water.

To these retorts are adapted earthenware receivers, into which some ordinary sulphuric acid is previously placed, to condense all the anhydrous sulphuric acid which comes over. The heat is raised gradually, and at last the retorts are subjected to an intense heat, which is kept up for several hours.

Some sulphurous acid gas escapes, arising from the decomposition of some of the sulphuric acid of the sulphate by the oxide of iron, and nothing remains in the retorts but sesquioxide of iron.

$$\underbrace{3FeSO^4}_{\text{Green vitriol.}} = \underbrace{Fe^2O^3}_{\text{Oxide of iron.}} + \underbrace{2SO^3}_{\text{Anhydrous sulphuric acid.}} + \underbrace{SO^2}_{\text{Sulphurous acid.}}$$

Anhydrous sulphuric acid. This is most easily obtained by subjecting the Nordhausen sulphuric acid to a gentle heat in a glass retort, to which is adapted a dry receiver placed in ice. White fumes of anhydrous sulphuric acid come over and are condensed in the receiver. Care must be taken to avoid water coming into contact with it, as it unites with it with some violence.

$$\underbrace{HSO^4SO^3}_{\text{Nordhausen sulphuric acid.}} = \underbrace{HSO^4}_{\text{Common sulphuric acid.}} + \underbrace{SO^3}_{\text{Anhydrous sulphuric acid.}}$$

It is best to have a receiver, which can be hermetically sealed as soon as the operation is completed.

Properties of the different Sulphuric Acids.

Anhydrous sulphuric acid. SO^3. This is a white crystalline body, very much resembling asbestos in appearance. Exposed to the air, some of it absorbs moisture, and the rest flies off in white fumes. Dropped into water it produces a hissing noise, just like red-hot iron, and in large quantities causes explosion. It melts at 66° Fahr., and boils at about 120° Fahr. The sp. gr. of the liquid, at 78° Fahr., is 1·97 (*Pereira*), and that of its vapour 3·0 (*Mitscherlich*). It does not present acid properties unless moisture be present.

Nordhausen sulphuric acid. HSO^4, SO^3. This is an oily liquid, generally of a brown colour (from some organic matter), which gives off white fumes of anhydrous sulphuric acid when exposed to the air. Its sp. gr. is about 1·9. It is imported in stoneware bottles, having a stoneware screw for a stopper. It is probably only a solution of anhydrous sulphuric acid in ordinary oil of vitriol, as, after being subjected to a gentle heat, nothing remains but the latter. It often contains several impurities. It is principally used for dissolving indigo, which it does completely without destroying the colour.

Ordinary sulphuric acid, or oil of vitriol. HSO^4. Sp. gr. 1·845. This is, when pure, a colourless, transparent, highly acrid, and most powerfully corrosive liquid. It is a very strong mineral acid, one drop being sufficient to communicate the power of reddening litmus paper to a gallon of water, and produces an ulcer if placed upon the skin. It chars most organic substances. This depends upon its attraction for water, which is so great that, when exposed in an open saucer, it imbibes one-third of its weight from the atmosphere in twenty-four hours, and fully six times its weight in a few months. Hence it should be kept excluded from the air. If four parts, by weight, of the strongest acid be suddenly mixed with one part of water, both being at 50° Fahr., the temperature will rise to 300° Fahr.; while, on the other hand, if four parts of ice be mixed with one of sulphuric acid, they immediately liquefy and sink the thermometer to 4° below zero. In this last case the heat, that would otherwise have been given off, has been employed in liquefying the ice. Upon the mixing the acid and water they both suffer condensation, the dilute acid, thus formed, occupying less space than the two separately, and hence the evolution of heat. This affinity for water, which sulphuric acid possesses, is often made use of for evaporating liquids at a low temperature. The liquid is placed in a dish over another dish containing sulphuric acid, and both are placed under the receiver of an air pump. Such is the rapidity with which the evaporation is carried on, that if a small vessel of water be so placed it will speedily be frozen. Sulphuric is decomposed by several substances when boiled with them; such are most organic substances, sulphur, phosphorus, and several of the metals, as mercury, copper, tin, &c.

Sulphuric acid of sp. gr. 1·845, boils at about 620° Fahr., and may be distilled unchanged. This is the best way to obtain it pure. It is a most powerful poison. If swallowed in its concentrated state, even a small quantity, it acts so powerfully on the throat and stomach as to cause intolerable agony and speedy death. Watery diluents mixed with chalk or magnesia are the readiest antidotes.

Ordinary oil of vitriol generally contains some sulphate of lead, which will be precipitated, as a white powder by dilution with water; since so much of it is made from iron pyrites at the present day, it contains arsenic in variable quantities. The best test for sulphuric acid, either free or combined, as soluble salts, is a salt of barium. An extremely small quantity of sulphuric acid, or a soluble salt of it, is thus easily detected by the greyish-white cloud of sulphates of baryta which it occasions in the solution. 100 parts of the concentrated acid are neutralised by 143 parts of dry pure carbonate of potash, and by 110 of dry pure carbonate of soda.

The presence of saline impurities in sulphuric acid may be determined by evaporating a certain quantity to dryness in a platinum capsule. If more than 2 grains of residue remain out of 500 of acid it may be considered impure.

Of all the acids, the sulphuric is most extensively used in the arts, and is, in fact, the primary agent for obtaining almost all the others, by disengaging them from their saline combinations. In this way nitric, hydrochloric, tartaric, acetic, and many other acids, are procured. It is employed in the direct formation of alum, of the sulphates of copper, zinc, potassa, soda; in that of sulphuric ether, of sugar by the saccharification of starch, and in the preparation of phosphorus, &c. It serves also for opening the pores of skins in tanning, for clearing the surfaces of metals, for determining the nature of several salts by the acid characters that are disengaged, &c.

According to Graham there are three hydrates of sulphuric acid besides the Nordhausen acid, viz.:—

Monohydrate of sulphuric acid, oil of vitriol, of sp. gr. 1·845. HSO^4. This acid is a dense oily, colourless liquid. Boils at 620° Fahr., and freezing at —29° Fahr., yielding sometimes regular six-sided prisms of a tabular form.

Binhydrate of sulphuric acid, sometimes called Eisöl (ice oil), sp. gr. 1·78. $HSO^4 + HO$.

In cold weather acid of this density readily freezes, and produces large, hard crystals, somewhat resembling crystals of carbonate of soda. The melting point of these crystals is 45° Fahr. If the density be either augmented or lessened the freezing point is lowered. The crystals have a sp. gr. of 1·924.

Terhydrate of sulphuric acid. Acid of sp. gr. 1·632. $HSO^4 + 2HO$. This acid is obtained by evaporating a dilute acid *in vacuo* at 212° Fahr. It is in the proportions contained in this hydrate that sulphuric acid and water undergo the greatest condensation when mixed.

The following Table shows the quantity of concentrated and dry sulphuric acid in 100 parts of dilute, at different densities, according to Dr. Ure.

Liquid.	Sp. Grav.	Dry.	Liquid.	Sp. Grav.	Dry.	Liquid.	Sp. Grav.	Dry.

H. K. B.

SULPHUROUS ACID. (SO^2.) Sulphur fumigations are mentioned by Homer, but sulphurous acid, of which these were composed, was first accurately examined by Stahl, Schelle, and Priestley, and more recently by Gay-Lussac, and Berzelius.

It escapes from the earth, in the gaseous form, in the vicinity of volcanoes, but is always prepared artificially when required for use, and for this purpose several processes are employed.

1. By heating copper cuttings, or mercury, with concentrated sulphuric acid in a glass flask; sulphate of copper, or persulphate of mercury and sulphurous acid are formed,

$$\underbrace{Cu}_{\text{Copper.}} + \underbrace{2(HSO^4)}_{\text{Sulphuric acid.}} = \underbrace{CuSO^4}_{\text{Sulphate of copper.}} + \underbrace{SO^2}_{\text{Sulphurous acid.}} + \underbrace{2HO.}_{\text{Water.}}$$

this latter is passed through a wash bottle, to remove any trace of sulphuric acid which sometimes comes over, and then through a tube containing chloride of calcium, if the gas be wanted dry; it may then be collected over mercury in the pneumatic trough, or by displacement of air; it cannot be collected over water, owing to its great solubility in that liquid.

2. By heating charcoal, or almost any organic substance, with concentrated sulphuric acid in the same apparatus as above, but in this case the sulphurous acid is contaminated with a large quantity of carbonic acid, which, however, does not interfere with it in many cases, as when employed in the manufacture of alkaline sulphites.

$$\underbrace{C}_{\text{Charcoal.}} + \underbrace{2HSO^4}_{\text{Sulphuric acid.}} = \underbrace{CO^2}_{\text{Carbonic acid.}} + \underbrace{2SO^2}_{\text{Sulphurous acid.}} + \underbrace{2HO.}_{\text{Water.}}$$

3. By the combustion of sulphur or iron pyrites in oxygen gas or in atmospheric air, and this is the process most generally employed on the large scale, as in the manufacture of sulphuric acid. See SULPHURIC ACID.

$$\underbrace{S}_{\text{Sulphur.}} + \underbrace{O^2}_{\text{Oxygen.}} = \underbrace{SO^2.}_{\text{Sulphurous acid.}}$$

Properties. At ordinary temperatures and atmospheric pressure sulphurous acid is a colourless, transparent gas, possessing the disagreeable odour so well known to those who have burnt a sulphur match. It is neither combustible, nor a supporter of combustion, and is always the product obtained by burning sulphur in air. It is a weak acid, and is very soluble in water, that liquid at 60° Fahr. dissolving more than thirty times its volume of the gas; the solution of sulphurous acid thus obtained—bleaches some vegetable colours, as well as the gas itself, viz. those of roses and violets, &c., but in most cases the colours may be restored by treating with a weak acid or alkali. It cannot be respired in the pure state, as it immediately causes spasm of the glottis; but if diluted with air and then breathed, it acts as a local irritant, exciting cough, pain, and a sense of dryness of the mouth and throat. Its sp. gr. is 2·2; 100 cubic inches weighing 68·69 grains. Its solution in water may be kept any time without change, as long as air is excluded, but when air gains access to it, it is gradually converted into sulphuric acid.

One volume of sulphurous acid gas contains one volume of oxygen and $\frac{1}{6}$th of a volume of sulphur vapour, condensed into one volume. When a mixture of sulphurous acid gas and aqueous vapour are passed into a vessel cooled to below 17° Fahr., a crystalline substance is formed which contains about 24·2 parts of acid and 75·8 parts of water.

At 0· Fahr., and under ordinary atmospheric pressure, sulphurous acid condenses to a colourless, limpid liquid, of sp. gr. 1·42 (Faraday), and boils at 14° Fahr. It dissolves bitumen (Pereira). At $-105°$ Fahr. it becomes a crystalline, colourless, transparent body.

The only salt of sulphurous acid which is made at all largely, is the hyposulphite of soda. See SODA HYPO-SULPHITE.

Uses. Sulphurous acid is often used as a bath in some kinds of skin diseases; also in commerce for bleaching straw hats and bonnets, &c., and silks, and for fumigating rooms; for these latter purposes, the sulphur is placed in a vessel in the centre of the room, and ignited, all the apertures of the windows, &c. being previously closed. When thus employed for bleaching, the articles are hung up in the room, which becomes filled with sulphurous acid, and is thus left for a certain time. Its principal use is in the manufacture of sulphuric acid.—H. K. B.

SULPHYDROMETRY, the determination of sulphur, which see.

SUNFLOWER OIL. See OILS.

SUNN consists of the fibre of the *Crotolaria juncea*, a totally different plant from the *Cannabis sativa*, from which hemp is obtained. Sunn is grown in various places of Hindostan. The strongest, whitest, and most durable species is produced at Comercolly.—*McCulloch.*

SUNSTONE. A variety of felspar, of a pale yellowish colour, found in Siberia. It is almost perfectly transparent when viewed in one direction; but by reflected light it appears full of minute golden spangles, owing to the presence of scales of oxide of iron, which are disseminated through the mass.—H. W. B.

SUSSEX MARBLE. Thin bands of shelly limestone, occurring here and there in the Weald Clay, especially in the upper part. This limestone is principally composed of the remains of freshwater snails, a species of *Paludina*, and it has been named Sussex marble in consequence of its great development in that county. Although the stone is not remarkable for any particular beauty of colour, being generally of a uniform bluish or greyish-green tint, the sections of the chambers of the shells give it, when polished, a pleasing appearance, and it has, in consequence, been frequently made use of in former times in the construction of tombs and sepulchral monuments in many of our older churches.—H. W. B.

SWALLOW, ESCULENT (*Hirundo esculenta*). These birds construct the edible nests which form so considerable a part of Chinese commerce. It is the *Larvet* of the Japanese, the *Salangana* of some writers on the Eastern Archipelago. The nests are made of a particular species of sea-weed (see ALGÆ), which the bird macerates and bruises before it employs the material in layers so as to form the whitish gelatinous cup-shaped nests so much prized as restoratives and delicacies by the Chinese.

SWAGES. Tools employed in shaping metals.

SWEEP-WASHER is the person who extracts from the sweepings, potsherds, &c. of refineries of silver and gold, the small residuum of precious metal.

SWORD MANUFACTURE. This is sufficiently described under DAMASKUS BLADES.

SYCAMORE. The wood of the *Acer pseudo-platanus*

SYENITE, or SIENITE, so called from its being obtained by the ancient Egyptians from Syene, in Upper Egypt. It is a granular, aggregated compound rock, consisting of felspar, quartz, and hornblende.

Any granitic rock in which hornblende predominates is termed syenitie. From true granite to the true greenstone the gradations are exceedingly easy.

SYNTHESIS is a Greek word, which signifies combination, and is applied to the chemical action which unites dissimilar bodies into a uniform compound; as sulphuric acid and lime into gypsum; or chlorine and sodium into culinary salt.

SYRUP is a solution of sugar and water. Cane juice, concentrated to a density of 1·300, forms a syrup which does not ferment in the transport home from the West Indies, and may be boiled and refined at one step into superior sugar-loaves, with eminent advantage to the planter, the refiner, and the revenue.

T

TABBYING, or WATERING, is the process of giving stuffs a wavy appearance by a peculiar manipulation with the calender. See MOIRE.

TACAMAHAC is a resin obtained from the *Fagura octandra*, a tree which grows in Mexico and the West Indies. It occurs in yellowish pieces, of a strong smell, and a bitterish aromatic taste. That from the island of Madagascar has a greenish tint.

TAFFETY is a light silk fabric, with a considerable lustre or gloss.

TAFIA is a variety of rum. See RUM.

TALC is a mineral genus, which is divided into two species, the common and the indurated. The first occurs massive, disseminated in plates, imitative, or crystallised in small six-sided tables. It is splendent, pearly, or semi-metallic, translucent, flexible, but not elastic. It yields to the nail; spec. grav. 2·77. Before the blowpipe, it first whitens, and then fuses into an enamel globule. It consists of—silica, 62; magnesia, 27; alumina, 1·5; oxide of iron, 3·5; water, 6. Klaproth found 2½ per cent. of potash in it. It is found in beds of clay-slate and mica-slate, in Aberdeenshire, Banffshire, Perthshire, Salzburg, the Tyrol, and St. Gothard. It is an ingredient in rouge for the toilette, communicating softness to the skin. It gives the flesh polish to soft alabaster figures, and is also used in porcelain paste.

The second species, or talc-slate, has a greenish-grey colour; is massive, with tabular fragments, translucent on the edges, soft, with a white streak; easily cut or broken, but is not flexible; and has a greasy feel. It occurs in the same localities as the preceding. It is employed in the porcelain and crayon manufactures; as also as a crayon itself, by carpenters, tailors, and glaziers. See STEATITE.

TALLOW (*Suif*, Fr.; *Talg*, Germ.); is the concrete fat of quadrupeds and man. That of the ox consists of 76 parts of stearine, and 24 of oleine; that of the sheep contains somewhat more stearine. See FAT and STEARINE.

Tallow *imported* into the United Kingdom in 1850, 1,240,645 cwts.; in 1851, 1,223,597 cwts. Retained for home consumption in 1850, 1,219,101 cwts.; in 1851, 1,085,660 cwts. Duty received, 1850, 78,270*l.*; 1851, 68,035*l.*

Under the article FAT the conditions of tallow and its mode of occurrence are fully dealt with.

Ox tallow was alone used formerly, and our great supply was from Russia. Australia now, however, exports to Europe a large quantity of mutton tallow, and America does also a large trade.

The drier the food upon which animals are fed the more solid is the tallow; hence the Russian tallow is the best, the animals being fed for eight months of the year on dry fodder.

In the animal the tallow exists in separate globules, and the object of melting it out is to combine all these into one mass. The *rendering* of tallow, as it is termed, consists in cutting the fat into small pieces, and placing it in a pan over a naked fire. The heat is regulated, and the first action is the bursting of the cells; these pour out their milky contents, which become clear gradually, as the water which it contains is evaporated.

Mechanical power is sometimes applied to aid in the rendering. The fat is placed under a mill-stone working on edge, and thus the cells are torn or crushed, and when this is once effected, the tallow separates with great ease at a moderate temperature. Dorrett employed weak sulphuric acid to act upon the tallow, by mixing this acid with boiling water, and retaining it after the fat has been placed within it, until the separation of the fatty matter is completed. Some admit steam to the melting mass, by which a larger quantity of tallow appears to be obtained. Tallow is generally so impure, that it has to be clarified by the candle maker. This is effected by remelting the tallow, and mixing with it some substances which render insoluble the gelatinous matters, and precipitate the adventitious admixtures. See CANDLES and FAT.

Our *importations* of tallow in 1858 were :—

	Cwts.	Computed real value.
Russia	1,004,563	£2,460,375
Prussia	8,036	21,210
Hamburg	6,021	15,682
Belgium	6,491	16,779
France	22,664	58,659
Turkey Proper	10,087	23,006
United States	14,945	38,635
Uruguay	38,425	97,881
Buenos Ayres	58,856	147,460
British East Indies	9,673	24,762
Australia	46,973	115,710
Other parts	9,055	22,222
	1,235,789	£3,042,381

The duty on tallow imported from British possessions is 1*d.* per cwt.

On that not derived from British possessions 1*s.* 6*d.* per cwt.

TALLOW, PINEY. See OILS.

TAMPING is a term used by miners to express the filling up of the hole which they have bored in a rock, after the gunpowder for blasting has been placed in the bottom of the hole, with sand, the debris of the rock or other matters. This, being beaten hard together, presents nearly as much resistance to the mechanical force of the powder, when exploded, as the rock itself See MINES.

TANGLE. *Laminaria digitata* of Lamoroux. See ALGÆ.

TANNIN, or TANNIC ACID. (*Tannin*, Fr.; *Gertstoff*, Germ.) Under the name *tannin* was formerly understood all those astringent principles which were capable of combining with the skins of animals to form leather, of precipitating gelatine, of forming bluish black precipitates with the persalts of iron, and of yielding nearly insoluble compounds with some of the organic alkalies. But it has of late years been proved that there are several different kinds of tannic acid, most of which possess an acid reaction.

These principles are widely diffused in the vegetable kingdom; most of our forest trees, as the oak, elm, pines, firs, &c.; pear and plum trees contain it in variable quantities.

It is also found in some fruits. Many shrubs, as the sumach and whortleberry, also contain it in large quantities, and on that account are largely used in dyeing and tanning. The roots of the tormentilla and bistort are also powerfully astringent from containing it. Coffee and tea also contain a modification of this principle. The astringent principle in all the above mentioned (except coffee) precipitate the persalts of iron bluish black, or if a free acid be present the solution becomes dark green. The astringent principle of many vegetables precipitate the persalts of iron of a dark green,—such are catechu, kino, &c. Some few plants contain another modification of this astringent principle, which precipitates the persalts of iron of a grey colour,—such are rhatany, the common nettle, &c.

Many of these tannic acids have received names which refer to the plants from which they are obtained. The most important and best known of all these is the *gallo-tannic acid*, or that which is extracted from gall-nuts. There are also *querci-tannic acid*, from the oak; *moritannic acid*, or that from the fustic (*morus tinctoria*), &c.

The only one which need be described here is the *gallo-tannic* acid; it is, in fact, the only one which is perfectly known. It is usually obtained from the gall-nuts, which are excrescences formed on the leaves of a species of oak (*quercus infectoria*), by the puncture of a small insect, by the process first proposed by M. Pelouze, which consists in exhausting the powdered gall-nuts by allowing ordinary ether to percolate through them in a proper apparatus. The ether, which always contains some water, separates in the bottom of the apparatus into two distinct layers, the under one, being the water, containing all the tannic acid, and the upper one the ether, containing the gallic acid and colouring matter. The solution of tannic acid is washed with ether and evaporated gently to dryness, when the gallo-tannic acid is left as a pale buff-coloured amorphous residue.

Some gall-nuts contain as much as 67 per cent. of gallo-tannic acid, and about 2 per cent of gallic acid (Guibourt). Gallo-tannic acid is freely soluble in water, soluble in diluted alcohol, slightly in ether. The tannic acids are all remarkable for the avidity with which they absorb oxygen; the *gallo-tannic* acid becoming *gallic* acid.

A saturated aqueous solution of gallo-tannic acid is precipitated by sulphuric, hydrochloric, phosphoric, and some other acids. When boiled for some time with diluted sulphuric or hydrochloric acid it is converted into sugar and gallic acid (Strecker); the latter crystallises on cooling, while the glucose remains in solution.

$$\underbrace{C^{54}H^{22}O^{34}}_{\text{Gallo-tannic acid.}} + 10HO = \underbrace{3(3HO\ C^{14}H^{3}O^{7})}_{\text{Gallic acid.}} + \underbrace{C^{12}H^{12}O^{12}\ 2aq.}_{\text{Glucose.}}$$

The composition of the gallo-tannates is but imperfectly known, and it is not decided if the acid be dibasic or tribasic. A solution of gallo-tannic acid gives, with persalts of iron, a bluish black precipitate, which is the basis of ordinary black writing ink. The most remarkable compound of gallo-tannic acid is that which it forms with gelatine, which is the basis of leather. See TANNING.

By the reaction of heat gallo-tannic acid is converted into pyrogallic acid, and this distinguishes it from the other species of tannic acid, as they do not yield pyrogallic acid when subjected to the same treatment.

The following formula will show the relation existing between gallo-tannic acid, gallic acid, and pyrogallic acid.

$$\underbrace{C^{54}H^{22}O^{34}}_{\text{Gallo-tannic acid.}} + 10HO = \underbrace{3(3HO^{1}\ C^{14}H^{3}O^{7})}_{\text{Gallic acid.}} + \underbrace{C^{12}H^{12}O^{12},\ 2\ aq.}_{\text{Glucose.}}$$

$$\underbrace{3HO,\ C^{14}H^{3}O^{7}}_{\text{Gallic acid.}} = \underbrace{C^{12}H^{6}O^{6}}_{\text{Pyrogallic acid.}} + 2CO^{2}$$

When powdered nut-galls are made into a paste, with water, and allowed to ferment for some considerable time, with occasional stirring to facilitate the absorption of oxygen, the gallo-tannic acid is almost entirely converted into gallic acid.

$$\left.\begin{array}{lr} \text{1 eq. tannic acid} & C^{54}H^{22}O^{34} \\ \text{24 eq. oxygen} & O^{24} \\ \hline & C^{54}H^{22}O^{58} \end{array}\right\} = \left\{\begin{array}{lr} \text{3 eq. gallic acid} & C^{42}H^{18}O^{30} \\ \text{4 eq. water} & H^{4}\ O^{4} \\ \text{12 eq. carbonic acid} & C^{12}\quad O^{24} \\ \hline & C^{54}H^{22}O^{58} \end{array}\right.$$

The following is the method proposed by Berzelius *for the purification of tannin with sulphuric acid.*

To a hot infusion of nut-galls in water, add a very small quantity of diluted sulphuric acid, and well shake the mixture; a flocculent coagulum will be formed, containing tannin and extractive, and which, in separating, carries with it any impurities present, in the same manner as in clarifying with white of eggs. Pass the fluid through a filter, and now add sulphuric acid mixed with its own weight of water, in small quantities at a time, until the precipitate, after standing for an hour, is found to form a semi-fluid glutinous mass. As soon as this change is found to have been effected, decant the liquid, and mix with care concentrated sulphuric acid until no further precipitate is formed; a yellowish white mass is thus obtained, which is a combination of sulphuric acid and tannin, and is insoluble in acidulated water. This must be put on a filter; washed with water mixed with a good deal of sulphuric acid; pressed between the filtering paper, and afterwards dissolved in pure water, with which it immediately forms a pale yellow solution. To the solution thus obtained, carbonate of lead in very fine powder is to be added in very small proportions, so as to saturate first the excess of acid, and afterwards, by allowing it to macerate for a short time, that portion of acid combined with the tannin. When the saturation is complete, the colour will become of a more decided yellow. The solution must now be filtered, and evaporated to dryness. The evaporation ought to be conducted *in vacuo*. The hard mass thus obtained will consist of tannin with a portion of *extractive* formed by the excess of the air. This mass being powdered is to be digested with ether, at a temperature of 86° Fahr., until nothing more is taken up by the menstruum; the ether is then allowed to evaporate spontaneously, and the tannin remains in the form of a transparent mass, slightly yellow, which does not change by contact with the air. That which remains undissolved by the ether is a brown extractive, not entirely soluble in water.

Berzelius also gives the following process for *the purification of tannin by means of potash.*

To a filtered infusion of nut-galls, add a concentrated solution of carbonate of potash, so as to form a white precipitate; but too much potash must not be added, as the precipitate is soluble in excess of the alkali. The precipitate, placed on a filter, is to be washed with *ice-cold water*, and afterwards dissolved in diluted acetic acid, which separates a brown extractive matter, formed by the action of the air during the previous washing. Having filtered the solution, precipitate the tannin by means of acetate of lead, wash the precipitate, and decompose it with hydro-sulphuric acid. The tannin will now form a colourless solution with water, and may be obtained in hard scales on the evaporation of the water *in vacuo* over potassa. Any extractive retained in this tannin may be separated by dissolving it in ether and allowing the ether to evaporate spontaneously.

A French pharmacien has observed, that sulphuret of mercury has the property of decolorising tannin, acting in the same way as powdered charcoal does on some substances.

The following Table shows the quantity of extractive matter and tan in 100 parts of the several substances:—

Substances.	In 480, by Davy.	In about 8 oz., by Biggins.	In 100 parts, by Cadet de Gassincourt.
White inner bark of old oak	72	- -	21
Do. young oak	77		
Do. Spanish chestnut	63	30	
Do. Leicester willow	79		
Coloured or middle bark of oak	19

H. K. B.

TANNING. (*Tanner*, Fr.; *Gärberei*, Germ.) This is the name given to the process employed for converting the skins of animals into leather, and is strictly a chemical process, it consisting in the combination of the tannic acid of the different tanning materials with the gelatine of the skins.

Many attempts have been made to quicken the tanning process, but the leather so formed is generally of inferior quality and less durable.

There are many astringent vegetable substances that serve for the process of tanning, but experience has shown that *oak bark* and *valonea* will produce the finest leather.

Skins are divided into three classes; hides, kips, and skins. Hides (properly so called) are the skins of the larger animals, as the buffalo, ox, horse, &c.

Kips are the skins of a small species of cattle which are very abundant in the

East Indies and Russia, but by far the greater number are imported from the East Indies. Small ox and cow hides are sometimes called kips.

Skins (so called) are the skins of the sheep, goat, and other small animals; thus no one would speak of a sheep's hide, or an ox skin. Each of these classes of skins require somewhat different processes for tanning, which we shall now proceed to describe.

Sole leather. — English ox, South American, and Australian wet and dry salted ox and cow hides are principally employed in the manufacture of this description of leather.

Dry salted hides are first soaked in water until sufficiently softened for the liming process; the time required varying from a week to a month, according to the time of the year, dryness of the hides, &c.

Wet salted hides and fresh market hides are merely soaked the day before they are limed.

Liming process. — The hides are first placed in milk of lime, which has served for the last liming of previous skins; they are placed horizontally one upon the other, and at the end of a week they are removed to a new milk of lime, in which they remain about ten days; during the whole of this period, which occupies from sixteen to twenty days, they are *drawn*, that is pulled up and down twice or three times a week, according to their age in the lime pit.

Depilation. — This is the next process, and for which the lime treatment prepares the hides. The hide is placed on a convex beam, and the hair is then taken off by means of a concave tool, having two handles, called a "worker," which, moved rapidly up and down over the surface of the hide, rubs off the hair. The *offal* (bellies and shoulders) is then cut off.

The next process is *fleshing*, which consists in the removal of the flesh which is left adhering to the hide after flaying. It is effected on the same convex beam, by the means of a two-handled knife similar in shape to the rubber above described, but having two sharp edges. During these processes the hides are repeatedly washed, and are ready for the tanning process, after being *scudded*, that is the working out of the lime from the pores, by rubbing the rubber rapidly up and down over the hide.

The *tan-pits* were formerly made with boards from 6 to 8 inches apart, having clay puddled between them, or else were built of stone or brick; stone and brick are doubtless the best, since they are far more durable, and also avoid the exudation of the mud from between the boards when the pits become old. A somewhat newer method is to construct them of planks 3 inches thick, placed vertically and fastened by an iron bolt, which runs through each plank from the top to the bottom of the pit. Before describing the tanning process we will just mention the way in which the liquors are made.

A certain quantity of bark, or other tanning material, is thrown into an empty pit or "letch," as it is called, and the strongest liquor which can be spared from the tanning pits is pumped over it and allowed to stand from two days to a week, and is then drawn off for the leather pits, and often the liquor which it replaces is pumped back on the letch in the place of it. When the tan is thus partially exhausted it is cast over into another pit, called the "spender," in which it is usually boiled with fresh water before being thrown away. The spenders are the only letches that are "watered up," the liquors being pumped back in rotation, a weak one on a stronger, and so on.

Tanning process. — Butts (thick skins for sole leather) are first immersed in a weak liquor, and are passed on from time to time into a stronger, as they become more tanned, the strength of which varies from 5° to 65° of the common hydrometer, which stands at 0° in distilled water. Great care must be taken that the hide is not kept too long in the weak liquors, as they will soften it and dissolve a considerable quantity of the gelatine of the hide; in fact, too weak liquors soften the hide nearly as much as the bate of pigeons' dung.

During the first few weeks the butts require to be frequently "handled," that is taken out and put in again, the object of which is to present a fresh portion of the liquid to the hide. There are various methods of effecting this; hitherto the one most in use is the following: — Two men stand at opposite corners of the pit, each with a hook attached to a long handle, and with "rising poles;" with the latter they elevate several hides at a time, and with the former they throw them up separately on the top of the next pit. Latterly many tanners suspend the butts on poles placed across the top of the pits used in the first part of the tanning process, when they require to be handled so often; by this means a great saving of labour is effected, and the leather is better "coloured off," as the liquor surrounds the hide.

The next step is to "lay away" the butts. A layer of butts is formed by strewing some bark or valonia, as the case may be, between the butts alternately; in new tanyards the pits generally hold a hundred butts. At first the layers are renewed once a week, then once in two weeks, and lastly every three or four weeks till the butts are completely tanned. Each time a fresh layer is made the strength of the liquor should be increased, until the maximum strength required is arrived at, and which is regulated to suit the sort of hide being tanned.

The time occupied in tanning ordinary sole leather varies from seven to twelve months, according to the weight of the hide, &c.; buffalo hides require from eighteen to twenty-four months to tan. Bellies are tanned in about three months, being first handled in the liquors for nine or ten weeks, and then laid away in the same manner as the butts, for the remainder of the time. They are chiefly cut up for insole, as they would never make a firm leather. When perfectly tanned they are hung up in drying sheds, with their thickest part always towards the wind, and when of a proper "temper" (dryness), they are "broken down" or rolled, then struck with a "pin," a three-edged sharp knife, which is passed with considerable pressure over the surface of the leather to take out the creases, and if wished to scrape off the *bloom* or deposit from the liquors on the leather; this is done in the north of England, and makes the leather of a redder hue. In the west of England as much bloom as possible is preferred.

The butts are then rolled two or three times more in order to compress the leather and make it firm. When quite dry a little bees'-wax and turpentine is rubbed over the grain to give a polish; after this the leather is ready for sale. Butts are used for sole leather, machinery straps, pumps, and many other purposes.

Upper leather. — Kips are chiefly employed for this purpose, and are imported either dry salted, or brined, but in either case the process is the same.

The first process is to soak them in water; they are then submitted to the action of stocks, similar in construction to fulling stocks, for two hours; this is to soften them all through alike, and to remove the hair, which is very short; they are next put into milk of lime, as described under butts. They are then fleshed in a similar manner to butts, and afterwards immersed in a bate of pigeons', fowls', or dogs' dung for two or three days, which softens them. It is curious that no substitute has yet been found for these substances; one tanner told me it cost him at least 100*l.* a year for pigeons' dung. In India, bullocks' blood is used for the purpose, and answers, but the smell from it is very offensive.

After being "grained" the kips are placed again in the stocks for twenty minutes, and are then ready for tanning.

The usual time allowed for tanning kips is six weeks; they are first placed in the weakest of a set of six pits, and shifted every day, except the two forward ones, which are shifted every alternate day, having a fresh liquor. They are afterwards placed in a warm decoction of *sumach*, principally for the colour which it imparts. When properly tanned they are dried in sheds in the same manner as butts, then oiled with some cheap oil, and again dried, and are then ready for the currier to prepare for the upper leather of boots, &c., &c.

Seal skins are imported in considerable numbers, and are principally used for women's and children's boots and shoes. Many other kinds of skins are used, but the above are the principal ones.

Skins (properly so-called). Sheep and goat skins are prepared for use in various ways, the usual tanning substance being sumach and bark. See Leather.

The *offals* (bellies, &c.) are often tanned at Warrington and other places in the north, by placing them in a barrel, two thirds filled with liquor, which is kept slowly revolving; by this means the skins are constantly being exposed to fresh portions of the liquid, and saves the labour of handling.

There have been several patents for quickening the tanning process, but we shall only mention one or two here.

The following is taken from the Bavarian Journal of Arts and Trades, and is known as Knoderer's tanning process.

It is well known that the absence of atmospheric air greatly facilitates the process of tanning, and in order to effect this the process must be carried on *in vacuo.*

The vessel, in which the tanning substance is kept, has to be made air tight, and at the same time no metal can be used but the expensive one, copper. Iron, as well as zinc, is affected by the tanning substance, and wood can only be used when its pores have been stopped by some varnish which effectually prevents the passage of air into the vessel.

The process is carried on as follows:— When the hides are taken from the wash, all the water contained in them is expelled by a powerful press. They are then placed in a barrel, having a rotatory motion, together with the necessary amount of tanning material, and enough water added to keep the contents of the barrel moist.

The man-hole is now closed, and the air pumped out as completely as possible;

this being done, the stop-cock is closed, and a piece of lead pipe is added to the conducting tube; this lead pipe communicates with a tank which contains tanning fluid of proper strength. If the stop-cock is now opened, the tanning fluid rushes rapidly into the barrel, and when a sufficient quantity has been admitted, the stop-cock is closed, and the barrel is now rotated for an hour, or half an hour, according to the quantity of hides contained in it. After two or three hours' rest, the rotation is again continued to the end of the operation.

The advantages of this process are, first by the air being rarefied the pores of the skins are opened, and thus more rapidly absorb the tanning principle; and the tannic acid is not so rapidly converted into *gallic acid*, which is of no use in tanning.

Secondly, the rotatory motion facilitates the extraction of the tannic acid from the bark, &c. Thus the hides are completely tanned in a much less time than without rotatory motion, as will be seen by the following table, based on actual experiments.

	Time required for tanning, *in vacuo*, without motion.		Time required when motion is employed.	
Calf skins - -	from 6	to 11 days. - -	4	to 7 days.
Horse hides - -	35	40 - -	14	18
Light cow hides -	30	35 - -	12	16
Cow hides (middling)	40	45 - -	18	20
Heavy cow hides -	50	60 - -	22	30
Ox hides (light) -	50	60 - -	20	30
Ox hides (first quality)	70	90 - -	35	40

At the same time a large per centage of bark is saved.

A patent was taken out by E. Welsford, of Bona, Algeria, in 1859. Instead of employing oak bark or the ordinary tanning substances, he uses the leaves of the different trees and shrubs of the family *Terebinthaceæ*, as the *Pistacea terebinthus*, *Pistacea Atlantica*, *Pistacea lentiscus*, &c., abounding on the coast of the Mediterranean and elsewhere. He forms an infusion or decoction of the leaves for tanning.

A machine has been invented by Mr. S. F. Cox, of Bristol, for effecting the various processes of depiling, scudding, striking, smoothing, sticking, and stretching, which are now usually effected by hand. The hide or skin is carried by a cylinder or roller, or by a moving bed or platform which presents it gradually to a revolving spiral bar rib knife or rubber. The spiral consists of a right and left handed screw, so arranged as to rub or scrape the hide, &c. from the centre towards the sides, or it may consist of a single thread of a screw, or several.

The roller or bed which carries the hide or skin is pressed towards the revolving spiral instruments by springs or otherwise, and is gradually advanced by a ratchet, so that the whole of the hide is uniformly and successively exposed to the action of the revolving spiral instruments. A treadle is employed for withdrawing the roller or bed from the revolving spiral to facilitate the adjustment of the hide.

Vegetable Substances used in Tanning.

No two substances will produce the same quality leather, either in texture or colour. Doubtless this is owing to a different variety of tannic acid contained in the materi·., though unfortunately very little is understood about it, the subject not having been much studied. Some things contain a large proportion of tannin but do no not fill up the pores of the hide; gambir, for instance, tans quickly, but does not make a heavy leather.

Oak bark (*Quercus pedunculata*).— This bark is preferred to all other materials for tanning, since it produces the best leather for most purposes. The oak bark of this country is considered superior to that of any other part of Europe. The bark season in England is usually from the middle of April to the end of May. It is essential that the sap should run well before the bark is stripped, as it contains most tannin when the sap begins to run.

English coppice oak bark.— This bark is very similar to timber oak bark, but is lighter and thinner, and contains more tannin, as there is not so much epidermis, (which contains none). It is preferred for tanning light goods. Coppice bark is stripped at the same time of year as the heavier sorts.

Belgium oak bark.— This bark is similar to the English, and is imported, chopped into small pieces, chiefly from Antwerp; it does not sell for so high a price as the English, for it is said not to contain so much tannin.

Chopped bark is simply bark with the rough epidermis scraped off and then chopped into pieces.

Cork-tree bark (*Quercus suber*).—This is the inner bark of the cork tree, the cork growing on the exterior contains no tannin. It is imported from the Island of Sardinia, Tuscany, and the coast of Africa; the Sardinian is the best, and may easily be distinguished by its colour and weight, being of a pinkish hue throughout, and is stouter and heavier than the Tuscan or African. Cork-tree bark contains a great deal of tannin, but deposits little "bloom" on the leather.

There are four species of oak chiefly used for tanning in America. Spanish oak bark is thick, black, and deeply furrowed, and is preferred for coarse leather. In the southern states the Spanish oak grows to the height of 80 feet with a diameter of 4 or 5 feet at the trunk, while in the north it does not exceed the height of 30 feet.

The common red oak, abundant in Canada and in the Northern States, is very generally employed, though inferior in several respects to the other kinds.

The rock chestnut oak abounds in elevated districts. On some of the Alleghany mountains it constitutes nine-tenths of the forest growth; its bark is thick, hard, and deeply furrowed, but only the bark of the small branches and young trees is used in tanning.

Quercitron bark (*Quercus tinctoria*), or black oak, grows through the States; its bark is not very thick, but deeply furrowed, and of a deep brown colour, the leather tanned with it is apt to tinge the stockings yellow. This tree often attains a height of 90 feet, and a diameter of 4 or 5 feet.

There are other varieties used, but it is needless to mention them here.

Valonia, (*Quercus ægilops*).—Valonia is the acorn cup of the *Quercus ægilops*. See LEATHER.

Sumac of commerce is the crushed or ground leaves of *Rhus corriaria*, and is imported from Sicily. In making the usual ground sumac the larger branches or sticks are taken out by hand; the smaller ones do not pulverise, and are taken out by sifting, the stem of the leaves are put under the mill a secoud time. In grinding the calculation is that 333 lbs. of leaves turn out 280 lbs. of fine ground sumac.

There is naturally, or at least unavoidably, from 3 to 4 per cent. of sand or dirt in the leaves as sent to the mills; this can only be taken out before grinding, but if thoroughly done would cost 1*s.* 6*d.* cwt. additional, which the trade will not pay.

Mimosa bark, is the bark of a tree belonging to the order *Fabaceæ*, subdivision *Mimosæ*. It is imported from Australia and Tasmania, but is also abundant in the East Indies. Mimosa bark is difficult to grind, it is also difficult to extract the tannin; it deposits no bloom, and is, therefore, not much esteemed by English tanners, but is used in the East Indies to a large extent.

Gambir, or *terra japonica*.—This astringent substance, sometimes called catechu, is produced by boiling and evaporating the brown hard wood of the acacia catechu in water, until the inspissated juice has acquired a proper consistency; the liquor is then strained, and soon coagulates into a mass.

It is frequently mixed with sand and other impurities, has little smell, but a sweet astringent taste in the mouth, and is gritty if it is perfectly pure; it will totally dissolve in water, and the impurities will fall to the bottom. It is chiefly used in England as in the East Indies (whence it is imported) for tanning kips. It is mixed with valonia and sumac.

Larch bark is used for tanning basils (sheepskins), for bookbinding, &c., principally in Scotland, where the bark is more abundant, though it is also used in England and Ireland.

Birch bark is used for tanning Russia leather; it is also used by the Laplanders.

Hemlock bark (*Abies Canadensis*), is one of the principal barks used in America for tanning; it makes a reddish coloured leather, and not nearly so good as oak bark leather.

There is a large collection of tanning materials in the Museum at the Royal Gardens at Kew, collected by Mr. W. G. Fry of Bristol, to whom we are indebted for the practical part of this paper.—H. K. B.

TANTALUM. This is an exceedingly rare substance; it is found in the minerals *tantalite* and *yttro-tantalite*. It was first discovered by Mr. Hutchett, in a mineral brought from North America, and he called it, on that account, *columbium*.

Ekeberg discovered it in the Swedish minerals, and, considering it a *new* metal, he called it *tantalum*. Dr. Wollaston, in 1809, proved that Hutchett's *columbium* aud Ekeberg's *tantalum* were both the same substance.

It has not yet been applied to any commercial purpose. — H. K. B.

TAP CINDER. Puddling furnace slag. See IRON and SLAG.

TAPESTRY is an ornamental figured textile fabric of worsted or silk, for lining the walls of apartments; of which the most famous is that of the Gobelins Royal Manufactory, near Paris. See the several articles of CARPETS, LACE, TEXTILE FABRICS, WEAVING.

TAPIOCA. (*Manioc* and *Cipipa*, Fr.; *Weisse Sago*, Germ.) Tapioca is cassava meal, which, while moist or damp, has been heated, for the purpose of drying it, on hot plates. By this treatment the starch grains swell, many of them burst, and the whole agglomerates in small irregular masses or lumps. The drying to which it is subjected renders it difficult of solution. In boiling water it swells up, and forms a viscous jelly-like mass. See STARCH.

Tapioca *imported* in 1858, 9010 cwts.

TAR (COAL). A few years since Dr. Ure wrote as follows:—There is not perhaps any waste article of our manufacturing industry which has been so singularly neglected as coal-tar, and yet there can be but very few which offer anything like so fair a field of remuneration for the exercise of skill and ingenuity. To begin: the article has hitherto been, and still in great measure continues, entirely valueless; it has in fact only a nominal price in the market, as is evidenced by the circumstance that it is consumed as fuel at many of our large metropolitan gas works, and at others is sold as low as at the rate of one penny for 5 gallons. This latter is, however, far from its real value even as fuel, for it has been found in practice that the average heating power of tar, as compared with coke, upon a long series of workings, is as more than two to one, or in other words, that a gallon of tar weighing about 10½ lbs. affords as much heat as half a bushel or 22 lbs. of good coke, and this too although the tar contains about one pound of water entangled in its substance or chemically combined, so as not to be separable by long standing. As we have before said, the tar thus adulterated with water is still equal to more than double its weight of good coke as a heating agent, when tested upon a large working scale for many months in succession. The high heating power of coal-tar ought to induce the managers of gas works either to use it themselves, or, where this cannot be done, to vend it at a price proportioned to its value in coke; thus, presuming a bushel of coke to be worth 4*d.*, then a gallon of tar as fuel would be worth 2*d.*; whereas, as we have seen, this tar has been sold as low as 5 gallons for one penny, a most convincing proof of the expensive nature of ignorance in some situations.

The consumption of tar as fuel is, however, after all, but a barbarous misapplication of ingenuity, and far beneath the intelligence of the age. This substance, when properly distilled, is capable of yielding naphtha, a fixed oil, and pitch, the two former of which are vastly more valuable than tar. The relative proportion of these products is, however, very variable, according to the kind and quality of the tar employed. Thus tar from the condenser is more valuable for its products than the tar of the same coal taken from the hydraulic main, and again cannel coal tar is always superior to common coal-tar. In general we may estimate the available amount of the volatile and fixed matters of coal somewhat in the following order:—

	Naphtha.	Dead oil.	Pitch.
Common coal tar	3	62	35
Ordinary cannel tar	9	60	31
Boghead cannel tar	15	67	18

Of these the naphtha is in large demand for the solution of caoutchouc, the lighting of lamps, and other purposes. The dead oil contains paraffine, and is an excellent lubricator for machinery: the uses of pitch need not be enumerated. By reference to the articles COAL-GAS, DESTRUCTIVE DISTILLATION, NAPHTHA, and others, it will be seen what chemistry has done with *coal-tar*. Every ton of coal distilled for gas yields from 10 to 12 gallons of tar. See TARTAR, WOOD.

TAR, WOOD (*Goudron*, Fr.; *Ther*, Germ.), is the viscid, brown-black, resino-oleaginous compound, obtained by distilling wood in close vessels, or in ovens of a peculiar construction. *Stockholm tar*, *Archangel tar*, and *American tar* come into our markets. According to Reichenbach, tar contains the peculiar proximate principles, *paraffine*, *eupion*, *creosote*, *picamar*, *pittacal*, besides pyrogenous resin, or *pyretine*, pyrogenous oil, or *pyroleine*, and vinegar. The resin, oil, and vinegar are called empyreumatic, in common language.

TARE, or VETCH, a plant—*Vicia sativa*—which has been cultivated in this country from the earliest times.

TARPAULIN (from *Tar*). Canvas imbued with tar, used to cover the hatchways of a ship to prevent rain or sea water from entering the hold, and for numerous other similar purposes.

TARSAS. See TRASS.

TARTAR (*Tartre*, Fr.; *Weinstein*, Germ.); called also argal or argol; is the crude bitartrate of potassa, which exists in the juice of the grape, and is deposited from wines in their fermenting casks, being precipitated in proportion as the alcohol is formed, in consequence of its insolubility in that liquid. There are two sorts of argal known in commerce, the white and the red; the former, which is of a pale-pinkish colour, is the crust let fall by white wines; the latter is a dark-red, from red wines.

The crude tartar is purified, or converted into cream of tartar, at Montpelier, by the following process:—

The argal having been ground under vertical mill-stones and sifted, one part of it is boiled with 15 of water in conical copper kettles tinned on the inside. As soon as it is dissolved, 3½ parts of ground pipe-clay are introduced. The solution being well stirred and then settled, is drawn off into crystallising vessels to cool; the crystals found concreted on the sides and bottom are picked out, washed with water, and dried. The mother-water is employed upon a fresh portion of argal. The crystals of the first crop are re-dissolved, re-crystallised, and exposed upon stretched canvas to the sun and air, to be bleached. The clay serves to abstract the colouring matter. The crystals formed upon the surface are the whitest, whence the name cream of tartar is derived.

Purified tartar, the bitartrate of potash, is thus obtained in hard clusters of small colourless crystals, which, examined by a lens, are seen to be transparent four-sided prisms. It has no smell, but a feebly acid taste; is unchangeable in the air, has a specific gravity of 1·953, dissolves in 16 parts of boiling water, and in 200 parts at 60° Fahr. It is insoluble in alcohol. It consists of 24·956 potash, 70·276 tartaric acid, and 4·768 water. See Argol, Potash, Bitartrate.

TARTARIC ACID, (*Acide tartrique*, Fr.; *Weinsteinsäure*, Germ.) This is prepared by adding gradually to a boiling-hot solution of 100 parts of tartar, *bitartrate of potash*, in a large copper boiler, 26 of chalk, *carbonate of lime*, made into a smooth pap with water. A brisk effervescence ensues, from the disengagement of the carbonic acid of the chalk, while its base combines with the acid excess in the tartar, and forms an insoluble precipitate of tartrate of lime. The supernatant liquor, which is a solution of neutral tartrate of potassa, must be drawn off by a syphon, and decomposed by a solution of chloride of calcium (muriate of lime). 28½ parts of the dry chloride are sufficient for 100 of tartar. The tartrate of lime, from both processes, is to be washed with water, drained, and then subjected in a leaden cistern to the action of 49 parts of sulphuric acid, previously diluted with 8 times its weight of water: 100 of dry tartrate take 75 of oil of vitriol. This mixture, after digestion for a few days, is converted into sulphate of lime and tartaric acid. The latter is to be separated from the former by decantation, filtration through canvas, and elutriation of the sulphate of lime upon the filter.

The clear acid is to be concentrated in leaden pans by a moderate heat, till it acquires the density of 40° B. (spec. grav. 1·38), and then it is run off, clear from any sediment, into leaden or stoneware vessels, which are set in a dry stove-room for it to crystallise. The crystals, being re-dissolved and re-crystallised, become colourless six-sided prisms. In decomposing the tartrate of lime, a very slight excess of sulphuric acid must be employed, because pure tartaric acid would dissolve any tartrate of lime that may escape decomposition. Bone black, previously freed from its carbonate and phosphate of lime, by muriatic acid, is sometimes employed to bleach the coloured solutions of the first crystals. Tartaric acid contains nearly 9 per cent. of combined water. It is soluble in two parts of water at 60°, and in its own weight of boiling water. In its dry state, as it exists in the tartrate of lime or lead, it consists of 36·8 of carbon, 3 of hydrogen, and 60·2 of oxygen. It is much employed in calico-printing, and for making sodaic powders.

In consequence of the great variation in the constituents of argol or rough tartar, the manufacture of tartaric acid is not nearly so simple as a first glance at its several processes might lead an inexperienced individual to suppose. The theory of preparing tartaric acid seems, indeed, a remarkably easy affair; and provided the materials operated upon were pure, or of uniform quality, no kind of manufacture could put on less the appearance of risk or speculation. But too many know, to their cost, with what ready facility the whole profit, and something more, of a large operation will occasionally ooze off through a variety of unknown channels, and present a sadly defective and truncated return of saleable produce. In fact, money is not unfrequently lost in this manufacture by very old and experienced makers. The differences in argol arise from the greater or smaller amount of tartrate of lime combined with the bitartrate of potash; these differences will, in a commercial way, amount to from 5 to 25 or even 30 per cent.; and herein resides a difficulty requiring more analytical skill and chemical knowledge than is commonly found amongst practical manufacturers. We will suppose that an argol has been purchased, containing by analysis 70 per cent. of bitartrate of potash, but also, though unknown to the purchaser, containing 20 per cent. of tartrate of lime. According to the process followed, this argol would be dosed with a definite proportion of chalk or carbonate of lime, so as to produce tartrate of lime with the extra tartaric acid of the supertartrate of potash. This tartrate of lime, being insoluble, would fall and mingle with the 20 per cent. already existing; but as in practice the quantity of sulphuric acid employed for subsequent decomposition of this tartrate of lime is proportioned to the amount of chalk originally employed, it follows that the tartrate of lime naturally present in the argol is left undecomposed, and comes to be regarded as sulphate of lime, to the great loss of the manufacturer, who probably finds his more intelligent neighbour able to buy as he buys, and yet capable of underselling him in the open market.

From the above description of the process of manufacture it will be seen that, unless the manufacturer is not only aware of the surplus tartrate of lime present in the rough tartar he buys, but has also a tolerably correct idea of its quantity, he runs a risk, almost amounting to a certainty, of leaving undecomposed tartrate of lime in his sulphate of lime; and as this latter is in great part a waste product, the two pass away from the works under one name, as mere refuse. But there is also an important consideration connected with the evaporation of solutions of tartaric acid. This is generally, and indeed we might say invariably, done in contact with atmospheric air, the solution meanwhile containing a perceptible excess of sulphuric acid; but, under such treatment, tartaric acid undergoes decomposition almost as readily as sugar: and therefore, like sugar, it ought to be operated upon *in vacuo*, or at least in a vessel similar to a vacuum pan, but lined with lead to prevent cupreous contamination. In this way, and by knowing the exact composition of the rough tartar used in every instance, the greatest certainty might be secured in this delicate manufacture.

The composition of tartaric acid, as determined by Berzelius, is carbon, 35·980; hydrogen, 3·807; oxygen, 60·213; or $C^4H^2O^5 + HO$. Liebig regards the equivalent weight as double that assumed, and considers the acid as a bibasic one; according to him, therefore, the formulæ for the crystallised acid is $C^8H^4O^{10} + 2HO$. Fremy has stated that crystallised tartaric acid lost by heating first $\frac{1}{2}HO$, being converted into *tartralic acid*; that it then, by the loss altogether of 1HO, changed into *tartrelic acid*; and that at last, by losing 2HO, it became anhydrous tartaric acid. Various metamorphoses have been stated to occur in tartaric acid upon exposing it to heat. Laurent, Gerhardt, and Pasteur have investigated this matter, and have given the names of *metatartaric acid* and *isotartaric acid* to two of the results. Another acid has been investigated by Arppe, the *pyrotartaric acid*. According to Millon and Reiset, the best mode of preparing it is to distil powdered tartaric acid with powdered pumice-stone. The aqueous is separated from the oily distillate by a wet filter, and evaporated at a gentle heat, till it commences to crystallise. The crystals are digested in nitric acid, then fused to expel the nitric acid, and thus the pure pyrotartaric acid $HO,C^5H^3O^3$ is obtained.

TARTRATES, are bibasic salts composed of tartaric acid and oxidised bases, in equivalent proportions. Some of the tartrates are employed in the arts, bitartrate of potash being used as a mordant in dyeing woollen fabrics. Tartrate of chromium is sometimes used in calico printing, and the tartrate of potash and tin in wool dyeing.

The Stockholm tar is regarded as the best; we have a description of the mode in which it is prepared, by Dr. Clarke, in his *Travels in Scandinavia*.

"The situation most favourable to the process is in a forest near to a marsh or bog, because the roots of the fir, from which tar is principally extracted, are always most productive in such places. A conical cavity is then made in the ground (generally on the side of a bank or sloping hill), and the roots of the fir, together with logs and billets of the same, being neatly trussed in a stack of the same conical shape, are let into the cavity. The whole is then covered with turf to prevent the volatile parts from being dissipated, which, by means of a heavy wooden mallet and wooden stamper, worked separately by two men, is beaten down and rendered as firm as possible about the wood. The stack of billets is then kindled, and a slow combustion of the fir takes place as in working charcoal. During this combustion the tar exudes, and a cast-iron pan being at the bottom of the funnel, with a spout which projects through the side of the bank, barrels are placed beneath this spout to collect the fluid as it comes away. As fast as the barrels are filled they are bunged and ready for immediate exportation.

Wood tar is obtained as a secondary product in the manufacture of acetic acid, in the dry distillation of wood.

Tar *imported*, in 1858, 10,107 lasts.

TAWING, is the process of preparing the white skins of the sheep, doe, &c. See Leather.

TEA (*Thé*, Fr.; *Thee*, Germ.). *Thea*, the tea plant, belongs to the natural order of Lindley *Ternströmiaceæ*. Considerable discussion has taken place with reference to this important substance, some contending that green and black tea are the productions of two different plants, the *Thea viridis* producing the green tea, and the *Thea Bohea* the black tea. There is a third variety, the *Thea Assamensis*, or Assam tea, which appears to resemble both the others. Mr. Fortune appears to have proved that the green and black teas of commerce do not depend upon specific differences, but that in the northern tea districts of China the black and green teas are both obtained from the same species or variety, namely, the *Thea viridis*, while in the Canton tea districts both the varieties of tea are made from the *Thea Bohea*.

The quality of the tea depends much on the season when the leaves are picked, the mode in which it is prepared, as well as on the district in which it grows. Green tea, it is stated, is coloured by the application of an extract of indigo, of Prussian blue, and gypsum, and that the fine odour which renders the "flowery" kinds remarkable is derived from the leaves of *Olea fragrans*, a species of camellia, and other similar plants.

To the black tea belongs the varieties known as *Bohea*, *Congou*, *Campoi*, *Souchong*, *Caper*, and *Pekoe*.

To the green tea, *Twankay*, *Hyson-skin*, *Hyson*, *Imperial*, and *Gunpowder*.

According to Frank, black and green teas are composed as follows: —

	Black.	Green.
Tannin - - - - - -	40·6	34 6
Gum - - - - - - -	6·3	5·9
Woody fibre - - - - - -	44·8	51·3
Glutinous matter - - - -	6·3	5·7
Volatile matter and loss - - -	2·0	2·5
	100·0	100·0

Sir Humphry Davy found more tannin in black than in green tea. This appears contrary to our experience, the astringency of green tea being much greater than that of black tea. Mr. Brande remarks, in the *Quarterly Journal of Science*, "Some years ago I examined the varieties of tea in common use, and found that the quantity of astringent matter precipitable by gelatine is somewhat greater in green than in black tea, though the excess is by no means so great as the comparative flavours of the two would lead us to expect. The entire quantity of soluble matter is also greater in green than in black tea; but the extractive, not precipitable by gelatine, is greater in the latter.

Brande, in his *Manual of Pharmacy*, has given a table from which the following facts are extracted: —

100 parts of Tea.	Soluble in water.	Soluble in alcohol.	Precipitated by jelly.	Insoluble. residue.
Green Hyson — Best -	41	44	31	56
„ Medium -	34	43	26	58
„ Lowest -	31	41	24	57
Black Souchong—Best -	35	36	28	64
„ Medium -	37	35	28	63
„ Lowest -	35	31	23	65

The most remarkable products in tea are — 1st. Tannin. 2nd. An essential oil, to which it owes its aroma, and which has great influence on its commercial value. 3rd. A crystalline substance, very rich in nitrogen, *theine*, which is also met with in coffee (whence it is frequently termed caffeine), and which is likewise found in Guarana, a remedy highly valued by the Brazilians.

Besides these three, M. Mulder extracted from tea eleven other substances, which are usually met with in all leaves. The same chemist found, in the various kinds of tea from China and Java, a little less than a half per cent. of their weight of theine. Dr. Stenhouse, in a recent investigation, obtained from 1·37 to 0·98 theine from 100 parts of tea.

An accurate knowledge of the amount of the nitrogenous principles contained in tea being of the utmost importance, he first determined the total amount of nitrogen contained in the leaf, in order thus to have a safe guide when subsequently isolating the substances between which this nitrogen is distributed.

On determining the nitrogen by M. Dumas's process, he obtained the following numbers: —

	Nitrogen in 100 parts tea dried at 230°.
Pekoe tea - - - - - - - - -	6·58
Gunpowder tea - - - - - - -	6·15
Souchong tea - - - - - - -	6·15
Assam tea - - - - - - - -	5·10

This amount of nitrogen is far more considerable than has been detected in any vegetable hitherto analysed. These first experiments prove, therefore, the existence of from 20 to 30 per cent. of nitrogenous substances in tea, while former analyses scarcely carry the proportion to more than three or four hundredths. He sought for these substances successively in the products of the leaf soluble in boiling water, in those which do not dissolve in water, and in each of the substances which might be separated either from the infusion or from the exhausted leaf.

He first determined the proportion of soluble products which boiling water extracts from tea, and operated upon 27 kinds of tea, taking into consideration the water already contained in the leaf, either from its desiccation in China not having been complete, or from having absorbed during or after its transport a certain quantity of atmospheric water. He found that the green teas contain, on an average, 10, the black teas 8 per cent. of water.

The proportion of products soluble in hot water varies considerably, and depends chiefly upon the age of the leaf, which is younger, and consequently less liqueous, in the green than in the black tea. On an average he found in 100 parts of

	Parts soluble in boiling water.
Dry black teas - - - - - - -	43·2
Dry green teas - - - - - - -	47·1
Black teas in their commercial state - - -	38·4
Green teas do. do. - - - -	43·4

When an infusion of tea is evaporated to dryness, a chocolate brown residue remains, which, when derived from green gunpowder, contains 4·35 per cent. of nitrogen; if from black souchong, 4·70 per cent. nitrogen.

These considerable quantities of nitrogen, do they belong to several principles contained in the infusion, or solely to the theine, which is the only nitrogenous substance hitherto noticed in it? He first endeavoured to solve this question: as the quantitative determination of theine is a difficult operation from its being soluble in water, alcohol, and ether, and not being precipitated by any reagent with the exception of tannin, he first ascertained whether the other substances which might be separated from the infusion contained any nitrogen.

The subacetate of lead throws down about half the soluble constituents contained in this infusion. The precipitate, which is of a more or less dark yellow, according to whether it is derived from green or black tea, contains the whole of the colouring matter, the whole of the tannin, and a peculiar acid, which affords an insoluble salt of a light yellow colour with the sub-acetate of lead.

Dr. Ure found this mixed precipitate to contain very little nitrogen; it is therefore in the portion of the infusion which is not precipitated that the substances containing this element must be sought for.

To determine the amount of theine, M. Mulder evaporates the infusion with caustic magnesia, and treats the residue with ether, which only dissolves out the theine. On modifying this process, Dr. Stenhouse has obtained the following quantities of theine from 100 parts of

Hyson - - - - - - - - -	2·40
Another kind - - - - - - -	2·56
Mixture in equal parts of gunpowder, hyson, imperial, caper and pekoe - - - - -	2·70
Gunpowder - - - - - - - -	4·1
Another kind - - - - - - -	3 5

These quantities are far more considerable than have been obtained either by M. Mulder or Dr. Stenhouse; but, at the same time, they do not account for the total amount of nitrogen of the infusion in the state of theine, for the composition of theine being represented by the formula $C^8H^5N^2O^2$, and this substance containing 29·0 per cent. of nitrogen, gunpowder tea should contain 7·4 and souchong 6·5 theine in 100 parts of these teas taken in their ordinary state, if no other nitrogenous substance accompanied the theine in the solution.

By the following very simple process, Dr. Ure states that he succeeded in obtaining a proportion of theine far more considerable than he at first found. To the hot infusion of tea subacetate of lead and then ammonia are added; the liquid is separated by filtration from the precipitate, and a current of sulphuretted hydrogen passed through it, the sulphuret of lead is removed from the solution, which is evaporated at a gentle heat; on cooling, an abundant crop of crystals of theine is obtained, and the mother lye affords more crystals on cautious evaporation. The first crystals are purified by recrystallisation from water, and then the mother lye is used to dissolve the second crop, so as to have the least possible quantity of mother lye and the largest amount of crystals. In this manner he obtained from 50 grammes of gunpowder tea 1·92 grammes of crystallised theine, which is equal to 3·84 per cent.

But there remains a syrupy liquid which still contains some theine. This he determined by means of a solution of tannin of known strength, which precipitates it alone, and entirely, if the liquid be cold and accurately neutralised with ammonia as the tannin is added.

On adding the fresh quantity of theine, isolated by this reagent, to that obtained as crystals, 100 parts of gunpowder tea, taken in its ordinary state, furnished 5·84 theine; 100 parts of the same tea in its dry state gave 6·22 of this substance.

These numbers approach very nearly to those which should be obtained if theine were the only nitrogenous substance contained in the infusion. There is, however, still a deficit of 0·75 nitrogen. It is possible that the infusion contained some ammoniacal salts, or that a small portion of the theine was decomposed during the evaporation of the liquid: this substance being very liable to alteration, like the compounds rich in nitrogen, which it resembles by its composition and properties.

However this be, it may be concluded from the above experiments — 1. That theine is the principal nitrogenous substance contained in the infusion of tea. 2. That it exists in larger quantity than has hitherto been admitted.

The portion of tea from which boiling water extracted no more soluble principle contained in 100 parts, dried 230°, 4·46 nitrogen for the souchong, and 4·30 for the gunpowder. These quantities, added to those of the infusion, represent very nearly the nitrogen ascertained by analysis to exist in the entire leaf.

On boiling for some time the exhausted leaves in water containing $\frac{1}{10}$ of their weight of potash, a brown liquid is obtained, which affords, on the addition of dilute sulphuric or acetic acid, a considerable flocculent and brown precipitate, which contains 8·45 per cent. nitrogen; the product of another preparation gave 9·93. Alcohol and ether remove from this precipitate about 30 per cent. of a green substance, which appears to contain a fat acid. This product is not pure after this treatment, for it is strongly coloured and contains pectic acid; nevertheless, that which contained 8·45 nitrogen afforded 11·35 of this element after being treated with alcohol and ether. Although I have not obtained this substance in a state of purity, I do not hesitate to consider it, from the general resemblance of its characters, as identical with the caseine from milk.

It is probable that this body exists in the insoluble portion of the leaf in combination with tannin, and that the potash acts by destroying this combination. The presence of this substance in tea is a fact the more worthy of attention as it occurs to a very large amount, if, as is probable, the greater portion of the nitrogen in the exhausted leaf is derived from it. On admitting, with MM. Dumas and Cahours, 16 per cent. of nitrogen in caseine, the exhausted leaves would contain no less than 28 hundredths of this principle; tea in its ordinary state would contain from 14 to 15 per cent.

Dr. Ure found it impossible to separate the whole of this caseine from the tea. He obtained, in one experiment, from 100 parts of exhausted leaves, 35 of the mixture above mentioned, containing from 8 to 10 per cent. nitrogen, which represent from 18 to 20 per cent. of caseine supposed pure; but the leaves, after being treated twice with potash, still contained 2·73 per cent. This nitrogen, in the state of caseine, would represent 5·7 per cent., so that we thus approach very close to the amount of the nitrogen indicated by analysis.

It will be seen from these experiments, that tea contains a proportion of nitrogen altogether exceptional; it must, however, be remembered that the leaf is not taken in its natural state, but that it comes to us after having been manufactured. It is well known that, before being delivered into commerce, tea is submitted to a torrefaction, which softens the leaf and allows of a rather considerable quantity of an acrid and slightly corrosive juice being expressed by means of the pressure of the hands; the leaf is then rolled up, and dried more or less rapidly according to whether green or black tea is to be made from it. Now it is possible that this juice contains little or no nitrogen, and that consequently its separation would increase the amount of nitrogen which remains in the leaf. On determining the quantity contained in fresh leaves from some tea plant cultivated in gardens near Paris, Dr. Ure found 4·37 nitrogen, in 100 parts of the dried tea. Perhaps the difference of climate and mode of culture may suffice to produce these variations.

Preparation of green tea. It is brought to Canton unprepared; as Bohea, *Saushung*, and is thrown into a hemispherical iron pan, kept red-hot over a fire. The leaves are constantly stirred till they are thoroughly heated, when they are dyed, by adding for each pound of tea, 1 spoonful of gypsum, 1 of turmeric, and 2 or three of Prussian blue. The leaves instantly change into a bluish green, and after being well stirred for a few minutes, are taken out, being shrivelled by the heat. They are now sifted; the small longish leaves fall through the first sieve, and form young Hyson; the roundest granular ones fall through the last, and constitute Gunpowder, or Choo-cha.

*The Chinese method of making Black Tea in Upper Assam.**—In the first place, the youngest and most tender leaves are gathered; but when there are many hands and a great quantity of leaves to be collected, the people employed nip off with the forefinger and thumb the fine end of the branch with about four leaves on, and sometimes even more, if they look tender. These are all brought to the place where they are to be converted into tea; they are then put into a large, circular, open-worked bamboo basket, having a rim all round, two fingers broad. The leaves are thinly scattered in these baskets, and then placed in a framework of bamboo, in all appearance like the side of an Indian hut without grass, resting on posts, 2 feet from the ground, with an angle of about 25°. The baskets with leaves are put in this frame to dry in the sun, and are pushed up and brought down by a long bamboo with a circular piece of wood at the end. The leaves are permitted to dry about two hours, being occasionally turned; but the time required for this process depends on the heat of the sun. When they begin to have a slightly withered appearance, they are taken down and brought into the house, where they are placed on a frame to cool for half an hour. They are then put into smaller baskets of the same kind as the former, and placed on a stand. People are now employed to soften the leaves still more, by gently clapping them between their hands, with their fingers and thumb extended, and tossing them up and letting them fall, for about five or ten minutes. They are then again put on the frame during half an hour, and brought down and clapped with the hands as before. This is done three successive times, until the leaves become to the touch like soft leather; the beating and putting away being said to give the tea the black colour and bitter flavour. After this the tea is put into hot cast-iron pans, which are fixed in a circular mud fireplace, so that the flame cannot ascend round the pan to incommode the operator. This pan is well heated by a straw or bamboo fire to a certain degree. About two pounds of the leaves are then put into each hot pan, and spread in such a manner that all the leaves may get the same degree of heat. They are every now and then briskly turned with the naked hand, to prevent a leaf from being burned. When the leaves become inconveniently hot to the hand, they are quickly taken out and delivered to another man with a close-worked bamboo basket ready to receive them. A few leaves that may have been left behind are smartly brushed out with a bamboo broom; all this time a brisk fire is kept up under the pan. After the pan has been used in this manner three or four times, a bucket of cold water is thrown in, and a soft brickbat and bamboo broom used, to give it a good scouring out; the water is thrown out of the pan by the brush on one side, the pan itself being never taken off. The leaves, all hot on the bamboo basket, are laid on a table that has a narrow rim on its back, to prevent these baskets from slipping off when pushed against it. The two pounds of hot leaves are now divided into two or three parcels, and distributed to as many men, who stand up to the table with the leaves right before them, and each placing his legs close together; the leaves are next collected into a ball, which he gently grasps in his left hand, with the thumb extended, the fingers close together, and the hand resting on the little finger. The right hand must be extended in the same manner as the left, but with the palm turned downwards, resting on the top of the ball of tea leaves. Both hands are now employed to roll and propel the ball along: the left hand pushing it on, and allowing it to revolve as it moves; the right hand also pushes it forward, resting on it with some force, and keeping it down to express the juice which the leaves contain. The art lies here in giving the ball a circular motion, and permitting it to turn under and in the hand two or three whole revolutions, before the arms are extended to their full length, and drawing the ball of leaves quickly back without leaving a leaf behind, being rolled for about five minutes in this way. The ball of tea leaves is from time to time gently and delicately opened with the fingers, lifted as high as the face, and then allowed to fall again. This is done two or three times, to separate the leaves; and afterwards the basket with the leaves is lifted up as often, and receives a circular shake to bring these towards the centre. The leaves are now taken back to the hot pans, and spread out in them as before, being again turned with the naked hand, and when hot taken out and rolled: after which they are put into the drying basket, and spread on a sieve which is in the centre of the basket, and the whole placed over a charcoal fire. The fire is very nicely regulated; there must not be the least smoke, and the charcoal should be well picked.

When the fire is lighted, it is fanned until it gets a fine red glare, and the smoke is all gone off; being every now and then stirred and the coals brought into the centre, so as to leave the outer edge low. When the leaves are put into the drying basket, they are gently separated by lifting them up with the fingers of both hands extended far apart, and allowing them to fall down again; they are placed 3 or 4 inches deep on the sieve, leaving a passage in the centre for the hot air to pass. Before it is put

* By C. A. Bruce, superintendent of tea culture.

over the fire, the drying basket receives a smart slap with both hands in the act of lifting it up, which is done to shake down any leaves that might otherwise drop through the sieve, or to prevent them from falling into the fire and occasioning a smoke, which would affect and spoil the tea. This slap on the basket is invariably applied throughout the stages of the tea manufacture. There is always a large basket underneath to receive the small leaves that fall, which are afterwards collected, dried, and added to the other tea; in no case are the baskets or sieves permitted to touch or remain on the ground, but always laid on a receiver with three legs. After the leaves have been half dried in the drying basket, and while they are still soft, they are taken off the fire, and put into large open-worked baskets, and then put on the shelf, in order that the tea may improve in colour.

Next day the leaves are all sorted into large, middling, and small; sometimes there are four sorts. All these, the Chinese informed me, become so many different kinds of teas; the smallest leaves they called Pha-ho, the second Pow-chong, the third Su-chong, and the fourth, or the largest leaves, Toy-chong. After this assortment they are again put on the sieve in the drying basket (taking great care not to mix the sorts), and on the fire, as on the preceding day; but now very little more than will cover the bottom of the sieve is put in at one time, the same care of the fire is taken as before, and the same precaution of tapping the drying basket every now and then. The tea is taken off the fire with the nicest care, for fear of any particle of the tea falling into it. Whenever the drying basket is taken off, it is put on the receiver, the sieve in the drying basket taken out, the tea turned over, the sieve replaced, the tap given, and the basket placed again over the fire. As the tea becomes crisp, it is taken out and thrown into a large receiving basket, until all the quantity on hand has become alike dried and crisp; from which basket it is again removed into the drying basket, but now in much larger quantities. It is then piled up eight and ten inches high on the sieve in the drying basket; in the centre a small passage is left for the hot air to ascend; the fire that was before bright and clear has now ashes thrown on it to deaden its effect, and the shakings that have been collected are put on the top of all; the tap is given, and the basket with the greatest care is put over the fire. Another basket is placed over the whole, to throw back any heat that may ascend. Now and then it is taken off, and put on the receiver; the hands, with the fingers wide apart, are run down the sides of the basket to the sieve, and the tea gently turned over, the passage in the centre again made, &c., and the basket again placed on the fire. It is from time to time examined, and when the leaves have become so crisp that they break by the slighest pressure of the fingers, it is taken off, when the tea is ready. All the different kinds of leaves underwent the same operation. The tea is now little by little put into boxes, and first pressed down with the hands and then with the feet (clean stockings having been previously put on).

There is a small room inside of the tea-house, 7 cubits square and 5 high, having bamboos laid across on the top to support a network of bamboo, and the sides of the room smeared with mud to exclude the air. When there is wet weather, and the leaves cannot be dried in the sun, they are laid out on the top of this room, on the network, on an iron pan, the same as is used to heat the leaves; some fire is put into it, either of grass or bamboo, so that the flame may ascend high; the pan is put on a square wooden frame, that has wooden rollers on its legs, and pushed round and round this little room by one man, while another feeds the fire, the leaves on the top being occasionally turned; when they are a little withered, the fire is taken away, and the leaves brought down and manufactured into tea, in the same manner as if it had been dried in the sun. But this is not a good plan, and never had recourse to if it can possibly be avoided.

The observations of Liebig afford a satisfactory explanation of the cause of the great partiality of the poor, not only for tea, but for tea of an expensive and superior kind. He says, "We shall never certainly be able to discover how men were first led to the use of the hot infusion of the leaves of a certain shrub (tea), or of a decoction of certain roasted seeds (coffee). Some cause there must be which will explain how the practice has become a necessary of life to all nations. But it is still more remarkable, that the beneficial effects of both plants on the health must be ascribed to one and the same substance (*théine* or *caffeine*), the presence of which in two vegetables, belonging to natural families, the products of different quarters of the globe, could hardly have presented itself to the boldest imagination. Yet recent researches have shown, in such a manner as to exclude all doubt, that *théine* and *caffeine* are in all respects identical." And he adds, "That we may consider these vegetable compounds, so remarkable for their action on the brain, and the substance of the organs of motion, as elements of food for organs as yet unknown, which are destined to convert the blood into nervous substance, and thus recruit the energy of the moving and thinking faculties." Such a discovery gives great importance to tea and coffee, in a physiological and medical point of view.

At a meeting of the Academy of Sciences, in Paris, lately held, M. Peligot read a paper on the Chemical Combinations of Tea. He stated, that tea contained essential principles of nutrition, far exceeding in importance its stimulating properties: and showed that tea is, in every respect, one of the most desirable articles of general use. One of his experiments on the nutritious qualities of tea, as compared with those of soup, was decidedly in favour of the former.—See THEINE. Consult *Ure's Dictionary of Chemistry.*

TELEGRAPHS. See ELECTRO-TELEGRAPHY.

TELLURIUM. One of the elementary bodies known to chemists. It is usually classed amongst the metals, but it presents so great an analogy to sulphur and selenium that many are disposed to remove it from the metallic bodies.

Tellurium was originally found in Transylvanian gold ores; and more recently it has been found with bismuth. Tellurium has a silvery lustre, its texture is crystalline and brittle. From its extreme rarity, and consequent cost, it has not yet found any application in the arts.

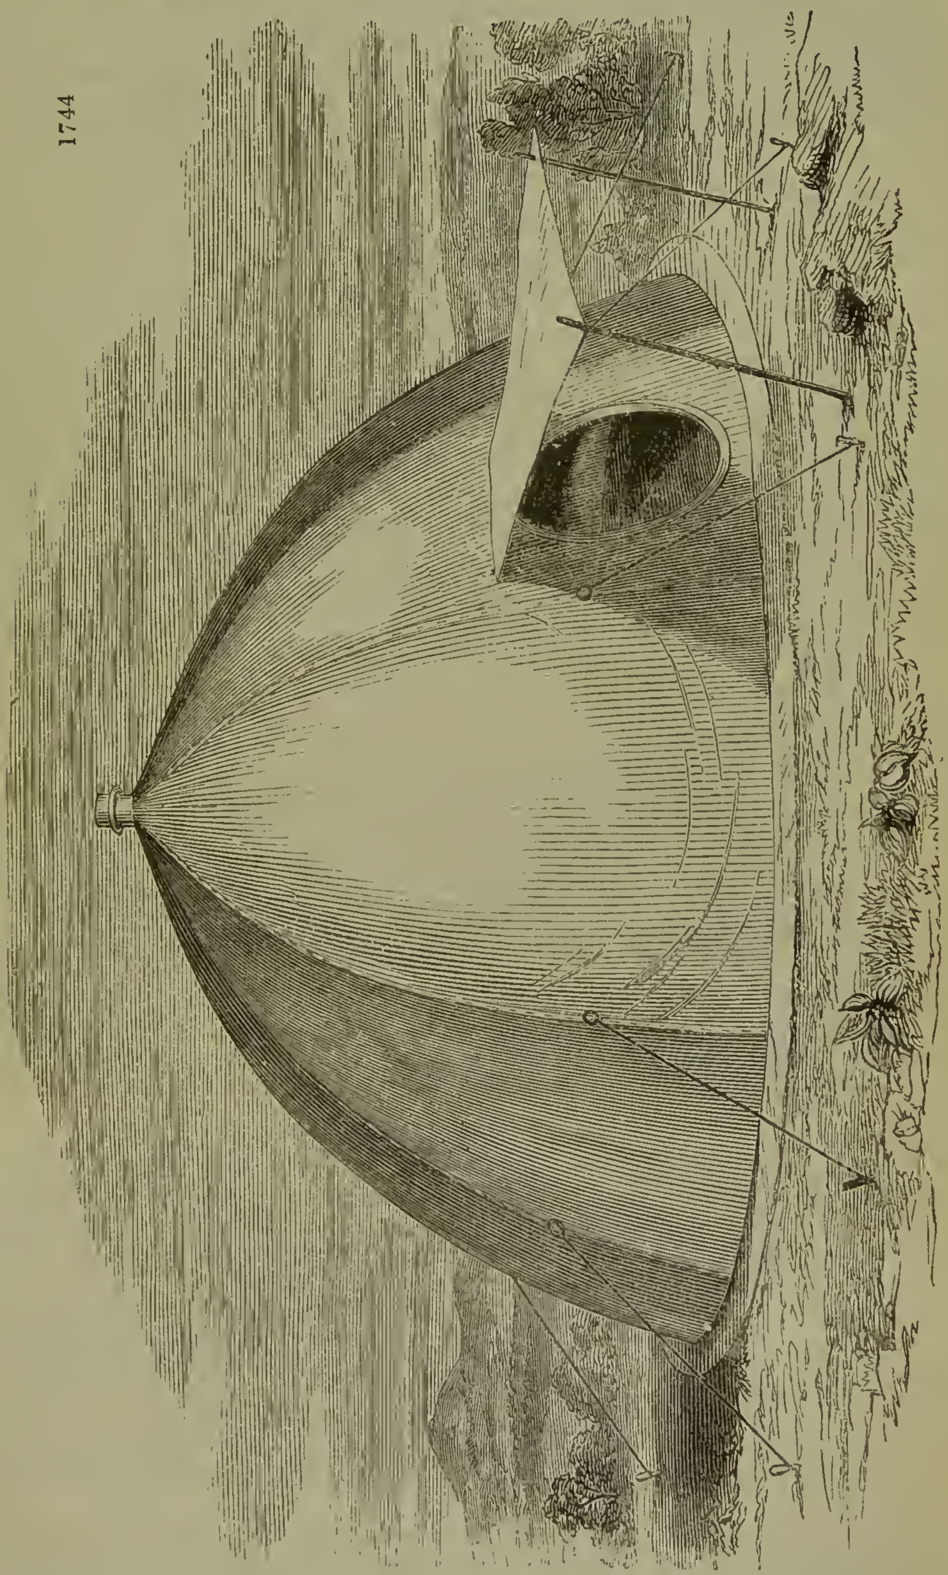
TENT. A portable lodge, consisting of canvas sustained by poles and stretched by cords, used for sheltering men, especially soldiers in camp, from the weather. Tents were commonly used in the earliest periods of man's history. The patriarchal tribes dwelt in tents. Layard describes one of the sculptured stones at Mosul as representing Sennacherib seated on a throne, placed at the entrance of a city. Behind the king was the royal tent supported by ropes, and an inscription, signifying "This is the *tent* of Sennacherib, King of Assyria." This was 700 years before Christ. We learn that Paul was a tent-maker, therefore in those days it was an important calling. The armies of Rome, of the Crusades, and the hosts which have through every age gone forth to the "shock of battles," have ever lodged in tents.

We have no space to enter into the history of tents or describe the varieties which have been used from time to time. A few words on modern tents must suffice:—

The hospital marquee is 29 feet long and 14½ feet wide and 15 feet high. This is supposed to accommodate not less than eighteen or more than twenty-four men. The height of each tent-pole is 13 feet 8 inches; the length of the ridge-pole 13 feet 10 inches; the height of the tent walls from the ground 5 feet 4 inches. The weight of all the material of such a tent is stated by Major Rhodes to be 652 lbs.

Of the *circular single-poled tents* we have two kinds, the new cotton circular tent,

1744

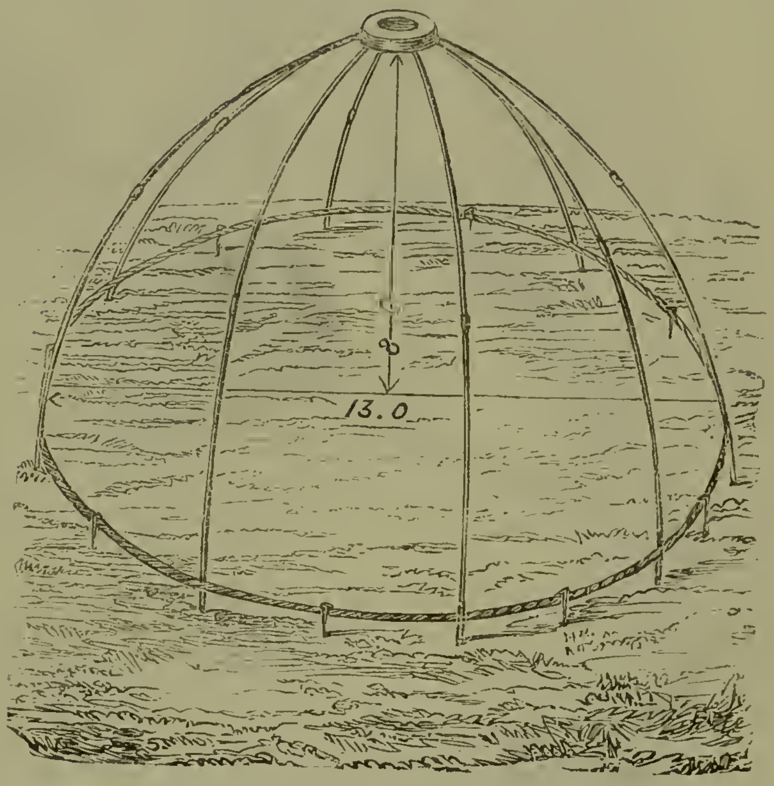


and the new pattern linen circular tent; each tent is provided with a vertical circular wall; that of the cotton tent is 2 feet 6 inches in height, and that of the linen tent is

1 foot. The diameter of each tent is 12 feet 6 inches; the length of the pole about 10 feet. Such a tent accommodates sixteen men.

Major Godfrey Rhodes has introduced a new and improved tent, which has no centre-pole. The frame of the tent is formed of stout ribs of ash, bamboo, or other flexible material. The ends of the ribs are inserted into a wooden head, fitted with iron sockets, and the butts are thrust into the ground, passing through a double twisted rope, having fixed loops at equal distances. The canvas is thrown over this frame-work, and secured within the tent by leather straps to the ground, or circular rope. The present hospital tent, when pitched, covers about 340 square yards. Major Rhodes' hospital tent covers only 63 square yards, and weighs 395 lbs., while it accommodates an equal number of men. The field tent is made up in one package, 5 feet 6 inches long, weighing 100 lbs.; the guard tent into one package 7 feet 6 inches long, weighing 52 lbs. The accompanying cuts, *figs.* 1743, and 1744, show

1745



Major Rhodes' field tent and the frame thereof. The difference, as it regards weight and convenience, in those tents introduced by Major Rhodes, is very great. We regret our space will not admit of more detail; this, however, is somewhat compensated, by the ample detail to be found in a book, *Tents and Tent Life*, published by the patentee.

The ventilation of tents has been admirably effected by Mr. Doyle, to whom we are indebted for the information contained in the following notes on the subject.

The old method of ventilating military tents was very defective. Ventilating openings were made at the top of the tent, but no means were provided for the admission of fresh air. The result was most unsatisfactory, as may be gathered from the following evidence given before the Sebastopol committee: —

"The tents were very close indeed at night. When the tent was closed in wet weather, it was often past bearing. The men became faint from heat and closeness." *

The problem then was to let in fresh air, and produce a draft without inconveniencing the soldiers as they slept.

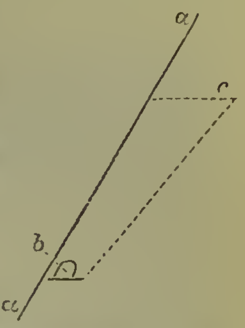
The question attracted Mr. Doyle's notice during the period of the camp at Chobham, and it appearing to him to be one of very great importance, he undertook, with the sanction of Lord Raglan, then Master-General of the Ordnance, to try the following experiment.

He caused two openings to be made in the wall of a tent, about 4 feet from the ground, and introduced the air between the wall and a piece of lining somewhat resembling a carriage pocket, thus: *a a*, the wall of the tent; *b*, the opening to admit air; *c*, the lining.

* Evidence of Sergeant Dawson, Grenadier Guards.

It will be seen that air so introduced would naturally take an upward direction, and that this communicating with the openings at the top of the tent, would probably produce the desired effect.

1746



The following extract from the report on this experiment will show the actual result:—

"The ventilators (Mr. Doyle's) were found of great use in clearing the tent of the fetid atmosphere consequent upon a number of men sleeping in so confined a space. The men state that the heavy smell experienced before the tent was altered is almost banished."

In subsequent experiments the number of the new openings was increased from two to three, and a greater amount of ventilation thus obtained. The result, according to an official letter of thanks received on the subject, was "quite successful." The improvement has been since adopted into the service, and by these very simple means one of the most fruitful causes of sickness among our soldiers in camp finally removed.

TENT, a wine, so called from the Spanish *tinto*—deep coloured—it being of a deep red colour. It comes chiefly from Galicia, or Malaga. See WINE.

TERRA COTTA. This term means literally *baked clay*. It is known in the arts as the name of the ancient vases, amphoræ, pateræ, lamps, statues, and bas-relievi. Monumental vases of terra cotta have been found in the tombs, after the lapse of 2,000 years, in a fine state of preservation. The ancient terra-cotta vases are generally painted black, on a red or buff ground; but on some there are blue, yellow, and other colours. The style of ornamentation is much alike in all — a few narrow lines, or fillets, with dots, meander fretwork, laurel, ivy leaf, and honeysuckle borders, adorning the rim, neck, and staud of the vases, the centre or body being covered with allegorical representations of gods, men, and animals. Terra cottas of the type of the early Greek, commonly called Etruscan vases, are found throughout the ancient Egyptian cities. The art of making the Greek terra cotta seems to have become extinct about 150 years before Christ. The modes in which the Greek works were made have been subjects of much controversy among the learned in art. The body, or substance, appears to a potter, in a commercial point of view, of the lowest grade, as it is common clay, very porous, and coarse-grained. By some authors it is said they were made of clay, mixed with sand only, and by others, with clay mixed with cement. The most probable conclusion is, that some were made of clay only, some of clay and sand, and others (such as those of a ground and monumental character, where it was important that the parts should be kept very true in firing), of clay mixed with potsherds and puzzolano or other detritus of lava. The works are less baked than modern pottery, and it is doubtful if it would stand exposure to the variations of such a climate as England. Among the remains of Greek pottery are gigantic amphoræ of very coarse grain, measuring as much as 8 feet in length by three feet in diameter, and of corresponding thickness. It is said that one of these great vessels was the tub of Diogenes. Vauquelin gives the following analysis of the Greek terra-cotta vases:—

Silica	53
Alumina	15
Lime	8
Oxide of iron, &c.	24
	100

The Roman terra cottas are of an entirely different character to those just described, and consist chiefly of cinerary urns, lamps, and pateræ; and these appear to have been moulded; the ornament is either incised or embossed, and odd fantastic shapes prevail.

Terra-cotta works of an architectural character are constantly met with in the buildings erected in Italy between the 12th and 17th centuries. The clay sketches and models of Michael Angelo, and other great sculptors, were rendered in terra cottas. Bramante employed terra cotta in decoration.

The merit of reviving in England the manufacture of terra cotta belongs to Josiah Wedgewood, who in 1770 established large works in Staffordshire. About 1790 a pottery was established at Lambeth for the manufacture of decorative works; and terra cotta was made for many years by a lady of the name of Coade, and afterwards by Coade and Sealey. The chief materials used by them were the Dorset and Devonshire clays, with fine sand, flint, and potsherds. The chief portion of the old coats of arms above the shop fronts of London were made of this terra cotta. Between 30 and 40 years ago, Mr. Babb, the sculptor, had a manufactory for terra cotta. The frieze of the Opera, in the Haymarket, is an example of his work.

To explain the mode of executing any work in terra cotta, it is best to describe the proper meaning of the words modelling, moulding, and casting.

A model is an original work made by the sculptor in clay, and worked out by the fingers and small tools made of bone and steel, varying from about 6 to 10 inches in length. This original work of the artist is allowed to dry, and then the moulding operation commences. This process is effected by mixing plaster of Paris with water to the consistency of thick cream; this is spread over the model, and when it has set it is removed in sections, which, when again carefully united, form the mould, in which either clay or metal can be cast, and receive the form of the original work. For terra-cotta work, unless many copies of the original are wanted, moulds are not employed.

When only one or two copies of a work are required, the original models are built up in a cellular manner, they are then dried and removed to a kiln and baked, being a perfectly original work.

When moulding is performed for terra-cotta works, sheets of clay are beaten on a bench to the consistency of glazier's putty, and pressed by the hand into the mould; according to the magnitude of the work and the weight it may have to sustain, the thickness of the clay is determined and arranged, and here consists a part of the art it would be impossible to describe, and which requires years of experience in such works to produce great works and fire them with certainty of success. At the Crystal Palace, Sydenham, are several large works manufactured by Mr. J. M. Blashfield, who has extensive terra-cotta works at Stamford. The figure of Australia, modelled by John Bele, nine feet in height, and burnt in one piece; the colossal Tritons modelled by the same artist, and other works, are examples. After the moulded article has become sufficiently dry, it is conveyed to a kiln. A slow fire is first made, and quickened until the heat is sufficient to blend and partially vitrify the material of which the mass is composed; when sufficiently baked, the kiln is allowed to cool, and the terra cotta is withdrawn.

TERRA DI SIENNA is a brown ferruginous ochre, employed in painting, obtained from Italy. It is a hydrous sesquioxide of iron combined with traces of arsenic; from which we may infer it is derived mainly from the decomposition of arsenical pyrites. It is calcined before being used as a pigment, and is then known as burnt sienna. Raw sienna is not much employed; it contains water, which the calcined does not.

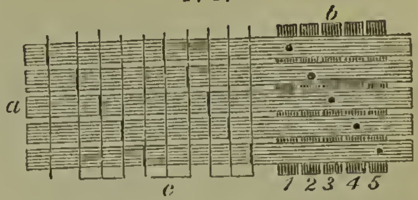
TERRA JAPONICA. See ACACIA, CATECHU.

Terra Japonica and Cutch *imported* in 1858, almost all from the British East Indies, 11,205 tons. Computed real value, 204,240*l.*

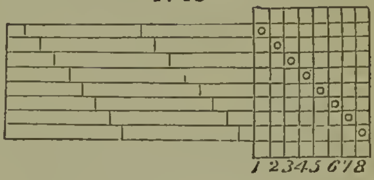
TESTS are chemical reagents of any kind, which indicate, by special characters, the composition of the body to which they are applied. Chemistry is based on the application of tests. See *Ure's Chemical Dictionary.*

TEXTILE FABRICS. The first business of the weaver is to adapt those parts of his loom which move the warp, to the formation of the various kinds of ornamental figures which the cloth is intended to exhibit. This subject is called the *draught*, drawing or reading in, and the cording of looms. In every species of weaving, whether direct or cross, the whole difference of pattern or effect is produced, either by the succession in which the threads of warp are introduced into the heddles, or by the succession in which those heddles are moved in the working. The heddles being stretched between two shafts of wood, all the heddles connected by the same shafts are called a leaf; and as the operation of introducing the warp into any number of leaves is called drawing a warp, the plan of succession is called the draught. When this operation has been performed correctly, the next part of the weaver's business is to connect the different leaves with the levers or treddles by which they are to be moved, so that one or more may be raised or sunk by every treddle successively, as may be required to produce the peculiar pattern. These connections being made by coupling the different parts of the apparatus by cords, this operation is called the cording. In order to direct the operator in this part of his business, especially if previously unacquainted with the particular pattern upon which he is employed, plans are drawn upon paper, specimens of which will be found in *figs.* 1747, 1748, &c. These plans are horizontal sections of a loom, the heddles being represented across the paper at *a*, and the treddles under them, and crossing them at right angles at *b*. In *figs.* 1747 and 1748 they are represented as if they were distinct pieces of wood, those across being the under shaft of each leaf of heddles, and those at the left hand the treddles. See WEAVING. In actual weaving the treddles are placed at right angles to the heddles, the sinking cords descending perpendicularly as nearly as possible to the centre of the latter. Placing them at the left hand, therefore, is only for ready inspection, and for practical convenience. At *c* a few threads of warp are shown as they pass through the heddles, and the thick lines denote the leaf with which each thread is connected. Thus, in *fig.* 1747, the right-hand thread, next to *a*, passes through the eye of a heddle upon the back leaf, and is disconnected with all the other leaves; the next thread passes through a heddle on the second leaf; the third, through the third leaf; the fourth, through the fourth leaf; and the fifth, through the fifth or front leaf. One set of the draught being now completed, the weaver recommences with the back leaf, and proceeds in the same succession again to the front. Two sets of the draught are represented in this figure, and the same succession, it is understood by weavers (who seldom draw more than one set), must be repeated until all the warp is included. When they proceed to apply the cords, the right-hand part of the plan at *b*, serves as a guide. In all the plans shown by these figures, excepting one which shall be noticed, a connection must be formed, by cording, between every leaf of heddles and every treddle; for all the leaves must either rise or sink. The raising motion is effected by coupling the leaf to one end of its correspondent top lever; the other end of this lever is tied to the long march below, and this to the treddle. The sinking connection is carried directly from under the leaf to the treddle. To direct a weaver which of these connections is to be formed with each treddle, a black spot is placed when a leaf is to be raised, where the leaf and treddle intersect each other upon the plan, and the sinking connections are left blank. For example, to cord the treddle 1, to the back leaf, put a raising cord, and to each of the other four, sinking cords; for the treddle 2, raise the second leaf, and sink the remaining four, and so of the rest; the spot always denoting the leaf or leaves to be raised. The *figs.* 1747 and 1748 are drawn for the purpose of rendering the general principle of this kind of plans familiar to those who have not been previously acquainted with them; but those who have been accustomed to manufacture and weave ornamented cloths, never consume time by representing either heddles or treddles as solid or distinct bodies. They content themselves with ruling a number of lines across a piece of paper, sufficient to make the intervals between these lines represent the number of leaves required. Upon these intervals, they merely mark the succession of the draught, without producing every line to resemble a thread of warp. At the left hand, they draw as many lines across the former as will afford an interval for each treddle: and in the squares produced by the intersections of these lines, they place the dots, spots, or ciphers which denote the raising cords. It is also common to continue the cross lines which denote the treddle a considerable length beyond the intersections, and to mark by dots, placed diagonally in the intervals, the order or succession in which the treddles are to be pressed down in weaving. The former of these modes has been adopted in the remaining *figs.* to 1756; but to save room, the latter has been avoided, and the succession marked by the order of the figures under the intervals which denote the treddles.

1747



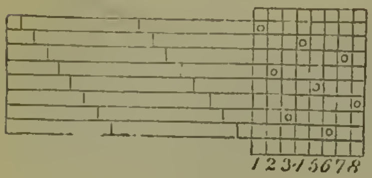
1748



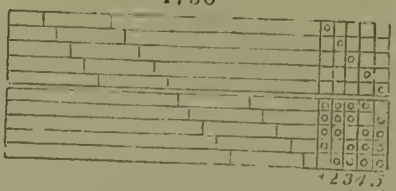
Some explanation of the various kinds of fanciful cloths represented by these plans may serve further to illustrate this subject, which is, perhaps, the most important of any connected with the manufacture of cloth, and will also enable a person who thoroughly studies them, readily to acquire a competent knowledge of the other varieties in weaving, which are boundless. *Figs.* 1747 and 1748 represent the draught and cording of the two varieties of tweeled cloth wrought with five leaves of heddles. The first is the regular or run tweel, which, as every leaf rises in regular succession, while the rest are sunk, interweaves the warp and woof only at every fifth interval, and as the succession is uniform, the cloth, when woven, presents the appearance of parallel diagonal lines, at an angle of about 45° over the whole surface. A tweel may have the regularity of its diagonal lines broken by applying the cording as in *fig.* 1748. It will be observed, that in both figures the draught of the warp is precisely the same, and that the whole difference of the two plans consists in the order of placing the spots denoting the raising cords, the first being regular and successive, and the second alternate.

Figs. 1749 and 1750 are the regular and broken tweels which may be produced with eight leaves. This properly is the tweel denominated satin in the silk manufacture, although many webs of silk wrought with only five leaves receive that appellation. Some of the finest Florentine silks are tweeled with sixteen leaves. When the broken tweel of eight leaves is used, the effect is much superior to what could be produced by a smaller number; for in this two leaves are passed in every interval, which gives a much nearer resemblance to plain cloth than the others. For this reason it is preferred in weaving the finest damasks. The draught of the eight leaf tweel differs in nothing from the others, excepting in the number of leaves. The difference of the cording in the broken tweel will appear by inspecting the ciphers

1749

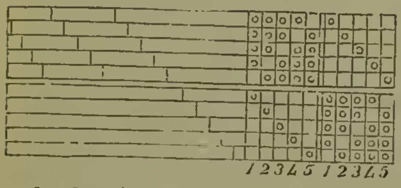


1750

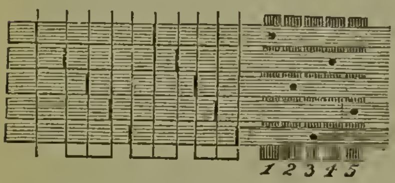


which mark the raising cords, and comparing them with those of the broken tweel of five leaves. *Fig.* 1751 represents the draught and cording of striped dimity of a tweel of five leaves. This is the most simple species of fanciful tweeling. It consists of ten leaves, or double the number of the common tweel. These ten leaves are moved by only five treddles, in the same manner as a common tweel. The stripe is formed by one set, of the leaves flushing the warp, and the other set, the woof. The figure represents a stripe formed by ten threads, alternately drawn through each of the two sets of leaves. In this case, the stripe and the intervals will be equally broad, and what is the stripe upon one side of the cloth will be the interval upon the other, and *vice versâ*. But great variety of patterns may be introduced by drawing the warp in greater or smaller portions through either set. The tweel is of the regular kind, but may be broken by placing the cording as in *fig.* 1748. It will be observed that the cording-marks of the lower or front leaves are exactly the converse of the other set; for where a raising mark is placed upon one, it is marked for sinking in the other; that is to say, the mark is omitted; and all leaves which sink in the one, are marked for raising in the other; thus, one thread rises in succession in the back set, and four sink; but in the front set, four rise, and only one sinks. The woof, of course, passing over the four sunk threads, and under the raised one, in the first instance, is flushed above; but where the reverse takes place, as in the second, it is flushed below; and thus the appearance of a stripe is formed. The analogy subsisting between striped dimity and dornock is so great, that before noticing the plan for fancy dimity, it may be proper to allude to the dornock, the plan of which is represented by *fig.* 1752.

1751



1752



The draught of dornock is precisely the same in every respect with that of striped dimity. It also consists of two sets of tweeling-heddles, whether three, four, or five leaves are used for each set. The right-hand set of treddles is also corded exactly in the same way, as will appear by comparing them. But as the dimity is a continued stripe from the beginning to the end of the web, only five treddles are required to move ten leaves. The dornock being checker-work, the weaver must possess the power of reversing this at pleasure. He therefore adds five more treddles, the cording of which is exactly the reverse of the former; that is to say, the back leaves, in the former case, having one leaf raised, and four sunk, have, by working with these additional treddles, one leaf sunk and four leaves raised. The front leaves are in the same manner reversed, and the mounting is complete. So long as the weaver continues to work with either set, a stripe will be formed, as in the dimity; but when he changes his feet from one set to the other, the whole effect is reversed, and the checkers formed. The dornock pattern upon the design paper, *fig.* 1752, may be thus explained: let every square of the design represent five threads upon either set of the heddles, which are said by weavers to be once over the draught, supposing the tweel to be one of five leaves; draw three parallel lines, as under, to form two intervals, each representing one of the sets; the draught will then be as follows:—

1753

4		1		4		1		1		4		1	
	4		4		1		1		1		4		4

The above is exactly so much of the pattern as is there laid down, to show its appearance; but one whole range of the pattern is completed by the figure 1, nearest to the right hand upon the lower interval between the lines, and the remaining figures, nearer to the right, form the beginning of a second range or set. These are to be repeated in the same way across the whole warp. The lower interval represents the five front leaves, the upper interval, the five back ones. The first figure 4, denotes that five threads are to be successively drawn upon the back leaves, and this operation repeated four times. The first figure 4, in the lower interval, expresses that the same is to be done upon the front leaves; and each figure, by its diagonal position, shows how often, and in what succession, five threads are to be drawn upon the leaves which the interval in which it is placed represents.

Dornocks of more extensive patterns are sometimes woven with 3, 4, 5, and even 6 sets of leaves; but after the leaves exceed 15 in number, they both occupy an inconvenient space, and are very unwieldy to work. For these reasons the diaper harness is in almost every instance preferred.

Fig. 1754 represents the draught and cording of a fanciful species of dimity, in which it will be observed that the warp is not drawn directly from the back to the front leaf, as in the former examples; but when it has arrived at either external leaf, the draught is reversed, and returns gradually to the other. The same draught is frequently used in tweeling, when it is wished that the diagonal lines should appear upon the cloth in a zigzag direction. This plan exhibits the draught and cording which will produce the pattern upon the design-paper in *fig.* 1747 *a*. Were all the squares produced by the intersection of the lines denoting the leaves and treddles, where the raised dots are placed, filled the same as on the design, they would produce the effect of exactly one fourth of that pattern. This is caused by the reversing of the draught, which gives the other side reversed as on the design; and when all the treddles, from 1 to 16, have been successively used in the working, one-half of the pattern will become complete. The weaver then goes again over his treddles, in the reversed order of the numbers, from 17 to 30, when the other half of the pattern will be completed. From this similarity of the cording to the design, it is easy, when a design is given, to make out the draught and cording proper to work it; and when the cording is given, to see its effect upon the design.

1754

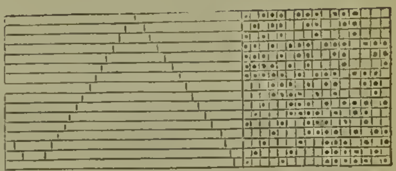


Fig. 1755 represents the draught of the diaper mounting, and the cording of the front leaves which are moved by treddles. From the plan, it will appear that five threads are included in every mail of the harness, and that these are drawn in single threads through the front leaves. The cording forms an exception to the general rules, that when one or more leaves are raised, all the rest must be sunk; for in this instance, one leaf rises, one sinks, and three remain stationary. An additional mark, therefore, is used in this plan. The dots, as formerly, denote raising cords; the blanks, sinking cords; and where the cord is to be totally omitted, the cross marks × are placed.

1755

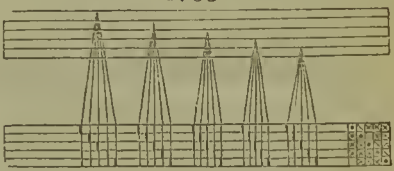

Fig. 1756 is the draught and cording of a spot whose two sides are similar, but reversed. That upon the plan forms a diamond, similar to the one drawn upon the design paper in the diagram, but smaller in size. The draught here is reversed, as in the dimity plan, and the treading is also to be reversed, after arriving at 6, to complete the diamond. Like it, too, the raising marks form one-fourth of the pattern. In weaving spots, they are commonly placed at intervals, with a portion of plain cloth between them, and in alternate rows, the spots of one row being between those of the other. But as intervals of plain cloth must take place, both by the warp and woof, 2 leaves are added for that purpose. The front, or ground leaf, includes every second thread of the whole warp; the second, or plain leaf, that part which forms the intervals by the warp. The remaining leaves form the spots; the first six being allotted to one row of spots, and the second six to the next row; where each spot is in the centre between the former. The reversed draught of the first is shown entire, and is succeeded by 12 threads of plain. One-half of the draught of the next row is then given, which is to be completed exactly like the first, and succeeded by 12 threads more of plain; when, one set of the pattern being finished, the same succession is to be repeated over the whole warp. As spots are formed by inserting woof of coarser dimensions than that which forms the fabric, every second thread only is allotted for the spotting. Those included in the front, or ground leaf, are represented by lines, and the spot threads between them, by marks in the intervals, as in the other plans.

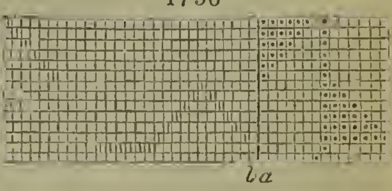
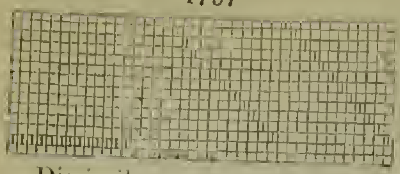
1756



The treddles necessary to work this spot are, in number, 14. Of these the two in the centre, *a*, *b*, when pressed alternately, will produce plain cloth; for *b* raises the front leaf, which includes half of the warp, and sinks all the rest; while *a* exactly reverses the operation. The spot-treddles on the right hand work the row contained in the first six spot-leaves: and those upon the left hand, the row contained in the second six. In working spots, one thread, or shot of spotting-woof, and two of plain, are successively inserted, by means of two separate shuttles.

1757



Dissimilar spots are those whose sides are quite different from each other. The draught only of these is represented by *fig.* 1757. The cording depends entirely upon the figure.

Fig. 1758 represents any solid body composed of parts *lashed* together. If the darkened squares be supposed to be beams of wood, connected by cordage, they will give a precise idea of textile fabric. The beams cannot come into actual contact, because, if the *lashing* cords were as fine even as human hairs, they must still require space. The thickness is that of one beam and one cord; but if the cords touch each other, it may then be one beam and two cords; but it is not possible in practical weaving to bring every thread of weft into actual contact. It may therefore be assumed, that the thickness is equal to the diameter of one thread of the warp, added to that of one yarn of the weft; and when these are equal, the thickness of the cloth is double of that diameter. Denser cloth would not be sufficiently pliant or flexible.

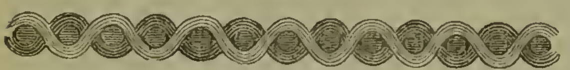
1758

1759

Fig. 1759 is a representation of a section of cloth of an open fabric, where the round dots which represent the warp are placed at a considerable distance from each other.

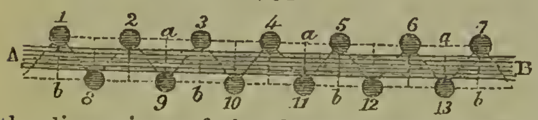
Fig. 1760 may be supposed a plain fabric of that description which approaches the most nearly to any idea we can form of the most dense or close contact of which yarn can be made susceptible. Here the warp is supposed to be so tightly stretched in the loom as to retain entirely the parallel state, without any curvature, and the whole flexure is therefore given to the woof. This mode of weaving can never really exist; but if the warp be sufficiently strong to bear any tight stretching, and the woof be spun very soft and flexible, something very near it may be produced. This way of making cloth is well fitted for those goods which require to give considerable warmth; but they are sometimes the means of very gross fraud and imposition; for if the warp is made of very slender threads, and the woof of slackly twisted cotton or woollen yarn, where the fibrils of the stuff, being but slightly brought into contact, are rough and oozy, a great appearance of thickness and strength may be given to the eye, when the cloth is absolutely so flimsy that it may be torn asunder as easily as a sheet of writing-paper. Many frauds of this kind are practised.

1760



In *fig.* 1761 is given a representation of the position of a fabric of cloth in section, as it is in the loom before the warp has been closed upon the woof, which still appears as a straight line. This figure may usefully illustrate the direction and ratio of contraction which must unavoidably take place in every kind of cloth, according to the density of the texture, the dimensions of the threads, and the description of the cloth. Let A, B, represent one thread of woof completely stretched by the velocity of the shuttle in passing between the threads of warp which are represented by the round dots, 1, 2, &c., and those distinguished by 8, 9, &c. When these threads are closed by the operation of the needles to form the inner texture, the first tendency will be to move in the direction 1 *b*, 2 *b*, &c., for those above, and in that of 8 *a*, 9 *a*, &c., for those below; but the contraction for A, B, by its deviation from a straight to a curved line, in consequence of the compression of the warp threads 1 *b*, 2 *b*, &c., and 1 *a*, 2 *a*, &c., in closing, will produce by the action of the two powers at right angles to each other, the oblique or diagonal direction denoted by the lines 1, 8 — 2, 9, to the left, for the threads above, and that expressed by the lines 2, 8 — 3, 9, &c., to the right, for the threads below. Now, as the whole deviation is produced by the flexure of the thread A, B, if A is supposed to be placed at the middle of the cloth, equidistant from the two extremities, or *selvages* as they are called by weavers, the thread at 1 may be supposed to move really in the direction 1 *b*, and all the others to approach to it in the directions represented, whilst those to the right would approach in the same ratio, but the line of approxima-

1761



tion would be inverted. *Fig.* 1762 represents that common fabric used for lawns, muslins, and the middle kind of goods, the excellence of which neither consists in the greatest strength, nor in the greatest transparency. It is entirely a medium between *fig.* 1759 and *fig.* 1760.

1762

In the efforts to give great strength and thickness to cloth, it will be obvious that the common mode of weaving, by constant intersection of warp and woof, although it may be perhaps the best which can be devised for the former, presents invincible obstructions to the latter beyond a certain limit. To remedy this, two modes of weaving are in common use, which, while they add to the power of compressing a great quantity of materials in a small compass, possess the additional advantage of affording much facility for adding ornament to the superficies of the fabric. The first of these is double cloth, or two webs woven together, and joined by the operation. This is chiefly used for carpets; and its geometrical principles are entirely the same as those of plain cloth, supposing the webs to be sewed together. A section of the cloth will be found in *fig.* 1763. See CARPETS.

1763

Of the simplest kind of tweeled fabric, a section is given in *fig.* 1764.

The great and prominent advantage of the tweeled fabric in point of texture, arises from the facility with which a very great quantity of materials may be put closely together. In the figure, the warp is represented by the dots in the same straight line as in the plain fabrics; but if we consider the direction and ratio of contraction, upon principles similar to those laid down in the explanation given of *fig.* 1761, we shall readily discover the very different way in which the tweeled fabric is affected.

1764

When the dotted lines are drawn at *a*, *b*, *c*, *d*, their direction of contraction, instead of being upon every second or alternate thread, is only upon every fifth thread, and the natural tendency would consequently be, to bring the whole into the form represented by the lines and dotted circles at *a*, *b*, *c*, *d*. In point, then, of thickness, from the upper to the under superficies, it is evident that the whole fabric has increased in the ratio of nearly three to one. On the other hand, it will appear, that four threads or cylinders being thus put together in one solid mass, might be supposed only one thread, or like the strands of a rope before it is twisted; but, to remedy this, the thread being shifted every time, the whole forms a body in which much aggregate matter is compressed; but where, being less firmly united, the accession of strength acquired by the accumulation of materials is partially counteracted by the want of equal firmness of junction.

The second quality of the tweeled fabric, *susceptibility of receiving ornament*, arises from its capability of being inverted at pleasure, as in *fig.* 1765. In this figure, we have, as before, four threads, and one alternately intersected; but here the four threads marked 1 and 2 are under the woof, while those marked 3 and 4 are above.

1765

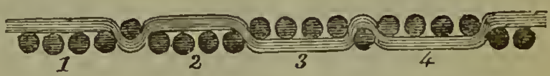


Fig. 1766 represents that kind of tweeled work which produces an ornamental effect, and adds even to the strength of a fabric, in so far as accumulation of matter can be considered in that light. The figure represents a piece of velvet cut in section, and of that kind which, being woven upon a tweeled ground, is known by the name of Genoa velvet. 1st. Because, by combining a great quantity of material in a small compass, they afford great warmth. 2nd. From the great resistance which they oppose to external friction, they are very durable. And, 3rd. Because, from the very nature of the texture, they afford the finest means of rich ornamental decoration.

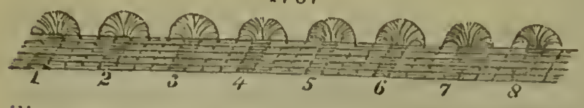
1766

The use of velvet cloths in cold weather is a sufficient proof of the truth of the first. The manufacture of plush, corduroy, and other stuffs for the dress of those exposed to the accidents of laborious employment, evinces the second; and the ornamented velvets and Wilton carpeting are demonstrative of the third of these positions.

In the figure, the diagonal form which both the warp and woof of cloth assume, is very apparent from the smallness of the scale. Besides what this adds to the strength of the cloth, the flushed part, which appears interwoven at the darkly-shaded intervals 1, 2, &c., forms, when finished, the whole covering or upper surface. The principle, in so far as regards texture, is entirely the same as any other tweeled fabric.

Fig. 1767, which represents corduroy, or king's cord, is merely striped velvet. The principle is the same, and the figure shows that the one is a copy of the other.

1767



The remaining figures represent those kinds of work which are of the most flimsy and open description of texture; those in which neither strength, warmth, nor durability are much required, and of which openness and transparency are the chief recommendations.

Fig. 1768 represents common gauze, or *linau*, a substance very much used for various purposes. The essential difference between this description of cloth and all others, consists in the warp being turned or twisted like a rope during the operation of weaving, and hence it bears a considerable analogy to *lace*. The twining of gauze is not continued in the same direction, but is alternately from right to left, and *vice versâ*, between every intersection of the woof. The fabric of gauze is always open, flimsy, and transparent; but from the turning of the warp, it possesses an uncommon degree of strength and tenacity in proportion to the quantity of material which it contains. This quality, together with the transparency of the fabric, renders it peculiarly adapted for ornamental purposes of various kinds, particularly for flowering or figuring, either in the loom or by the needle. In the warp of gauze, there arises a much greater degree of contraction during the weaving, than in any other species of cloth; and this is produced by the turning. The twisting between every intersection of weft amounts precisely to one complete revolution of both threads: hence this difference exists between this and every other species of weaving, namely, that the one thread of warp is always above the woof, and the contiguous thread is always below.

1768

1769

Fig. 1769 represents a section of another species of twisted cloth, which is known by the name of catgut, and which differs from the gauze only, by being subjected to a greater degree of twine in weaving; for in place of one revolution between each intersection, a revolution and a half is always given; and thus the warp is alternately above and below, as in other kinds of weaving.

Fig. 1770 is a superficial representation of the most simple kind of ornamental network produced in the loom. It is called a whip-net by weavers, who use the term whip for any substance interwoven in cloth for ornamental purposes when it is distinct from the ground of the fabric. In this the difference is merely in the crossing of the warp; for it is very evident that the crossings at 1, 2, 3, 4, and 5, are of different threads from those at 6, 7, 8, and 9.

1770

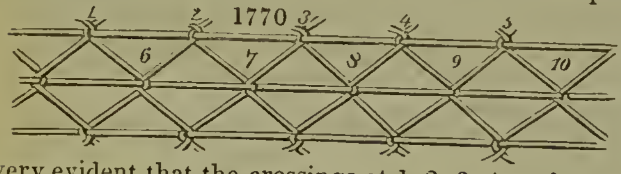


Fig. 1771 represents, superficially, what is called the mail-net, and is merely a combination of common gauze and the whip-net in the same fabric. The gauze here being in the same direction as the dotted line in the former figure, the whole fabric is evidently a continued succession of right-angled triangles, of which the woof forms the basis, the gauze part the perpendiculars, and the whip part the hypothenuses. The contraction here being very different, it is necessary that the gauze and whip parts should be stretched upon separate beams.

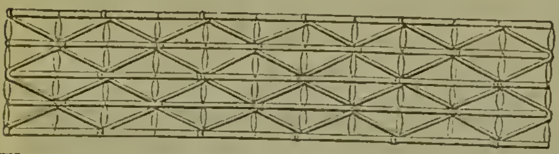
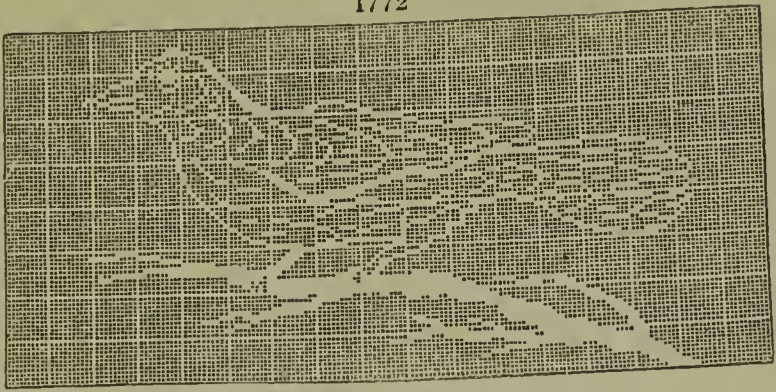
1771



In order to design ornamental figures upon cloths, the lines which are drawn from the top to the bottom of the paper may be supposed to represent the warp; and those drawn across, the woof of the web; any number of threads being supposed to be included between every two lines. The paper thus forms a double scale, by which, in the first instance, the size and form of the pattern may be determined with great precision; and the whole subsequent operations of the weaver regulated, both in mounting and working his loom. To enable the projector of a new pattern to judge properly of its effects, when transferred from the paper to the cloth, it will be essentially necessary that he should bear constantly in his view the comparative scale of magnitude which the design will bear in each, regulating his ideas always by square or superficial measurement. Thus, in the large design, *fig.* 1772, representing a bird perched upon the branch of a tree, it will be proper, in the first place, to count the number of spaces from the point of the bill to the extremity of the tail; and to render this the more easy, it is to be observed that every tenth line is drawn con-

1772

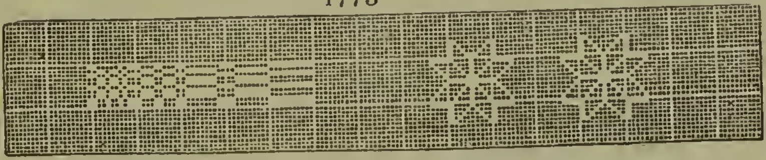


siderably bolder than the others. This number in the design is 135 spaces. Counting again, from the stem of the branch to the upper part of the bird's head, he will find 76 spaces. Between these spaces, therefore, the whole superficial measure of the pattern is contained. By the measure of the paper, this may be easily tried with a pair of compasses, and will be found to be nearly $6\frac{5}{10}$ inches in length, by $3\frac{3}{16}$ inches in breadth. Now, if this is to be woven in a reed containing 800 intervals in 37 inches, and if every interval contains five threads, supposed to be contained between every two parallel lines, the length will be 6·24 inches, and the breadth 3·52 inches nearly; so that the figure upon the cloth would be very nearly of the same dimensions as that upon the paper; but if a 1200 reed were used, instead of an 800, the dimension would be proportionally contracted.

A correct idea being formed of the design, the weaver may proceed to mount his loom according to the pattern; and this is done by two persons, one of whom takes from the design instructions necessary for the other to follow in tying his cords.

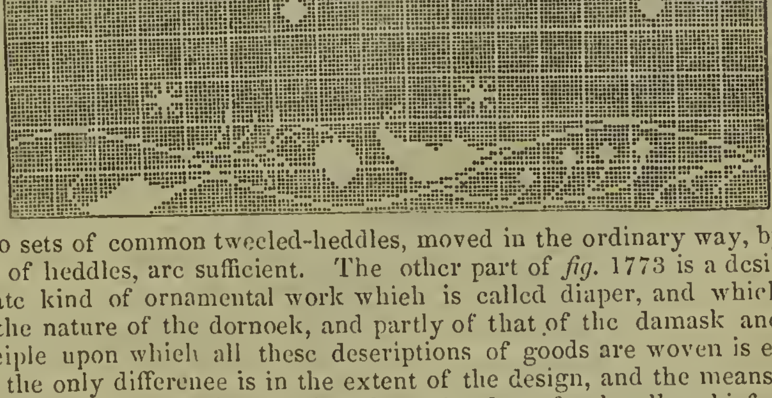
Fig. 1773 is a representation of the most simple species of table linen, which is

1773



merely an imitation of checker-work of various sizes; and is known in Scotland, where the manufacture is chiefly practised, by the name of Dornock. When a pattern is formed upon tweeled cloth, by reversing the flushing, the two sides of the fabric being dissimilar, one may be supposed to be represented by the black marks, and the other by the part of the figure which is left uncoloured. For such a pattern

1774



as this, two sets of common tweeled-heddles, moved in the ordinary way, by a double succession of heddles, are sufficient. The other part of *fig.* 1773 is a design of that intermediate kind of ornamental work which is called diaper, and which partakes partly of the nature of the dornock, and partly of that of the damask and tapestry. The principle upon which all these descriptions of goods are woven is entirely the same, and the only difference is in the extent of the design, and the means by which it is executed. *Fig.* 1774 is a design for a border of a handkerchief or napkin, which may be executed either in the manner of damask, or as the spotting is practised in the lighter fabrics.

TEXTILE FIBRES CONDENSED. Mr. John Mercer's plan of transforming cotton and flax into fibres of a fine silky texture, while their strength and substance are increased, excited much interest a few years since. He subjected them to the action of caustic alkaline lye, sulphuric acid, or to solution of chloride of zinc, of such strength and at such a temperature as produced certain remarkable changes in them, quite the reverse of what most people would have expected. The mode of operating according to this invention, upon cloth made wholly or partially of any vegetable fibres and bleached, is as follows:—The cloth is passed through a padding machine charged with caustic soda or caustic potash at 60° or 70° of Twaddle's hydrometer, at the common temperature of the atmosphere (say 60° Fahr. or under); then, without being dried, it is washed in water; and, after this, it is passed through dilute sulphuric acid, and washed again. Or the cloth is conducted over and under a series of rollers in a cistern containing caustic soda or caustic potash at 40° to 50° Twaddle, at the ordinary temperature (the last two rollers being set so as to squeeze the excess of soda or potash back into the cistern); and then it is passed over and under rollers placed in a series of cisterns, which are charged at the commencement of the operation with water only; so that when the cloth arrives at the last cistern, nearly all the alkali has been washed out of it. After the cloth has either gone through the padding machine or through the cisterns, it is washed in water, passed through dilute sulphuric acid, and again washed in water.

When grey or unbleached cloth, made from the above-mentioned fibrous material, is to be treated, it is first boiled or steeped in water, so as to wet it thoroughly; then most of the water is removed by the squeezer or hydro-extractor; and, after this, it is passed through the soda or potash solution, &c., as before described.

Warps, either bleached or unbleached, are treated in the same manner; but, after passing through the cistern containing the alkali, they are passed through squeezers or through a hole in a metal plate, to remove the alkali; and then the warps are conducted through the water cisterns, "soured," and washed, as before described.

When thread or hank yarn is to be operated upon, the threads or yarns are immersed in the alkali and then wrung out (as is usually done in sizing or dyeing them); and afterwards they are subjected to the above-mentioned operations of washing, souring, and washing in water.

When any fibre in the raw state, or before it is manufactured, is to be treated, it is first boiled in water, and then freed from most of the water by the hydro-extractor or a press; after which it is immersed in the alkaline solution, and the excess of alkali is removed by the hydro-extractor or a press; then it is washed in water, soured with dilute sulphuric acid, and washed again; and finally the water is removed by the hydro-extractor or a press.

The following are the effects produced by the above operations upon cloth made of vegetable fibrous material, either alone or mixed with animal fibrous material:—The cloth will have shrunk in length and breadth, or have become less in its external dimensions, but thicker and closer; so that by the chemical action of caustic soda or caustic potash on cotton and other vegetable fabrics, an effect will be produced somewhat analogous to that which is produced on woollen by the process of fulling or milling; the cloth will likewise have acquired greater strength and firmness—greater force being required to break each fibre—it will be found to have become heavier than it was previously to being acted upon by the alkali, if in both cases it be weighed at the temperature of 60° Fahr., or under. It will also have acquired greatly augmented and improved powers of receiving colours in printing and dyeing.

THALLOGENS. See Exogenous.

THEBAINE. $C^{38}H^{21}NO^{6}$. One of the numerous alkaloids contained in opium.

THEINE. Syn. *Caffeine.* $C^{16}H^{10}N^{4}O^{4}+2$ aq. A feeble base contained in tea, coffee, and, in fact, in most of the plants used in the manner of tea; such as Paraguay and Guarana tea. The following are the percentages in the various teas and coffees, with the names of the observers:—

Teas	Hyson	2·5 to 3·4	Peligot.
	Gunpowder	2·2 to 4·1	"
	Paraguay	0·13	Stenhouse.
Coffees	Martinique	·36	Rabiquel and Boutron.
	Mocha	·21	"
	Cayenne	·20	"

THENARD'S BLUE, or COBALT BLUE, is prepared by digesting the oxide of cobalt with nitric acid, evaporating the nitrate of cobalt formed, almost to dryness, diluting it with water, and filtering, to separate some arseniate of iron, which usually prec pitates. The clear liquor is to be poured into a solution of phosphate of soda, when an insoluble phosphate of cobalt falls. This being well washed, is to be intimately mixed in its soft state with eight times its weight of well-washed gelatinous alumina, which has been obtained by pouring a solution of alum into water of ammonia in excess. The uniformly coloured paste is to be spread upon plates, dried in a stove, then bruised dry in a mortar, enclosed in a crucible, and subjected to a cherry-red heat for half an hour. On taking out the crucible, and letting it cool, the fine blue pigment is to be removed into a bottle, which is to be stoppered till used.

The arseniate of cobalt may be substituted, in the above process, for the phosphate, but it must be mixed with sixteen times its weight of the washed gelatinous alumina. The arseniate is procured by pouring the dilute nitrate of cobalt into a solution of arseniate of potassa. If nitrate of cobalt be mixed with alumina, and the mixture be treated as above described, a blue pigment will also be obtained, but paler than the preceding, showing that the colour consists essentially of alumina stained with oxide of cobalt.

THEOBROMINE is a chemical principle found in cocoa beans. It is extracted by boiling with water, filtering, precipitating with acetate of lead, seperating the precipitate after washing it, then decomposing it by sulphuretted hydrogen; or boiling it with alcohol, from which, on cooling, the theobromine separates in a crystalline powder. It is purified by recrystallisation. It is little soluble in water or alcohol.

THERMOMETER. An instrument used, as its name signifies, as a measure of heat. A description of this valuable instrument belongs to physics. The principle upon which it is constructed depends upon the expansion of some fluid or solid by heat. In all bodies the rate of expansion is uniform for equal increments of heat; therefore we may adopt any body as our heat measurer, if we determine by previous experiments the rate of expansion to which it is subject, and construct a fixed scale. Usually either mercury or spirits of wine are employed.

Thermometrical Table, by Dr. Alfred S. Taylor, F.R.S.—The accompanying thermometrical table of Dr. A. Taylor has been copied from a thermometer in his possession, graduated on the scales of Fahrenheit, Reaumur, and Celsius, or the Centigrade. It has been designed to obviate the necessity for those perplexing calculations, so often rendered necessary by the use of different methods of graduation in England and on the continent. In most chemical works, we find, besides the rules given for the conversion of the degrees of one scale into those of another, comparative tables, which however, convey no information beyond the bare fact of the correspondence of certain degrees. In this table, the attempt has been made to make it convey information on numerous interesting points, connected with temperature in relation to climatology, physical geography, chemistry, and physiology.

There is another advantage which a table of this kind must possess over those hitherto published in works on chemistry. In the latter, the degrees on one scale only run in arithmetical progression, while the corresponding degrees on the other scale are necessarily given in fractional or decimal parts, and at unequal intervals. Thus, in some of the best works on chemistry, a comparative table is printed, which is only fitted for the conversion of the Centigrade into Fahrenheit degrees, so that a person wishing to convert the Fahrenheit into Centigrade degrees, would have to revert to one of the old formulæ of conversion. This process must also be adopted whenever the Centigrade degrees are given in decimal parts, for all the tables yet published in English works wrongly assume that the Centigrade degrees are always given in whole numbers. The present table renders such calculations unnecessary, since the value of any degree, or of any part of a degree on one scale, is immediately found on the other, by looking at the degree in a parallel line with it. The main divisions will, I believe, be found perfectly accurate. In single degrees a little inequality may be occasionally detected; but I have not found the error to be such as to affect the calculated temperature.

Although the Fahrenheit and Centigrade scales are the two which are chiefly used in Europe, it has been thought advisable to carry out the parallel degrees of Réaumur's scale, by dots on the drawing of the tube. This table, therefore, comprises in itself six distinct tables, assuming the necessity for each scale to be represented in whole degrees, with the additional advantages: 1st, that the space occupied is smaller; and 2nd, the value of any fractional part of a degree on one may be at once determined on the other two scales.

It is extraordinary, considering the great advances which have been recently made in physical science, and in the manufacture of philosophical instruments, that the makers of thermometers should still adhere to the old and absurd practice of marking on the Fahrenheit scale, the unmeaning words Temperate, Summer-heat, Blood-heat, Fever-heat, Spirits boil, &c., when the instrument might be easily made to convey a large amount of information in respect to climate, as it is dependent on temperature.

It will be seen that the table here published ranges from 12° to 374° Fahr., from — 11° to + 190 Centigrade, and from — 9° to + 152 Réaumur.

It will be only necessary to state generally those facts which the table is intended to illustrate. They will be found arranged opposite to their respective degrees, either on the Centigrade or Fahrenheit side, according to the space afforded.

The facts connected with temperature, placed on the scale, may be arranged under the heads of Climatology, Physical Geography, Chemistry, and Physiology.

Climatology. 1. The mean temperatures of the principal countries, towns, and cities in the world, with the maxima and minima, as well as the mean summer and winter temperature of some of the most important localities.

2. The maximum degrees of heat, and the minimum degrees of cold, observed on the surface of the globe, including the accumulated temperatures of air at Edinburgh and Geneva.

Physical Geography. 1. The temperature of the atmosphere, as observed on the summits of the principal mountains of the Old and New World, with the respective elevations attached — at the sea level in various latitudes, from the Arctic to the Antarctic seas, as well as in deep mines and other excavations in Europe and America.

2. The temperature of the ocean at the surface, and at various depths to 12,420 feet, including the temperature of the Polar Seas, of the Mediterranean, Atlantic and Pacific, with the temperature of the Gulf Stream.

3. The temperature of the waters of lakes and rivers at various depths, with the respective fathomings attached.

4. The temperature of the strata of the earth at various depths, observed in some of the deepest mines in the Old and New World.

5. The temperature of water raised in Artesian wells in Europe from depths varying from 250 to 1794 feet.

6. The temperature of the principal thermal springs and baths observed in Europe, Africa, the West Indies, and South America.

7. The temperature at which water boils at all the elevated and inhabited spots in the world, including the summits of the mountains of Switzerland, South America, and Central Asia; the boiling point for all elevations up to 5415 feet, and for 1054 feet depression below the level of the sea.

Chemistry. 1. The evaporating, boiling, fusing, melting, subliming, and congealing points of the principal solids and liquids in chemistry, from 12° to 374° Fahr., from — 11° to + 190° Cent. and from — 9 to + 152° Réau., including the boiling points of the saturated solutions of numerous salts, and the melting points of a large number of alloys.

2. The temperature for fermentation of various kinds, malting, putrefaction, etherification, and other chemical processes.

3. The boiling points of alcohol and acids of various specific gravities, with the respective densities of their vapours.

4. The pressure or elastic force of the vapour of water, alcohol, oil of turpentine, and ether, at various temperatures.

5. The temperatures, with the corresponding pressures required for the liquefaction of the gases.

6. The temperature for the explosion and ignition of fulminating and combustible substances.

Physiology. 1. The maximum degrees of natural and artificial heat, and minimum degrees of cold, borne by man and animals.

2. The temperature of the body in man, mammalia, birds, reptiles, fishes, and insects.

3. The temperature at which hybernation takes place in certain animals.

4. The temperature for the germination of seeds, incubation, the artificial hatching of the ova of birds, fishes and insects.

5. The temperature for the growth of the sugar-cane, date, indigo, cotton tree, and for the cultivation of the vine.

6. The temperature for warm, tepid, and vapour baths; the vapour baths of Russia and Finland.

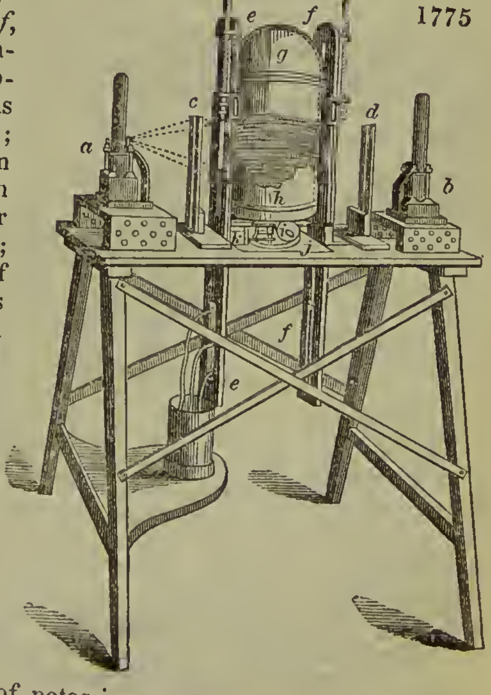
As the value of a table of this kind, depends less on the compiler than on the observers on whom he relies, I feel bound to state that I am chiefly indebted to the following authorities: — for Climatology and Physical Geography: to Humboldt, Bonpland, Saussure, Boussingault, Rose, Ermann, Baer, Von Wrangell, Breislak, Phipps, Scoresby, Franklin, Parry, Back, Ross, Pachtusoff, Zivolka, Cordier, Gay-Lussac, Pouillet, Biot, Arago, Bertrand, Desfontaines, Gerard, Lhotsky, Schomburgk, Davidson, Forbes, Brewster, D'Abbadie, Moore, and Beke; — for Chemistry and Physiology: to Berzelius, Dumas, Mitscherlich, Gaultier de Claubry, Peligot, Davy, Faraday, Ure, Brande, Graham, Turner, Dr. Davy, and Liebig. In respect to the department of Physical Geography, I am much indebted to the foreign correspondence of the *Athenæum.*

Many of the facts I was enabled to collect or verify by personal observation during a journey through France, Italy, and Switzerland. Some of the chemical phenomena have also been derived from direct experiment. It is very probable that a few of the temperatures, in each department, will be found to differ from those given in some works on Chemistry; and, on this point, I have one remark to make, namely, that the greatest discrepancies will often be found among respectable authorities in regard to temperature. It is impossible here to enter into the causes of these discrepancies. I have invariably acted on the principle of selecting the best authorities; and where these differed, I have endeavoured to arrive at an approximation to the truth by experiment, or where this was impossible, by seeking for corroborative circumstances. A large number of observations, made by travellers, I have been obliged to reject, in some instances, owing to the omission or confusion of the + and — signs; and in others, owing to the observers having omitted to state what thermometers they employed. During the researches into which the compilation of this table has led me—occupying as it has done the occasional leisure of four years — my mind has been strongly impressed with the benefits which would accrue to science, if the philosophers of Europe would agree to employ only one scale, with small degrees, and so adjusted as to render entirely unnecessary the use of the + and — signs.

Thermometer. Self-registering by photography. The first person who in this country proposed to apply photography, and actually did apply it, as a means of registering the movements of the mercury in the thermometer and barometer, and also for registering the variations in the magnetic intensity, was Mr. Thomas B. Jordan, at that time secretary to the Royal Cornwall Polytechnic Society. The results of this gentleman's methods, and the description of his plans, will be found in the *Sixth Annual Report of the Royal Cornwall Polytechnic Society for* 1838.

Mr. Ronalds, of the Kew Observatory, also devised an arrangement for employing photography as the means of registering meteorological inventions, and subsequently Mr. Brook perfected the following method: — The registering apparatus consists of a pair of vertical concentric cylinders, supported on a table. The bulbs of the thermometers are underneath the table, through which the stems pass vertically, and are placed between the opposite sides of the cylinders and two lights. A narrow vertical line of light brought to a focus by a cylindrical lens falls on the stem of the thermometer, and passing through the empty portion of the bore affects the paper. The boundary between the darkened and undarkened portion indicates the position of the mercury in the stem of the thermometer. Fine wires are placed across the slit in the frame, through which the light falls on the stem. They intercept narrow portions of the light, and thus the scale of the thermometer is continuously impressed on the register, as well as the temperature. *a, b, fig.* 1775, are camphine lamps; *c, d,* cylindrical lenses, by which a bright focal line of light is obtained; *e,* the psychrometer, or wet bulb thermometer; *f,* the dry bulb thermometer; *g,* two concentric cylinders, between which the photographic paper is placed; *h,* the register, as it appears after the impression is developed; *i,* one of the rollers of a turn-table, on which the cylinders rest; *j,* the frame which contains the time-piece; *k,* a bent pin, or carrier, attached to the axis of the cylinders; this is carried round by a fork at the end of the hour hand of the time-piece. As this apparatus is necessarily placed in the open air, when in actual operation it is provided with—1. An inner cylindrical zinc case, with sliding doors, to protect the sensitive paper from light, when the cylinder is removed from, and brought back to the photographic room. 2. An outer wind and water-tight zinc case, with water-tight doors for removing and replacing the cylinders, and for trimming the lamps, if lamps are used.

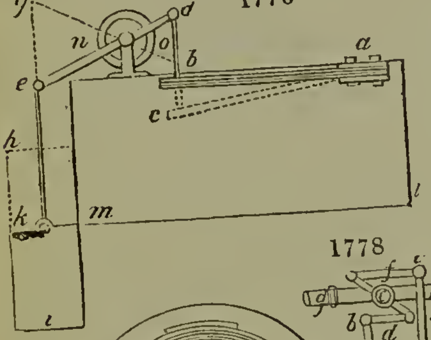
1775



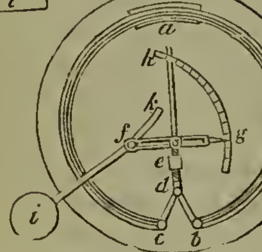
The paper is prepared so as to render it extremely sensitive to light, being first washed with a solution of isinglass, bromide of potassium and iodide of potassium, in the proportion of 1, 3, and 2, respectively; and when required for use, it is washed with an aqueous solution of nitrate of silver which causes the paper to be sufficiently sensitive to the action of light, so that if a beam of light be allowed to fall upon it, an impression is made upon that part where the light falls, which becomes visible on being washed with a solution of gallic acid, with a small admixture of acetic acid. A light is placed near a small aperture, through which rays pass and fall upon a concave mirror carried by a part of the suspension apparatus of the magnet, and this reflection falls upon a plano-cylindrical lens of glass placed at the distance of its focal length from the paper on the cylinder. As the magnet is ever varying and making small excursions on one or other side of its mean position, the point of light traces a corresponding zigzag on the paper. The thermometer apparatus has no mirror and no reflector, the mercury in the tubes themselves intercepting the pencils of light; and thus this apparatus, throughout the day and night, is constantly recording the slightest change of position of the magnets and the smallest changes of temperature.

THERMOSTAT, is the name of an apparatus for regulating temperature, in vaporisation, distillations, heating baths or hothouses, and ventilating apartments, &c.; for which Dr. Ure obtained a patent in the year 1831. It operates upon the physical principle, that when two thin metallic bars of different expansibilities are riveted or soldered facewise together, any change of temperature in them will cause a sensible movement of flexure in the compound bar, to one side or other; which movement may be made to operate, by the intervention of levers, &c., in any desired degree, upon valves, stopcocks, stove-registers, air-ventilators, &c.; so as to regulate the temperature of the media in which the said compound bars are placed. Two long rulers, one of steel, and one of hard hammered brass, riveted together, answer very well; the object being not simply to *indicate*, but to *control* or *modify* temperature. The following diagrams will illustrate a few out of the numerous applications of this instrument:—

1776



1778



1777

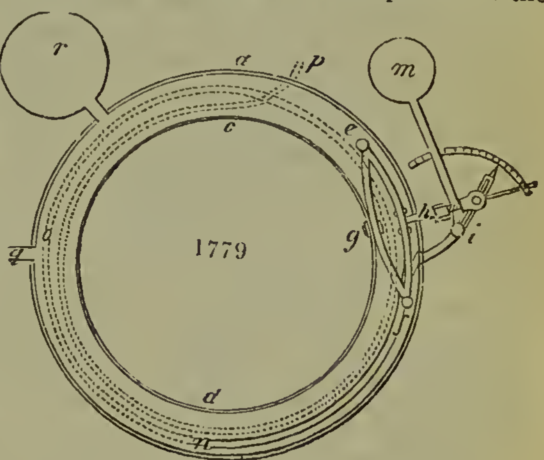
Fig. 1776, *a*, *b*, is a single thermostatic bar, consisting of two or more bars or rulers of differently expansible solids (of which, in certain cases, wood may be one): these bars or rulers are firmly riveted or soldered together, face to face. One end of the compound bar is fixed by bolts at *a*, to the interior of the containing cistern, boiler, or apartment, *a l m b*, whereof the temperature has to be regulated, and the other end of the compound bar at *b*, is left free to move down towards *c*, by the flexure which will take place when its temperature is raised.

The end *b*, is connected by a link *b d*, with a lever *d e*, which is moved by the flexure into the dotted position *b g*, causing the turning-valve, air-ventilator, or register *o n*, to revolve with a corresponding angular motion, whereby the lever will raise the equipoised slide-damper *k i*, which is suspended by a link from the end *e*, of the lever *e d*, into the position *k h*. Thus a hothouse or a water-bath may have its temperature regulated by the contemporaneous admission of warm, and discharge of cold air, or water.

Fig. 1777, *a b c*, is a thermostatic hoop, immersed horizontally beneath the surface of the water-bath of a still. The hoop is fixed at *a*, and the two ends *b*, *c*, are connected by two links *b d*, *c d*, with a straight sliding-rod *d h*, to which the hoop will give an endwise motion, when its temperature is altered; *e*, is an adjusting screw-nut on the rod *d h*, for setting the lever *f g*, which is fixed on the axis of the turning-valve or cock *f*, at any desired position, so that the valve may be opened or shut at any desired temperature, corresponding to the widening of the points *b*, *c*, and the consentaneous retraction of the point *d*, towards the circumference *a b c* of the hoop. *g h*, is an arc graduated by a thermometer, after the screw-piece *e* has been adjusted. Through a hole at *h*, the guide-rod passes; *i*, is the cold-water cistern; *i f k*, the pipe to admit cold water; *l*, the over-flow pipe, at which the excess of hot water runs off.

Fig. 1778 shows a pair of thermostatic bars, bolted fast together at the ends *a*. The free ends *b*, *c*, are of unequal length, so as to act by the cross links *d*, *f*, on the stopcock *e*. The links are jointed to the handle of the turning plug of the cock, on opposite sides of its centre; whereby that plug will be turned round in proportion to the widening of the points *b*, *c*. *h g*, is the pipe communicating with the stopcock.

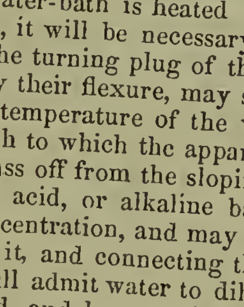
Suppose that for certain purposes in pharmacy, dyeing, or any other chemical art, a water-bath is required to be maintained steadily at a temperature of 150° Fahr.; let the combined thermostatic bars, hinged togther at *e*, *f*, *fig*. 1779, be placed in the bath, between the outer and inner vessels *a*, *b*, *c*, *d*, being bolted fast to the inner vessel at *g*; and have their sliding-rod *k*, connected by a link with a lever fixed upon the turning-plug of the stopcock *i*, which introduces cold water from a cistern *m*, through a pipe *m i n*, into the bottom part of the bath. The length of the link must be so adjusted that the flexure of the bars, when they are at a temperature of 150°, will open the said stopcock, and admit cold water to pass into the bottom of the bath through the pipe *i n*, whereby hot water will be displaced at the top of the bath through an open overflow-pipe at *q*. An oil bath may be regulated on the same plan; the hot oil overflowing from *q*, into a refrigeratory worm, from which it may be restored to the cistern *m*. When a water-bath is heated by the distribution of a tortuous steam pipe through it, as *i n o p*, it will be necessary to connect the link of the thermostatic bars with the lever of the turning plug of the steam-cock, or of the throttle valve *i*, in order that the bars, by their flexure, may shut or open the steam passage more or less, according as the temperature of the water in the bath shall tend more or less to deviate from the pitch to which the apparatus has been adjusted. The water of the condensed steam will pass off from the sloping winding-pipe *i n o p*, through the sloping orifice *p*. A saline, acid, or alkaline bath has a boiling temperature proportional to its degree of concentration, and may therefore have its heat regulated by immersing a thermostat in it, and connecting the working part of the instrument with the stopcock *i*, which will admit water to dilute the bath whenever by evaporation it has become concentrated, and has acquired a higher boiling point. The space for the bath, between the outer and inner pans, should communicate by one pipe with the water-cistern *m*; and by another pipe with a safety cistern *r*, into which the bath may be allowed to overflow during any sudden excess of ebullition.



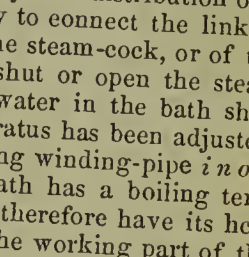
1779

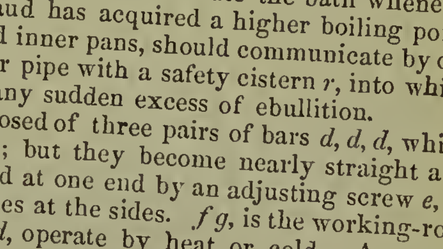
Fig. 1782 is a thermostatic apparatus, composed of three pairs of bars *d*, *d*, *d*, which are represented in a state of flexure by heat; but they become nearly straight and parallel when cold. *a b c* is a guide-rod, fixed at one end by an adjusting screw *e*, in the strong frame *f c*, having deep guide-grooves at the sides. *f g*, is the working-rod, which moves endways when the bars *d*, *d*, *d*, operate by heat or cold. A square register-plate *h g*, may be affixed to the rod *f g*, so as to be moved backwards and forwards thereby, according to the variations of temperature; or the rod *f*, *g*, may cause the circular turning air-register *i*, to revolve by rack and wheel-work, or by a chain and pulley. The register-plate *h g*, or turning-register *i*, is situated at the ceiling or upper part of the chamber, and serves to let out hot air. *k*, is a pulley, over which a cord runs to raise or lower a hot-air register *l*, which may be situated near the floor of the apartment or hot-house, to admit hot air into the room. *c*, is a milled head, for adjusting the thermostat, by means of the screw at *e*, in order that it may regulate the temperature to any degree.

1780



1781





1782

Fig. 1783 represents a chimney furnished with a *pyrostat*, *a b c*, acting by the links *b*, *d*, *c*, *c*, on a damper *f h g*. The more expansible metal is in the present example supposed to be on the outside. The plane of the damper-plate will, in this case, be turned more directly into the passage of the draught through the chimney by increase of temperature.

Fig. 1781 represents a circular turning register, such as is used for a stove, or stove-grate, or for ventilating apartments; it is furnished with a series of spiral thermostatic bars, each bar being fixed fast at the circumference of the circle *b*, *c*, of the fixed plate of the air-register; and all the bars act in concert at the centre *a*, of the turning part of the register, by their ends being inserted between the teeth of a small pinion, or by being jointed to the central part of the turning-plate by small pins.

1783

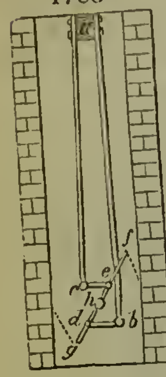


Fig. 1780 represents another arrangement of my thermostatic apparatus applied to a circular turning register, like the preceding, for ventilating apartments. Two pairs of compound bars are applied so as to act in concert, by means of the links *a c*, *b c*, on the opposite ends of a short lever, which is fixed on the central part of the turning plate of the air-register. The two pairs of compound bars *a*, *b*, are fastened to the circumference of the fixed plate of the turning register, by two sliding rods *a d*, *b e*, which are furnished with adjusting screws. Their motion or flexure is transmitted by the links *a c*, and *b c*, to the turning plate about its centre, for the purpose of shutting or opening the ventilating sectorial apertures, more or less, according to the temperature of the air which surrounds the thermostatic turning register. By adjusting the screws *a d*, and *b c*, the turning register is made to close all its apertures at any desired degree of temperature, but whenever the air is above that temperature, the flexture of the compound bars will open the apertures.

THIALDINE. $C^{12}H^{13}NS^{4}$. A curious alkaloid, formed by the action of sulphuretted hydrogen on aldehyde ammonia.

THIEVES' VINEGAR. (*Le Vinaigre des quatre Voleurs*, Fr.) See Aromatic Vinegar.

THIMBLE (*Dé à coudre*, Fr.; *Fingerhut* (*fingerhat*), Germ.) is a small truncated metallic cone, deviating little from a cylinder, smooth within, symmetrically pitted on the outside with numerous rows of indentations, which is put upon the tip of the middle finger of the right hand, to enable it to push the needle readily and safely through cloth or leather, in the act of sewing. This little instrument is fashioned in two ways; either with a pitted round end, or without one; the latter, called the open thimble, being employed by tailors, upholsterers, and, generally speaking, by *needle-men*. The following ingenious process for making this essential implement, the contrivance of MM. Rouy and Berthier, of Paris, has been much celebrated, and very successful. Sheet-iron, one twenty-fourth of an inch thick, is cut into strips, of dimensions suited to the size of the intended thimbles. These strips are passed under a punch-press, whereby they are cut into discs of about 2 inches diameter, tagged together by a tail. Each strip contains one dozen of these blanks. A child is employed to make them red-hot, and to lay them on a mandril nicely fitted to their size. The workman now strikes the middle of each with a round-faced punch, about the thickness of his finger, and thus sinks it into the concavity of the first mandril. He then transfers it successively to another mandril, which has five hollows of successively increasing depth; and, by striking it into them, brings it to the proper shape.

A second workman takes this rude thimble, sticks it in the chuck of his lathe, in order to polish it within, then turns it outside, marks the circles for the gold ornament, and indents the pits most cleverly with a kind of milling tool. The thimbles are next annealed, brightened, and gilt inside, with a very thin cone of gold leaf, which is firmly united to the surface of the iron, simply by the strong pressure of a smooth steel mandril. A gold fillet is applied to the outside, in an annular space turned to receive it, being fixed by pressure at the edges, into a minute groove formed on the lathe.

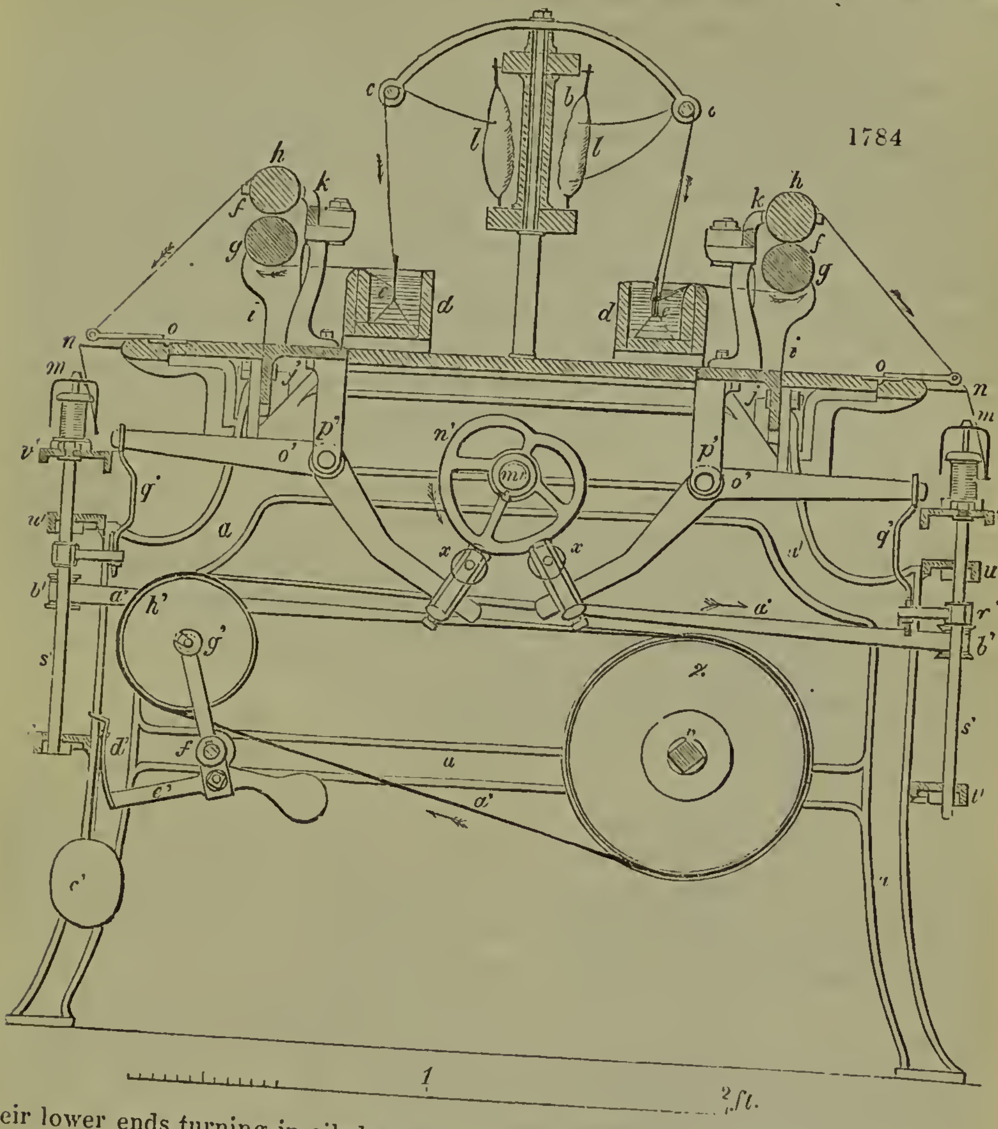
Thimbles are made in this country by means of moulds in the stamping machine. See Stamping of Metals.

THORINA, is a primitive earth, with a metallic basis, discovered in 1828 by Berzelius. It was extracted from the mineral *thorite*, of which it constitutes 58 per cent., and where it is associated with the oxide of iron, lead, manganese, tin, and uranium, besides earths and alkalies, in all twelve substances. Pure thorina is a white powder, without taste, smell, or alkaline reaction on litmus. When dried and calcined it is not affected by either the nitric or muriatic acid. It may be fused with borax into a transparent glass, but not with potash or soda.

THORINUM or THORIUM. A rare metal found in the mineral *thorite*, which contains about 57 per cent. of thorina, the oxide of this metal.

THREAD MANUFACTURE. The doubling and twisting of cotton or linen yarn into a compact thread for weaving bobbin-net, or for sewing garments, is performed by a machine resembling the throstle of the cotton-spinner. *Fig.* 1784 shows the thread-frame in a transverse section, perpendicular to its length. *a*, is the strong framing of cast iron; *b*, is the *creel*, or shelf, in which the bobbins of yarn *l*, *l*, are set loosely upon their respective skewers, along the whole line of the machine,

1784



their lower ends turning in oiled steps, and their upper in wire eyes; *c*, is a glass rod across which the yarn runs as it is unwound; *d*, *d*, are oblong narrow troughs, lined with lead and filled with water, for moistening the thread during its torsion; the threads being made to pass through eyes at the bottom of the fork *e*, which has an upright stem for lifting it out without wetting the fingers, when anything goes amiss; *f*, *f*, are the pressing rollers, the under one *g*, being of smooth iron, and the upper one *h*, of boxwood; the former extends from end to end of the frame, in lengths comprehending eighteen threads, which are joined by square pieces, as in the drawing-rollers of the mule-jenny. The necks of the under rollers are supported at the ends and the middle, by the standards *i*, secured to square bases *j*, both made of cast iron. The upper cylinder has an iron axis, and is formed of as many rollers as there are threads; each roller being kept in its place upon the lower one by the guides *k*, whose vertical slots receive the ends of the axes.

The yarn delivered by the bobbin *l*, glides over the rod *c*, and descends into the trough *d e*, where it gets wetted; on emerging, it goes along the bottom of the roller *g*, turns up so as to pass between it and *h*, then turns round the top of *h*, and finally proceeds obliquely downwards, to be wound upon the bobbin *m*, after traversing the guide-eye *n*. These guides are fixed to the end of a plate which may be turned up by a hinge-joint at *o*, to make room for the bobbins to be changed.

There are three distinct simultaneous movements to be considered in this machine: 1. that of the rollers, or rather of the under roller, for the upper one revolves merely by friction; 2. that of the spindles *m*, *s'*; 3. the up-and-down motion of the bobbins upon the spindles.

The first of these motions is produced by means of toothed wheels, upon the right hand of the under set of rollers. The second motion, that of the spindles, is effected by the drum z, which extends the whole length of the frame, turning upon the shaft v, and communicating its rotary movement (derived from the steam pulley) to the whorl b' of the spindles, by means of the endless band or cord a'. Each of these cords turns four spindles, two upon each side of the frame. They are kept in a proper state of tension by the weights e', which act tangentially upon the circular arc d', fixed to the extremity of the bell-crank lever e' f' g', and draw in a horizontal direction the tension pulleys h, embraced by the cords. The third movement, or the vertical traverse of the bobbins, along the spindles m, takes place as follows: —

The end of one of the under rollers carries a pinion, which takes into a carrier wheel that communicates motion to a pinion upon the extremity of the shaft m', of the heart-shaped pulley n'. As this eccentric revolves, it gives a reciprocating motion to the levers o', o', which oscillate in a vertical plane round the points p', p'. The extremities of these levers on either side act by means of the links q', upon the arms of the sliding sockets r', and cause the vertical rod s', to slide up and down in guide-holes at t', u', along with the cast-iron step v', which bears the bottom washer of the bobbins. The periphery of the heart-wheel u', is seen to bear upon friction wheels x, x', set in frames adjusted by screws upon the lower end of the bent levers, at such a distance from the point p', as that the traverse of the bobbins may be equal to the length of their barrel.

By adapting change pinions and their corresponding wheels to the rollers, the delivery of the yarn may be increased or diminished in any degree, so as to vary the degree of twist put into it by the uniform rotation of the drum and spindles. The heart motion being derived from that of the rollers, will necessarily vary with it.

Silk thread is commonly twisted in lengths of from 50 to 100 feet, with hand reels, somewhat similar to those employed for making ropes by hand.

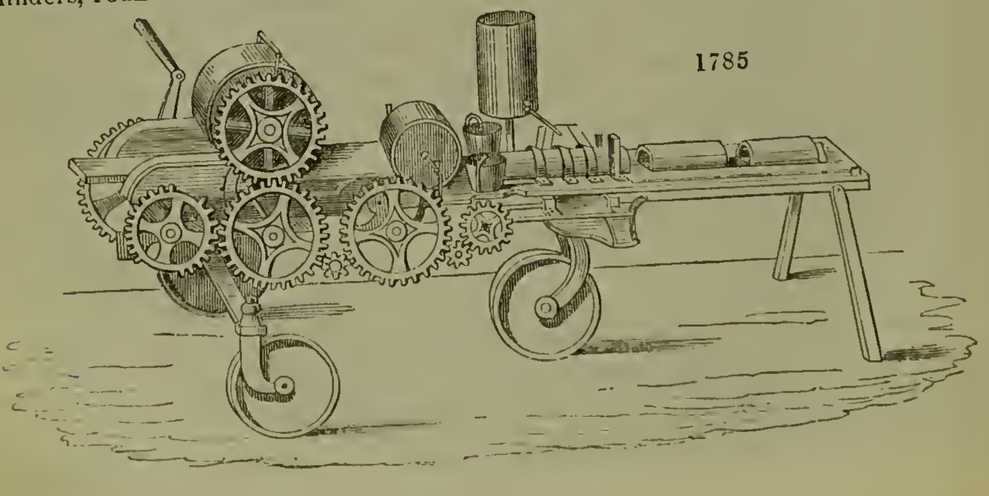
TILES and TESSERÆ. Tile manufacture is a very comprehensive term, embracing the following varieties: —

Paving bricks or tiles.
Plain tiles.
Ridge tiles.
Oven tiles.
Pan tiles.
Circulars.
Foot tiles.
Hip tiles.
Drain tiles, &c.

The clay used for making tiles is purer and stronger than that used for making bricks. When the clay is too strong, that is, too adhesive, it is mixed with sand before passing it through the pug-mill. As a usual practice the clay is *weathered*; this is effected by spreading it out in layers of about two inches in thickness during the winter, and each layer is allowed the benefit of at least one night's frost before the succeeding layer is put over it. This *weathering* is sometimes effected by exposing the layers to sunshine, which is said to answer equally well with frost. What this weathering does is by no means clear: it is said "to open the pores of the clay." We believe that what really takes place is, that under the influences to which it is exposed, the particles break up into smaller particles, and that we have the clay in a more finely comminuted state. The next process is that of *tempering*. After the clay has been allowed to "mellow, or ripen," in pits, under water, it is passed through the pug-mill and well kneaded or tempered. It is then *slung*, that is, cut into slices with a string: during which process the stones fall out, or are removed by the hand; it is then ready for the operation of moulding. This may be performed by hand, or by any one of the many machines which have been devised.

Fig. 1785 shows Mr. Hunt's machine for making tiles. It consists of two iron cylinders, round which webs or bands of cloth revolve, whereby the clay is pressed

1785



into a slab of uniform thickness, without adhering to the cylinders. It is then carried over a covered wheel, curved on the rim, which gives the tile the semi-cylindrical or other required form; after which the tiles are polished and finished by passing through three iron moulds of a horse-shoe form, as shown in the centre of the cut, while they are at the same time moistened from a water cylinder placed above them. The tiles are next cut off to such lengths as are wanted, and carried away by an endless web, whence they are transferred by boys to the drying shelves.

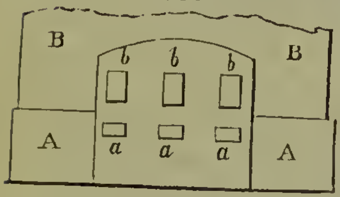
Flat tiles, for sole pieces to draining tiles, are formed in nearly the same manner, being divided into two portions while passing through the moulds: the quantity of clay used for one draining tile being as much as for two soles.

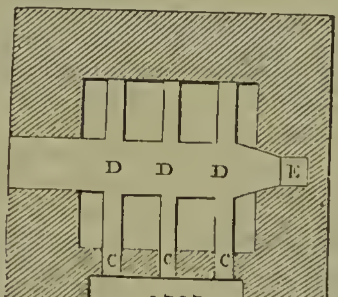
By hand, the work is divided between a moulder and a rough moulder. The latter, a boy, takes a piece of clay and squares it up, that is, beats it up into a slab nearly the shape of the mould, and about 4 inches thick, from which he cuts off a thin slice the size of a tile, and passes it to the moulder. The moulder sands his stock-board, and, regulating the thickness of the tile by four pegs, on which the mould is placed, he puts the piece of clay with which he is supplied into the mould; he then smooths the surface with his very wet hands, removes the superfluous clay, and moulds it into a curved shape. They are then placed to dry, with the convex side uppermost; when half-dry the tiles are taken out one by one, placed on the *thwacking* frame, and beaten with the thwacker to produce the required shape; when dry they are kilned.

The following plan of a furnace, or kiln, for burning tiles has been found very convenient: —

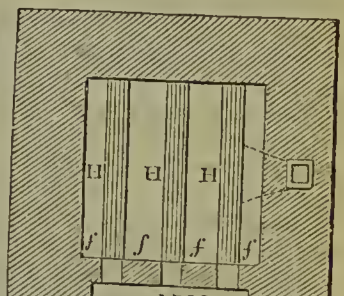
Fig. 1786, front view, A A, B B, the solid walls of the furnace; *a a a*, openings to the ash-pit, and the draught hole; *b b b*, openings for the supply of fuel, furnished with a sheet-iron door. *Fig.* 1787, plan of the ash-pits and air channels C C C. The

1786





1787



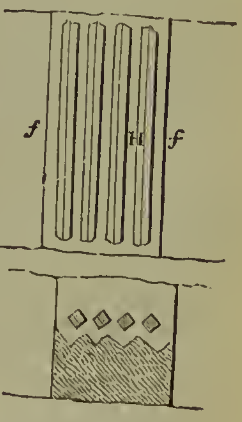
1788

principal branch of the ash-pit D D D, is also the opening for taking out the tiles, after removing the grate; E, the smoke flue. *Fig.* 1788, plan of the kiln seen from above. The grates, H H H. The tiles to be fired are arranged upon the spaces *f f f f.*

Fig. 1789 is the plan and section of one of the grates upon a much larger scale than in the preceding figures.

The Roman tesseræ, of which many very fine examples have been discovered in this country, were, often, natural stones (sometimes coloured artificially), but generally of baked clay. The beauty of many of these has led to the production of modern imitations, which have been gradually improved, until, in the final result, they far exceed any work of the Romans.

1789



About half a century since Mr. C. Wyatt obtained a patent for a mode of imitating tesselated pavements, by in-laying stone with coloured cements. Terra cotta, inlaid with coloured cements, has also been employed, but with no very marked success.

Mr. Blashfield produced imitations of those pavements, by colouring cements with the metallic oxides: these stood exceedingly well when under cover, but they did not endure the winter frosts, &c. Bitumen, coloured with metallic oxyds, was also employed by Mr. Blashfield. In 1839 Mr. Singer, of Vauxhall, introduced a mode of forming tesseræ from thin layers of clay. These were cut into the required forms, dried and baked. In 1840 Mr. Prosser, of Birmingham, discovered that if the material of porcelain (china clay) be reduced to a dry powder, and in that state be compressed between steel dies, the powder is condensed into about a fourth of its bulk, and is converted into a compact solid substance of extraordinary hardness and density.

This process was first applied to the manufacture of buttons, but was eventually taken up by Mr. Minton, and in conjunction with Mr. Blashfield, Messrs. Wyatt, Parker, and Co., was carried to a high degree of perfection for making tesseræ.

The new process, invented by Mr. Prosser, avoided the difficulty altogether of using wet clay.

This change in the order of the potter's operations, although very simple in idea (and a sufficiently obvious result of reflection on the difficulties attending the usual course of procedure), has nevertheless required a long series of careful experiments to find out the means of rendering it available in practice.

The power which the hand of the potter has exercised over his clay has been proverbial from time immemorial, but it is limited to clay in its moist or plastic state; and clay in its powdered state is an untractable material, requiring very exact and powerful machinery to be substituted for the hand of the potter; in order, by great pressure, to obtain the requisite cohesion of the particles of clay.

In the new process, the clay, or earthy material, after being prepared in the usual manner, and brought to the plastic state, as above described (except that no kneading or tempering is requisite), is formed into lumps, which are dried until the water is evaporated from the clay.

The lumps of dried clay are then broken into pieces, small enough to be ground by a suitable mill into a state of powder, which is afterwards sifted, in order to separate all coarse grains and obtain a fine powder, which it is desirable should consist of particles of uniform size as nearly as can be obtained. The powder, so prepared, is the state in which the clay is ready for being moulded into the form of the intended article by the new process.

The machine and mould used for moulding articles of a small size, in powdered clay, is represented in the annexed drawing, wherein *fig.* 1790 is a lateral elevation of the whole machine.

A A is the wooden bench or table whereon the whole is fixed, that bench being sustained on legs standing on the floor. B D E is the frame, formed in one piece of cast iron; the base, B, standing on the bench, and being fixed thereto by screw bolts; the upright standard, D, rising from the base, and sustaining at its upper end the boss, E, wherein the nut or box, *a*, is fixed for the reception of the vertical screw, F. The screw, F, works through the box, *a*, and has a handle, G, *g*, *h*, applied on the upper end of the screw; the handle is bended downwards at *g*, to bring the actual handle, *h*, to a suitable height for the person who works that machine to grasp the handle, *h*, in his right hand, and, by pulling the handle, *h*, toward him, the screw, F, is turned round in its box, *a*, and descends. The lower end of the screw, F, is connected with a square vertical slider, H, which is fitted into a socket, I, fixed to the upright part, D, of the frame, and the slider, H, is thereby confined to move up or down, with an exactly vertical motion, when it is actuated by the screw, without deviation from the vertical.

Thus far the machine is an ordinary screw press, such as is commonly used for cutting and compressing metals for various purposes. The tools with which the press is furnished for the purpose of this new process consist of a hollow mould, *e e*, formed of steel, the exterior cavity of the mould being the exact size of the article which is to be moulded. The mould, *e e*, is firmly fixed on the base, B, of the frame, so as to be exactly beneath the lower end of the piston *a*, or plug, *f*, which is fastened to the lower end of the square slider, H, and the plug, *f*, is adapted to descend into the hollow of the mould, *e e*, when the slider, H, is forced downwards by action of the screw, F, the plug *f* being very exactly fitted to the interior of the mould, *e e*.

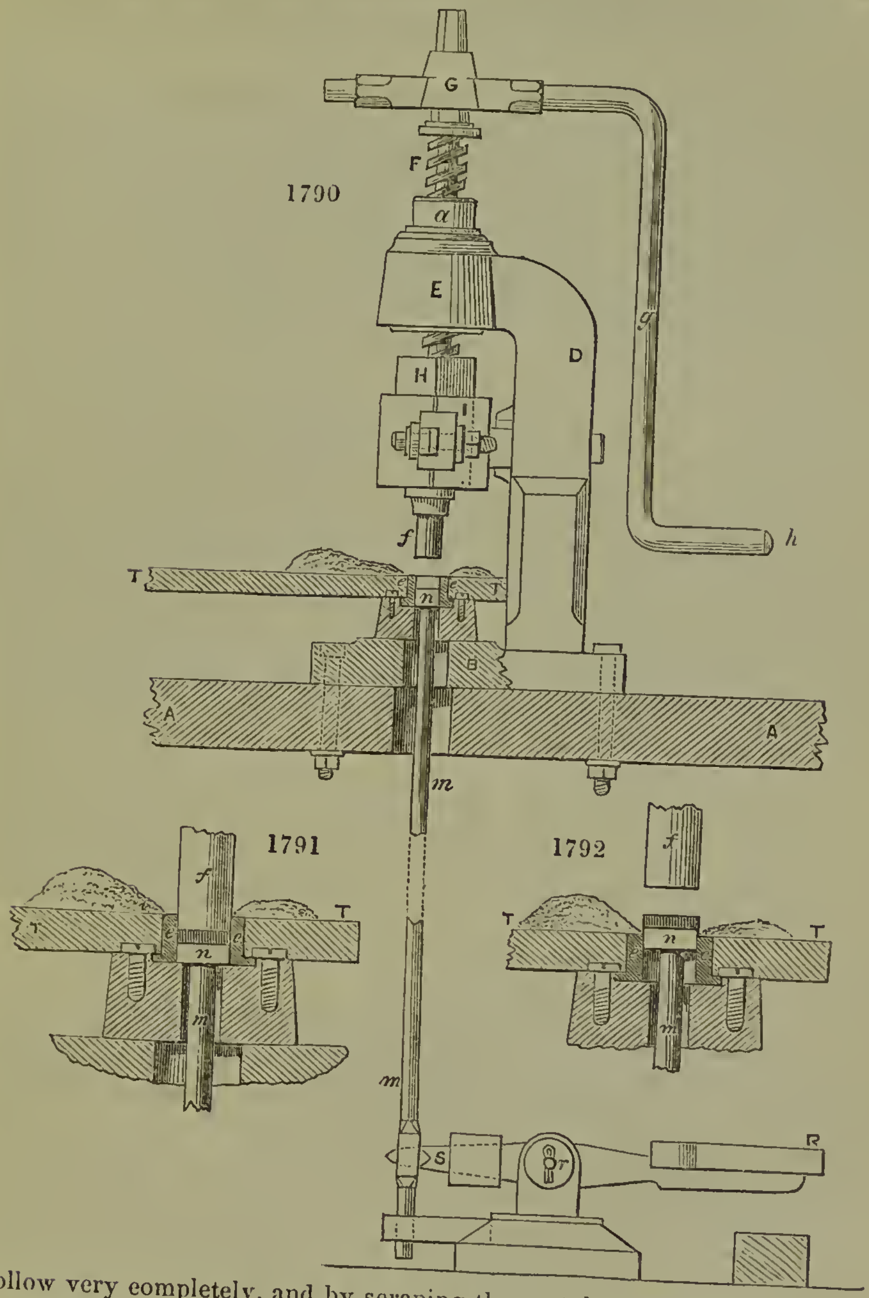
The bottom of the mould, *e e*, is a movable piece, *n*, which is exactly fitted into the interior of the mould, but which lies at rest in the bottom of the mould, *e e*, during the operation of moulding the article therein; but afterwards the movable bottom, *n*, can be raised up by pressing one foot upon one end, R, of a pedal lever, R S, the fulcrum of which is a centre pin, *r*, supported in a standard resting upon the floor, and the end, S, of the lever operates on an upright rod, *m*, which is attached at its upper end to the movable bottom, *n*, of the mould, *e e*.

A small horizontal table, T T, is fixed round the mould, *e e*, and on that table a quantity of powdered clay is laid in a lump in readiness for filling the mould.

The two detached figures, marked figures 1791 and 1792, are sections of the mould *e e*, and the plug, *f*, on a larger scale than figure 1790, in order to exhibit their action more completely.

The operation is extremely simple; the operator, holding the handle, *h*, with his right hand, puts it back from him, so as to turn back the screw, F, and raise the slider, H, and the plug, *f*, quite out of the mould, *e e*, and clear above the orifice of the mould, as shown in figure 1790.

Then with a spatula of bone, held in the left hand, a small quantity of the powder is moved laterally from the heap, along the surface of the table, T, T, towards the mould *e e*, and gathered into the hollow of the mould with a quiet motion, so as to fill



that hollow very completely, and by scraping the spatula evenly across over the top of the mould *e e*, the superfluous powder will be removed, leaving the hollow cavity of the mould exactly filled with the powder in a loose state, and neither more nor less than filled.

Then the handle, *h*, being drawn forwards with a gentle movement of the right hand, it turns the screw, F, so as to bring the slider, H, and the plug, *f*, which thereby descends into the mould, *e e*, upon the loose powder wherewith the mould has been filled, and begins to press down that powder, which must be done with a gentle motion without any jerk, in order to allow the air that is contained in the loose powder to make its escape; but the pressure, after having been commenced gradually, is continued and augmented to a great force, by pulling the handle strongly at the last, so as to compress the earthy material down upon the bottom, *n*, of the mould, into about one-third the space it had occupied when it was in the state of loose powder. The section, *fig.* 1791, shows this state of the mould *e e*, and the plug *f*, and the compressed material.

Then the handle, *h*, is put backwards again, so as to turn back the screw, F, and raise up the slider, H, and the plug, *f*, until the latter is drawn up out of the mould *e e*, and clear above the orifice of the mould, as in *fig.* 1790, and immediately afterwards by pressure of one foot on the pedal, R, of the pedal lever, R, S, and by action of the upright rod, *m*, the movable bottom, *n*, of the mould is raised upwards in the mould *e e*, so as to elevate the compressed material which is resting upon the bottom, *n*, and carry the same upwards, quite out of the mould *e e*, and above the orifice of the mould, as is shown in *fig.* 1792, and then the compressed material can be removed by the finger and thumb.

The compressed material which is so withdrawn is a solid body, retaining the exact shape and size of the interior cavity of the mould, and possessing sufficient coherence to enable it to endure as much handling as is requisite for putting a number of them into an earthenware case or pan, called a sagger, in which they are to be enclosed, according to the usual practice of potters, in preparation for putting them into the potter's kiln for firing; the sagger protects the articles from discoloration by smoke, and from partial action of the flame, which, if a number of small articles were exposed thereto without being so enclosed, might operate more strongly upon some than upon others of those articles; but by means of the saggers the heat is caused to operate with clearness, uniformity, and certainty upon a number of small articles at once.

After the firing is over, the articles being removed from the saggers, are in the state of what is termed biscuit, and are ready for use, unless they are required to be glazed, in which case they may be dipped into a semi-liquid composition of siliceous and other matters, ground in water to the consistency of cream, and the surface of the articles which are so dipped becomes covered with a thin coating of the glazed composition, and then the articles are again put into saggers, and subjected to a second operation of firing in another kiln, the heat whereof vitrifies the composition and gives a glassy surface to the articles, all which is the usual course of making glazed earthenware or porcelain; but for articles formed by the new process, a suitable glazing composition is more usually applied within the saggers, into which the articles are put for the first firing, and the glazing is performed at the same time with the first burning, without any other burning being required. Or, in other cases, the composition of earthy materials which is chosen for the articles may be such as will become partially vitrified by the heat to which they are exposed in the kiln, and thereby external glazing is rendered unnecessary.

The great contraction which must take place in drying articles which have been moulded from clay in the moist state is altogether prevented, and consequently all uncertainty in the extent of that contraction is avoided. Tiles, tesseræ, and other articles are now made by this machine; and very beautiful pavements are constructed, excelling the finest works of the Romans in form, in colour, and in all the mechanical conditions.

Number of tiles *exported* in 1858, 784,768; declared real value, £6489.

TILTING OF STEEL. See Steel.

TIN (*Etain*, Fr.; *Zinn*, Germ.), in its pure state, has nearly the colour and lustre of silver. In hardness it is intermediate between gold and lead; it is very malleable, and may be laminated into foil less than the thousandth of an inch in thickness; it has an unpleasant taste, and exhales on friction a peculiar odour; it is flexible in rods or straps of considerable strength, and emits in the act of bending a crackling sound, called the creaking of tin, as if sandy particles were intermixed. A small quantity of lead, or other metal, deprives it of this characteristic quality. Tin melts at 442° Fahr., and is very fixed in the fire at higher heats. Its specific gravity is 7·29. When heated to redness with free access of air, it absorbs oxygen with rapidity, and changes first into a pulverulent grey oxide, and by longer ignition into a yellow-white powder, called *putty* of tin. This is the peroxide, consisting of 100 of metal + 27·2 of oxygen.

Tin has been known from the most remote antiquity. It is probably mentioned in the books of Moses; and the ships of Tarshish appear to have brought this metal from islands eastward of the Persian Gulf. The Phœnicians carried on a lucrative trade in it with Spain and Cornwall.

The earliest navigators appear to have taken tin from the east and from the west to supply the wants of Egypt and of Greece. That the Phœnicians, with whom, in those days, the maritime trade of the world rested, collected tin from our own islands is certain; at the same time it is highly probable that the Indian islands were another source from which they obtained this metal in considerable quantities.

"Kassiteros," says Humboldt, "is the ancient Indian Sanscrit word Kastire; *Zinn* in German, *Den* in Icelandic, *Tin* in English, and *Tenn* in Swedish, is in the Malay and Javanese language *Timah*, a similarity of sound which reminds us of that of the old German word *Glessum* (the name given to transparent amber) to the modern 'glas,' glass. The names of articles of commerce pass from nation to nation, and become adopted into the most different languages. Through the intercourse which the Phœnicians, by means of their factories in the Persian Gulf, maintained with the east coast of India, the Sanscrit word *Kastira* became known to the Greeks, even before Albion and the British Cassiterides had been visited."

The Cassiterides, or Tin Islands, have been supposed to be, by some, the Islands of Scilly. This idea has been far too hastily adopted, seeing that the Scilly Islands produce no tin. In all probability this name was given by the Phœnicians to the whole of the western promontory of Cornwall, the only part of this country with which they were acquainted, the name being without doubt derived from the *Kassiteros* of the East.

There are only two ores of tin; the peroxide, tin-stone, or Cassiterite, and tin pyrites, sulphide of tin, or stannine, the former of which alone has been found in sufficient abundance for metallurgic purposes. The external aspect of tin-stone has nothing very remarkable. It occurs sometimes in twin crystals; its lustre is adamantine; its colours are very various, as white, grey, yellow, red, brown, black; specific gravity, 6·9 at least; which is, perhaps, its most striking feature. It does not melt by itself before the blowpipe, but is reducible in the smoky flame or on charcoal. It is insoluble in acids. It has somewhat of a greasy aspect, and strikes fire with steel.

Tin-stone occurs disseminated in granite, gneiss, clay slate, chlorite and mica slate; also in beds and veins, in large irregular masses; and in pebbles, in the beds of ancient torrents: these occasionally take a ligneous aspect, and are termed *wood-tin*.

This ore has been found in but a few countries in a workable quantity. Its principal localities are, Cornwall, Bohemia, and Saxony, in Europe; and Malacca, Banca, and Billitan, in Asia. The tin mines of the Malay peninsula lie between the 10th and 6th degrees of south latitude. The mines in the island of Banca, to the east of Sumatra, discovered in 1710, are said to have furnished, in some years, nearly 3500 tons of tin. Small quantities occur in Galicia in Spain, the department of Haute Vienne in France, and in the mountain chains of the Fichtel and Riesengebürge in Germany. The columnar pieces of pyramidal tin-ore from Mexico and Chile are found in the alluvial deposits. Small groups of black twin crystals have been discovered in the albite rock of Chesterfield in Massachusetts.

The county of Cornwall is the most important mineral district of the United Kingdom for the number of its metalliferous minerals, many of which are not found in any other part of the island. At a very early period of our history mines were worked around the sea-coasts of Cornwall, of which the evidences are still to be seen at Tol-pedden-Penwith, near the Land's End; in Gwennap, near Truro; and at Cadwith, near the Lizard Point. The traditionary statements, that the Phœnicians traded for tin with the Britons in Cornwall, are very fairly supported by corroborative facts; and it is not improbable that the Ictes, or Iktis, of the ancients was St. Michael's Mount, near Penzance, and other similar islands on the coast.

In the reign of King John the mines of the western portion of England appear to have been principally in the hands of the Jews. The modes of working must have been very crude, and their metallurgical processes exceedingly rough. From time to time remains of furnaces, called *Jews' houses*, have been discovered, and small blocks of tin, known as *Jews' tin*, have not unfrequently been found in the mining localities.

Till a comparatively recent date, tin was the only metal which was sought for; and in many cases the mines were abandoned when the miners came to the "*yellows*," that was the yellow sulphide of copper. A great quantity of tin has been produced by "streaming" (as washing the débris in the valleys is termed); and this variety, called "stream tin," produces the highest price in the market.

The conditions under which these deposits occur are curious and instructive. At the Carnon Tin Stream Works, north of Falmouth, the rounded pebbles of tin are found at a depth of about 50 feet from the surface, beneath the bottom of an estuary, where trees are discovered in their place of growth, together with human skulls and the remains of deer, amidst the vegetable accumulation which immediately covers the stanniferous beds. According to Mr. Henwood's measurement, the section presents first about 50 feet of schlich and gravel; then a bed of 18 inches in thickness of wood, leaves, nuts, &c., resting on the tin ground, composed of the débris of quartz, slate, and granite, and the tin ore. At the Pentuan Works, near St. Austell, similar deposits occur, proving a material alteration in the level, during the period expended in the formation of this deposit.

The Cornish ores occur—1, in small strata or veins, or in masses; 2, in congeries of small veins; 3, in large veins; and 4, disseminated in alluvial deposits, as described.

The stanniferous small veins, or thin flat masses, though of small extent, are sometimes very numerous, interposed between certain rocks, parallel to their beds, and are commonly called tin-floors. In the mine of Bottalack a *tin-floor* has been found in the killas (a schistose rock), thirty-six fathoms below the level of the sea; it is about a foot and a half thick, and occupies the space between a principal vein and its ramification; but there seems to be no connection between the *floor* and the great vein.

2. Stockwerks, as the Germans term the disseminated masses, occur in granite and in the felspar porphyry, called in Cornwall *elvan*. The most remarkable of these, in the granite, is at the tin-mine of Carclase, near *St. Austell*. The works are carried on in the open air, in a friable granite, containing felspar — *kaolin*, or china clay, which is traversed by a great many small veins, composed of tourmaline, quartz, and a little tin-stone, that form black delineations on the face of the light-grey granite. The thickness of these little veins rarely exceeds 6 inches, including the adhering solidified granite, and is occasionally much less. Some of them run nearly east and west, with an almost vertical dip; others, with the same direction, incline to the south at an angle with the horizon of 70 degrees.

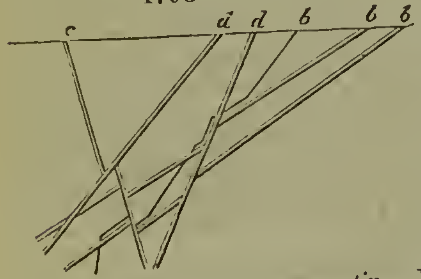
Stanniferous masses are much more frequent in the elvan (porphyry); of which the mine of Trewidden is a remarkable example. It was worked among flattened masses of *elvan*, separated by strata of *killas*, which dip to the east-north-east at a considerable angle. The tin ore occurred in small veins, varying in thickness from half an inch to 8 or 9 inches, which were irregular, and so much interrupted that it was difficult to determine either their direction or their inclination.

3. The large and proper metalliferous veins are not equally distributed over the surface of Cornwall and the adjoining part of Devonshire, but are grouped into three districts; namely, 1. In the south-west of Cornwall, beyond Truro; 2. In the neighbourhood of St. Austell; and 3. In the neighbourhood of Dartmoor in Devonshire.

The first group is by far the richest and the best explored. The formation most abundant in tin mines is principally granitic; though with numerous exceptions. The great tin veins are the most ancient metalliferous veins in Cornwall; yet they are not all of one formation, but belong to two or more different systems. Their direction is, however, nearly the same, but some of them dip towards the north, and others towards the south. It was formerly thought by the Cornish miners that tin occurred in the upper portions of the mineral lodes only, and mines were abandoned, as we have already stated, when in sinking the miners came to the "yellows"— copper pyrites, which were said "to have cut out the tin." Within the last few years, however, tin has been found at very great depths below the surface and beneath the copper. Dolcoath mine is a very remarkable example of this. This mine was first worked as a tin mine for a very long period; then as a copper mine for half a century; and then, upon persevering in depth, the lode was found to become more and more rich in tin, which is now worked to great advantage.

At Trevaunance mine the two systems of tin veins are, both, intersected by the oldest of the copper veins; indicating the prior existence of the tin veins. In *fig.* 1793, *b* marks the first system of tin veins; *c* the second; and *d* the east and west copper veins. Some of these tin veins, as at Poldice, have been traced over an extent of two miles; and they vary in thickness from a small fraction of an inch to several feet, the average width being from 2 to 4 feet; though this does not continue uniform for any length, as these veins are subject to continual narrowings and expansions. The gangue is quartz, chlorite, tourmaline, and sometimes decomposed granite and fluor spar.

1793

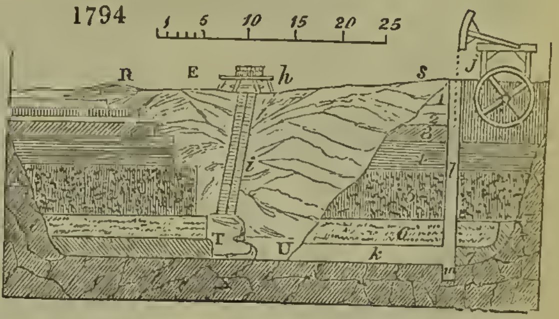


4. *Alluvial tin ore, stream tin.*—Peroxide of tin occurs disseminated both in the *alluvium* which covers the gentle slopes of the hills adjoining the rich tin mines, and also in the alluvium which fills the valleys that wind round their base; and in these deposits the tin-stone has been so abundant that for centuries the whole of the tin of Cornwall was derived from them; and it is still so to some extent. The most important explorations of *alluvial tin ore* are grouped in the environs of St. Just and St. Austell, where they are called *stream-works*, because water is the principal agent employed to separate the metallic oxide from the sand and gravel.

The most extensive and productive stream-works were formerly those of Pentewan, near St. Austell.

Fig. 1794 represents a vertical section of the Pentewan deposit, taken from the stream-work *Happy Union*. A vast excavation, R, T, U, *s*, has been hollowed out in the open air, in quest of the alluvial tin ore T, which occurs here at an unusual depth, below the level of the strata R, *s*. Before getting at this deposit, several successive layers had to be sunk through, namely, 1, 2, 3, the gravel, containing in its middle a band of ochreous earth, 2, or ferruginous clay; 4, a black peat, perfectly combustible, of a coarse texture, composed of reeds and woody fibres, cemented into a mass by a fine loam; 5, coarse sea-sand, mingled with marine shells; 6, a blackish marine mud, filled with shells. Below these the deposit of tin-stone occurs, including fragments of various size, of clay slate, flinty slate, quartz, iron ore, jasper; in a word, of all the rocks and gangues to be met with in the surrounding territory, with the exception of granite. Among these fragments there occurred, in rounded particles, a coarse quartzose sand, and the tin-stone, commonly in small grains and crystals. Beneath the bed T, is the clay slate called *killas* (A, X, Y), which supports all the deposits of more recent formation.

1794



The system of mining employed in stream-works is very simple. The successive beds, whose thickness is shown in the figure, are visibly cut out into steps or platforms. By a level or gallery of efflux *k*, the waters flow into the bottom of the well *l*, *m*, which contains the drainage pumps; and these are put in action by a machine *j*, moved by a water-wheel. The extraction of the ore is effected by an inclined plane *i*, cut out of one of the sides of the excavation, at an angle of about 45 degrees. At the lower end of this sloping pathway there is a place of loading; and at its upper end *h*, a horse-gin, for alternately raising and lowering the two baskets of extraction on the pathway *i*.

Mine tin—as distinguished from *Stream tin*, the former being worked by the miner out of the lode,—requires peculiar care in its mechanical preparation or dressing, on account of the presence of foreign metals, from which, as we have stated, stream tin is free.

1. As the mine tin is for the most part extremely dispersed through the gangue, it must be all stamped and reduced to a very fine powder, to allow the metallic particles to be separated from the stony matters.

2. As the density of tin-stone is much greater than that of most other metallic ores, it is less apt to run off in the washing; and may, therefore, be dressed, by care, so as to be cleaned of almost every matter not chemically combined.

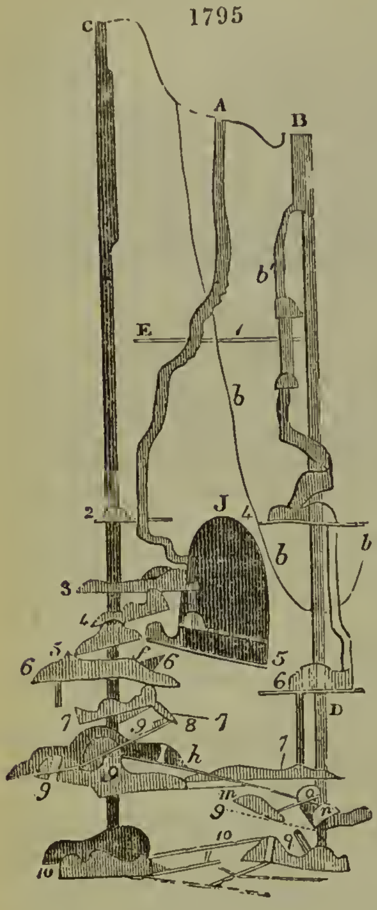
3. As the peroxide of tin is not affected by a moderate heat, it may be exposed to calcination; whereby the specific gravity of the associated sulphides and arsenides is so diminished as to facilitate their separation.

Tin ore, therefore, should be first of all pounded very fine in the stamp-mill, then subjected to reiterated washings, and afterwards calcined. The order of proceeding in Cornwall and other parts is fully described in the article ORE DRESSING, which see. See also METALLURGY for a description of the roasting processes.

The tin ores of Cornwall and Devonshire are all smelted within the counties where they are mined: the vessels which bring the fuel from Wales, for smelting these ores, return to Swansea and Neath loaded with copper ores.

The tin mine of Altenberg, in Saxony (*fig.* 1795, which is a vertical projection in a plane passing from west to east), is remarkable for an interlaced mass of ramifying veins, which has been worked ever since the year 1458. The including rock is a primitive porphyry, superposed upon gneiss; becoming very quartzose as it approaches the lode. This is usually disseminated in minute particles, and accompanied with wolfram, copper and arsenical pyrites, *fer oligiste*, sulphide of molybdenum, and bismuth, having gangues of fluor spar, mica, and felspar. The ore occupies the heart of the quartz, the former being often so dispersed among the latter as to seem to merge into it; whence it is called by the workmen *zwitter*, or *ambiguous*. In 1620 the mine was worked by 21 independent companies, in a most irregular manner, whereby it was damaged to a depth of 170 fathoms by a dreadful downfall of the roofs. This happened on a Sunday, providentially, when the pious miners were all at church. The depth of this abyss, marked by the curved line *b*, *b*, *b*, is 66 fathoms; but the devastation is manifest to a depth of 95 fathoms below that curve, and 35 fathoms below the actual workings, represented at the bottom of the shaft under B. The parts excavated are shaded black in the figure. There are two masses of ore, one under the shaft B, and another under the shaft C; which at the levels 5 and 10 are in communication, but not at 6, 7. There is a direct descent from 8 to 9. The deposits are by no means in one vertical plane, but at a considerable horizontal distance from each other. A is the descending shaft; B is the extraction shaft, near the mouth of which there is a water-wheel; C is another extraction shaft, worked also by means of a water-wheel. A and C are furnished with ladders, but for B the ladders are placed in an accessory shaft *b′*; under D a shaft is sunk for pumping out the water, by means of an hydraulic wheel at D; E is the gallery or drift for admitting the water which drives the wheels. This falls 300 feet, and ought to be applied to a water-pressure engine, instead of the paddles of a wheel. At D is the gallery of discharge for the waters, which serves also to ventilate the mine, being cut to the day, through 936 toises of syenitic porphyry and gneiss. J is a great vaulted excavation. The mine has 13 stages of galleries, of which 11 serve for extracting the ore; 1 is the mill-course; the rest are marked with the numbers 2, 3, 4, &c.; each having besides a characteristic German name. The rare mineral called *topaz pycnite* is found in this mine, above 10, between the shafts C and D.

1795



The only rule observed in taking ore from this mine has been to work as much out of each of these levels as is possible, without endangering the superincumbent or collateral galleries; on which account many pillars are constructed to support the roofs. The mine yields annually 1600 quintals (Leipsic) of tin, being four-fifths of the whole furnished by the district of Altenberg; to produce which, 400,000 quintals of ore are raised. 1000 parts of the rock yield 8 of concentrated schlich, equivalent to only 4 of metal: being only 1 in 250 parts.

The smelting-works belong in general to individuals who purchase at the cheapest rate the ores from the mining proprietors. The ores are appraised according to their contents in metal and its fineness; conditions which they determine by the following mode of assay. When a certain number of bags of ore, of nearly the same quality, are brought to the works, a small sample is taken from each bag, and the whole are well blended. Two ounces of this average ore are mixed with about 4 per cent. of ground coal, put into an open earthen crucible, and heated in an air furnace (in area about 10 inches square) till reduction takes place. As the furnace is very hot when the crucible is introduced, the assay is finished in about a quarter of an hour. The metal thus revived is poured into a mould, and what remains in the crucible is pounded in a mortar, that the grains of tin may be added to the ingot.

This method serves the smelter's purpose, as it affords him a similar result to what he would get on the large scale. A more exact assay would be obtained by fusing, in a crucible lined with hard-rammed charcoal, the ore mixed with 5 per cent. of ground glass of borax. To the crucible a gentle heat should be applied during the first hour, then a strong heat during the second hour, and, lastly, an intense heat for a quarter of an hour. This process brings out from 4 to 5 per cent. more tin than the other; but it has the inconvenience of reducing the iron, should any be present; which by subsequent solution in nitric acid will be readily shown. This assay would be too tedious for the smelter, who may have occasion to try a great many samples in one day.

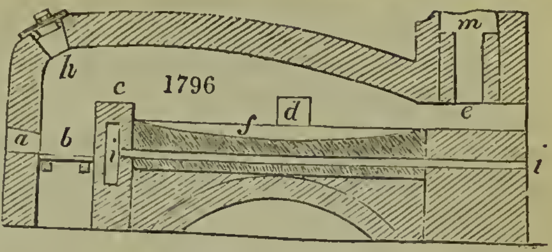
The smelting of tin ores has been effected by two different methods: —

In the first, a mixture of the ore with anthracite was exposed to heat on the hearth of a reverberatory furnace fired with coal.

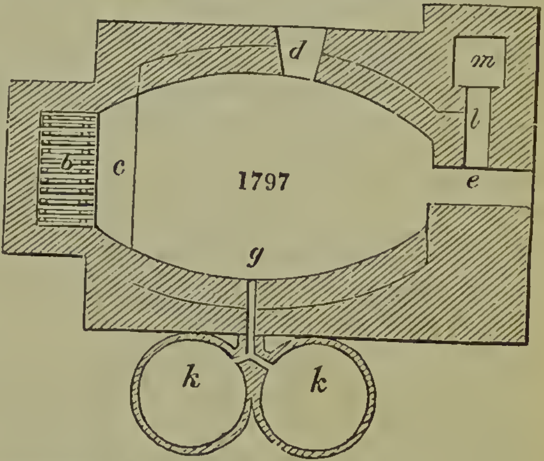
In the second, the tin ore was fused in a blast furnace, called a blowing-house, supplied with wood charcoal. This method is not now practised in England.

In the *smelting-houses*, where the tin is worked in reverberatories, two kinds of furnaces are employed; the reduction and the refining furnaces.

Figs. 1796 and 1797 represent the furnaces for smelting tin at Truro, in Cornwall; the former being a longitudinal section, the latter a ground plan. *a* is the fire-door, through which pitcoal is laid upon the grate *b*; *c* is the fire-bridge; *d*, the door for introducing the ore; *e*, the door through which the ore is worked upon the hearth *f*; *g*, the stoke-hole; *h*, an aperture in the vault or roof, which is opened at the discharge of the waste schlich, to secure the free escape of the fumes up the chimney; *i*, *i*, air channels, for admitting cold air under the fire-bridge and the sole of the hearth, with the view of protecting them from injury by the intensity of the heat above. *k*, *k*, are basins into which the melted tin is drawn off; *l*, the flue; *m*, the chimney, from 35 to 50 feet high. The roasted and washed schlich is mixed with small coal or culm, along with a little slaked lime, or fluor spar, as a flux; each charge of ore amounts to from 15 to 24 cwt., and contains from 60 to 70 per cent. of metal.



1796

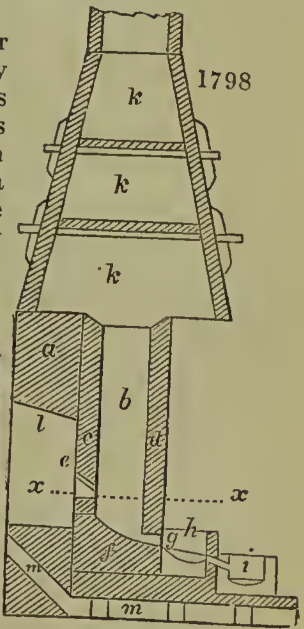


1797

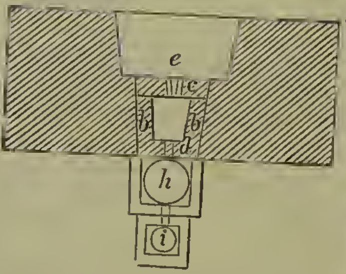
Fig. 1798 represents in a vertical section through the tuyère, and *fig.* 1799, in a horizontal section, in the dotted line *x*, *x*, of *fig.* 1798, the furnace employed for smelting tin at the Erzegebirge mines in Saxony. *a*, are the furnace pillars, of gneiss; *b*, *b*, are shrouding or casing walls; *c*, the tuyère wall; *d*, front wall, both of granite; as also the tuyère *e*. *f*, the sole stone, of granite, hewn out basin-shaped; *g*, the *eye*, through which the tin and slag are drawn off into the fore-hearth *h*; *i*, the stoke-hearth; *k*, *k*, the light ash chambers; *l*, the arch of the tuyère; *m*, *m*, the common flue, which is placed under the furnace and the hearths, and has its outlet under the vault of the tuyère.

In the smelting furnaces at Geyer the following dimensions are preferred: length of the tuyère wall, 11 inches; of the breast wall, 11 inches; depth of the furnace, 17 inches. High chimney-stalks are advantageous where a great quantity of ores is to be reduced, but not otherwise.

The *refining furnaces* are similar to those which serve for reducing the ore; only, instead of a basin of reception, they have a refining basin placed alongside, into which the tin is run. This basin is about 4 feet in diameter, and 32 inches deep; it consists of an iron pan, placed over a grate, in which a fire may be kindled. Above this pan there is a turning gib, by means of which a billet of wood may be thrust down into the bath of metal, and kept there by wheeling the gibbet over it, lowering a rod, and fixing it in that position.



1798



1799

Formerly in Cornwall nearly all the tin was smelted in blast furnaces; these works were called *blowing-houses.* The smelting furnaces were 6 feet high, from the bottom of the crucible (concave hearth) to the throat, which is placed at the origin of a long and narrow chimney, interrupted by a chamber, where the metallic dust, carried off by the blast, was deposited. This chamber was not placed vertically over the furnace; but the lower portion of the chimney had an oblique direction from it. The furnace was lined with an upright cylinder of cast iron, coated internally with loam, with an opening in it for the blast. This opening, which corresponds to the lateral face opposite to the charging side, receives a *tuyère*, in which the nozzles of two cylinder single bellows, driven by a water-wheel, were planted. The *tuyère* opens at a small height above the sole of the furnace. On a level with the sole, the iron cylinder presents a slope, below which was the hemispherical basin of reception, set partly beneath the interior space of the furnace, and partly without. Near the corner of the building there was a second basin of reception, larger than the first, which could discharge itself into the former by a sloping gutter. Near this basin there was another, for the refining operation. These were all made either of brick or cast iron. These blast furnaces are now entirely superseded in this country by the reverberatory furnace.

The quality of the average ground-tin ore prepared for smelting is such, that 20 parts of it yield from 12½ to 13 of metallic tin (62½ to 65 per cent.). The treatment consists of two operations, *smelting* and *refining*.

First operation; deoxidisation of the ore, and fusion of the tin.— Before throwing the ore into the smelting furnace, it is mixed with from one-fifth to one-eighth of its weight of *blind coal*, in powder, called *culm*; and a little slaked lime is sometimes added, to render the ore more fusible. These matters are carefully blended, and damped with water, to render the charging easier, and to prevent the draught from sweeping any of it away at the commencement. From 20 to 25 cwt. are introduced at a charge; and the doors are immediately closed and luted, while the heat is progressively raised. Were the fire too strong at first, the tin oxide would unite with the quartz of the gangue, and form an enamel. The heat is applied for 6 or 8 hours, during which the doors are not opened; of course the materials are not stirred. By this time the reduction is in general finished; the door of the furnace is removed, and the melted mass is worked up to complete the separation of the tin from the scoriæ, and to ascertain if the operation be in sufficient forwardness. When the reduction seems to be finished, the scoriæ are taken out at the same door, with an iron rake, and divided into three sorts; those of the first class A, which constitute at least three-fourths of the whole, are as poor as possible, and may be thrown away; the scoriæ of the second class B, which contain some small grains of tin, are sent to the stamps; those of the third class C, which are last removed from the surface of the bath of tin, are set apart, and re-smelted, as containing a considerable quantity of metal in the form of globules. These scoriæ are in small quantity. The stamp slag contains fully 5 per cent. of metallic tin.

As soon as the scoriæ are cleared away, the channel is opened which leads to the basin of reception, into which the tin consequently flows out. Here it is left for some time, that the scoriæ which may be still mixed with the metal may separate, in virtue of the difference of their specific gravities. When the tin has sufficiently settled, it is lifted out with ladles, and poured into cast-iron moulds, in each of which a bit of wood is fixed, to form a hole in the ingot, for the purpose of drawing it out when it becomes cold.

Refining of tin. — The object of this operation is to separate from the tin, as completely as possible, the metals reduced and alloyed along with it. These are, principally, iron, copper, arsenic, and tungsten; to which are joined, in small quantities, some sulphides and arsenides that have escaped decomposition, a little unreduced oxide of tin, and also some earthy matters which have not passed off with the scoriæ.

Liquation. — The refining of tin consists of two operations; the first being a liquation, which, in the interior, is effected in a reverberatory furnace, similar to that employed in smelting the ore (*figs.* 1796, 1797). The blocks being arranged on the hearth of the furnace, near the bridge, are moderately heated; the tin melts, and flows away into the refining basin; but, after a certain time, the blocks cease to afford tin, and leave on the hearth a residuum, consisting of a very ferruginous alloy.

Fresh tin blocks are now arranged on the remains of the first; and thus the liquation is continued till the refining-basin be sufficiently full, when it contains about 5 tons. The residuums are set aside, to be treated as shall be presently pointed out.

Refining proper. — Now begins the second part of the process. Into the tin-bath, billets of green wood are plunged, by aid of the gibbet above described. The disengagement of gas from the green wood produces a constant ebullition in the tin; bringing up to its surface a species of froth, and causing the impurest and densest parts to fall to the bottom. That froth, composed almost wholly of the oxides of tin and foreign metals, is successively skimmed off, and thrown back into the furnace. When it is judged that the tin has boiled long enough, the green wood is lifted out, and the bath is allowed to settle. It separates into different zones, the upper being the purest; those of the middle are charged with a little of the foreign metals; and the lower are much contaminated with them. When the tin begins to cool, and when a more complete separation of its different qualities cannot be looked for, it is lifted out in ladles, and poured into cast-iron moulds. It is obvious that the order in which the successive blocks are obtained is that of their purity; those formed from the bottom of the basin being usually so impure, that they must be subjected anew to the refining process, as if they had been directly smelted from the ore.

The refining operation takes five or six hours; namely, an hour to fill the basin, three hours to boil the tin with the green wood, and from one to two hours for the subsidence.

Sometimes a simpler operation, called *tossing*, is substituted for the above artificial ebullition. To effect it a workman lifts some tin in a ladle, and lets it fall back into the boiler from a considerable height, so as to agitate the whole mass. He continues this manipulation for a certain time; after which, he skims with care the surface of the bath. The tin is afterwards poured into moulds, unless it be still impure. In this case the separation of the metals is completed by keeping the tin in a fused state in the boiler for a certain period, without agitation; whereby the upper portion of the bath (at least one-half) is pure enough for the market.

The moulds into which the tin blocks are cast are usually made of granite. Their capacity is such, that each block shall weigh a little more than three hundredweight. This metal is called block tin. The law requires them to be stamped or *coined* by public officers, before being exposed to sale. The purest block tin is called refined tin.

The treatment just detailed gives rise to two stanniferous residuums, which have to be smelted again. These are—

1. The scoriæ B and C, which contain some granulated particles of tin.
2. The dross found on the bottom of the reverberatory furnace, after re-melting the tin to refine it.

The scoriæ C are smelted without any preparation; but those marked B are stamped in the mill, and washed, to concentrate the tin grains; and from this rich mixture, called *prillion*, smelted by itself, a tin is procured of very inferior quality This may be readily imagined, since the metal which forms these granulations is what, being less fusible than the pure tin, solidified quickly, and could not flow off into the metallic bath.

Whenever all the tin blocks have thoroughly undergone the process of liquation, the fire is increased, to melt the less fusible residuary alloy of tin with iron and some other metals, and this is run out into a small basin, totally distinct from the refining basin. After this alloy has reposed for some time the upper portion is lifted out into block moulds, as impure tin, which needs to be refined anew. On the bottom and sides of the basin there is deposited a white, brittle alloy, with a crystalline fracture, which contains so great a proportion of foreign metals that little use can be made of it. About 3½ tons of coal are consumed in producing 2 of tin.

To test the quality of tin, dissolve a certain weight of it with heat in hydrochloric acid; should it contain arsenic, brown-black flocks will be separated during the solution, and arseniuretted hydrogen gas will be disengaged, which, on being burned at a jet, will deposit the usual grey film of metallic arsenic upon a white saucer held a little way above the flame. Other metals present in the tin are to be sought for by treating the above solution with nitric acid of spec. grav. 1·16, first in the cold, and at last with heat and a small excess of acid. When the action is over, the supernatant liquid is to be decanted off the peroxidised tin, which is to be washed with very dilute nitric acid, and both liquors are to be evaporated to dissipate the acid excess. If, on the addition of water to the concentrated liquor, a white powder falls, it is a proof that the tin contains bismuth; if, on adding sulphate of ammonia, a white precipitate appears, the tin contains lead; water of ammonia added to supersaturation will occasion reddish-brown flocks, if iron is present; and on evaporating the supernatant liquid to dryness, the copper will be obtained.

For the purification of tin from tungsten, see TUNGSTEN.

The uses of tin are very numerous. Combined with copper, in different proportions, it forms bronze, and a series of other useful alloys; for an account of which see COPPER. With iron, it forms tin-plate; with lead, it constitutes pewter, and solder of various kinds. (See LEAD.) Tin-foil coated with quicksilver makes the reflecting surface of glass mirrors. (See GLASS.) Nitrate of tin affords the basis of the scarlet dye on wool, and of many bright colours to the calico-printer and the cotton-dyer. (See SCARLET and TIN MORDANTS.) A compound of tin with gold gives the fine crimson and purple colours to stained glass and artificial gems. See PURPLE OF CASSIUS. Enamel is made by fusing oxide of tin with the materials of flint glass. This oxide is also an ingredient in the white and yellow glazes of pottery-ware.

There has been a remarkable uniformity in the quantity of tin produced in Cornwall during a long period, as will be seen from the following table:—

Years.	Tons.	Years.	Tons.
1750 - -	1,600	1800 - -	1,500
1760 - -	1,800	1810 - -	1,400
1770 - -	2,000	1820 - -	1,700
1780 - -	1,800	1830 - -	3,500
1790 - -	2,000	1840 - -	5,000

The produce of the Cornish and Devonshire mines in recent years has been as follows:—

1848 -	10,176 tons of tin ore.			
1849 -	10,719	do.		
1850 -	10,383	do.		
1851 -	9,455	do.		
1852 -	9,674	do.		
1853 -	8,866	do.	producing	6,000 tons of tin.
1854 -	8,747	do.	,,	5,947 do.
1855 -	8,949	do.	,,	5,998 do.
1856 -	9,350	do.	,,	6,177 do.
1857 -	9,783	do.	,,	6,582 do.
1858 -	10,618	do.	,,	6,920 do.

Tin of British produce *exported* in 1858 : —

	Cwts.	Declared real value. £
Unwrought - - - - -	46,542	270,698

Tin ore and regulus - - -	628 tons.
Tin in blocks, ingots, bars, or slabs	59,115 ,,

TINCAL. Crude borax.

TINCTORIAL MATTER. The colouring matter employed in dyeing. See Dyeing; Madder; Turkey Red, &c.

TINCTURE is a title used by apothecaries to designate alcohol, in a somewhat dilute state, impregnated with the active principles of either vegetable or animal substances.

TIN-GLASS is a name of bismuth.

TIN MORDANTS for dyeing scarlet. See Mordant.

Mordant A, as commonly made by the dyers, is composed of 8 parts of nitric acid, 1 part of common salt or sal-ammoniac, and 1 of granulated tin. This preparation is very uncertain.

Mordant B.— Pour into a glass globe with a long neck, 3 parts of pure nitric acid at 30° B.; and 1 part of muriatic acid at 17°; shake the globe gently, avoiding the corrosive vapours, and put a loose stopper in its mouth. Throw into this nitro-muriatic acid, one-eighth of its weight of pure tin, in small bits at a time. When the solution is complete, and settled, decant it into bottles, and close them with ground stoppers. It should be diluted only when about to be used.

Mordant C, by Dambourney. — In 2 drams Fr., 144 grs., of pure muriatic acid, dissolve 18 grains of Malacca tin. This is reckoned a good mordant for brightening or fixing the colour of peachwood.

Mordant D, by Hellot.— Take 8 ounces of nitric acid, diluted with as much water; dissolve in it half an ounce of sal-ammoniac, and 2 drams of nitre. In this acid solution dissolve 1 ounce of granulated tin of Cornwall, observing not to put in a fresh piece till the preceding be dissolved.

Mordant E, by Scheffer.— Dissolve 1 part of tin in 4 of a nitro-muriatic acid, prepared with nitric acid diluted with its own weight of water, and one thirty-second of sal-ammoniac.

Mordant F, by Poerner.— Mix 1 pound of nitric acid with 1 pound of water, and dissolve in it an ounce and a half of sal-ammoniac. Stir it well, and add, by very slow degrees, 2 ounces of tin turned into thin ribbons upon the lathe.

Mordant G, by Berthollet.— Dissolve in nitric acid of 30° B., one-eighth of its weight of sal-ammoniac, then add by degrees one-eighth of its weight of tin, and dilute the solution with one-fourth of its weight of water.

Mordant K, by Dambourney.— In 1 dram (72 grs.) of muriatic acid at 17°, one of nitric acid at 30°, and 18 grains of water, dissolve slowly, and with some heat, 18 grains of fine Malacca tin.

Mordant L, is the birch bark prescribed by Dambourney.— This bark, dried, and ground, is said to be a very valuable substance for fixing the otherwise fugitive colours produced by woods, roots, archil, &c.

TIN PLATES. Some of the earliest historical records refer to the tin mines of Britain, and to the intelligence and skill of the miners who worked them. The works of Herodotus (450 years B.C.), and later of Diodorus Siculus and Pliny, prove the great importance of the tin mines of this country, more than 2000 years past. Since that time they have been constantly worked, and so far from being exhausted, the tin mines of Cornwall seem now to be only beginning to open out, and to prove that the store of ore that district contains is practically inexhaustible.

The Government official returns, for the year 1858, made under the able superintendence of Mr. Robert Hunt, show that 10,618 tons of tin ore were raised in Great Britain. This quantity is greater than that of any preceding year; and as many of the deep mines in Cornwall are changing from copper into tin ore, increased supplies will be obtained to meet any demand. About four-fifths of all the tin ore to supply the world is raised in Great Britain. The same race of men who worked the mines more than 2000 years since, still work them and preserve their customs and nationality.

The art of coating copper with tin seems to have been known at an early period. Pliny refers to this, and from his description it is probable the vessels to be covered were dipped into melted tin, and the "*vasa stannea*" of the Romans were copper vessels covered with tin. The difficulty of coating iron with tin was, however, much greater; and the processes of hammering the iron into sheets sufficiently thin, and cleaning the surface, which latter work had often to be done by filing, were serious hindrances to the extensive use of the invention.

The art of tinning iron appears to have been first practised in Bohemia, and about the year 1620 to have been introduced into Saxony.

Beckmann states that, "in the year 1670, a company sent to Saxony, at their expense, an ingenious man named Andrew Yarrenton, in order to learn the process of tinning. Having acquired the necessary knowledge, he returned to England with some German workmen, and manufactured tin plate which met with general approbation. Before the company could carry on business on an extensive scale, a man of some distinction, having made himself acquainted with Yarrenton's process, obtained a patent for this art, and the first undertakers were obliged to give up their enterprise, which had cost them a great deal of money, and yet no use whatever was made of the patent which had been obtained." About the year 1720 works for the manufacture of tin plates were established at Pontypool, and these seem to be the earliest of such works in England which were permanently successful.

In 1728, John Payne invented a process for rolling iron. This seems to have at once led to the use of the flat or sheet rolls for the manufacture of iron for tin plates; but it is very remarkable that no further progress was made in this discovery of rolling iron until 1783, when Henry Cort invented the grooved rolls. This discovery was not appreciated for some years. Mr. Reynolds, of Ketley, erected Cort's rolls in 1785. In 1790 Henry Cort was engaged by Mr. Richard Crawshay to erect the mills at Cyfarthfa, and, soon after, this important improvement in the iron manufacture was generally adopted. The writer proposes to give in this paper a short résumé, first, of the process for cleaning and tinning the iron plate, and after, of the methods of preparing the iron for this purpose.

The affinity of iron for tin is much greater than is generally supposed. The point at which the metals cohere is no doubt an *actual alloy*; and advantage is taken of this by the manufacturers of articles for domestic use, made in iron—as bridle bits, common stirrups, small nails, &c. When the iron, whether wrought or cast, *is perfectly clean and free from rust*, and brought in contact with melted tin, at a high temperature, an alloy seems to be at once formed, protecting the iron from oxidisation whilst the tin lasts. Many plans are used for tinning iron articles, of small size, by the manufacturers. One of the common methods of the manufacturers of bridle bits and small ware, in South Staffordshire, is to clean the surface of the articles to be tinned, by steeping them for sufficient time in a mixture of sulphuric and hydrochloric acids, diluted with water, then washing them well with water, but taking great care they do not rust, at once placing them in a partially closed stone-ware vessel (such as a common bottle), which contains a mixture of tin and hydrochlorate of ammonia. This vessel is then placed on a smith's hearth, duly heated, and frequently agitated to secure the complete distribution of the tin over the iron. The articles, when thus tinned, are thrown into water to wash away all remains of the sal-ammoniac; and lastly, cleaned in hot bran, or sawdust, to improve the appearance for sale.

The plans of cleaning and preparing the iron for tinning have undergone many changes in the past century. About 1720 the plan of cleaning was to scour the plates with sand and water, and file off the rough parts, then cover with resin, and dip them in the melted tin. About 1747 the plates were, after being cold rolled, soaked for a week in the lees of bran, which had been allowed to stand in water about ten days, to become, by fermentation, sufficiently acid, and then scoured with sand and water. In 1760 the plates were pickled in dilute hydrochloric acid before annealing, and cleaned with dilute sulphuric acid after being taken out of the bran lees. An improvement of great importance in this process was made about 1745; the inventor seems to have been Mr. Mosely, who carried on tin plate works in South Staffordshire. This invention was the use of the grease pot, and in this department little, if any, improvement has since been made. The plan was introduced into South Wales in 1747 by Mr. John Jenkins, and his descendants are still amongst the principal manufacturers in the trade. The process of cleaning and tinning at some of the best works now is as follows: when the sheet iron leaves the plate mill, and after separating the plates, and sprinkling between each plate a little sawdust, the effect of which is to keep them separate, they are then immersed, or as technically termed "pickled," in dilute sulphuric acid, and after this placed in the annealing pot, and left in the furnace about 24 hours; on coming out, the plates are passed through the cold rolls; after passing the cold rolls, the plates seem to have too much the character of steel, and are not sufficiently ductile: to remedy this they are again annealed at a low heat, washed in dilute sulphuric acid, to remove any scale of oxide of iron, and scoured with sand and water; the plates in this state require to be perfectly clean and bright, and may be left for months immersed in pure water without rust or injury; but a few minutes' exposure to the air rusts them. With great care to have them perfectly clean, they are taken to the stow, *fig.* 1800, being a section through the line K K of the plan *fig.* 1801. Taken from right to left,

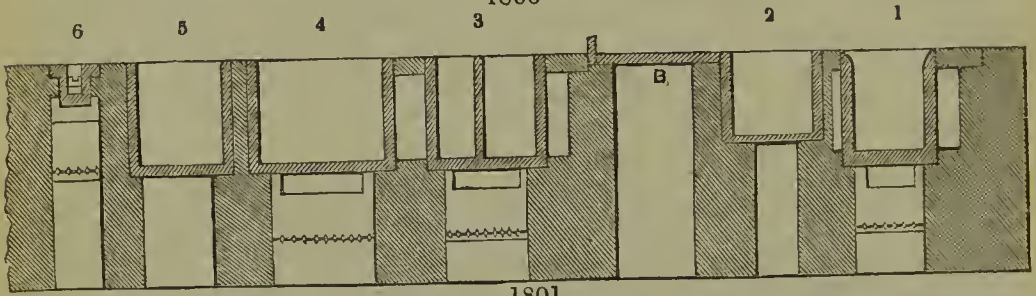
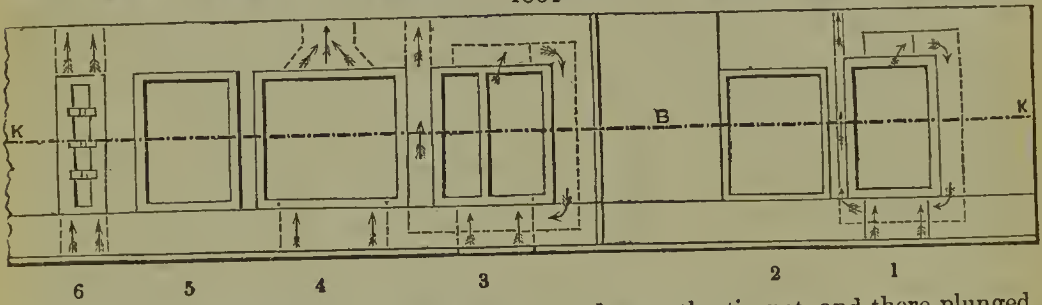
6 „ the List pot.

The tinman's pan is full of melted grease: in this the plates are immersed, and left there until all aqueous moisture upon them is evaporated, and they are completely

1800



1801

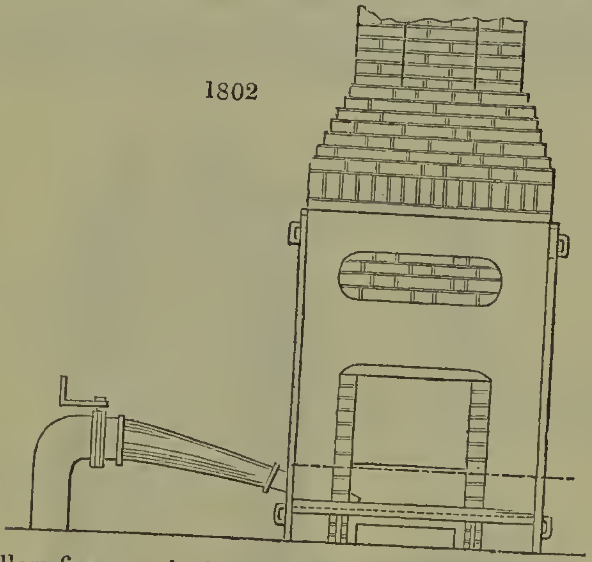


covered with the grease; from this they are taken to the tin pot, and there plunged into a bath of melted tin, which is covered with grease; but as in this first dipping the alloy is imperfect, and the surface not uniformly covered, the plates are removed to the dipping or wash pot; this contains a bath of melted tin covered with grease, and is divided into two compartments. In the larger compartments the plates are plunged, and left sufficiently long to make the alloy complete, and to separate any superfluous tin which may have adhered to the surface; the workman takes the plate and places it on the table marked B on the plan and wipes it on both sides with a brush of hemp; then to take away the marks of the brush, and give a polish to the surface, he dips it in the second compartment of the wash pot. This last always contains the purest tin, and as it becomes alloyed with the iron it is removed on to the first compartment, and after to the tin pot. The plate is now removed to the grease pot (No. 4): this is filled with melted grease, and requires very skilful management as to the temperature it is to be kept at. The true object is to allow any superfluous tin to run off, and to prevent the alloy on the surface of the iron plate cooling quicker than the iron. If this were neglected the face of the plate would be cracked. The plate is removed to the cold pot (No. 5): this is filled with tallow, heated to a comparatively low temperature. The use of the grease pots, Nos. 4 and 5, is the process adopted in practice for annealing the alloyed plates. The list pot (No. 6) is used for the purpose of removing a small wire of tin, which adheres to the lower edge of the plate in all the foregoing processes. It is a small cast-iron bath, kept at a sufficiently high temperature, and covered with tin about one-fourth of an inch deep. In this the edges of the plates are dipped, and left until the wire of tin is melted, and then detached by a quick blow on the plate with a stick. The plates are now carefully cleaned with bran to free them from grease. Lastly, they are taken to the sorting room, where every plate is separately examined and classed, and packed in boxes for market as hereafter described.

The tests of quality for tin plates are—ductility, strength, and colour. To obtain these, the iron must be of the best quality, and the manufacture must be conducted with proportionate skill. This necessity will explain to some extent the cause why nearly all the improvements in working iron during the past century have been either originated or first adopted by the tin-plate makers, and a sketch of the processes used at different times, in working iron for tin plates, will be, in fact, a history of the trade.

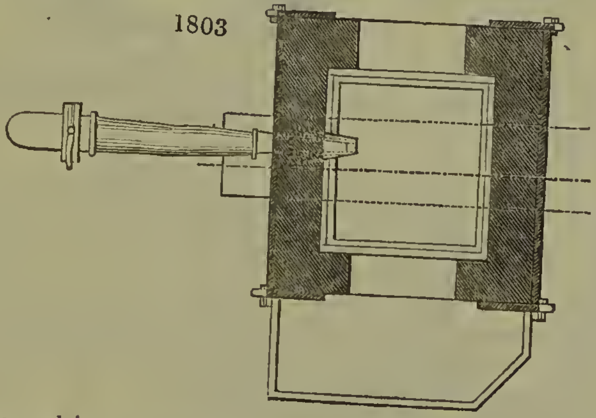
The process of preparing the best or charcoal iron seems to have undergone but little change from 1720 to 1807. The finery, the chafery, and the hammer, were the modes of bringing the iron from the pig to the state of finished bars. The finery was of the exact form of the *figs.* 1802, 1803, 1804, but less in size than those now used.

1802



The chafery or hollow fire was, in fact, the same as the present smiths' forge fire, but on a larger scale; and the "*hollow*" or chamber, in which the bloom was heated, was

1803



made by coking the coal in the centre with the blast, and taking care not to disturb the mass of coal above, which was used to reverberate the heat produced. Both the finery and chafery were worked by blast.

The hammers were of two descriptions: the forge hammer, a heavy mass for shaping the blooms, and the tilt hammer, much lighter and driven quicker, for shaping the bars.

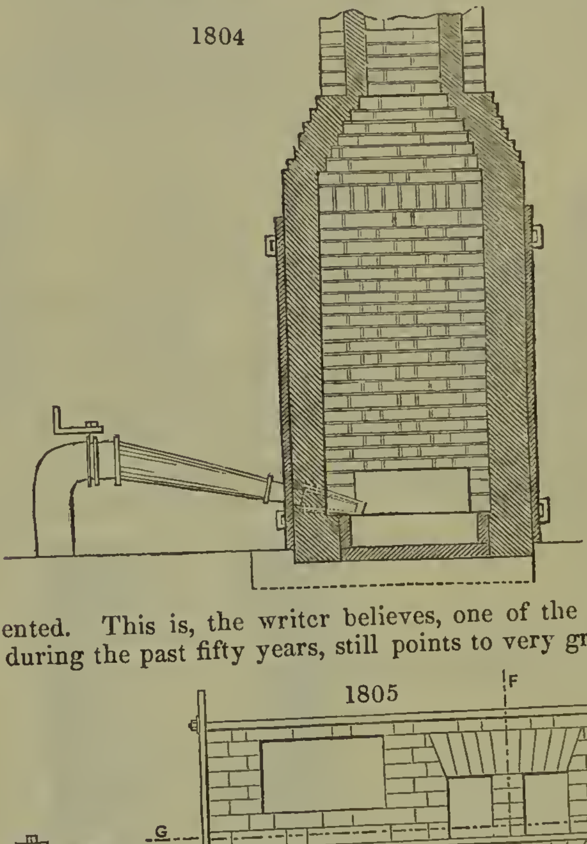
The charge for the finery was about $1\frac{1}{2}$ cwt. of pig iron: this, under the first process, was reduced to $1\frac{1}{4}$ cwt. It was, when ready, put under the forge hammer, and shaped into a "bloom," about 2 feet long and 5 inches thick; this was then heated in the chafery, and under the tilt hammer drawn out to a "bar," 3 to 4 inches wide, and half inch thick.

The manufacture up to this point, until a recent period, was carried on by the iron masters, and the iron in this state was sold under the name of "tin bars" to the plate makers. The average price for these bars, from 1780 to 1810, was 21*l.* per ton. The sheet and cold rolls were then in use nearly as at the present time.

In 1807, Mr. Watkin George, whose position had been established as one of the first engineers of his time, by the erection of the great water-wheel and works at Cyfarthfa, removed to Pontypool, and undertook the remodelling of the old works there. He clearly saw that the secret of the manufacture was to produce the largest possible quantity with least possible machinery and labour. His inventions, to this end, worked a complete change in the trade. His plans were: to first reduce the pig iron in a finery under coke, and then bring this "refiners' metal" (so termed) into the charcoal finery. The charcoal finery was built as shown in *figs.* 1802, 1803, and 1804: *fig.* 1802 being a front elevation, *fig.* 1803 a horizontal, and *fig.* 1804 a vertical section.

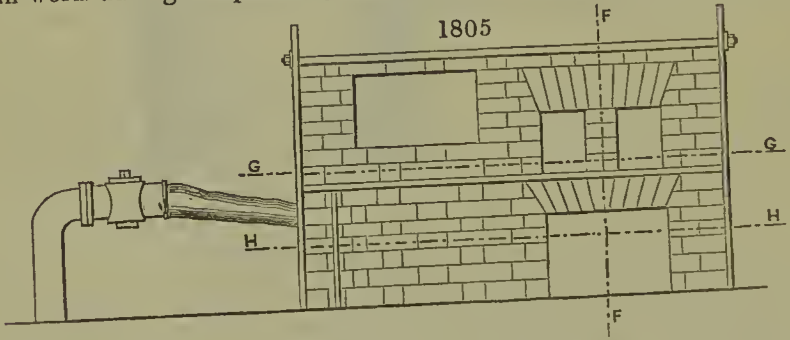
A charge of 3 cwt. of iron was used in this, and as it became malleable it was reduced under the hammer to what he termed a "stamp:" this was a piece of iron about 1 inch thick, and of any shape horizontally. It was next broken in pieces of a convenient size, and about 84 lbs. were "piled" on a flat piece of tilted iron, with a handle about 4 feet long. This rough shovel, or holder, was called the "portal," or the "staff." To re-heat this "pile" in the chafery would be a work of great cost and difficulty, and the brick hollow fire (as shown in *figs.* 1805, 1806, 1807, 1808, 1809, and 1810; *figs.* 1805 and 1806 being elevations, and *figs.* 1807, 1808, 1809, and 1810,

1804



sections) was invented. This is, the writer believes, one of the inventions which, although in work during the past fifty years, still points to very great improvements

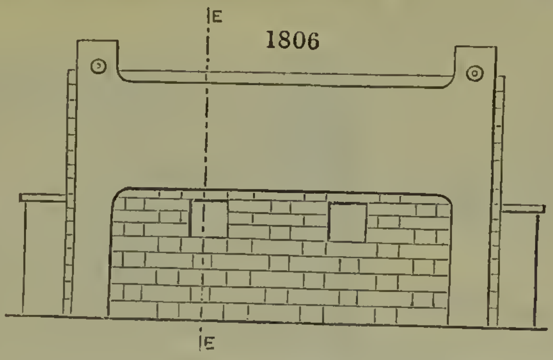
1805



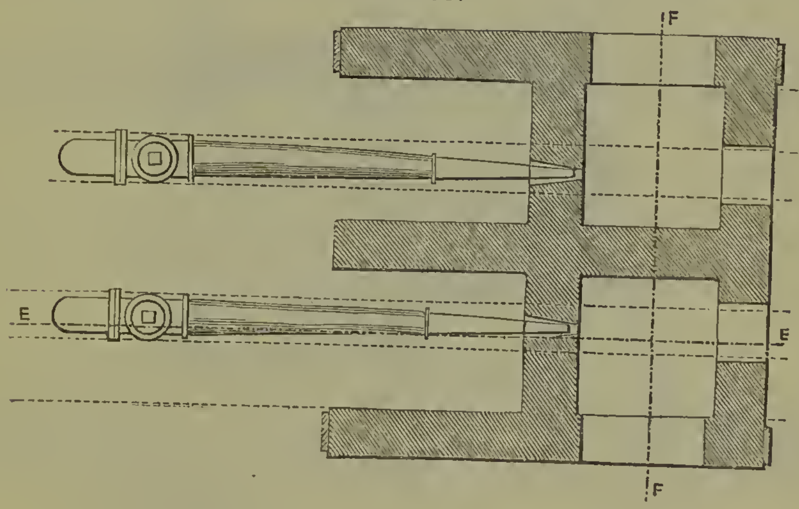
in the manufacture of iron. It is in substance the plan of using the gases produced by the decomposition of fuel for the working of iron.

The *charcoal finery* is also worked by the use of the gases to a much greater extent than is generally known. The workman sends his blast directly into the mass of iron, and the charcoal seems to be simply the means by which he is better enabled to manipulate the iron in the finery, and keep it covered, so as to revive the oxidised metal, and thus prevent waste. A few hours spent with any intelligent workman at the side of his charcoal finery would show the wasteful and expensive character of the so-called *new* schemes for converting cast into wrought iron by the use of air alone. The late belief in these schemes, by men of high repute and practical knowledge in the trade, is a direct proof of the deficiency in knowledge of exact science, as at present applied to the manufacture of iron.

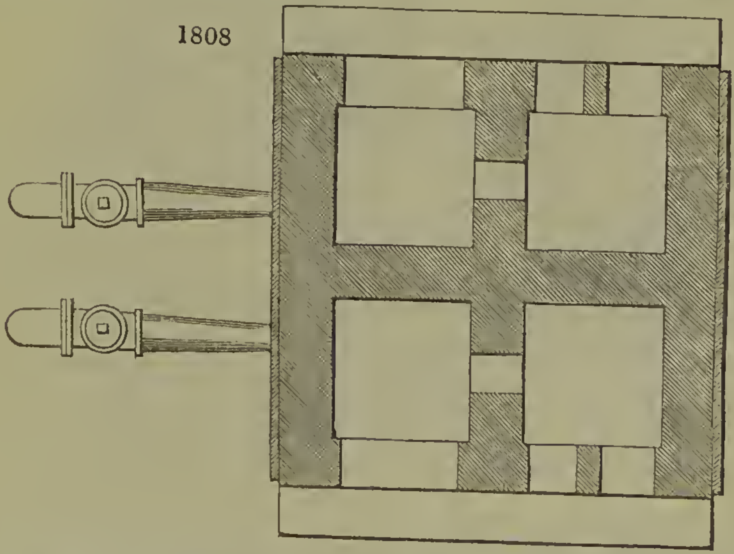
The pile was now placed in the hollow fire, and brought to a soft welding or washing heat—again hammered out to "slabs," 6 inches wide and three-quarters



inch thick; these were re-heated, cut up, and aftewards passed through rolls, reducing them to "bars" 6 inches by half-inch. These were known in the trade as "hollow

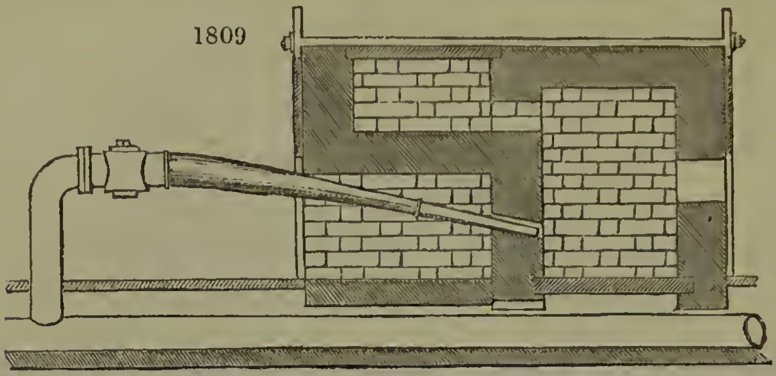


fire iron," or "tin bars." The result of Mr. Watkin George's improvements was, to reduce the cost and double the production with the same outlay in machinery. All



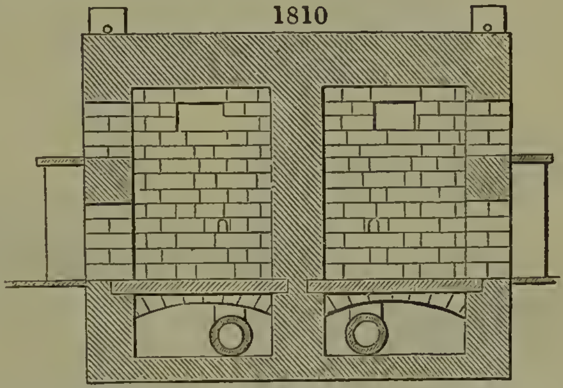
the tin plates made at this time had the great defect of a rough and smooth side. In the year 1820, Mr. Wm. Daniell, (a gentleman still living, and for whose invention the trade is and will be under great obligation,) found a mode to remedy this defect. Himself a maker of tin bars and plates, he had observed that the smooth side of the plate was always that corresponding to the flat part of the "portal," or "staff;" he at once, having ascertained this cause, remedied the defect by hammering out the pile, notching it, and doubling it over, so that the tilted blade of the "staff" was on

1809



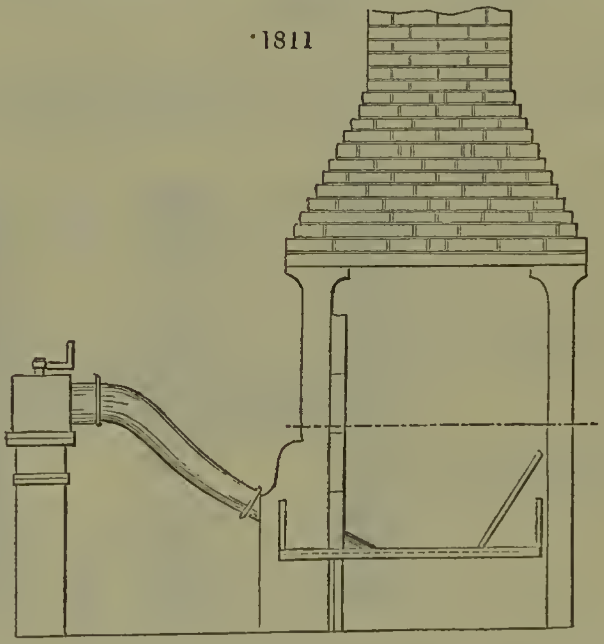
the top as well as the bottom of the pile. This was the invention of "tops and bottoms," and the writer need not remind practical men of the immense sums made by this discovery during the past thirty-seven years.

1810



Another improvement since 1807, is the use of the running-out fire: it is still adopted in only a few works. This is represented by *figs.* 1811, 1812, and 1813. *Fig.* 1811 is a front elevation; *fig.* 1812 a horizontal section; and *fig.* 1813 a vertical

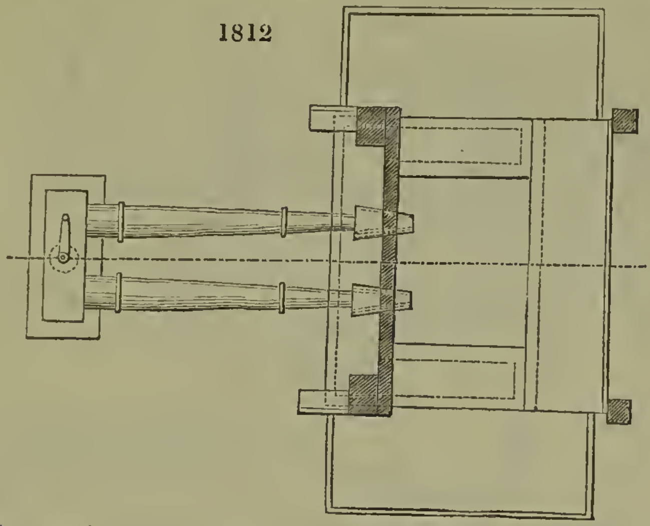
1811



section. This process saves waste of heat and labour, by running the refined metal at once into the charcoal finery.

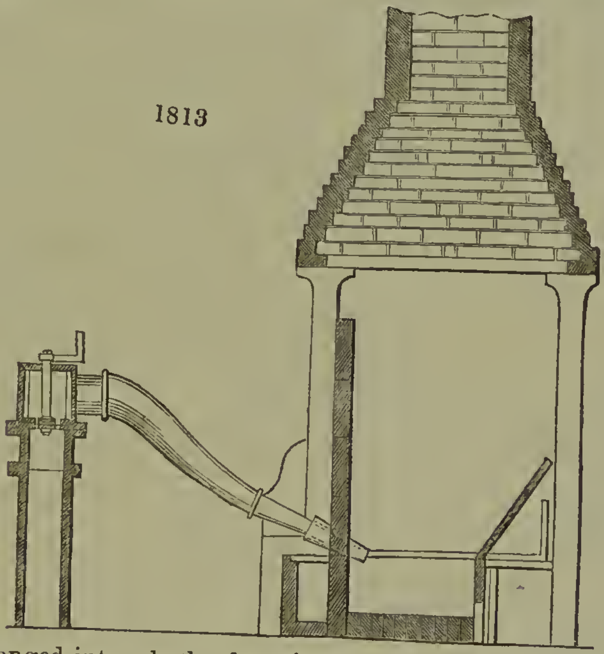
The "tin bars" before referred to, 6 inches by half-inch, are heated and run through rollers until they form a sheet of sufficient width; this sheet is then doubled and passed through the rolls, and this repeated until this sheet is quadrupled.—the laminæ are then cut to size, and separated as before described. The writer asks careful attention to the fact, that the last part of the rolling is done when the iron is nearly cold. These sheets are next annealed, and were formerly bent separately by

1812



hand, into a saddle, forming two sides of a triangle, thus ∧, and placed in a reverberatory furnace, so that the flame should play amongst them, and heat them to redness;

1813



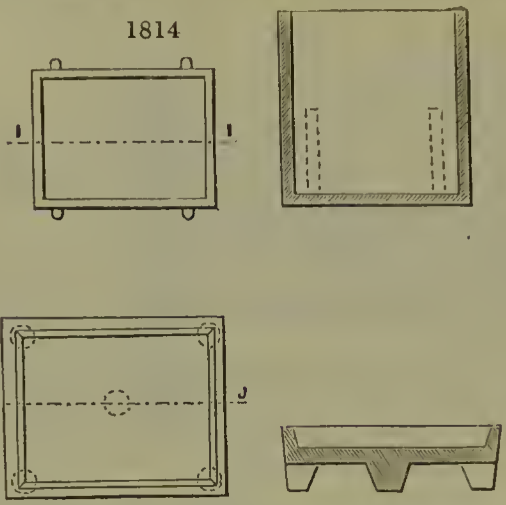
they were then plunged into a bath of muriatic acid, or sulphuric acid and water, for a few minutes, taken out, and drained on the floor, and again heated in a furnace; after which, a scale of oxide of iron separates from the plate during the work of bending them again straight, on a cast-iron block.

The plates should be now free from rust or scale, and are then passed cold through the chilled rolls: this last process is most important, as the ductility and the strength and colour of the tin plate depend upon this; at this point bad iron will crack or split, and any want of quality in the iron, or skill in the manufacture, will be shown.

A great improvement in the process of annealing was made in 1829 by Mr. Thomas Morgan: the plates were piled on a stand, and covered with a cast-iron box, now termed an "annealing pot;" in this they were exposed to a dull red heat in a reverberatory furnace for 24 hours. This annealing pot with its stand is represented by *fig.* 1814, in plan and vertical section.

A very important invention in the manufacture of iron for tin plates, and which is yet only partially carried out, was made by Mr. William Daniell in 1845. About 2½ cwt. of refined metal is placed in the charcoal finery; this is taken out in one lump, put under the hammer and "nobbled," then passed at once through the balling rolls, and reduced to a bar 6 inches square and about 2 feet 6 inches long. This bar is either cut or sawed off in pieces 6 inches long, and these rolled endways to give a bar about 6 inches wide, 2½ inches thick, and 12 inches long, and in this state the inventor calls it a "billet." This is heated in a small balling furnace and rolled down to a bar one-quarter inch thick and eleven inches wide, and will be about six feet long.

1814



This is taken at once to the tin plate mill, and the process saves great expense in fuel and machinery.

By the old method of annealing, a box of tin plates required about 13 lbs. of tin. This is now done with about 9 lbs. for charcoal and 8 lbs. for coke plates.

In referring to tin plates the standard for quotation is always taken as 1 C. (Common, No. 1.) This is a box containing 225 plates which should weigh exactly 112 lbs.

The following are the Marks, Weights, and Measurement of the Tin Plates now in common use : —

One of the great items of expense in the manufacture of best iron, as before described, is the cost of charcoal for the fineries. This limits at present the production of iron made by these means; but the superior quality of iron made in the charcoal finery is always admitted. About 1850 the attention of the writer was directed to the use of a substitute for charcoal in the finery. Careful thought and experiment led him to the conclusion that some coals could be charred in such a way as to produce a mechanical structure analogous to charcoal, and, at the same time, when deprived of sulphur might be used in the finery. These experiments resulted in the manufacture of a substance the writer names "*charred coal.*" This material has been worked at several of the principal manufactories in South Wales, and declared equal in every respect to charcoal. Some tin plates made by this process were shown at the Great

Exhibition in 1851; as also the charred eoal used in the finery. (See the *Juror's Reports, &c.*) The quality of the plates was admitted as equal to the best ehareoal.

The preparation of the "*charred coal*" is very simple. The coal is first redueed to small, and washed by any of the ordinary means: it is then spread over the bottom of a reverberatory furnace to a depth of about 4 inehes; the bottom of the furnaee is first raised to a red heat. When the small eoal is thrown over the bottom a great volume of gases is given off, and mueh ebullition takes plaee: this ends in the production of a light spongy mass which is turned over in the furnace, and drawn in about one hour and a half. To eompletely clear off the sulphur, water is now freely sprinkled over the mass until all smell of the sulphuretted hydrogen gas produeed ceases. The result is "charred coal." The quantities of "charred coal" hitherto produced have been made on the floor of an ordinary coke oven, whilst red hot after drawing the charge of coke. The following analysis of the coal from whieh this "charred eoal" is made, is extracted from the "Report on the Coals suited to the Steam Navy," by Sir H. De la Beehe and Dr. Playfair:—

Abercarn Coal.

Carbon	81·26
Hydrogen	6·31
Nitrogen	·77
Oxygen	9·96
Sulphur	1·86
Ash	2·04

Some points of great praetieal value may be elicited from this deseription of the manufacture of iron for tin plates. The stamp iron is highly erystalline, and falls to pieces under the hammer unless eautiously handled. The pile itself, after heating, is also crystalline and brittle; but after passing through the rolls it becomes less crystalline. When redueed to a sheet it is still less erystalline and more duetile; but after passing the cold rolls all the erystalline charaeter is apparently destroyed, and it beeomes a homogeneous mass, and very duetile, hard, and tough. The hammering and rolling appears to alter the strueture of the iron, and, instead of allowing the atoms to arrange themselves in crystals, to bring them into a homogeneous or amorphous mass, whieh is then held together by the law of eohesion, and is more dense and eloser than when crystallised. In practice this principle is eonstantly used. Every smith knows the practical result of what is termed "hammer hardening."

Tin coating of iron and zinc, by Mr. Morries Stirling's patent process. For this purpose the sheet, plate, or other form of iron, previously eoated with zinc, either by dipping or by depositing from solutions of zine, is taken, and after eleaning the surfaee by washing in acid or otherwise, so as to remove any oxide or foreign matter which would interfere with the perfect and equal adhesion of the more fusible metal or alloy with whieh it is to be eoated, it is dipped into melted tin, or any suitable alloy thereof, in a perfeetly fluid state, the surface of which is eovered with any suitable material, sueh as fatty or oily matters, or the chloride of tin, so as to keep the surface of the metal free from oxidation; and such dipping is to be eondueted in a like manner to the proeess of making tin plate or of coating iron with zine. When a fine surfaee is required, the plates or sheets of iron coated with zine may be passed between polished rolls (as already described) before and after, or either before or after they are eoated with tin or other alloy thereof. It is preferred in all eases to use for the eoating pure tin of the deseription known as grain tin.

Another part of the invention consists in covering either (wholly or in part) zinc and its alloys with tin, and sueh of its alloys as are suffieiently fusible. To effect this, the following is the process adopted: — A sheet or plate of zinc (by preferenee sueh as has been previously rolled, both on aeeount of its ductility and smoothness) is taken, and after eleaning its surface by hydrochlorie or other acid, or otherwise, it is dried, and then dipped or passed in any eonvenient manner through the melted tin, or fusible alloy of tin. It is found desirable to heat the zinc, as nearly as may be, to the temperature of the melted metal, previous to dipping it, and to eonduet the dipping, or passing through, as rapidly as is consistent with thorough coating of the zinc, to prevent as mueh as possible the zine beeoming alloyed with the tin. It is reeommended also that the tin or alloy of tin should not be heated to a higher temperature than is neeessary for its proper fluidity. The metal thus eoated, if in the form of sheet, plate, or eake, ean then be rolled down to the required thiekness; and should the eoating of tin or alloy be found insuffieient or imperfect, the dipping is to be repeated as above deseribed, and the rolling also, if desired, either for smoothing the surfaee or further redueing the thiekness.

Another part of the invention consists in coating lead or its alloys with tin or alloys thereof. The process is to be conducted as before described for the coating of zinc, and the surface of lead is to be perfectly clean. The lead may, like the zinc, be dipped more than once, either before or after being reduced in thickness by rolling.

Lead and its alloys may also be coated with tin or its alloys of greater fusibility than the metal to be coated, as follows:—The cake, or other form to be coated, is to be placed as soon after casting as may be in an iron, gun metal, or other suitable mould, or if this cannot be conveniently done, the surfaces are to be cleansed and prepared for the reception of the coating metal, either by previously tinning the surface, or by applying other suitable material to facilitate the union, as heretofore practised. At one end of the mould is to be attached chambers, of more than sufficient capacity to contain the quantity of metal to be used for coating, which may with advantage form an integral part of the mould, or such chamber may surround the mould, and by one or more sluices or valves in such chamber or chambers, the melted metal is to be allowed to run on to the surface of the metal to be coated, when the metal is to be coated on one side only. When it is intended to coat the metal on both sides, the vertical position will be found convenient, and the coating metal is to be formed into a chamber or chambers attached to the mould, and to be introduced into the lower part of the mould by opening a sluice or valve, sufficient space being left on each side of the cake or other form to allow of the coating being of the required thickness; the sluice or valve should be of nearly the width or length of the cake or other form, and the melted metal should be allowed to flow into the bottom of the mould. The surface of the plate or cake ought to be smooth and true, and the mould, if horizontal, to be perfectly so, and if upright, quite perpendicular, so as to ensure in either case an equal footing. The surface of the lead should also be clean, and it will be found advantageous to raise its temperature to a point somewhat approaching the melting point of tin or of the alloy employed for coating, as by this means the union of the two metals is facilitated. It is recommended also, that a somewhat larger quantity of the tin or alloy than is necessary for the coating of the lead or other metal, or alloy, should be employed, and that when the requisite thickness of coating has been given, the flow of the coating metal be stopped, as by this means the impurities on the surface of the tin will be prevented passing through the opening on to the surface of the cake: the chamber or chambers should be kept at such temperature as to ensure the proper fluidity of the coating metal. Zinc and its alloys may in like manner be coated with tin and its alloys, by employing a like apparatus to that just described for coating lead and its alloys, and it constitutes a part of this invention thus to coat zinc. The coating of zinc with tin, however, is not claimed, that having been done by pouring on tin.

Crystallised tin-plate. See MOIRE METALLIQUE. It would seem that the acid merely lays bare the crystalline structure really present on every sheet, but masked by a film of redundant tin. Though this showy article has become of late years vulgarised by its cheapness, it is still interesting in the eyes of the practical chemist. The English plates marked F, answer well for producing the *Moirée*, by the following process. Place the tin-plate, slightly heated, over a tub of water, and rub its surface with a sponge dipped in a liquor composed of four parts of aquafortis and two of distilled water, holding one part of common salt or sal-ammoniac in solution. Whenever the crystalline spangles seem to be thoroughly brought out, the plate must be immersed in water, washed either with a feather or a little cotton (taking care not to rub off the film of tin that forms the feathering), forthwith dried with a low heat, and coated with a lacquer varnish, otherwise it loses its lustre in the air. If the whole surface is not plunged at once in cold water, but if it be partially cooled by sprinkling water on it, the crystallisation will be finely variegated with large and small figures. Similar results will be obtained by blowing cold air through a pipe on the tinned surface, while it is just passing from the fused to the solid state; or a variety of delineations may be traced by playing over the surface of the plate with the pointed flame of a blowpipe.

TITANIUM is a rare metal, discovered by Klaproth, in Menachanite, in 1794. Small cubes of a copper-red colour, and so hard as to scratch quartz, which have been found in some of the blast furnaces in Yorkshire, Wales, and Cumberland, were thought to be titanium; they have recently been shown to be represented by the formula $TiCy,3Ti^3N$. This metal is very brittle, so hard as to scratch steel, and very light, having a specific gravity of only 5·3. It will not melt in the heat of any furnace, nor dissolve, when crystallised, even in nitro-muriatic acid; but only when in fine powder. According to Hassenfratz, its presence in small quantity does not impair the malleability of iron. By calcination with nitre, it becomes oxygenated, and forms titanate of potassa. Traces of this metal may be detected in many irons, both wrought and cast. The principal ores of titanium are *sphene*, common and foliated, *rutile*, *iserine*, *menachanite*, and *octahedrite* or *pyramidal titanium ore*. None of them has been hitherto applied to any use.

TOBACCO. It is said that the name tobacco was given by the Spaniards to the plant, because it was first observed by them at Tabasco, or Tabaco, a province of Yucatan in Mexico. Others derive the name from Tabac, an instrument used by the natives of America in smoking this herb. In 1560, Nicot, the French ambassador to Portugal, having received some tobacco from a Flemish merchant, showed it, on his arrival in Lisbon, to the grand prior, and, on his return to France, to Catherine of Medicis, whence it has been called Nicotiana by the botanists. Admiral Sir Francis Drake, having on his way home from the Spanish Main, in 1586, touched at Virginia, and brought away some forlorn colonists, is reported to have first imported tobacco into England. But, according to Lobel, this plant was cultivated in Britain before the year 1570; and was consumed by smoking in pipes by Sir Walter Raleigh and companions, so early as the year 1584.

Tobacco is prepared as follows:—The plants are hung up to dry during four or five weeks; taken down out of the sheds in damp weather, for in dry they would be apt to crumble into pieces; stratified in heaps, covered up, and left to sweat for a week or two, according to their quality and the state of the season; during which time they must be examined frequently, opened up, and turned over, lest they become too hot, take fire, or run into putrefactive fermentation. This process needs to be conducted by skilful and attentive operatives. An experienced negro can form a sufficiently accurate judgment of the temperature, by thrusting his hand down into the heap.

The tobacco thus prepared, or often without fermentation, is sent into the market; but, before being sold, it must undergo the inspection of officers, appointed by the state, who determine its quality, and brand an appropriate stamp upon its casks, if it be sound; but if it be bad, it is burned.

Our respectable tobacconists are very careful to separate all the damaged leaves before they proceed to their preparation, which they do by spreading them in a heap upon a stone pavement, watering each layer in succession with a solution of sea salt, of spec. grav. 1·107, called *sauce*, till a ton or more be laid; and leaving their principles to react on each other for three or four days, according to the temperature and the nature of the tobacco. It is highly probable that ammonia is the volatilising agent of many odours, and especially of those of tobacco and musk. If a fresh green leaf of tobacco be crushed between the fingers, it emits merely the herbaceous smell common to many plants; but if it be triturated in a mortar along with a little quick-lime or caustic potash, it will immediately exhale the peculiar odour of snuff. Now, analysis shows the presence of muriate of ammonia in this plant, and fermentation serves further to generate free ammonia in it; whence, by means of this process, and lime, the odoriferous vehicle is abundantly developed. If, on the other hand, the excess of alkaline matter in the tobacco of the shops be saturated by a mild dry acid, as the tartaric, its peculiar aroma will entirely disappear.

Tobacco contains a great quantity of an azotised principle, which by fermentation produces abundance of ammonia; the first portions of which saturate the acid juices of the plant, and the rest serve to volatilise its odorous principles. The salt water is useful chiefly in moderating the fermentation, and preventing it from passing into the putrefactive stage; just as salt is sometimes added to saccharine worts in tropical countries, to temper the fermentative action. The sea salt, or concentrated sea water, which contains some muriate of lime, tends to keep the tobacco moist, and is therefore preferable to pure chloride of sodium for this purpose. Some tobacconists mix molasses with the salt *sauce*, and ascribe to this addition the violet colour of the *macouba* snuff of Martinique; and others add a solution of extract of liquorice. The following prescription is that used by a skilful manufacturer:—In a solution of the liquorice juice, a few figs are to be boiled for a couple of hours; to the decoction, while hot, a few bruised anise-seeds are to be added, and when cold, common salt to saturation. A little spirit of wine being poured in, the mixture is to be equably, but sparingly, sprinkled with a watering-pot, over the leaves of the tobacco, as they are successively stratified upon the preparation floor.

The fermented leaves, being next stripped of their middle ribs by the hands of children, are sorted anew, and the large ones are set apart for making cigars. Most of the tobaccos on sale in our shops are mixtures of different growths; one kind of smoking tobacco, for example, consists of 70 parts of Maryland and 30 of meagre Virginia; and one kind of snuff consists of 80 parts of Virginia, and 30 parts of either Mumesfort or Warwick. The Maryland is a very light tobacco, in thin yellow leaves; that of Virginia is in large brown leaves, unctuous or somewhat gluey on the surface, having a smell somewhat like the figs of Malaga; that of Havannah is in brownish light leaves, of an agreeable and rather spicy smell; it forms the best cigars. The

Carolina tobacco is less unctuous than the Virginian; but in the United States it ranks next to the Maryland. The slag tobacco is dried to the proper point upon sheets of copper.

Tobacco is cut into what is called shag tobacco by knife-edged chopping stamps. For grinding the tobacco leaves into snuff, conical mortars are employed, somewhat like that used by the Hindoos for grinding sugar-canes; but the sides of the snuff-mill have sharp ridges from the top to near the bottom.

Mr. L. W. Wright obtained a patent in August, 1827, for a tobacco-cutting machine, which bears a close resemblance to the well-known machines with revolving knives for cutting straw into chaff. The tobacco, after being squeezed into cakes, is placed upon a smooth bed within a horizontal trough, and pressed by a follower and screws to keep it compact. These cakes are progressively advanced upon the bed, or fed in, to meet the revolving blades. The speed of the feeding-screw determines the degree of fineness of the sections or particles into which the tobacco is cut.

Dr. Ure was employed some years ago by the Excise to analyse a quantity of snuff, seized on suspicion of having been adulterated by the manufacturer. He found it to be largely drugged with pearl-ashes, and to be thereby rendered very pungent, and absorbent of moisture; an economical method of rendering an effete article at the same time active and aqueous.

The Editor of this work knows that the refuse leaves and roots, such as senna, rhubarb, and the like, after their medicinal properties have been extracted in the manufacture of infusions, extracts, and tinctures, by the druggists, are ground, coloured with burnt sienna or yellow ochre, made pungent with ammonia, and then sold in large quantities to the snuff manufacturers.

According to the recent analysis of Posset and Reimann, 10,000 parts of tobacco-leaves contain 6 of the peculiar chemical principle *nicotine;* 1 of *nicotianine;* 287 of slightly bitter extractive; 174 of gum, mixed with a little malic acid; 26·7 of a green resin; 26 of vegetable albumen; 104·8 of a substance analogous to gluten; 51 of malic acid; 12 of malate of ammonia; 4·8 of sulphate of potassa; 6·3 of chloride of potassium; 9·5 of potassa, which had been combined with malic and nitric acids; 16·6 of phosphate of lime; 24·2 of lime, which had been combined with malic acid; 8·8 of silica; 496·9 of fibrous or ligneous matter; traces of starch; and 88·28 of water.

In *Silliman's Journal*, vol. vii. p. 2, a chemical examination of tobacco is given by Dr. Covell, which shows its components to have been but imperfectly represented in the above German analysis. He found, 1, gum; 2, a viscid slime, equally soluble in water and alcohol, and precipitable from both by subacetate of lead; 3, tannin; 4, gallic acid; 5, chlorophylle (leaf-green); 6, a green pulverulent matter, which dissolves in boiling water, but falls down again when the water cools; 7, a yellow oil, possessing the smell, taste, and poisonous qualities of tobacco; 8, a large quantity of a pale yellow resin; 9, nicotine; 10. a white substance, analogous to morphia, soluble in hot, but hardly in cold, alcohol; 11, a beautiful orange-red dye stuff, soluble only in acids: it deflagrates in the fire, and seems to possess neutral properties; 12, nicotinine. In the infusion and decoction of the leaves of tobacco, little of this substance is found; but after they are exhausted with ether, alcohol, and water, if they be treated with sulphuric acid, and evaporated near to dryness, crystals of sulphate of nicotianine are obtained. Ammonia precipitates the nicotianine from the solution in the state of a yellowish white, soft powdering matter, which may be kneaded into a lump, and is void of taste and smell, as all its neutral saline combinations also are: its most characteristic property is that of forming soluble and uncrystallisable compounds with vegetable acids.

A strict royal monopoly (*régie*) exists in Austria Proper, France, Sardinia, the

Duchies of Parma and Lucca, and the Grand Duchy of Tuscany; and in Portugal, Spain, Naples, and the States of the Church, the license to manufacture is periodically sold to companies, which regulate the prices of tobacco as they please. It will be found that the situation of all these countries where the monopolies and high prices are kept up, is nearly the same, as to illicit trade in tobacco, as in England.

The total quantities of tobacco retained for home consumption in 1842 amounted to nearly 17,000,000 lbs. Professor Schleiden gives a singular illustration of the quantity of tobacco consumed. North America alone produces annually upwards of 200,000,000 lbs. of tobacco. The combustion of this mass of vegetable material would yield about 340,000,000 lbs. of carbonic acid gas, so that the yearly produce of carbonic acid gas, from tobacco-smoking alone, cannot be estimated at less than 1,000,000,000 lbs.; a large contribution to the annual demand for this gas made upon the atmosphere by the vegetation of the world.

It has been observed by Lane, the learned annotator of the *Arabian Nights* (and the observation is confirmed by the experience of Mr. Layard, M.P., the explorer of Assyria), that the growth and use of tobacco amongst oriental nations has gradually reduced the resort to intoxicating beverages; and Mr. Crawford, in a paper "*On the History and Consumption of Tobacco*," in the Journal of the Statistical Society for March 1853, remarks, that simultaneously with the decline in the use of spirits in Great Britain, has been a corresponding increase in the use of tobacco.

Year.	Population.	Quantity of Tobacco consumed.	Consumption per head.
1821	21,282,960	15,598,152	11·71 oz.
1831	24,410,439	19,533,841	12·80 ,,
1841	27,016,972	22,309,360	13·21 ,,
1851	27,452,262	28,062,978	16·86 ,,

Number of rolls of tobacco exported from Bahia, which nearly all goes to Portugal:—

1841 to 1843	4,460	rolls annually.
1844 to 1846	2,775	,,
1847 to 1849	2,350	,,
1850 to 1852	2,323	,,
1853 to 1855	1,486	,,

Bales of tobacco exported from Bahia:—

1841 to 1843	3,970	bales annually.
1844 to 1846	12,270	,,
1847 to 1849	13,150	,,
1850 to 1852	49,480	,,
1853 to 1855	62,010	,,

Of mangotes of tobacco there were exported in 1853, 21,273 mangotes; in 1854, 26,839; 1855, 41,114 mangotes. Of the three varieties the quantity in tons was, for the three years ending 1855:—1853, 5,860 tons, value 151,383; 1854, 7,270, value 161,863; 1855, 7,128, value 154,440.

The quantity of tobacco imported into this country was as follows, in the last three years:—

		Retained for home consumption.
1857	43,747,959 lbs.	32,851,365 lbs.
1858	62,217,705 ,,	34,110,851 ,,
1859	50,671,264 ,,	34,791,261 ,,

TOBACCO-PIPES. The practice of smoking tobacco has become so general in many nations as to render the manufacture of tobacco-pipes a considerable branch of industry.

Tobacco-pipes are made of a fine-grained plastic white clay, to which they have given the name. It is worked with water into a thin paste, which is allowed to settle in pits, or it may be passed through a sieve, to separate the siliceous or other stony impurities; the water is afterwards evaporated till the clay becomes of a doughy consistence, when it must be well kneaded to make it uniform. Pipe-clay is found chiefly in the Isle of Purbeck, in Dorsetshire, and in Devonshire, at Newton Abbot. It is distinguished by its perfectly white colour, and its great adhesion to the tongue after it is baked, owing to the large proportion of alumina which it contains.

A child fashions a ball of clay from the heap, rolls it out into a slender cylinder upon a plank, with the palms of his hands, in order to form the stem of the pipe. He sticks a small lump to the end of the cylinder for forming the bowl; which having done, he lays the pieces aside for a day or two, to get more consistence. In proportion as he makes these rough figures, he arranges them by dozens on a board, and hands them to the pipemaker.

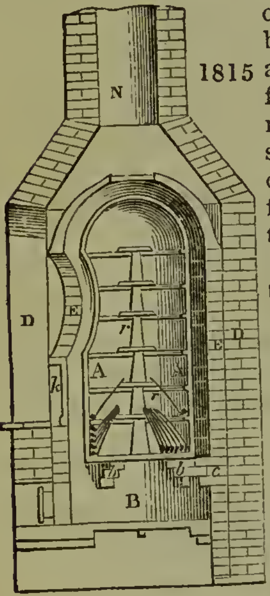
The pipe is finished by means of a folding brass or iron mould, channelled inside, of the shape of the stem of the bowl, and capable of being opened at the two ends. It is formed of two pieces, each hollowed out like a half-pipe, cut as it were lengthwise; and these two jaws, when brought together, constitute the exact space for making one pipe. There are small pins in one side of the mould, corresponding to holes in the other, which serve as guides for applying the two together with precision.

The workman takes a long iron wire, with its end oiled, and pushes it through the soft clay in the direction of the stem, to form the bore, and he directs the wire by feeling with his left hand the progress of its point. He lays the pipe in the groove of one of the jaws of the mould, with the wire sticking in it; applies the other jaw, brings them smartly together, and unites them by a clamp or vice, which produces the external form. A lever is now brought down, which presses an oiled stopper into the bowl of the pipe while it is in the mould, forcing it sufficiently down to form the cavity; the wire being meanwhile thrust backwards and forwards so as to pierce the tube completely through. The wire must become visible at the bottom of the bowl, otherwise the pipe will be imperfect. The wire is now withdrawn, the jaws of the mould opened, the pipe taken out, and the redundant clay removed with a knife. After drying for a day or two, the pipes are scraped, polished with a piece of hard wood, and the stems being bent into the desired form, they are carried to the baking kiln, which is capable of firing 50 gross in from 8 to 12 hours. A workman and a child can easily make 5 gross of pipes in a day.

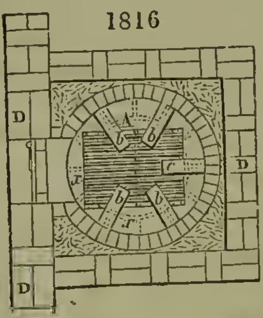
No tobacco-pipes are so highly prized as those made at Natolia, in Turkey, out of meerschaum, a somewhat plastic magnesian stone, of a soft greasy feel, which is formed into pipes after having been softened with water. It becomes white and hard in the kiln.

A tobacco-pipe kiln should diffuse an equal heat to every part of its interior, while it excludes the smoke of the fire. The crucible, or large sagger, A, A, *figs.* 1815 and 1816, is a cylinder, covered in with a dome. It is placed over the fireplace B, and enclosed within a furnace of ordinary brickwork D D, lined with fire-bricks E, E. Between this lining and the cylinder, a space of about 4 inches all round is left for the circulation of the flame. There are 12 supports or ribs between the cylinder and the furnace lining, which form so many flues, indicated by the dotted lines *x*, in *fig.* 1816 (the dotted circle representing the cylinder). These ribs are perforated with occasional apertures, as shown in *fig.* 1815, for the purpose of connecting the adjoining flues; but the main bearing of the hollow cylinder is given by five piers, *b*, *b*, *c*, formed of bricks projecting over and beyond each other. One of these piers *c*, is placed at the back of the fireplace, and the other four at the sides *b*, *b*. These project nearly into the centre, in order to support and strengthen the bottom; while the flues pass up between them, unite at the top of the cylinder in the dome L, and discharge the smoke by the chimney N.

1815



1816



The lining F, E, E, of the chimney is open on one side to form the door, by which the cylinder is charged and discharged. The opening is permanently closed as high as *k*, *fig.* 1815, by an iron plate plastered over with fire-clay; above this it is left open, and shut merely with temporary brick-work while the furnace is going. When this is removed, the furnace can be filled or emptied through the opening, the cylindric crucible having a correspondent aperture in its side, which is closed in the following ingenious way, while the furnace is in action. The workman first spreads a layer of clay round the edge of the opening: he then sticks the stems of broken pipes across from one side to the other, and plasters up the interstices with clay, exactly like the lath-and-plaster work of a ceiling. The whole of the cylinder, indeed, is constructed in this manner, the bottom being composed of a great many fragments of pipe stems, radiating to the centre; these are coated at the circumference with a layer of clay. A number of bowls of broken pipes are inserted in the clay; in these other fragments are placed upright to form the sides of the cylinder. The ribs round the outside, which form the flues, are made in the same way, as well as the dome L; by which means the cylindric case may be made very strong, and yet so thin as to require little clay in the building, a moderate fire to heat it, while it is not apt to split asunder. The pipes are arranged within, as shown in the figure, with their bowls resting against the circumference, and their ends supported on circular pieces of clay *r*, which are set up in the centre for that purpose. Six small ribs are made to project inwards all round the crucible, at the proper heights to support the different ranges of pipes, without having so many resting on each other as to endanger their being crushed by the weight. By this mode of distribution, the furnace may contain 50 gross, or 7200 pipes, all baked within eight or nine hours; the fire being gradually raised, or damped if occasion be, by a plate partially slid over the chimney top.

TODDY, *Sura*, *Mee-ra*, sweet juice. The proprietors of coco-nut plantations in the peninsula of India, and in the Island of Ceylon, instead of collecting a crop of nuts, frequently reap the produce of the trees by extracting sweet juice from the flower-stalk. When the flowering branch is half shot, the toddy-drawers bind the stock round with a young coco-nut leaf in several places, and beat the *spadix* with a short baton of ebony. This beating is repeated daily for ten or twelve days, and about the end of that period a portion of the flower-stalk is cut off. The stump then begins to bleed, and an earthen vessel (chatty) or a calabash is suspended under it, to receive the juice, which is by the Europeans called *toddy*.

A thin slice is taken from the stump daily, and the toddy is removed twice a day. A coco-nut frequently pushes out a new spadix once a month; and after each spadix begins to bleed, it continues to produce freely for a month, by which time another is ready to supply its place. The old spadix continues to give a little juice for another month, after which it withers; so that there are sometimes two pots attached to a tree at one time, but never more. Each of these spadices, if allowed to grow, would produce a bunch of nuts from two to twenty. Trees in a good soil produce twelve bunches in the year; but when less favourably situated, they often do not give more than six bunches. The quantity of six English pints of toddy is sometimes yielded by a tree daily.

Toddy is much in demand as a beverage in the neighbourhood of villages, especially where European troops are stationed. When it is drunk before sunrise, it is a cool, delicious, and particularly wholesome beverage; but by eight or nine o'clock fermentation has made some progress, and it is then highly intoxicating.*

TOLUIDINE. $C^{14}H^{9}N$. A volatile base isomeric with lutidine, formed from toluole, by processes analogous in all respects to those by which aniline is produced from benzole.—C. G. W.

TOLUOLE. $C^{14}H^{8}$. Syn., *Hydruret of toluenyle*. A hydrocarbon produced in the destructive distillation of the resin of Tolu. It is also produced by the decomposition of toluylic acid by baryta at a high temperature. Coal naphtha contains it in large quantity. For its physical properties, see CARBO-HYDRIDES.—C. G. W.

TOLU is a brownish-red balsam, extracted from the stem of the *Myroxylon toluiferum*, a tree which grows in South America. It is composed of resin, oil, and benzoic acid. Having an agreeable odour, it is sometimes used in perfumery. It has a place in the Materia Medica.

TOMBAC. White copper. See ALLOY.

TON. An English weight of 20 cwt., according to the statute, or 2240 lbs. It varies in different districts:—

South Wales, from 2400 lbs. to 2618 lbs.
Ayrshire, from 2464 lbs. to 2520 lbs.
North Staffordshire, coal, 2400 lbs.
Do. do. stone, 2520 lbs.

Copper ores are sold by the ton of 21 cwt. of 112 lbs. or 2352 lbs.

In Newcastle the leases are by the ton of 440 bolls of 36 gallons each = 48 tons, 11 cwt. 2 qrs. 17 lbs. statute.

TONKA BEAN. The fruit of the *Dipterix odorata*, affords a concrete crystalline volatile oil (*stearoptene*), called *coumarine* by the French. It is extracted by digestion with alcohol, which dissolves the stearoptene and leaves a fat oil. It has an agreeable smell, and a warm taste. It is fusible at 122° Fahrenheit, and volatile at higher heats.

TOOTH FACTORY. Teeth are made of the best ivory; the following, however, is one of the processes adopted for the artificial manufacture of teeth. Pure crystallised quartz is calcined by a moderate heat. When taken from the fire it is thrown immediately into cold water, which breaks it into numberless pieces. The larger pieces are broken into smaller, and the whole put into a mill, which is itself made of quartz. Here the pieces of calcined quartz are ground up into fine powder. Next fluor spar, free from all impurities, is ground up in like manner into a fine

* Contributions to the History of the Coco-nut Tree. By Henry Marshall, Esq., Deputy Inspector of Hospitals

powder. Artificial teeth are composed of two parts, called the body and enamel. The body of the tooth is made first, the enamel is added last.

The next step is to mix together nearly equal parts, by weight, of the powdered spar and quartz. This mixture is again ground to a greater fineness. Certain metallic oxides, as of tin, are now added to it, for the purpose of producing an appropriate colour, and water and china clay to make it plastic and give it consistence. This mixture resembles soft paste, which is transferred to the hands of females, who are engaged in filling moulds with it, or otherwise working upon it. After the paste has been moulded into proper shape, two small platina rivets are inserted near the base of each tooth, for the purpose of fastening it (by the dentist), to a plate in the mouth. They are now transferred to a furnace, where they are "cured," as it is technically called; that is, half baked or hardened. The teeth are now ready to receive the enamel, which is done by women; it consists of spar and quartz which has been ground, pulverised, and reduced to the state of a soft paste, which is evenly spread over the half-baked body of the tooth by means of a delicate brush. The teeth must be next subjected to an intense heat. They are put into ovens, lined with platina and heated by a furnace, in which the necessary heat is obtained. The baking process is superintended by a workman, who occasionally removes a tooth to ascertain whether those within have been sufficiently baked. This is indicated by the appearance of the tooth. When they are done, the teeth are placed in jars ready for use. An experiment tests the hardness of these artificial teeth. One of them taken indiscriminately out from a jar-ful is driven without breaking into a fine board, until it is even with the surface of the wood.

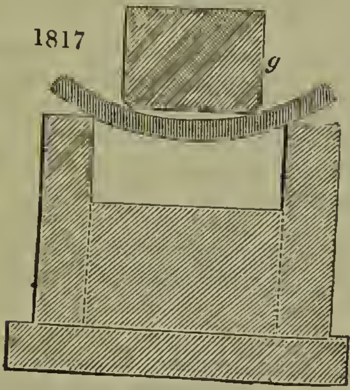
TOPAZ. The fundamental form is a scalene 4-sided pyramid; but the secondary forms have a prismatic character, and are frequently observed in oblique 4-sided prisms, acuminated by 4 planes. The lateral planes of the prism are longitudinally striated. Fracture conchoidal, uneven; lustre vitreous; colours, white, yellow, green, blue, generally of pale shades. Hardness 8; spec. grav. 3·5. Prismatic topaz consists, according to Berzelius, of alumina, 57·45; silica, 34·24; fluoric acid, 7·75. In a strong heat the faces of crystallisation, but not those of cleavage, are covered with small blisters, which however immediately crack. With borax, it melts slowly into a transparent glass. Its powder colours the tincture of violets green. Those crystals which possess different faces of crystallisation on opposite ends acquire the opposite electricities on being heated. By friction it acquires positive electricity.

Most perfect crystals of topaz have been found in Siberia, of green, blue, and white colours, along with beryl, in the Uralian and Altai mountains, as also in Kamtschatka; in Brazil, where they generally occur in loose crystals, and pebble forms of bright yellow colours; and in Mucla in Asia Minor, in pale straw-yellow regular crystals. They are also met with in the granitic detritus of Cairngorm in Aberdeenshire. The blue varieties are absurdly called *oriental aquamarine* by lapidaries. If exposed to heat, the Saxon topaz loses its colour and becomes white; the deep yellow Brazilian varieties assume a pale pink hue, and are then sometimes mistaken for spinelle, to which, however, they are somewhat inferior in hardness. Topaz is also distinguishable by its double refractive property. Tavernier mentions a topaz, in the possession of the Great Mogul, which weighed 157 carats, and cost 20,000*l.* sterling. There is a specimen in the Museum of Natural History at Paris which weighs 4 ounces 2 gros. Topazes are not scarce enough to be much valued by the lapidary.

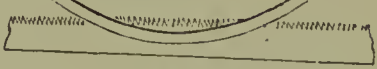
TORTOISE-SHELL, or rather scale a horny substance, that covers the hard strong covering of a bony contexture, which encloses the *Testudo imbricata*, Linn. The lamellæ or plates of this tortoise are thirteen in number, and may be readily separated from the bony parts by placing fire beneath the shell, whereby they start asunder. They vary in thickness from one-eighth to one quarter of an inch, according to the age and size of the animal, and weigh from 5 to 25 pounds. The larger the animal, the better is the shell. This substance may be softened by the heat of boiling water; and if compressed in this state by screws in iron or brass moulds, it may be bent into any shape. The moulds being then plunged in cold water, the shell becomes fixed in the form imparted by the mould. If the turnings or filings of tortoise-shell be subjected skilfully to gradually increased compression between moulds immersed in boiling water, compact objects of any desired ornamental figure or device may be produced. The soldering of two pieces of scale is easily effected, by placing their edges together, after they are nicely filed to one bevel, and then squeezing them strongly between the long flat jaws of hot iron pincers, made somewhat like a hairdresser's curling-tongs. The pincers should be strong, thick, and just hot enough to brown paper slightly without burning it. They may be soldered also by the heat of boiling water, applied along with skilful pressure. But in whatever way this process is attempted, the surfaces to be united should be made very smooth, level, and clean; the least foulness, even the touch of a finger, or breathing upon them, would prevent their coalescence. See HORN.

Tortoise-shell is manufactured into various objects, partly by cutting out the shapes and partly by agglutinating portions of the shell by heat. When the shell has become soft by dipping it in hot water, and the edges are in the cleanest possible state without grease, they are pressed together with hot flat tongs, and then plunged into cold water, to fix them in their position. The teeth of the larger combs are parted in their heated state, or cut out with a thin frame saw, while the shell, equal in size to two combs, with their teeth interlaced, as in *fig.* 1817, is bent like an arch in the direction of the length of the teeth, as in *fig.* 1818. The shell is then flattened, the points are separated with a narrow chisel or *pricker*, and the two combs are finished, while flat, with coarse single-cut files and triangular scrapers. They are finally warmed, and bent on the knee over a wooden mould, by means of a strap passed round the foot, just as a shoemaker fixes his last. Smaller combs of horn and tortoise-shell are parted, while flat, by an ingenious machine, with two chisel-formed cutters placed obliquely, so that each cut produces one tooth. See Rogers's comb-cutting machine, *Trans. Soc. Arts*, vol. xlix. part 2., since improved by Mr. Kelly. In making the frames for eye glasses, spectacles, &c. the apertures for the glasses were formerly cut out to the circular form with a tool something like a carpenter's centre-bit, or with a crown saw in the lathe. The discs so cut out were used for inlaying in the tops of

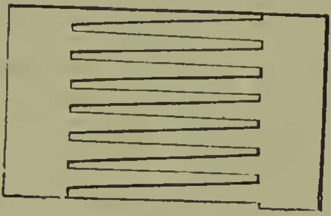
1817



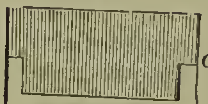
1818



1819

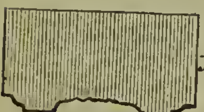


1823

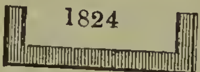


1820

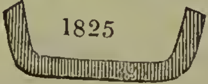
1821



1824



1825



1822

boxes, &c. This required a piece of shell as large as the front of the spectacle; but a piece one third of the size will now suffice, as the eyes are *strained* or *pulled*. A long narrow piece is cut out, and two slits are made in it with a saw. The shell is then warmed, the apertures are pulled open, and fastened upon a taper triblet of the appropriate shape; as illustrated by *figs.* 1820, 1821 and, 1822. The groove for the edge of the glass is cut with a small circular cutter, or sharp-edged saw, about three eighths or half an inch in diameter; and the glass is sprung in when the frame is expanded by heat.

In making tortoise-sheel boxes, the round plate of shell is first placed centrally over the edge of the ring, as in *fig.* 1823; it is slightly squeezed with the small round edgeblock *g*, and the whole press is then lowered into the boiling water: after immersion for about half an hour, it is transferred to the bench, and *g* is pressed entirely down, so as to bend the shell into the shape of a saucer, as at *fig.* 1825, without cutting or injuring the material; and the press is then cooled in a water-trough. The same processes are repeated with the die *d*, which has a rebate turned away to the thickness of the shell, and completes the angle of the box to the section *fig.* 1824, ready for finishing in the lathe. It is always safer to perform each of these processes at two successive boilings and coolings. Two thin pieces are cemented together by pressure with the die *e*, and a device may be given by the engraved die *f*. See *Holtzapffel's Turning and Mechanical Manipulation*, vol. i. p. 129.

Tortoise or Turtle shell *imported* in 1850, 43,085 lbs.

TOUCH-NEEDLES, and TOUCH-STONE, are means of ascertaining the quality of gold trinkets. See Assay.

The touch-needles are bars of known composition, and the touch-stone is black basalt; according to the streak made by the article to be tested, as compared with that made by the needles, its quality is inferred.

TOW. See Flax.

TRAGACANTH, GUM. (*Gomme adracante*, Fr.; *Traganth*, Germ.) See Gum.

TRASS, or TARRAS. A German term for a tertiary earth—probably volcanic, which occupies wide areas in the Eifel district of the Rhine. Its basis appears to be pumice stone, mixed with fragments of basalt and calcined slate. When powdered it is used like the pozzolano of Italy—as an hydraulic cement.

TRAVERTIN. A white concretionary limestone deposited from springs holding lime in solution. Travertin is compact. Tufa is a porous body.

TREACLE is the viscid brown uncrystallisable syrup which drains from the sugar-refining moulds. Its spec. grav. is generally 1·4, and it contains upon an average 75 per cent. of solid matter, by Dr. Ure's experiments.

TRIPOLI (*Terre pourrie*, Fr.; *Tripel*, Germ.) is a mineral of an earthy fracture, a yellowish-grey or white colour, composition impalpably fine, meagre to the touch, does not adhere to the tongue, and burns white.

M. Ehrenberg has shown that these friable homogeneous rocks, which consist almost entirely of silica, are actually composed of the exuviæ or rather the skeletons of infusoria (*animalcula*) of the family of *Barcillariæ*, and the genera *Cocconema*, *Gonphonema*, &c. They are recognised with such distinctness in the microscope, that their analogies with living species may be readily traced; and in many cases there are no appreciable differences between the living and the petrified. The species are distinguished by the number of partitions or transverse lines upon their bodies. The length is about $\frac{1}{288}$ of a line. M. Ehrenberg made his observations upon the tripolis of Billen in Bohemia, of Santafiora in Tuscany, of the Isle of France, and of Franeisbad, near Eger.

Tripoli is said by Brooke and Miller to be found "near Prague in Saxony, France, England, (?) Tripoli, Corfu." Tripoli has been confounded by many writers with the English Rottenstone. Mr. Kirwan, in his *Elements of Mineralogy*, says, "Mr. Haase, who has lately analysed it, found 100 parts of it to contain 90 of siliceous earth, 7 of argill, and 3 of iron; but the red sort probably contains more iron. According to M. Gerhard, magnesia has sometimes been extracted from it. It is evidently a volcanic product; for a coal mine near St. Etienne having accidentally taken fire, and the fire in its progress having extended to some strata of schistus and bitumen, tripoli was found in those parts of the strata that the fire had acted upon, but not in any other."

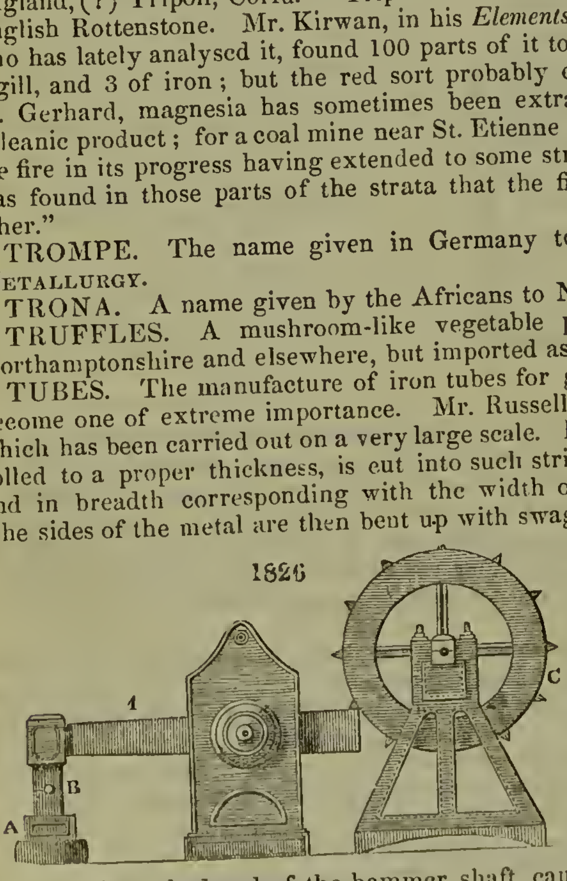
TROMPE. The name given in Germany to the water-blowing engine. See Metallurgy.

TRONA. A name given by the Africans to Natron, which see.

TRUFFLES. A mushroom-like vegetable production found underground in Northamptonshire and elsewhere, but imported as a luxury from Italy.

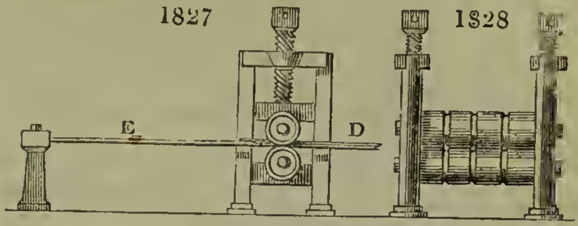
TUBES. The manufacture of iron tubes for gas, water, and other purposes has become one of extreme importance. Mr. Russell of Wednesbury patented a process which has been carried out on a very large scale. In this process plate iron, previously rolled to a proper thickness, is cut into such strips or lengths as may be desirable, and in breadth corresponding with the width of the tube intended to be formed. The sides of the metal are then bent up with swages in the usual way, so as to bring the two edges as close as possible together. The iron thus bent is then placed in an air or blast furnace, and brought to a welding heat, in which state it is withdrawn and placed under the hammer. *Fig.* 1826, A, is the anvil having a block or bolster, with a groove suited to and corresponding with a similar groove B, in the face of the block. C is a wheel with projecting knobs, which, striking in succession upon the iron-shod end of the hammer shaft, causes it to strike rapidly on the tube. In this process the tube is repeatedly heated and hammered, until the welding is

1826



complete from end to end. A mandril may be inserted or not during this operation. When the edges of iron have been thus thoroughly united, the tube is again heated in a furnace, and then passed through a pair of grooved rollers similar to those used in the production of rods, *fig*, 1827. Suppose a tube D, to be passing through these rollers, of which *fig*. 1828, represents a cross section, immediately upon its being delivered from the groove it receives an egg-shape core of metal fixed upon the extremity of the rod E, over which the tube sliding on its progress, the inside and outside are perfected together. Mr. Cort patented a similar process for the manufacture of gun barrels.

1827 1828



Brass or copper tubes are formed of rolled metal, which is cut to the required breadth by means of revolving discs: in the large sizes of tubes the metal is partially curved in its length by means of a pair of rolls; when in this condition it is passed through a steel hole or a die, a plug being held in such a position as allows the metal to pass between it and the interior of the hole. Oil is used to lubricate the metal; the motion is communicated by power, the drawing apparatus being a pair of huge nippers, which holds the brass, and is attached to a chain and revolves round a windlass or cylinder. The tube in its unsoldered state is annealed, bound round at intervals of a few inches with iron wire, and solder and borax applied along the seam. The operation of soldering is completed by passing the tube through an air stove, heated with "cokes" or "breezes," which melts the solder, and unites the two edges of the metal, and forms a perfect tube; it is then immersed in a solution of sulphuric acid, to remove sealy deposits on its surface, the wire and extra solder having been previously removed: it is then drawn through a "finishing hole plate," when the tube is completed.

Mandril-drawn tubes, as the name indicates, are drawn upon a very accurately turned steel mandril; by this means the internal diameter is rendered smooth; the tube formed by this process is well fitted for telescopes, syringes, small pump-cylinders, &c.

Lead pipes are produced by forcibly squeezing the lead through a circular orifice over a mandril.

TUBULAR BRIDGES, *and other structures*. In the former edition of this work there was a long article bearing the heading of FAIRBAIRN'S TUBULAR BRIDGES. This article no longer appears. In the first place, it ought never to have formed a place in a work which has nothing whatever to do with engineering science; and in the next place, it was calculated to inflict the most serious injury on the names of two men to whom this country is much indebted for works of surpassing magnitude and durability. Mr. Fairbairn has obtained a reputation for his mechanical, experiments, his engineering skill, and his extensive knowledge, so great that he is placed far above the necessity of seeking to assume any position to which he is not fairly entitled.

Without attempting to enter into the discussion which was, with much unfortunate feeling, obtruded in the last edition of the Dictionary, we purpose merely retaining so much of the original article as is purely descriptive of the applications of iron to tubular structures. The whole question is so completely settled by Mr. Fairbairn himself in his *Account of the Construction of the Britannia and Conway Tubular Bridges*, that beyond quoting his own words nothing need be said:—

1st. "I, however, cherish the hope that the perusal of this correspondence will establish the fact that it was in a great degree owing to my determined perseverance that *Mr. Stephenson's original conception* has been successfully carried into execution, and that the elaborate series of experiments which I performed have established the true principle upon which tubular bridges should be constructed. *To this early conception I make no claim*, but with regard to the services which I afterwards rendered I must leave the estimate of their merits to the unbiased judgment of the reader."—*Fairbairn, Preface*, p. 7.

2nd. "Mr. Robert Stephenson conceived the *original idea of a high tubular bridge to be constructed of riveted plates*, and supported by chains, and of such dimensions as to allow of the passage of locomotive engines and railway trains through the interior of it."—*Fairbairn*, p. 2.

This honest statement by Mr. Fairbairn himself shows that he had no intention of assuming the position which belongs to the originator of a great idea. Indeed, the following, the third quotation, shows exactly what was Mr. Fairbairn's position.

3rd. "I was asked whether such a design was practicable, and whether I could accomplish it; and it was ultimately arranged that the subject should be investigated experimentally to determine *not only the value of Mr. Stephenson's original conception*, but that of any other *tubular form of bridge* which might present itself in the prosecution of my researches" —*Fairbairn*, p. 3.

With the other matters in dispute we have little to do; a most careful study of Mr. Fairbairn's own work shows:—

1st. That Mr. Robert Stephenson conceived the idea of a tubular bridge through which railway trains should pass.

2nd. That Mr. William Fairbairn carried out the preliminary experiments for Mr. Robert Stephenson, and determined that the use of chains as supporting the tube might be done away with entirely.

3rd. That Mr. Eaton Hodgkinson also made experiments and calculations for determining the strength of tubular constructions. A careful study of the work already quoted by Mr. Fairbairn, and "*The Britannia and Conway Tubular Bridges*," by Edwin Clark, will place the above three engineers, each one in his proper, and each one in a most honourable position. They have built for themselves an enduring monument, which will speak to future ages of the engineering powers, of the originating mind, and of the mechanical and mathematical skill by the agency of which that grand idea became a sublime material fact. The Britannia and Conway Bridges exist, the pride of the country which possesses them, triumphs of the constructive arts, and immortal monuments to the men who were associated in their contrivance and execution. It is to be deplored in every respect that jealousies and rivalries should have arisen under circumstances where so much renown and merit was to be divided.

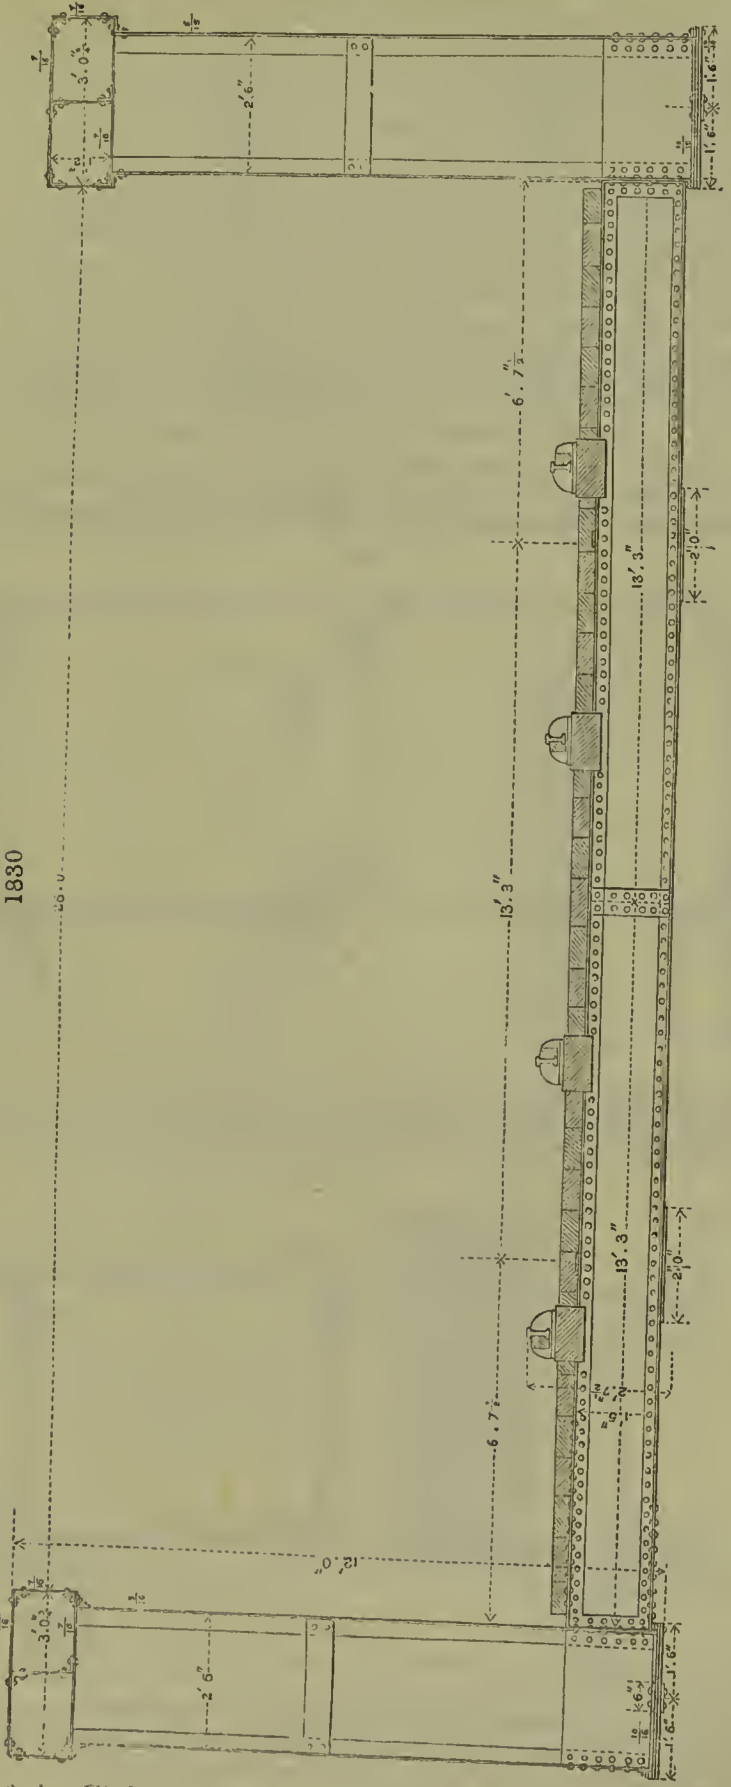
As an outgrowth of the remarkable introductory experiments made in connection with these wonders of North Wales, we must regard the equally important, though less imposing tubular girder system. A tubular girder, as the name implies, is a hollow beam constructed of metal plates firmly riveted or fastened together. When subjected to a transverse strain or load tending to break it, the law, which is applicable to every body, be it solid or hollow, is observable. The parts of the girder above the neutral axis have to arrange themselves to a resistance of a compressive strain, while those below that line are violently subjected to a force tending to draw them asunder. The extreme ductility of wrought iron, and its great power to resist tension, were well known, and in the earlier stages of the inquiry it was considered feasible, and frequent efforts were made to arrange the parts in such manner that these known properties might be taken advantage of in both the upper and lower sides of the girder, but every experiment baffled the ingenuity of the contrivance, and nature soon taught the constructor that her unerring laws were not to be disregarded.

The description of one of the best constructed tubular girders will give the most correct idea of their power and peculiarity. We select for illustration the beautiful bridge erected across the Trent at Gainsborough. *Fig.* 1829 represents a general

1829

elevation of the bridge which carries the Lincolnshire railway across the Trent. Its total length is 332 feet, the two main spans being 154 feet each. The width of roadway between the two main girders is 26 feet, giving ample room for double lines of railway. The width of the centre pier is 12 feet, and the tubular girders have a bearing on each land abutment of 6 feet. *Fig.* 1830 represents a cross-section form of the main girders, and to this we must direct especial attention in order to make the peculiarities of the system well understood. The height of each girder from end to end is 12 feet; this parallelism is not the best form to give a maximum resistance with a minimum amount of material; but from the greater facilities of construction is preferable to the parabolic form, and practically the proportions of the strength may be adjusted by varying the thicknesses, instead of the linear dimensions of the parts.

The Bottom of the Girder.—The bottom is framed of double thicknesses of long rolled plates, connected together in the manner hereafter described. Being subjected solely to a tensile strain, the material is condensed as much as possible, so as to assimilate that part of the structure to one unbroken solid sheet, which, if practicable, would be the best distribution or form. Each plate is 12 feet long by 18 inches wide, varying in thickness according to its position from the centre line of each span, where the greatest amount of material is accumulated. The bottom is necessarily connected to the sides of the girder by long bars of heavy angle iron, firmly riveted to both.



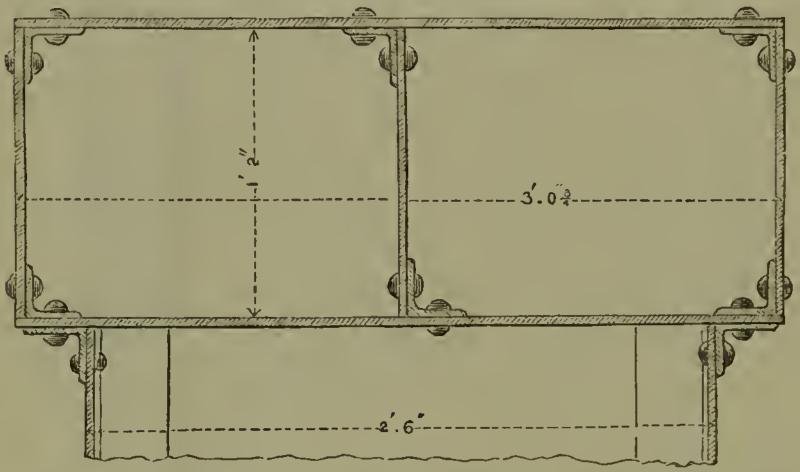
1830

The Sides of the Girder.—The side plates are 2 feet wide throughout, and of uniform thickness, excepting in the immediate neighbourhood of the piers and abutments, where they are strengthened and stiffened by pillars of strong T iron, to offer a due resistance to the dead weight of the girder itself. The joints are made with external covering plates 4½ inches wide, and internal ribs of T iron, which suffice to keep the side plates rigid, and enable them to accomplish their duty of separating the top and bottom of the girder.

The Top of the Girder.—In this part the principal novelty and ingenuity are observable. A single sheet of iron, like a sheet of paper, is easily put out of shape by a compressive strain. It crumples up, and at once loses all power of resistance. A sheet of common writing paper, which when placed on edge will merely support itself, when rolled into a cylinder, say of 1 inch diameter, will carry a considerable weight. In the same manner a given sectional area of plate, if placed in that simple form in the top of the Trent girder, would crumple up with a comparatively small weight, but when distributed according to the cellular system, as indicated by the Millwall experiments, it offers extraordinary resistance to compression.

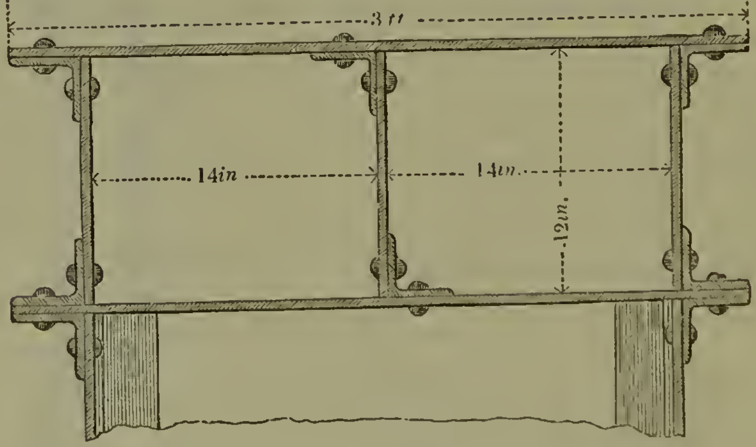
The value of this arrangement will be understood when it is stated that, notwithstanding the superior tenacity of wrought iron, a well constructed tubular girder only requires an excess of sectional area in the top over the bottom of $\frac{1}{12}$. In the Trent girder (see *fig.* 1831) the top compartment is 3 feet ¾ inches wide, and 15 inches deep, divided by a vertical plate into two rectangular cells, and all firmly connected by rivets and angle iron. Those angle irons constitute important elements in its strength.

1831



Since the construction of the Trent bridge, the cost of construction of tubular girders has been much diminished by a different arrangement of the parts of the top compartment, as shown in the following, *fig.* 1832. This form is equally powerful in its

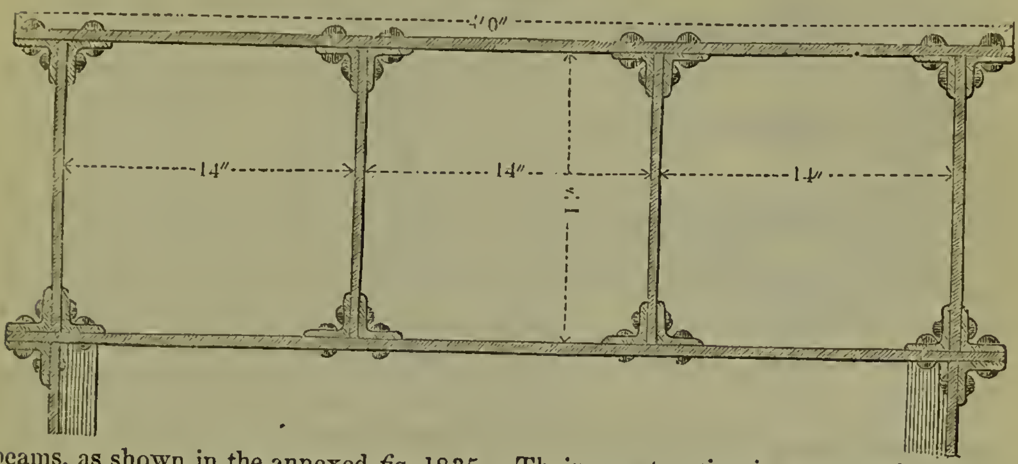
1832



resistance. When the span of the bridge reaches 180 or 200 feet, the top compartment is arranged as shown in *fig.* 1833, and when it is under 60 feet as shown in *fig.* 1834. It will be noticed that in every case the cells are proportioned, so as to admit of the entrance of a man for the purposes of painting or repairs.

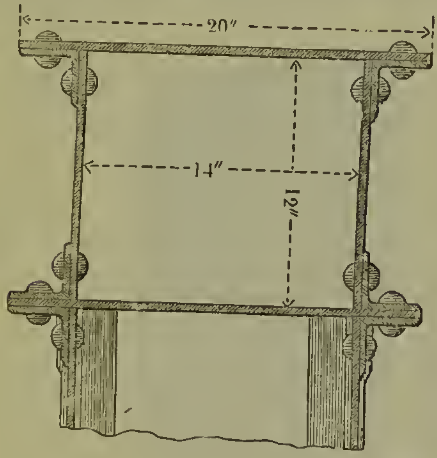
The Cross Beams or Supports of the Roadway.—These are generally, and ought to be universally, made of iron. In the Trent bridge they are made hollow or box

1833

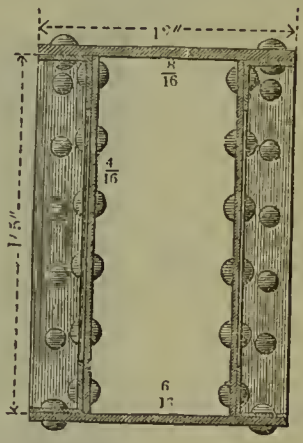


beams, as shown in the annexed *fig.* 1835. Their construction is now much simpler and equally good, thus, *fig.* 1836.

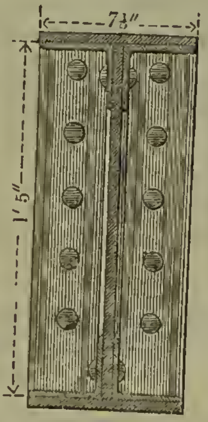
1834



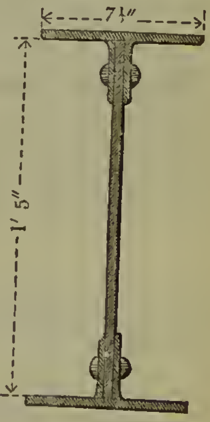
1835



The Riveting. — Upon the judicious fastenings of the plates together depends in a great measure the safety of a tubular girder bridge. The system of riveting followed in the several parts should have reference to the strains which occur in those parts. What are technically called "lap joints," where the ends of the plate overlap each other, and are connected by a single row of rivets (vide *fig.* 1837), should be avoided in every part of the structure, as they have been proved to be weak and insufficient. Mr. Fairbairn (*Phil. Trans.* part ii. 1852) gives the value of single and double-riveted joints as 70 and 56 respectively, the solid plate being assumed to be 100.



1836



"Butt joints" and covering plates are used throughout the girder, the length and substance of these covering plates and the number of rivets varying according to situation. In the top compartment the ends of the plates having been carefully fitted to each other, so as to take their portion of the strain the moment the load is applied, are covered by strips of sufficient width to receive a double row of rivets, one on each side of the joint, thus, as shown in *fig.* 1838. This arrangement effectually prevents some such effect as indicated in *fig.* 1839, which would occur were the lap joint used, and the load very great. In the tops the rivets are generally spaced 3 inches apart from centre to centre.

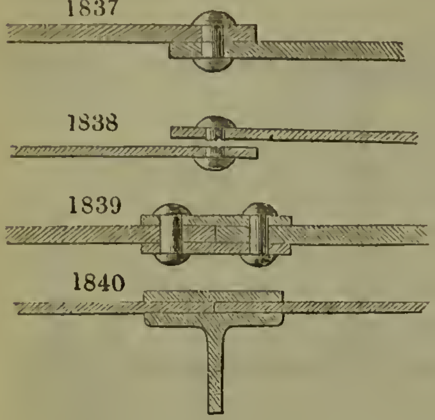
As before mentioned, instead of simple strips covering the vertical joints of the side plates, inside T iron bars are used to afford stiffness, and prevent the approach of the top and bottom (vide *fig.* 1840). Thus, the rivets being spaced 3 inches, the strips give to the external elevation of the girder the appearance of a series of panels.

1837

1838

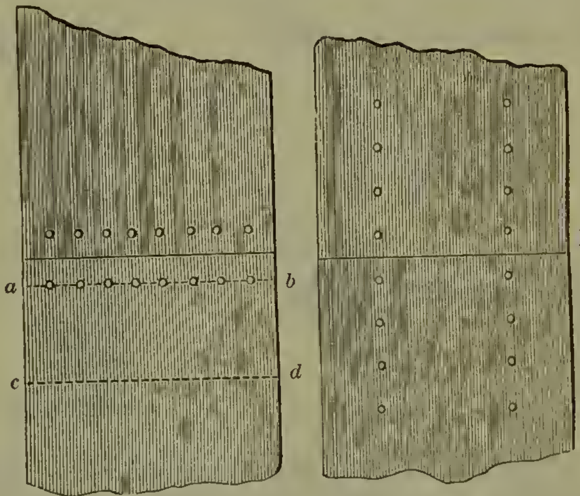
1839

1840



In the bottom an exceedingly ingenious and beautiful arrangement of riveting has been introduced by Mr. Fairbairn. It is evident that to join two plates together (these two plates having to resist a force tending constantly to separate them) a certain number of rivets or pins are required, and according to the old system of jointing, these rivets were placed in single rows along the edge of the plates, being in fact either single lap joints or single butt joints. Suppose the plates in *fig.* 1841 to be each 2 feet wide, and ½ inch thick, and that to connect them there were wanted 16 rivets, each 1 inch diameter: it is evident the resisting powers of the plates are weakened exactly by the amount of material punched out, in this case one-third, the section of resistance being through the line *a b*, and not through the line *c d*. But if these 16 rivets, instead of being placed all parallel with the joint, are arranged as shown in *fig.* 1842, and covered with long "covering plates" instead of "strips," it is

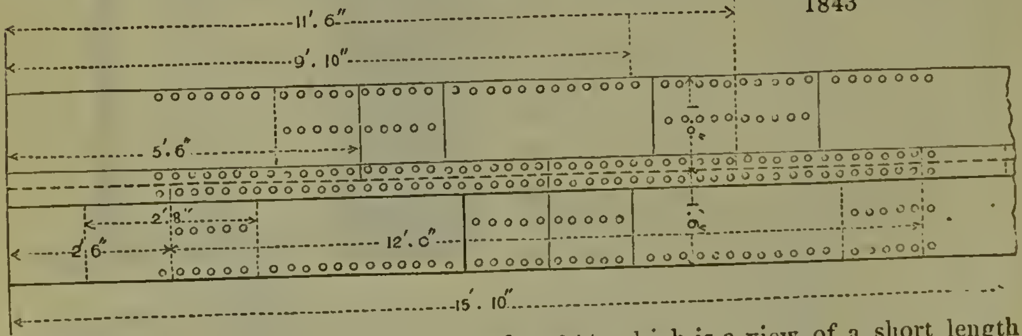
1841



1842

equally evident that they are in this position equally fitted to their duty of joining the plates and that the punching has weakened the resisting powers of the plates only $\frac{1}{12}$ instead of $\frac{1}{3}$. These proportions will readily explain the saving in material and weight which Mr. Fairbairn's "chain riveting" has effected, and the following figure of the "bottom" of the Trent bridge will show how it is practically applied (*fig.* 1843). The joints of the angle irons in the bottom are also jointed by long

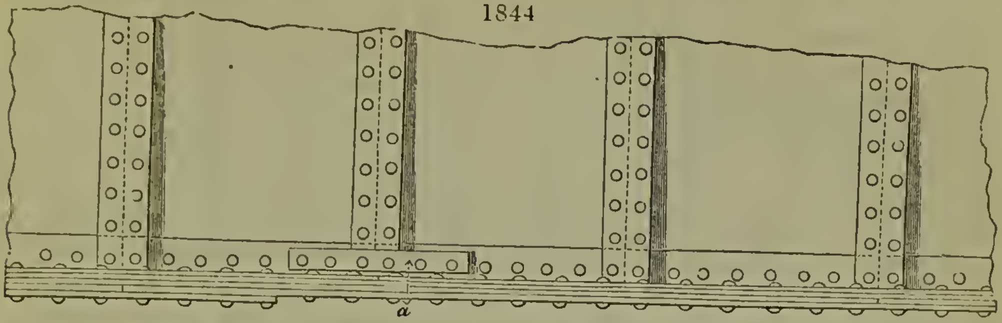
1843



corner pieces, as may be noticed at *a* in *fig.* 1844, which is a view of a short length of the bottom of the main Trent girder. Having thus described the tubular girder bridge in its best and most generally adopted form, a glance at the following figures (*figs.* 1845, 1846) will indicate modifications of the system which have gained favour in some quarters.

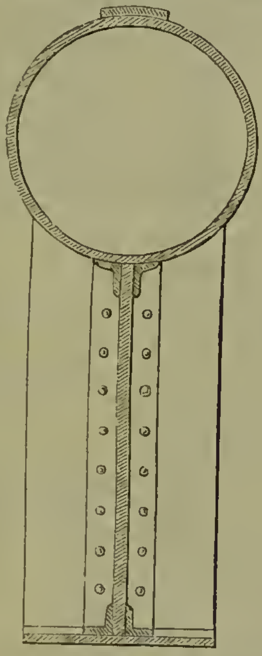
The Proportions and Strength of Tubular Girders.—The limits of this article will not admit of a lengthened examination of these interesting topics. A well proportioned beam or girder should have such a sectional distribution of its material, that when subjected to a transverse strain, the top should yield to compression and the bottom

1844

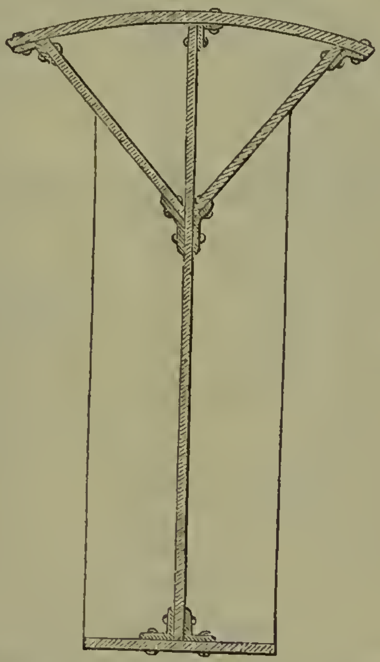


to extension at one and the same time; and as nearly all materials offer unequal resistances to the two forces, direct experiment can alone determine the exact relative proportions of the two parts. Thus, the resisting power of cast iron to compression is nearly six times greater than that which it offers to extension; but Mr. Fairbairn's ingenious distribution of the wrought-iron plates in the "cellular top" has enabled

1845



1846



him to fix the relative sectional areas of the tops and bottoms of tubular beams in the ratio of 12 to 11.

The tables in the following page show the proportions for tubular girder bridges of spans from 30 up to 300 feet.

Mr. Fairbairn's formula for calculating the strength of tubular girder bridges has been much disputed, but at the same time it has had many able defenders, and may be followed with perfect reliance and safety. If it errs, it errs on the right side—that of understating the real strength; it is

$$w=\frac{a\,d\,c}{l}$$

where w=the centre breaking weight in tons irrespective of the weight of the girder;
a=sectional area of bottom in inches;
d=depth of beam in inches;
c=a constant derived from experiment for the particular form of girder; and
l=length of girder between the supports in inches.

The formula always assumes a well made and well proportioned girder, having the relative areas of 12 to 11 in the top and bottom and the chain riveting.

The constant c for the tubular girders we have described was ascertained to be 80. Let us now find by this formula the strength of one of the spans of the Trent bridge which we have described. By reference to *fig.* 1830 it will be observed that here a=58·5, d=144, and l=1848.

$$w=\frac{a\,d\,c}{l}=\frac{58\times144\times80}{1848}=364{\cdot}6\text{ tons}$$

as the weight which a tubular girder 154 feet between the supports will carry suspended from one point in the centre before fracture. Now the actual weight of this girder itself is under 70 tons, and it may safely be asserted that no other form of construction would give so favourable a result. The centre breaking weight of one girder being 364½ tons, it would carry 729 tons equally distributed along its entire length, and there being two main girders to the bridge, the ultimate strength of the structure is in round numbers 1500 tons. It would be possible, by both lines of railway being covered with heavy goods trains, to have a load on the bridge of about 250 tons at one and the same time, and we thus see there is a margin of strength of six times the greatest possible load. Engineers differ in opinion as to the excess of strength which it is desirable that railway structures should possess: some are satisfied with even as low an ultimate breaking strength as three times the load; but with a comparatively untried material, and one moreover liable to deterioration from atmospheric influences, the larger excess is the better.

Table showing the Proportions of Tubular Girder Bridges, from 30 *to* 150 *Feet Span.*

Explanation of the Engravings, descriptive of the Hollow Girder Bridge over the Turnpike Road near Blackburn.

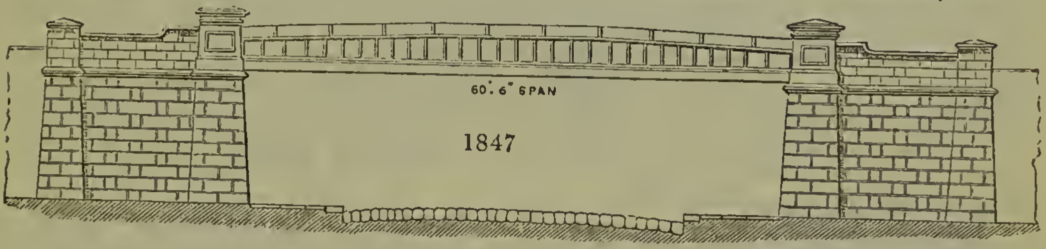
Fig. 1847 is an elevation or side view of the girder, eaeh 66 ft. long, and bedded on east-iron base plates.

Fig. 1848 is a transverse seetion of the bridge, showing the sides of the eross-beams, and the eross seetions of the outside and middle girders.

Fig. 1849 is an enlarged transverse seetion of the outside girder, showing the attachment of the eross-beams, which are riveted to the bottom of the girder, exelusive of two bolts *a a*, whieh extend through the bottom plates and angle iron of the girder. and the top and bottom plates of the cross-beam.

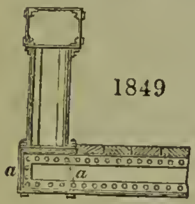
Fig. 1850 is an enlarged view of a part of the side of the large girder, exhibiting a transverse seetion of the eross-beam at *b*, whieh is made of wrought-iron, with the top and bottom plates so proportioned as to equalise its powers of resistanee to the foree of compression on the top, and that of tension on the bottom. It also exhibits the mode of riveting up the joints of the side plates with the eovering strip *c c c*, and the additional strength as obtained by the attaehment of T iron in the interior of the tube.

Fig. 1851 is a plan of the bridge. showing on one side the platform and the rails, and on the other the cross-beams, whieh in this bridge are plaeed 6 ft. asunder ; but in

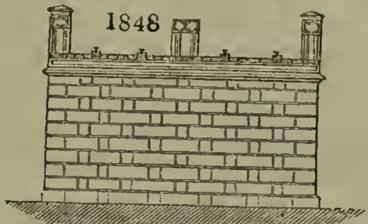


1847

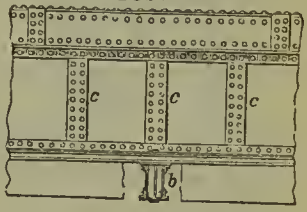
1849



1848



1850



1851

those more reeently construeted, I have plaeed them at distances of only 4 ft., and consider this arrangement preferable.

From the above deseription it will be seen that the whole is a strong and perfeetly rigid strueture. With three longitudinal girders, a bridge of this deseription will support a load equally distributed of 760 tons ; and in order to render it safe under every speeies of strain, the middle girder is made nearly double the strength of those on the outside. This is essential, as two trains may be passing the bridge at the same moment ; in whieh ease the middle girder would be subjeeted to a pressure equal to double the load on the outside girders.

In the eonstruetion of bridges of larger span, engineers generally prefer only two large longitudinal girders with strong eross-beams every four feet, of suffieient length to admit two lines of rails, and suffieient room for two trains to pass at the same time. This mode of eonstruetion is preferable to the three girders, as it effeets greater simplieity in the strueture, and, from every appearanee, renders the bridge equally effeetive and seeure.

For the details of the strueture of the Conway and Britannia Bridges, the interested reader must be referred to the works already quoted.

TUFA. A voleanie produet. See Mortar, Hydraulic.

TUFA, or TUF, is a grey deposit of calcareous carbonate from springs and streams.

TULA METAL is an alloy of silver, copper, and lead; made at Tula in Russia.

TUNGSTEN. (*Tungsténe*, Fr.; *Wolframium*, Germ.) Symbol, Ts or W. Its name is derived from the principal mineral from which it is obtainable. Tungsten, Swedish, *tung*, heavy, *sten*, stone, or Wolfram, German. This metal was discovered by the brothers De Luyart, about 1784, shortly after the discovery of tungstic acid by Scheele, from whom it is sometimes called Scheelium. It is never found in the native state, but is produced by a variety of processes. First, and most easily, by mixing the dried and finely-powdered tungstate or bitungstate of soda with finely-divided charcoal, such as lamp-black, placing the mixture in a crucible lined with charcoal, covering it with charcoal in powder, and then exposing the whole to a steady red heat for two or three hours. On removal of the crucible and cooling it, a porous mass is found, from which the soda is removed by solution in water, and the unconsumed carbon is separated by washing it off, the metal being left as a bright, glistening, blackish-grey metallic powder. It may also be obtained by treating tungstic acid in a similar manner, or by exposing the acid at a bright red heat, in an iron or glass tube, to a current of hydrogen gas. Tungsten is one of the heaviest metals known, its specific gravity being 17·22 to 17·6. It requires such a very high temperature for fusion that it has never yet been obtained in mass, more commonly as a fine powder, but sometimes in small grains. It is not magnetic. It is very hard and brittle. Alone it has not been rendered available for any useful purpose, but it has lately been employed for the manufacture of certain alloys. Tungsten is comparatively a rare substance, and is remarkable for the very limited extent to which in nature it is found to have been mineralised by combination with other substances. In none of these does it exist as a salifiable base, but as an acid, as in wolfram, Scheelite, yttrotantalite, and the tungstate of lead.

The most common ore of this metal is wolfram, known also to the Cornish miner as cal or callen, and gossan. It is most commonly found associated with tin ores, which contain besides the black oxide of tin or cassiterite, the metallic minerals, arsenical iron, copper, lead, and zinc sulphides; but its peculiarly characteristic associate is the metal molybdenum, for the most part mineralised as a sulphide. This metal is remarkable in connection with tungsten as producing isomeric compounds, and as having both its equivalent and its specific gravity equal to about one half that of tungsten, they being respectively as follows:—equivalents, Ts, 96, Mo, 48; sp. gr. Ts, 16·22, Mo, 8·615.

Amongst miners wolfram has the reputation of being an abundant mineral, but on close inquiry it is found to be comparatively rare, schorl, specular, and other iron ores, and gossan being commonly mistaken for it. From its association with tin ores, it has been until lately the source of great loss to the miner, as it was found quite impossible to separate it even to a moderate extent from the ore in consequence of its specific gravity 7·1 to 7·4, being so near to that of black tin, 6·3 to 7·0.

Pryce, in his Mineralogia Cornubiensis, 1778, says, "After the tin is separated from all other impurities by repeated ablutions, there remains a quantity of this mineral substance (gal), which being of equal gravity cannot be separated from the tin ore by water, therefore it impoverishes the metal and reduces its value down to 8 or 9 parts of metal for twenty of mineral, which without its brood, so called, might fetch twelve for twenty." This description of tin ores containing wolfram was still applicable until a very recent period, when a new process was invented by Mr. Robert Oxland, of Plymouth, and by him successfully introduced at the Drake Walls Tin Mine, at Gunnis Lake, on the banks of the Tamar, where it has been continued in operation ever since. At this mine, although the tin ore raised was of excellent quality, in spite of all that could be done by the old processes, it was left associated with so much wolfram that the ore fetched the lowest price of any mine in Cornwall.

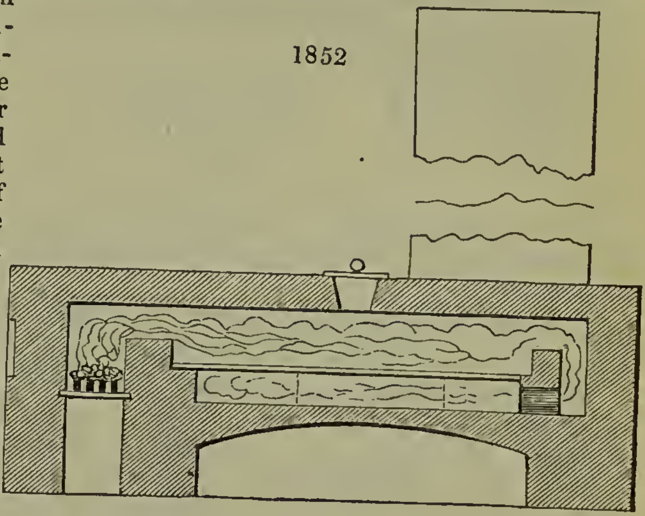
At the time of the introduction of the process the greater portion of the ore was sold for £42 per ton. The improvement effected by it was so great that the same sort of ore sold for £56 per ton. The Drake Walls ores are now known as the best of the mine ores in Cornwall.

The process is a neat illustration of the advantages obtainable by the careful direct application of scientific principles, guided by practical experience, to the improvement of the results obtainable by mining operations.

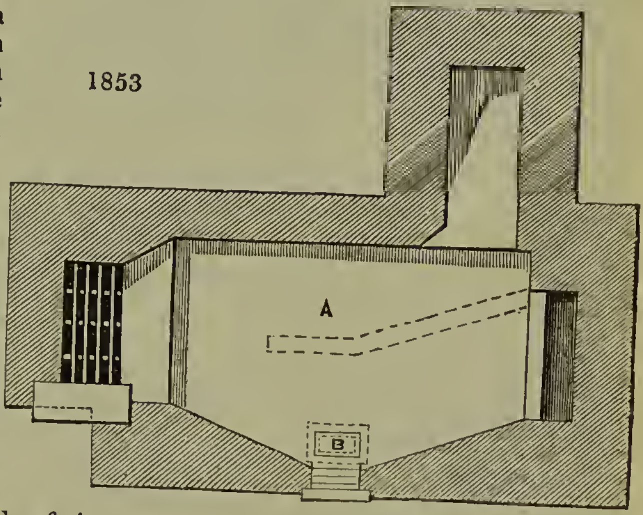
The process consists in taking tin ores mixed with wolfram, dressed as completely as possible by the old process, and having ascertained by analysis the quantity of wolfram contained therein, then mixing therewith such a quantity of soda ash of known value as shall afford an equivalent of soda for combination with the tungstic acid of the wolfram, which is the tungstate of iron and manganese; the object of the process being by calcination to convert the insoluble tungstate of iron and manganese into the soluble tungstate of soda, leaving the oxides of iron and manganese in a very finely-divided state and of low specific gravities, so that they can be easily washed off with water.

The mixture, in charges of five to ten cwt., is roasted in a reverberatory furnace on a cast-iron bed of the construction shown in the annexed engraving. The use of the cast-iron bed is attended with considerable economy in the consumption of fuel, and it is admirably well adapted for the calcination of the raw ores, for the evolution of the sulphur and arsenic contained in them, but it is especially necessary instead of fire-brick or tile, to avoid the loss which would accrue from the reaction of the soda ash on the silica of the brick, and the formation of soda silicate of tin which would consequently take place. The mixture is introduced to the bed through a hole in the crown of the furnace; from a side door it is equally distributed over the bed, and from time to time it is turned over by the furnace-man until the whole mass is of a dull red heat, emitting a slight hissing sound, and in an incipient pasty condition. In successive quantities the charge is then drawn through a hole in the bed of the furnace into the *wrinkle* or arch beneath, whence it is removed to cisterns, in which it is lixiviated with water, and the tungstate of soda is drawn off in solution. The residuary mass left in the cisterns, — the whole of the soluble matter having been washed out, — is removed to the burning-house floors, and is there dressed over again in the usual manner, the final product of the operations being very nearly pure black oxide of tin.

1852



1853



The liquid obtained is either evaporated sufficiently for crystallisation when set aside to cool, or is at once dried down to powder. The crystals of tungstate of soda thus obtained are colourless, translucent, of a beautiful pearly lustre, having the form of rhombic prisms or of four-sided laminæ. The composition of the crystallised and of the anhydrous tungstate of soda is as follows: —

	Anhydrous.	Crystalline.
Soda	20·63	18·44
Tungstic acid	79·37	70·92
Water	·00	10·64
	100·00	100·00

It has been proposed to use this substance as a mordant for dyeing purposes, as a source of supply of metallic tungsten for the manufacture of alloys, for the manufacture of the tungstates of lime, barytes, and of lead to be used as pigments; and still more recently it has been found to be valuable, and preferable to any other substance, for rendering fabrics not inflammable, so as to prevent the terrible accidents constantly occurring from the burning of ladies' dresses. For this purpose a patent has lately been obtained by Messrs. Versmann and Oppenheim.

For the manufacture of metallic alloys a patent has been obtained by Mr. R. Oxland, as a communication from Messrs. Jacob and Koeller. Steel of very superior quality, manufactured under this patent, is now coming extensively into use in Germany. It is prepared by simply melting with cast steel, or even with iron only, either metallic tungsten, or preferably, what has been termed the native alloy of tungsten, in the proportion of two to five per cent. The steel obtained works exceedingly well under the hammer. It is very hard and fine grained, and for tenacity and density is superior to any other steel made. The native alloy is obtained by exposing to strong heat in a charcoal-lined crucible a mixture of clean powdered wolfram with fine carbonaceous matter. A black, steel-grey metallic spongy mass is obtained resembling metallic tungsten. The composition of the alloy is shown in the following statement of the composition of wolfram:—

Tungstic acid.		Oxide of iron.		Oxide of manganese.		
Tungsten	76·25	Iron	17·75	Manganese	6·00	= 100
Oxygen	19·06	Oxygen	5·07	Oxygen	1·71	= 25·84
						125·84

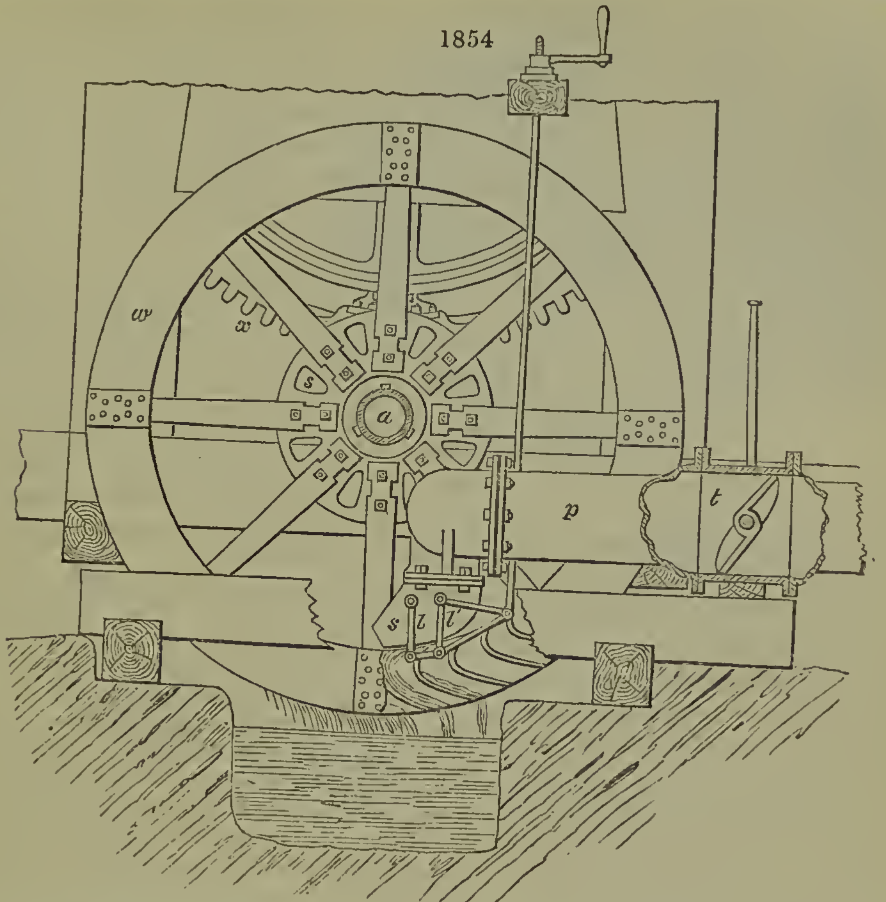
The tungstate of soda is used in dyeing; metallic tungsten, or native alloy, is also used for the manufacture of packfong or Britannia metal, by alloying with copper and tin.

By these useful applications this metal has already become a desideratum, which only a few years since was regarded as one of the most deleterious associates of tin ores, and the only one that was perfectly unmanageable.—R. O.

TURBINE. Numberless are the varieties, both of principle and of construction, to be met with in the mechanisms by which motive power may be obtained from falls of water. The chief modes of action of the water are, however, reducible to three, as follows. First: The water may act directly, by its weight, on a part of the mechanism which descends while loaded with water, and ascends while free from load. The most prominent example of the application of this mode is afforded by the ordinary bucket water-wheel. Second: The water may act by fluid pressure, and drive before it some part of the vessel, by which it is confined. This is the mode in which the water acts in the water-pressure-engine, analogous to the ordinary high-pressure steam-engine. Third: The water, having been brought to its place of action, subject to the pressure due to the height of its fall, may be allowed to issue through small orifices with a high velocity, its inertia being one of the forces essentially involved in the communication of the power to the mechanism. Throughout the general class of wheels called Turbines, which is of wide extent, the water acts according to some of the variations of which this third mode is susceptible. The name Turbine is derived from the Latin word *turbo*, a top, because the wheels to which it is applied almost all spin round a vertical axis, and so bear some considerable resemblance to the top. In our own country, and more especially on the continent, turbines have attracted much attention, and many forms of them have been made known by published descriptions.

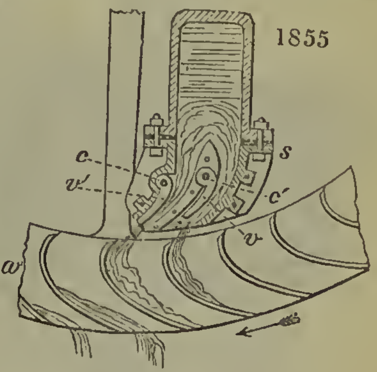
Turbines for mining purposes. Although the horizontal water-wheel has been known and employed under various forms from the highest antiquity, and has latterly been improved by Fourneyron, Fontaine, Jouval, and others, so as to rank among the most perfect of hydraulic motors, it has only recently been applied to mining uses (pumping, loading, &c.), and where so employed its success can scarcely be said to be yet decided. The failures may be attributed to the following causes. First: The plan of causing the water to flow simultaneously through all the buckets, necessitates the use of wheels of small dimensions, making a very great number of revolutions per minute, and thus requiring a considerable train of intermediate gear to reduce the speed to the working rate. Second: The complex nature of the ring sluices employed between the guide curves and the mouths of the buckets, renders them uncertain in action, and from their small dimensions liable to be easily choked by any mechanical impurities in the water; and lastly, the lubrication of the foot spindle of the vertical wheel, revolving at very great velocity, is attended with considerable difficulty and inconvenience, especially where the engine-room is at a considerable distance below the surface of the earth, and it is requisite, as in the case of pumping wheels, to keep the machinery in action continuously for long periods of time. The form of wheel of which a notice is here appended, was introduced into the Saxon mines about the year 1849 by Herr Schwamkrug, inspector of machinery at the Royal Mines and Smelting Works at Freyberg, and since that time several have been introduced for pumping, winding, driving stampheads, &c. The example selected for illustration was built to take the place of two overshot waterwheels, employed in pumping water at the mine "Churprinz Friedrich August;" it differs from the usual form of turbine in having the wheel placed vertically, and in having the water supplied through a small number of guide curves near the lowest part. In this latter respect it resembles the tangential turbine of General Poncelet, with this difference, that the water flows from the inner to the outer circumference, instead of the reverse way, as is the case in Poncelet's wheel. The construction of the wheel is as follows: *a*, *fig.* 1854, is the tubular axle of cast iron which carries the seating for the arms, *s*, which is similar to that usually used for large water wheels; to the ends of the arms is attached the wheel *w*, which is formed of two brags or shroudings of sheet iron, each 13

1854



inches deep, measured radially, and of a total height of 10 feet 2 inches; these two rings are maintained at a distance of 6 inches apart, by means of 44 sheet-iron buckets of the form shown in the smaller detailed figure, *fig.* 1855; the driving water is admitted through the pressure pipe, *p*, in which is placed the admission throttle, *t*, and turned through a pipe of rectangular section (shown in the smaller figure) into the sluice box, *s*, which contains the two guide curves, *v*, *v'*, which are movable about the centres, *c*, *c'*, by means of the levers, *l*, *l'*, by means of these guide curves when fully opened, as shown in the figure; the water is admitted into the buckets in two parallel streams or jets of $5\frac{3}{4}$ inches in breadth, and $1\frac{3}{10}$ inches in thickness; the power is transmitted from the axle of the wheel by a pinion with 28 teeth, which draws the large toothed wheel, *x*, which acts on a third shaft carrying the pump cranks. The wheel is constructed to work under a head of 147 feet, and makes about 130 revolutions per minute, with a maximum quantity of 550 cubic feet of water, equal to nearly 175 horse power. A series of dynamometrical experiments on a wheel of similar construction of 7 feet 9 inches in diameter, with a discharge varying from 39 to 134 cubic feet, with a head of 103 feet, gave an available duty of from 58 to 79 per cent., the number of revolutions varying from 112 to 148 per minute.

1855



In conclusion it may be remarked that the vertical turbine may be employed with advantage where the available fall of water is too great to be employed on a single overshot water-wheel; and although a less perfect machine than the water-pressure engine, it is of simpler construction, and may be preferred where, from the hardness or yielding nature of the rock, it becomes difficult to construct large machine rooms or wheel pits underground. In practice it is found necessary to surround the wheel with a casing of wood, in order to prevent the affluent water being projected to a distance from centrifugal action.

A fine model of one of these turbines, with two sets of buckets, constructed for the purpose of winding (*Turbinengöpel*), may be seen at the Museum of Practical Geology, Jermyn Street.

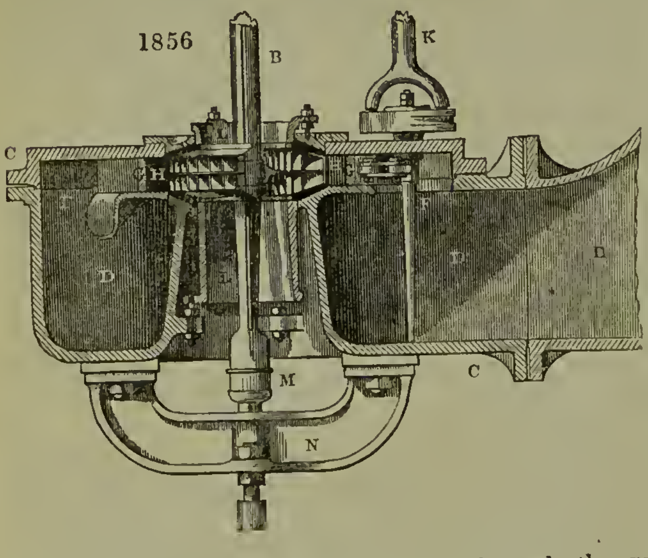
For further information on this subject, we may refer to the *Polytechnisches Central Blatt*, Nos. 8 and 9, for 1849, and No. 3 for 1850; to the *Jahrbuch für den Berg- und Huttenmann*, for 1850 and 1853. The subject of turbines is treated in great detail in Wenbach's *Mechanics of Machinery and Engineering*. Redlenbache's *Theorie und Bau der Turbinen und Ventilatoren*, Mannheim, 1844, is the best and most complete work on the subject. Notices of Fourneyron's, Jouval's, and Fontaine's turbines are to be found in Glyn's Rudimentary Treatise on Water Power, in Weale's series; the original notice of Fourneyron's turbine is published in the *Bulletin de la Société d'Encouragement*, for 1834, and several new forms are noticed in the various volumes of Armergand's *Publication Industriel.*

The name of Vortex Wheel has been given to a modification of the turbine by Mr. James Thomson of Belfast. In this machine the moving wheel is placed within a chamber of a nearly circular form. The water is injected into the chamber tangentially at the circumference, and thus it receives a rapid motion of rotation. Retaining this motion, it passes towards the centre, where alone it is free to make its exit. The wheel, which is placed within the chamber, and which almost entirely fills it, is divided by thin partitions into a great number of radiating passages. Through these passages the water must flow in its course towards the centre; and, in doing so, it imparts its own rotatory motion to the wheel. The whirlpool of water, acting within the wheel chamber, being one principal feature of this turbine, leads to the name *Vortex*, as a suitable designation for the machine as a whole.

The vortex admits of several modes of construction; but the two principal forms are the one adapted for high falls, and the one for low falls. The former may be called the high-pressure vortex, and the latter the low-pressure vortex. An example of each of these two kinds is delineated in the accompanying figures.

Figs. 1856 and 1857 are respectively a vertical section and a plan of a vortex constructed for employing a very high fall near Belfast to drive a flax-mill.* A A is the water wheel. It is fixed on the upright shaft B, which conveys away the power to the machinery to be driven. The water wheel occupies the central part of the upper division of a strong cast-iron case C C. This part of the case is called the *wheel chamber*. D D is the lower division of the case, and is called the supply chamber. It receives the water directly from the supply pipe, of which the lower extremity is shown at E, and delivers it into the outer part of the upper division by four large openings F, in the partition between the two divisions. This outer part of the upper division is called the *guide-blade chamber*, from its containing four guide-blades, G, which direct the water tangentially into the wheel chamber. Immediately after being injected into the wheel chamber the water is received by the curved radiating passages of the wheel, which are partly to be seen in *fig.* 1857, at a place where both the cover of the wheel chamber, and the upper plate of the wheel, are broken away for the purpose of exposing the interior to view. The water on reaching the inner ends of these curved passages, having already done its work, is allowed to make its exit by two large central orifices shown distinctly on the figures at or adjacent to the letters L L, the one leading upwards and the other downwards. Close joints between the case and the wheel, to hinder the escape of water otherwise than through the radiating passages, are made by means of two annular pieces L, L, called *joint rings*, fitting to the central orifices of the case, and capable of being adjusted, by means of studs and nuts, so as to come close to the wheel without impeding its motion by friction. The four openings H, H, *fig.* 1857, through which the water flows into the wheel chamber, each situated between the point or edge of one guide-blade and the middle of the next, determine, by

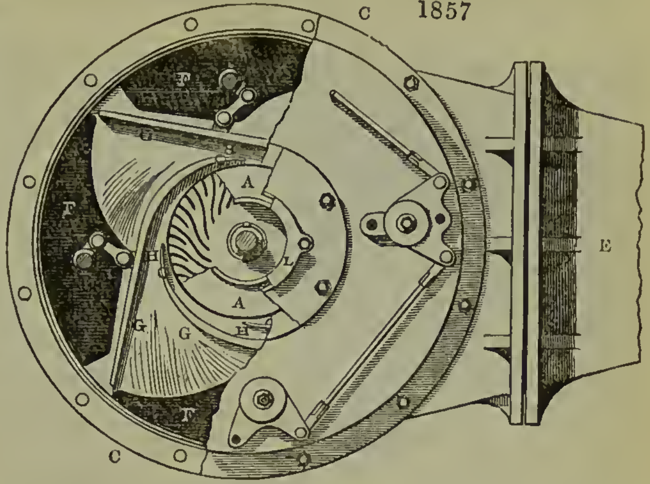
1856



* In these figures, as also in *figs*. 1858, 1859, some unimportant modifications are made for the purpose of simplifying the drawings, and rendering them more easily understood than they would otherwise be.

their width, the quantity of water admitted, and consequently the power of the wheel. To render this power capable of being varied at pleasure, the guide-blades are made movable round gudgeons or centres near their points; and a spindle K, worked by a handle in any convenient position, is connected with the guide-blades by means of links, cranks, &c. (see the figures), in such a way that when the handle is moved, the four entrance orifices are all enlarged or contracted alike. The gudgeons of the guide-blades, seen in *fig.* 1857 as small circles near the points, are sunk in sockets in the floor and roof of the guide-blade chamber, and so they do not in any way obstruct the flow of the water. M is the pivot-box of the upright shaft, and is constructed with peculiar provisions for oiling the pivot, which, by reason of its being under water, does not admit of being oiled by ordinary means. N is a hanging bridge which forms the fixture of the pivot.

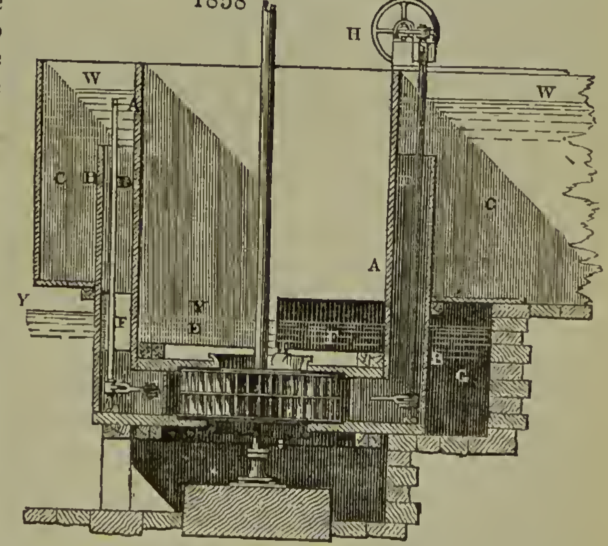
1857



This vortex is calculated for 50 horse-power, with a fall varying from 90 to 100 feet. On account of the great height of the fall, the machine comes to be of very small dimensions; the diameter of the water-wheel itself being only about 15 inches, and the extreme diameter of the case 3 feet 9 inches. The speed for which the wheel is calculated, in accordance with its diameter and the velocity of the water entering its chamber, is 768 revolutions per minute.

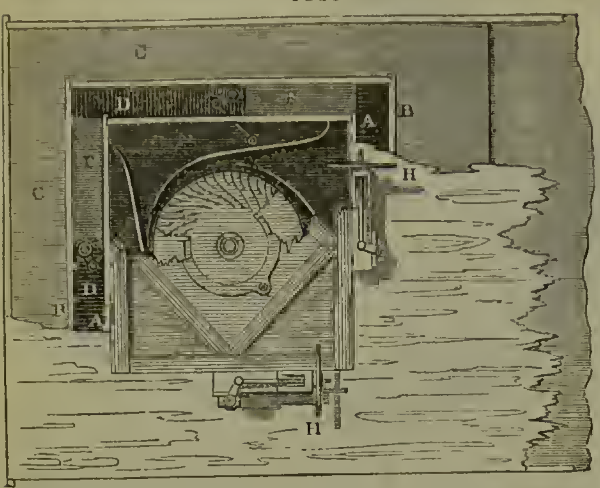
A low-pressure vortex constructed for another mill near Belfast, is represented in vertical section and plan, in *figs.* 1858 and 1859. This is essentially the same in principle as the vortex already described, but it differs in the material of which the case is constructed, and in the manner in which the water is led to the guide-blade chamber. In this the case is almost entirely composed of wood. The water flows with a free upper surface W W, into this wooden case, which consists chiefly of two tanks A A, and B B, one within the other. The water-wheel chamber, and the guide-blade chamber, are situated in the open space between the bottom of the outer and that of the inner tank, and will be readily distinguished by reference to the figures. The water of the head race having been led all round the outer tank in the space C C, flows inwards over its edge, and passes downwards by the space D D, between the sides of the two tanks. It then passes through the guide-blade chamber and the water-wheel, just in the same way as was explained in respect to the high-pressure vortex already described; and in this one likewise it makes its exit by two central orifices, the one discharging upwards and the other downwards. The part of the water which passes downwards flows away at once to the tail race, and that which passes upwards into the space E, within the innermost tank, finds a free escape to the tail race through boxes and other channels F and G, provided for that purpose. The wheel is completely submerged under the surface of the water in the tail race, which is represented at its ordinary level at Y Y, *fig.* 1858, although in floods it may rise to a much greater height. The power of the wheel is regulated in a similar way to that already described, in reference to the high pressure vortex. In this case, however, as will be seen by the figures, the guide-blades are not linked together, but each is provided with a hand wheel H, by which motion is communicated to itself alone.

1858



The foregoing descriptions are sufficient to explain the principal points in the structural arrangements of these water-wheels.

1839



And now a few words more in respect to their principles may be added. In these machines the velocity of the circumference of the wheel is made the same as the velocity of the entering water, and thus there is no impact between the water and the wheel; but, on the contrary, the water enters the radiating conduits of the wheel gently, that is to say, with scarcely any motion in relation to their mouths. In order to attain the equalisation of these velocities, it is necessary that the circumference of the wheel should move with the velocity which a heavy body would attain in falling through a vertical space equal to half the vertical fall of the water, or, in other words, with the velocity *due* to half the fall; and that the orifices through which the water is injected into the wheel-chamber should be conjointly of such an area, that, when all the water required is flowing through them, it also may have the velocity due to half the fall.

Thus one half only of the fall is employed in producing velocity in the water; and, therefore, the other half still remains, acting on the water within the wheel-chamber at the circumference of the wheel, in the condition of fluid pressure. Now, with the velocity already assigned to the wheel, it is found that this fluid pressure is exactly that which is requisite to overcome the centrifugal force of the water in the wheel, and to bring the water to a state of rest at its exit, the mechanical work due to both halves of the fall being transferred to the wheel during the combined action of the moving water and the moving wheel. In the foregoing statements, the effects of fluid friction, and of some other modifying influences, are for simplicity left out of consideration.

TURBITH'S MINERAL. The yellow sub-sulphate of mercury, called Queen's yellow.

TURF (*Peat*, Scotch; *Tourbe*, Fr.: *Torf*, Germ.) consists of vegetable matter, chiefly of the moss family, in a state of partial decomposition by the action of water. Cut, during summer, into brick-shaped pieces, and dried, it is extensively used as fuel by the peasantry in every region where it abounds. The dense black turf, which forms the lower stratum of a peat moss, is much contaminated with iron, sulphur, sand, &c., while the lighter turf of the upper strata, though nearly pure vegetable matter, is too bulky for transportation, and too porous for factory fuel. These defects have been removed, several processes having been patented for converting the lightest and poorest beds of peat-moss, or bog, into the four following products: 1. A brown combustible solid, denser than oak; 2. A charcoal, twice as compact as that of hard wood; 3. A factitious coal; and 4. A factitious coke; each of which possesses very valuable properties.

Mr. D'Ernst, artificer of fireworks to Vauxhall, has proved, by the severe test of coloured fires, that turf charcoal is 20 per cent. more combustible than that of oak. Mr. Oldham, engineer of the Bank of England, applied it in softening his steel plates and dies, with remarkable success. A prospect is thus opened up of turning to admirable account the unprofitable bogs of Ireland; and of producing, from their inexhaustible stores, a superior fuel for every purpose of arts and engineering.

The turf is treated as follows: — Immediately after being dug, it is triturated under revolving edge-wheels, faced with iron plates perforated all over their surface, and is forced by the pressure through these apertures, till it becomes a species of pap, which is freed from the greater part of its moisture by squeezing in a hydraulic press between layers of caya cloth, then dried, and coked in suitable ovens. (See CHARCOAL, and PITCOAL, COKING OF.) Mr. Williams, by his patent, makes his factitious coal by incorporating with pitch or rosin, melted in a cauldron, as much of the above charcoal, ground to powder, as will form a doughy mass, which is moulded into bricks in its hot and plastic state. From the experiments of M. Le Sage, detailed in the 5th volume of *The Repertory of Arts* charred ordinary turf seems to be capable of producing a far more intense heat than common charcoal. It has been found preferable to all other fuel for case-hardening iron, tempering steel, forging horse-shoes, and welding gun-barrels. Since turf is partially carbonised in its native state, when it is condensed by the hydraulic press, and fully charred, it must evidently afford a charcoal very superior in calorific power to the porous substance generated from wood by fire. See PEAT.

TURKEY RED, is the name given to one of the most beautiful and durable of known dyes. The art of dyeing cotton with this colour seems to have originated in India. In his *Philosophy of Permanent Colours*, Bancroft has given a detailed account of the process as practised in that country, and this process will be found to agree in all essential particulars with that pursued by the Turkey-red dyers of Europe, except that in India the chaya root is employed as the dyeing material in the place of madder. In the middle ages the art was practised in various parts of Turkey and Greece, especially in the neighbourhood of Adrianople, and hence this colour is often called *Adrianople red*. Even as late as the end of last century the manufacture of Turkey-red yarn seems to have been extensively carried on at Ambelakia and other places in the neighbourhood of Larissa. An interesting account of the manufactures and trade of this then flourishing district, by Felix, will be found in the *Annales de Chimie*, t. xxi. 1799. About the middle of last century the art of Turkey-red dyeing was introduced into France by means of dyers brought over from Greece. The French were also the first to dye pieces with this colour, the art having previously been applied merely to the dyeing of yarn. The first establishments for dyeing this colour in Great Britain were founded and conducted by Frenchmen. At the present day Turkey-red dyeing is carried on in various parts of France and Switzerland, at Elberfeld in Germany, in Lancashire, and at Glasgow.

Turkey-red dyeing is essentially distinguished from other dyeing processes by the application previous to dyeing of a peculiar preparation consisting of fatty matter combined with other materials. Without the use of oil or some fatty matter it would be impossible to produce this colour, of which indeed it seems to form an essential constituent. If the colour of a piece of Turkey-red cloth be examined in the manner described above, (see MADDER,) it will be found to consist of red colouring matter and fat acid, combined with alumina and a little lime. The colouring matter thus obtained is so little contaminated with impurities as to appear on evaporating its alcoholic solution in yellowish-red crystalline needles. What part the fat acid plays, whether it merely serves to give to the compound of colouring matter and alumina the power of resisting the action of the powerful agents used after the operation of dyeing, or whether it also modifies and imparts additional lustre to the colour itself, is quite unknown. The formation of this triple compound of colouring matter, fat acid, and alumina, seems at all events to be the final result which is attained. Nevertheless, this apparently simple result can only be arrived at by means of a long and complicated process, each step of which seems to be essential for its final success. The details of the process vary considerably both in their nature and number, in different countries and different dyeing establishments. They may however be described in general terms as follows:—

The goods, after being passed through a soap bath or weak alkaline lye, are oiled. For this purpose a mere impregnation with oil would not be sufficient. The oil must be mixed with a solution of carbonate of potash or soda, to which there is often added a quantity of sheep or cow dung, the ingredients being well mingled, so as to form a milky liquid or emulsion. Olive or Gallipoli oil is the kind generally used, and an impure, mucilaginous oil is preferred to one of a finer quality. Drying oils are not adapted for the purpose. In this liquid, the goods are steeped for a short time, so as to become thoroughly impregnated with it. In the case of pieces the liquid is generally applied by means of a padding machine. After being taken out of this liquid the goods are often left to lie for some days in heaps, and if the weather is fine, they are then exposed on the grass to the action of the air; otherwise, they must be hung up in a hot stove. This process of steeping and exposing to the air is repeated a number of times, until the fabric is thoroughly impregnated with fatty matter. During this part of the process there can be no doubt that the oil undergoes a partial decomposition and oxidation, so as to become capable of uniting, on the one hand, with the vegetable fibre, and, on the other hand, with the colouring matter, with which it is subsequently brought into contact. The dung, by inducing a state of fermentation among the ingredients probably promotes the decomposition of the oil into fatty acid and glycerine, and the alkali serves to convey the fatty acid into every part of the fabric, and to assist in its oxidation on exposure to the air. The process of oxidation which takes place is sometimes so active as to produce spontaneous combustion of the goods in the stove. It might be supposed that by previously saponifying the oil, impregnating the goods with the soap, and after sufficient exposure, decomposing the latter by means of an acid, the same object might be more easily attained than by the long process usually employed. This is, however, not the case, which proves that we are still ignorant of the exact chemical nature of the change which takes place during the oiling process. The supposition formerly entertained, that the effect of the oiling consisted in a so-called *animalisation* of the vegetable fibre, is quite untenable. In some establishments, the goods, after being oiled and stoved, are passed through a bath of very dilute nitric acid, and then exposed to the air before being oiled again, the process being repeated after every oiling. The nitric acid is supposed to contribute to the oxidation of the oil. Several years ago a patent was taken out by Messrs. Mercer and Greenwood for preparing the oil, previous to its being applied to the cotton, by treating it with sulphuric acid, and then with chloride of soda, but their invention, though apparently of some importance, has not generally been adopted by Turkey-red dyers.

After being oiled, the goods are steeped for some hours in a weak tepid solution of carbonate of potash or soda. This operation, which is called by the French *dégraissage*, serves to remove the excess of fatty acid, or that portion which has not thoroughly combined with the vegetable fibre. The liquid thus obtained is carefully preserved for the purpose of being mixed with the liquid used for the oiling of fresh goods, the quality of which it serves to improve.

To this operation succeeds that of galling and mordanting. The goods, after being washed, are passed through a warm solution of tannin, prepared by extracting galls or sumac with boiling water and straining, after which they are impregnated with a solution of alum, to which sometimes a little chalk or carbonate of potash is added, or with a solution of acetate of alumina, prepared by double decomposition from alum and acetate of lead. Sometimes the alum is dissolved in the decoction of galls, and thus the two operations are combined into one. The goods, after being dried in the stove, passed through hot water containing chalk, and rinsed, are now ready to be dyed. It has been asserted that the galling is not an essential part of the process, that it merely serves to fix the alumina of the mordant, and may be dispensed with when acetate of alumina is used instead of alum. It is certainly difficult to conceive how it can permanently affect the appearance of the colour, since the tannin of the galls is undoubtedly removed from the fibre during the subsequent stages of the process.

The dyeing is performed in the usual manner. (See MADDER and CALICO PRINTING.) The materials employed are madder, chalk, sumac, and blood, in various relative proportions. The heat of the dye bath is gradually raised to the boiling point, and the boiling is continued for some time. The part played by the chalk in dyeing with madder has been explained above. (See MADDER.) It was formerly supposed that the red colouring matter of the blood contributed in producing the desired effect in Turkey-red dyeing; but to the modern chemist this supposition does not appear probable. Nevertheless, it is certain that the addition of blood is of some benefit, though it is uncertain in what the precise effect consists. Glue is occasionally employed in the place of blood. Sometimes a second mordanting with galls and alum, and a second dyeing, is allowed to succeed the first mordanting and dyeing.

After being dyed the goods appear of a dull brownish-red colour, and they must therefore be subjected to the brightening process, in order to make them assume the bright red tint required. For this purpose they are first treated with a boiling solution of soap and carbonate of potash or carbonate of soda, and then with a mixture of soap and muriate of tin crystals. This operation is usually performed in a close vessel under pressure. The alkalies remove the brown colouring matters and the excess of fat acid contained in the colour, and the tin salt probably acts by extracting a portion of the alumina of the mordant, and substituting in its place a quantity of oxide of tin, which has the effect of giving the colour a more fiery tint. The last finish is given to the colour by treating the goods with bran or with chloride of soda.

The chief objects which the Turkey-red dyer seeks to attain are, 1st, to obtain the desired effect with the least possible expenditure of time and material; 2nd, to produce a perfect uniformity of tint in the same series of dyeings; and, 3rd, to impart to his goods a colour which, though perfectly durable, shall be fixed as much as possible on the surface of the fabric. The last point is one of importance in the case of calicoes dyed of this colour, since this kind of goods is much employed for the production of a peculiar style of prints, in which portions of the colour are discharged, in order either to remain white or to be covered with other colours. (See CALICO PRINTING.) And if the red dye is too firmly fixed, or too deeply seated, it becomes more difficult to discharge it. In this respect the art has in modern times attained to such a degree of perfection, that the interior of each thread of Turkey-red cotton will be found on examination to be perfectly white. This is particularly the case with the Turkey reds from the establishment of Mr. Steiner of Accrington, Lancashire, whose productions in this branch of the art of dyeing are also unrivalled for the brilliancy and purity of their colour.—E. S.

TURMERIC (*Curcuma*, *Terra merita*, *Souchet* or *Safran des Indes*, Fr.; *Gelb-*

wurzel, Germ.) is the root of the *Curcuma longa* and *rotunda*, a plant which grows in the East Indies, where it is much employed in dyeing yellow, as also as a condiment in curry sauce or powder. The root is knotty, tubercular, oblong, and wrinkled; pale-yellow without, and brown-yellow within; of a peculiar smell, a taste bitterish and somewhat spicy. It contains a peculiar yellow principle, called *curcumine*, a brown colouring-matter, a volatile oil, starch, &c. The yellow tint of turmeric is changed to brown-red by alkalies, alkaline earths, subacetate of lead, and several metallic oxides; for which reason, paper stained with it is employed as a chemical test.

Turmeric is employed by the wool-dyers for compound colours which require an admixture of yellow, as for cheap browns and olives. As a yellow dye it is employed only upon silk. It is a very fugitive colour. A yellow lake may be made by boiling turmeric powder with a solution of alum, and pouring the filtered decoction upon pounded chalk.

Turmeric *imported* in 1858, 2541 tons.

TURNSOLE. See ARCHIL and LITMUS.

TURPENTINE. (*Térébinthine*, Fr.; *Turpenthin*, Germ.) The term *Turpentine* is applied to a liquid or soft solid product of certain coniferous plants, and of the *Pistachia Terebinthus*.

The following varieties are those which are usually found in the market:—

American or *White Turpentine.*
Bordeaux Turpentine.
Venice Turpentine.
Strasburg Turpentine.
Canadian Turpentine, or Canada Balsam.
Chio Turpentine.
Frankincense.

In nearly all cases the processes of collecting are similar. A hollow is cut in the tree yielding the turpentine, a few inches from the ground, and the bark removed for the space of about 18 inches above it. The turpentine runs into this hollow for several months, especially during the summer months. In general character these turpentines have much in common, they are oleo-resins varying slightly in colour, consistency, and smell; they enter into the composition of many varnishes.

Turpentine *imported* in 1858, 246,458 cwts.

TURPENTINE, OIL OF. This is obtained by distilling American turpentine (which has been melted and strained) with water in an ordinary copper still. The distilled product is colourless, limpid, very fluid, and possessed of a very peculiar smell. Its specific gravity, when pure, is 0·870; that of the oil commonly sold in London is 0·875. It always reddens litmus paper, from containing a little succinic acid. According to Oppermann, the oil which has been repeatedly rectified over chloride of calcium, consists of 84·60 carbon, 11·735 hydrogen, and 3·67 oxygen. Rectified oil of turpentine is known as spirits or essence of turpentine. When oil of turpentine contains a little alcohol, it burns with a clear flame; but otherwise it affords a very smoky flame. (See CAMPHINE.) Chlorine inflames this oil; and hydrochloric acid converts it into a crystalline substance, like camphor. It is employed extensively in varnishes, paints, &c., as also in medicine.

TURQUOISE. This gem is a compound of phosphate of alumina, phosphate of lime, with silica, oxide of iron, and copper, according to Berzelius.

The Silesian turquoise, according to John—alumina, 44·50, phosphoric acid, 30·90, water, 19·00, oxide of copper, 3·75, oxide of iron, 1·80; while the blue Oriental turquoise was found by Hermann to consist of alumina, 47·45, phosphoric acid, 27·34, water, 18·18, oxide of copper, 2·02, oxide of iron, 1·10, manganese, 0·50, and phosphate of lime, 3·41.

Turquoise occurs in the mountainous ranges of Persia, and when finely coloured it is highly esteemed as a gem. The King of Persia is said to retain for his own use all the more remarkable specimens.

Major Macdonald discovered a new locality for the turquoise in Arabia Petrea. Of the discovery of these, Major Macdonald gives the following account:—

"In the year 1849, during my travels in Arabia in search of antiquities, I was led to examine a very lofty range of mountains composed of iron sandstone, many days' journey in the desert, and whilst descending a mountain of about 6000 feet high by a deep and precipitate gorge, which in the winter time served to carry off the water, I found a bed of gravel, where I perceived a great many small blue objects mixed with the other stones; on collecting them I found they were turquoises of the finest colour and quality. On continuing my researches through the entire range of mountains, I discovered many valuable deposits of the same stones, some quite pure, like pebbles, and others in the matrix. Sometimes they are found in nodules varying in size from a pin's head to a hazel nut; and when in this formation they are usually of the finest quality and colour. The action of the weather gradually loosens them from the rock, and they are rolled into the ravines, and, in the winter season, mixed up by the torrents with beds of gravel, where they are found. Another formation is, where they appear in veins, and sometimes of such a size as to be of immense value. They also occur in a soft yellow sandstone, enclosed in the centre, and of a surpassing brilliancy of colour. Another very curious formation is where they are combined with innumerable small coloured quartz crystals, and which has the appearance of a mass of sand, small pebbles, and turquoise, all firmly cemented together. This formation is one of the most peculiar in the whole collection."

The price of turquoise has of late years much diminished, that of an Oriental gem is generally four times higher than the occidental; one the size of a pea is worth about 23*s*. " A good turquoise, sky blue and oval cut, five lines long, and four and a half lines broad, was sold in France for 241 francs; and a light blue, greenish lustre, and oval cut, five and a half lines long, and five broad, was sold for 500 francs; whereas an occidental turquoise, four lines long, and three and a half broad, brought only 121 francs."—*Feuchswanger, Treatise on Gems.*

The occidental turquoise, frequently called the bone turquoise, is said to be fossil bones, or teeth, coloured with oxide of copper.

Turquoise is imitated by adding to the ammonia sulphate of copper, or oxide of copper dissolved in ammonia, finely powdered calcined ivory. They are allowed to remain together for about a week, at a moderate heat. The coherent mass is dried and exposed to a gentle heat.

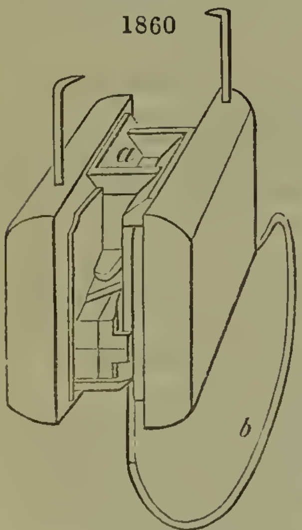
TUTENAG or TUTENAGUE, and NICKEL, sometimes called *Chinese silver.* It is the *packfong* of the East Indies.

A white metal of the Chinese, frequently stated to be an alloy of copper and zinc. It is in fact a compound resembling German silver: and nickel, in combination with zinc and copper, is found in most specimens. This name is given in commerce to the zinc or spelter of China.

TYPE. (*Caractère*, Fr.; *Druckbuchstabe*, Germ.) The first care of the letter-cutter is to prepare well-tempered steel punches, upon which he draws or marks the exact shape of the letter, with pen and ink if it be large, but with a smooth blunted point of a needle if it be small; and then, with a proper sized and shaped graver and sculpter, he digs or scoops out the metal between the strokes upon the face of the punch, leaving the marks untouched and prominent. He next works the outside with files till it be fit for the matrix. Punches are also made by hammering down the hollows, filing up the edges, and then hardening the soft steel. Before he proceeds to sink and justify the matrix, he provides a mould to justify them by, of which a good figure is shown in *plate* xv., *Miscellany, figs.* 2, 3, of *Rees's Cyclopædia.*

A matrix is a piece of brass or copper, about an inch and a half long, and thick in proportion to the size of the letter which it is to contain. In this metal the face of the letter intended to be cast is sunk, by striking it with the punch to a depth of about one-eighth of an inch. The mould, *fig.* 1860, in which the types are cast, is composed of two parts. The outer part is made of wood, the inner of steel. At the top it has a hopper-mouth *a*, into which the fused type-metal is poured. The interior cavity is as uniform as if it had been hollowed out of a single piece of steel; because each half, which forms two of the four sides of the letter, is exactly fitted to the other. The matrix is placed at the bottom of the mould, directly under the centre of the orifice, and is held in its position by a spring *b*. Every letter that is cast can be loosened from the matrix only by removing the pressure on the spring.

1860



A good type-foundry is always provided with several furnaces, each surmounted with an iron pot containing the melted alloy, of 3 parts of lead and 1 of antimony. Into this pot the founder dips the very small iron ladle, to lift merely as much metal as will cast a single letter at a time. Having poured in the metal with his right hand, and returned the ladle to the melting-pot, the founder throws up his left hand, which holds the mould, above his head, with a sudden jerk, supporting it with his right hand. It is this movement which forces the metal into all the interstices of the matrix; for without it, the metal, especially in the smaller moulds, would not be able to expel the air and reach the bottom. The pouring in the metal, the throwing up the mould, the unclosing it, removing the pressure of the spring, picking out the cast letter, closing the mould again, and reapplying the spring to be ready for a new operation, are all performed with such astonishing rapidity and precision, that a skilful workman will turn out 500 good letters in an hour, being at the rate of one every eighth part of a minute. A considerable piece of metal remains attached to the end of the type as it quits the mould. There are nicks upon the lower edge of the types, to enable the compositor to place them upright without looking at them.

From the table of the *caster* the heap of types turned out of his mould is transferred from time to time to another table, by a boy, whose business it is to break off the superfluous metal, and this he does so rapidly as to clear from 2000 to 5000 types in an hour; a very remarkable despatch, since he must seize them by their edges, and not by their feeble flat sides. From the breaking-off boy the types are taken to the *rubber*, a man who sits in the centre of the workshop with a grit-stone slab on a table before him, and having on the fore and middle finger of his right hand a piece of tarred leather, passes each broad side of the type smartly over the stone, turning it in the movement, and that so dexterously as to be able to rub 2000 types in an hour.

From the rubber the types are conveyed to a boy, who with equal rapidity sets them up in lines, in a long shallow frame, with their faces uppermost and nicks outwards. This frame containing a full line is put into the dresser's hands, who polishes them on each side, and turning them with their faces downwards, cuts a groove or channel in their bottom, to make them stand steadily on end. It is essential that each letter be perfectly symmetrical and square; the least inequality of their length would prevent them from making a fair impression; and were there the least obliquity in their sides, it would be quite impossible, when 200,000 single letters are combined, as in one side of *The Times* newspaper, that they could hold together as they require to do, when wedged up in the chases, as securely as if that side of the type formed a solid plate of metal. Each letter is finally tied up in lines of convenient length, the proportionate numbers of each variety, small letters, points, large capitals, small capitals, and figures, being selected, when the fount of type is ready for delivery to the printer.

The sizes of types cast in this country vary, from the smallest, called diamond, of which 205 lines are contained in a foot length, to those letters employed in placards, of which a single letter may be several inches high. The names of the different letters and their dimensions, or the number of lines which each occupies in a foot, are stated in the following table: —

Double Pica	$41\frac{1}{2}$	Small Pica	83	Minion	128
Paragon	$44\frac{1}{2}$	Long Primer	89	Nonpareil	143
Great Primer	$51\frac{1}{4}$	Bourgeois	$102\frac{1}{4}$	Pearl	178
English	64	Brevier	$112\frac{1}{2}$	Diamond	205
Pica	$71\frac{1}{2}$				

U.

ULTRAMARINE (*Outremer*, Fr.; *Ultramarins*, Germ.) is a beautiful blue pigment, obtained from the blue mineral called lazulite (*lapis lazuli*) by the following process:— Grind the stone to fragments, rejecting all the colourless bits, calcine at a red heat, quench in water, and then grind to an impalpable powder along with water, in a mill, or with a porphyry slab and muller. The paste being dried, is to be rubbed to powder, and passed through a silk sieve. 100 parts of it are to be mixed with 40 of rosin, 20 of white wax, 25 of linseed oil, and 15 of Burgundy pitch, previously melted together. This resinous compound is to be poured hot into cold water; kneaded well first with two spatulas, then with the hands, and then formed into one or more small rolls. Some persons prescribe leaving these pieces in the water during fifteen days, and then kneading them in it, whereby they give out the blue pigment, apparently because the ultramarine matter adheres less strongly than the *gangue*, or merely siliceous matter of the mineral, to the resinous paste. MM. Clement and Desormes, who were the first to divine the true nature of this pigment, think that the soda contained in the lazulite, uniting with the oil and the rosin, forms a species of soap, which serves to wash out the colouring matter. If it should not separate readily, water heated to about 150° Fahr. should be had recourse to. When the water is sufficiently charged with blue colour, it is poured off and replaced by fresh water; and the kneading and change of water are repeated till the whole of the colour is extracted. Others knead the mixed resinous mass under a slender stream of water, which runs off with the colour into a large earthen pan. The first waters afford, by rest, a deposit of the finest ultramarine; the second a somewhat inferior article, and so on. Each must be washed afterwards with several more waters before they acquire the highest quality of tone; then dried separately, and freed from any adhering particles of the pitchy compound by digestion in alcohol. The remainder of the mass being melted with oil, and kneaded in water containing a little soda or potash, yields an inferior pigment, called *ultramarine ashes.* The best *ultramarine* is a splendid blue pigment, which works well with oil, and is not liable to change by time.

The blue colour of *lazulite* had been always ascribed to iron, till MM. Clement and Desormes, by a most careful analysis, showed it to consist of — silica, 34; alumina, 33; sulphur, 3; soda, 22; and that the iron, carbonate of lime, &c. were accidental ingredients, essential neither to the mineral nor to the pigment made from it. By another analyst the constituents are said to be — silica, 44; alumina, 35; and soda, 21; and by a third, potassa was found instead of soda, showing shades of difference in the composition of the stone.

ULTRAMARINE, ARTIFICIAL. Till a few years ago every attempt failed to make ultramarine artificially. At length, in 1828, M. Guimet resolved the problem, guided by the analysis of MM. Clement and Desormes, and by an observation of M. Tassaert, that a blue substance like ultramarine was occasionally produced on the sandstone hearths of his reverberatory soda furnaces. M. Gmelin, of Tübingen, has published a prescription for making it; which consists in enclosing carefully in a Hessian crucible a mixture of 2 parts of sulphur and 1 of dry carbonate of soda, heating them gradually to redness until the mass fuses, and then sprinkling into it by degrees another mixture, of silicate of soda, and aluminate of soda; the first containing 72 parts of silica, and the second 70 parts of alumina. The crucible must be exposed after this for an hour to the fire. The ultramarine will be formed by this time; only it contains a little sulphur, which can be separated by means of water. M. Persoz, professor of chemistry at Strasbourg, has likewise succeeded in making an ultramarine, of perhaps still better quality than that of M. Guimet. Lastly, M. Robiquet has announced, that it is easy to form ultramarine by heating to redness a proper mixture of kaolin (China clay), sulphur, and carbonate of soda. It would therefore appear, from the preceding details, that ultramarine may be regarded as a compound of silicate of alumina, silicate of soda, with sulphide of sodium, and that to the reaction of the last constituent upon the former its colour is due.

The price of the finest ultramarine was formerly as high as five guineas the ounce; since the mode of making it artificially has been discovered, however, its price has fallen to a few shillings the pound, and even to a little more than one shilling wholesale, for a fair article. The chief French manufactories of ultramarine are situated in Paris, and the two largest ones in Germany are those of Meissen in Saxony and of Nuremberg in Franconia. Two kinds of ultramarine occur in commerce, the blue and the green, which are true ultramarines; that is, sulphur compounds.

Both native and artificial ultramarine have been examined very carefully by several eminent chemists. The following are a few specimens of these analyses, and others equally discordant might easily be added:—

	Lapis Lazuli, by Clement and Desormes.
Soda	23·2
Alumina	24·8
Silica	35·8
Sulphur	3·1
Carbonate of lime	3·1

	Parisian artificial ultramarine, by C. G. Gmelin.
Soda and potash	12·863
Lime	1·546
Alumina	22·000
Silica	47·306
Sulphuric acid	4·679
Resin, sulphur, and loss	12·218

	Analysis of Ultramarine, by Warrentrap. Lapis Lazuli.	Artificial from Meissen.	*By Elsner.* Blue.	Green.
Potash		1·75		
Soda	9·09	21·47	40·0	25·5
Alumina	31·07	23·30	29·5	30·0
Silica	42·50	45·00	40·0	39·9
Sulphur	0·95	1·68	4·0	4·6
Lime	3·52	0·02		
Iron	0·86	1·06	1·0	0·9
Chlorine	0·42			
Sulphuric acid	5·89	3·83	3·4	0·4
Water	0·12			

Dr. Elsner published a very elaborate paper upon ultramarine in the 23rd number of *Erdmann's Journal.* The first part of Dr. Elsner's paper is historical, and contains an account of the accidental discovery of artificial ultramarine by Tassaert and Kuhlman in 1814, and of the labours of subsequent chemists. He then gives a detailed account of his own experiments, which have been very numerous, and from these he deduces the following conclusions:—1st, that the presence of about 1 per cent. of iron is indispensable to the production of ultramarine; he supposes the iron to be in a state of sulphuret; 2nd, that the green ultramarine is first formed, and that as the heat is increased, it passes by degrees into the blue. The cause of this change is, he affirms, that part of the sodium absorbs oxygen from the atmosphere, as the operation is conducted in only partially closed vessels, and combines with the silica, while the rest of the sodium passes into a higher degree of sulphuration. Green ultramarine, therefore, contains simple sulphurets, and blue polysulphurets.

Dr. Elsner's paper does not, however, furnish any details by which ultramarine could be manufactured successfully on the great scale. The process of Robiquet, published nearly ten years ago, is the best which scientific chemists possess, though undoubtedly the manufacturers have greatly improved upon it. Robiquet's process consists in heating to low redness a mixture of one part of porcelain clay, one and a half sulphur, and one and a half parts anhydrous carbonate of soda, either in an earthenware retort or covered crucible, so long as vapours are given off. When opened, the crucible usually contains a spongy mass of a deep blue colour, containing more or less ultramarine mixed with the excess of sulphur employed, and some unaltered clay and soda. The soluble matter is removed by washing, and the ultramarine separated from the other impurities by levigation. It is to be regretted, however, that the results of Robiquet's process are by no means uniform; one time it yields a good deal of ultramarine of excellent quality, and perhaps, at the very next repetition of the process in circumstances apparently similar, very little ultramarine is obtained, and that of an inferior quality.

Ultramarine *imported* in 1858—it is not stated in the returns whether real or artificial; it is inferred to be chiefly the latter — 14,562 cwt. Declared value, 77,268*l.*

UMBER. A mechanical mixture of limnite (brown hematite) and hydrated oxide of manganese and clay. It occurs in beds with brown jasper in the island of Cyprus. It is used by painters as a brown colour, raw or burnt.

URANIUM is one of the rare metals, and was first discovered by Klaproth in 1786 in the mineral called *pechblende*, which was, previous to this, mistaken for an ore of zinc. He called it uranium after the planet discovered by Herschel about the same time. The ores of uranium are few; the principal are, *pechblende* (*pitchblende*), a brownish or velvet-black mineral, containing about 79 to 87 per cent. of protoxide of uranium, with silica, lead, iron, and some other impurities. It occurs in veins with ores of lead and silver in Saxony, and with tin in Cornwall. *Uranite*, a phosphate of copper and uranium, occurs in France; and is found of great beauty near Callington in Cornwall. *Samarskite*, *urano-tantalite*, oxide of uranium with niobic and tungstic acids. *Johannite*, uran vitriol, sulphate of uranium.

The metal itself can only be obtained by the intervention of potassium or sodium, in the same manner as magnesium. It is described as a black coherent powder, or a white malleable metal, according to the state of aggregation, not oxidised by air or water, but very combustible when exposed to heat. It unites also with great violence with chlorine and with sulphur. M. Peligot admits three distinct oxides of uranium, and two other compounds of the metal and oxygen, which he designates as suboxides.

Protoxide, UO.—This is the body formerly considered as the metal. It is a brown powder, sometimes highly crystalline.

Proto-sesquioxide; black oxide; U^4O^5, or $2UO + U^2O^3$.—This oxide was formerly considered as the protoxide, and is produced whenever either of the other oxides are strongly heated in the air, the sesquioxide losing, and the protoxide gaining, oxygen. It forms no salts, but is resolved by solution in acids into protoxide and sesquioxide.

Sesquioxide, U^2O^3.—This is the best known and most important of the oxides. It forms a number of beautiful yellow salts; its colour, when prepared by heating the nitrate to 480° in an oil bath till no more nitrous fumes are disengaged, is a chamois yellow. It may be obtained from *pitchblende*, by acting on the finely powdered mineral with nitric acid, which dissolves the lead, iron, and uranium; but if excess of the mineral has been used, no iron dissolves; then the solution of lead and uranium is saturated with sulphuretted hydrogen, which separates the lead; after filtration, the solution of uranium, which should contain a little free nitric acid, to prevent the formation of subsalts, is evaporated, and the nitrate of uranium crystallised out, which is purified by recrystallisation, and lastly by dissolving it in alcohol and again crystallising. When the iron is dissolved with it, the solution, after the separation of the lead, is treated with an *excess* of carbonate of ammonia, which precipitates the iron, leaving the uranium in solution, when, on expelling the carbonate of ammonia by boiling, the oxide of uranium precipitates, and may be collected and dried, and from this all the other compounds may be prepared.

Pitchblende is sometimes more impure, and contains copper, nickel, cobalt, and zinc, as well as lead and iron, which makes the separation of the uranium more tedious.

The only application of uranium is to enamel-painting and glass staining; the protoxide giving a fine black colour, probably by absorbing oxygen and becoming black oxide, and the sesquioxide a delicate yellow.

Uranium has been found in a German blue pigment used by paper-hanging manufacturers. It contained both copper and uranium; but it is not known for what purpose it is mixed with the copper, if to improve the colour or not, or if present previously in the mineral from which the pigment was made.—H. K. B.

URAO. See Natron.

UREA. This is one of the principal constituents of urine, being always present in it, but in variable quantities; the average quantity in healthy urine is about 14 or 15 parts in 1000 of urine, but of course this varies from several circumstances, as in disease, drinking a large quantity of liquid, &c. The urine passed the first in the morning gives a fair estimate of the quantity of urea yielded by the urine of an individual. It seems to be the principal form in which the waste nitrogenous compounds of the body are eliminated from the system. It is very prone to decomposition when in contact with albumen, mucus, or any fermentable matter; and this is the cause of urine, which, when first passed, is generally slightly acid, becoming alkaline, and a precipitate being formed; the change being much more rapid in hot than in cold weather, the mucus, &c. beginning to ferment sooner. The urea is decomposed into carbonate of ammonia, water being at the same time assimilated.

$$\underbrace{C^2H^4N^2O^2}_{\text{Urea.}} + \underbrace{4HO}_{\text{Water.}} = \underbrace{2(NH^4,CO^3)}_{\text{Carbonate of ammonia.}}$$

The carbonate of ammonia neutralises the acid which keeps the phosphates in solution, and hence the precipitate.

In some diseases the quantity of urea in the urine amounts to 30 parts, and even more, in the 1000 parts of urine.

It is interesting as being the first organic base which was made artificially. It was found that cyanate of ammonia, which has exactly the same ultimate composition as urea, when dissolved in water and boiled for some time, became completely changed, neither cyanic acid nor ammonia being detected by the ordinary test in the solution, and that it had in fact been converted by a molecular change into urea.

$$\underbrace{NH^4,C^2NO^2}_{\text{Cyanate of ammonia.}} = \underbrace{C^2H^4N^2O^2}_{\text{Urea.}}$$

Its presence in the urine is detected thus: evaporate a portion of the urine over a water bath to about one-fourth of its bulk, and when cold add half its volume of *pure* nitric acid, when after a little time abundant crystals of nitrate of urea will be formed.

The *quantity* of urea in any sample of urine may easily be estimated by a process invented by Liebig. It consists in treating the urine with a standard solution of pernitrate of mercury. A copious white precipitate is formed, with liberation of nitric acid. As this acid prevents the further action of the nitrate, the urine is previously treated with a solution of two vols. of saturated baryta water, and one vol. of saturated solution of nitrate of baryta, which precipitates the phosphates, and the excess of baryta neutralises the nitric acid as soon as it is liberated. The addition of the nitrate of mercury is continued until the last portion added causes a yellow *binoxide of mercury* instead of a white precipitate. The quantity of urea present in a given sample of urine may thus be readily deduced from the quantity of the nitrate required to precipitate it completely, the solution of nitrate of mercury being so arranged that every 100 grains of it shall be equal to one grain of urea.

It is also to be noticed that no precipitate is formed in the presence of common salt; *that* therefore has to be also removed by addition of nitrate of silver before using the nitrate of mercury. By an ingenious application of this fact, the quantity of common salt in any sample of urine may also be determined by the same solution of nitrate of mercury. Urea when in solution acts as an alkali on test paper; it unites with acids forming salts, the nitrate and oxalate being the least soluble of them. Although urea is so easily decomposed, a *pure* solution of it may be kept a considerable time unchanged.—H. K. B.

V.

VACUUM PAN. For a description of it, see SUGAR.

VALUE. Two methods have been adopted for ascertaining the value of our exports; one by means of the *official* value, the other according to the *declared* value. In *Lowe's Present State of England* (1822), there is a very succinct and clear account of these methods, which is here extracted: —

"The *official* value of goods means a computation of value formed with reference not to the prices of the current year, but to a standard, fixed so long ago as 1696, the time when the office of Inspector-General of the imports and exports was established, and a Custom-house ledger opened to record the weight, dimensions, and value of the merchandise that passed through the hands of the officers. One uniform rule is followed, year by year, in the valuation, some goods being estimated by weight, others by the dimensions, the whole without reference to the market price. [Worsted stuffs are valued at 1*l.* 11*s.* 8*d.* the piece, according to MacGregor's Commercial Statistics.] This course has the advantage of exhibiting, with strict accuracy, every increase or decrease in the quantity of our exports.

"Next as to the value of these exports in the market: — In 1798 there was imposed a duty of 2 per cent. on our exports, the value of which was taken, not by the official standard, but by the declaration of the exporting merchants. Such a declaration may be assumed as a representation of, or at least an approximation to, the market price of merchandise, there being on the one hand no reason to apprehend that merchants would pay a percentage on an amount beyond the market value, while on the other the liability to seizure afforded a security against undue valuation."

VALONIA is a kind of acorn, imported from the Levant and the Morea for the use of tanners, as the husk or cup contains abundance of tannin. See LEATHER. Valonia *imported* in 1858, 19,572 tons.

VANADIUM is a metal discovered by Sefström, in 1830, in a Swedish iron remarkable for its ductility, extracted from the iron mine of Jaberg, not far from Jonkoping. Its name is derived from Vanadis, a Scandinavian idol. This metal has been found in the state of vanadic acid in a lead ore from Zimapan, in Mexico. The finery cinder of the Jaberg iron contains more vanadium than the metal itself. It exists in it as vanadic acid. For the reduction of this acid to vanadium, see Berzelieus's *Traité de Chimie*, vol. iv. p. 644. Vanadium is white, and when its surface is polished it resembles silver or molybdenum more than any other metal. It combines with oxygen into two oxides and an acid.

The vanadate of ammonia, mixed with infusion of nutgalls, forms a black liquid, which is a very excellent writing-ink.

VANILLA is the oblong narrow pod of the *Epidendron vanilla*, Linn., of the natural family *Orchideæ*, which grows in Mexico, Columbia, Peru, and on the banks of the Oronoco.

The best comes from the forests round the village of Zentila, in the Intendancy of Oaxaca.

The vanilla plant is cultivated in Brazil, in the West Indies, and some other tropical countries, but does not produce fruit of such a delicious aroma as in Mexico. It clings like a parasite to the trunks of old trees, and sucks the moisture which their bark derives from the lichens, and other cryptogamia, but without drawing nourishment from the tree itself, like the ivy and misletoe. The fruit is subcylindric, about 8 inches long, one-celled, siliquose, and pulpy within. It should be gathered before it is fully ripe.

When about 12,000 of these pods are collected, they are strung like a garland by their lower end, as near as possible to the foot-stalk; the whole are plunged for an instant in boiling water to blanch them; they are then hung up in the open air, and exposed to the sun for a few hours. Next day they are lightly smeared with oil, by means of a feather, or the fingers; and are surrounded with oiled cotton, to prevent the valves from opening. As they become dry, on inverting their upper end they discharge a viscid liquid from it, and they are pressed at several times with oiled fingers, to promote its flow. The dried pods lose their appearance, grow brown, wrinkled, soft, and shrink into one-fourth of their original size. In this state they are touched a second time with oil, but very sparingly; because, with too much oil, they would lose much of their delicious perfume. They are then packed for the market, in small bundles of 50 or 100 in each, enclosed in lead foil, or tight metallic cases. As it comes to us, vanilla is a capsular fruit, of the thickness of a swan's quill, straight, cylindrical, but somewhat flattened, truncated at the top, thinned off at the ends, glistening, wrinkled, furrowed lengthwise, flexible, from 5 to 10 inches long, and of a reddish-brown colour. It contains a pulpy parenchyma, soft, unctuous, very brown, in which are embedded black, brilliant, very small seeds. Its smell is ambrosial and aromatic; its taste hot, and rather sweetish. These properties seem to depend upon an essential oil, and also upon benzoic acid, which forms efflorescences upon the surface of the fruit. The pulpy part possesses alone the aromatic quality; the pericarpium has hardly any smell.

The kind most esteemed in France is called *leq* vanilla; it is about 6 inches long, from $\frac{1}{4}$ to $\frac{1}{3}$ of an inch broad, narrowed at the two ends, and curved at the base, somewhat soft and viscid, of a dark-reddish colour, and of a most delicious flavour, like that of balsam of Peru. It is called vanilla *givrées*, when it is covered with efflorescences of benzoic acid, after having been kept in a dry place, and in vessels not hermetically closed.

The second sort, called *vanilla simarona*, or bastard, is a little smaller than the preceding, of a less deep brown hue, drier, less aromatic, destitute of efflorescence. It is said to be the produce of the wild plant, and is brought from St. Domingo.

A third sort, which comes from Brazil, is the *vanillon*, or large vanilla of the French market; the *vanilla pamprona* or *bova* of the Spaniards. Its length is from 5 to 6 inches; its breadth from $\frac{1}{2}$ to $\frac{3}{4}$ of an inch. It is brown, soft, viscid, almost always open, of a strong smell, but less agreeable than the *leq.* It is sometimes a little spoiled by an incipient fermentation. It is cured with sugar, and enclosed in tin-plate boxes, which contain from 20 to 60 pods.

Vanilla, as an aromatic, is much sought after by makers of chocolate, ices, and creams; by confectioners, perfumers, and liquorists, or distillers. It is difficultly reduced to fine particles; but it may be sufficiently attenuated by cutting it into small bits, and grinding these along with sugar. The odorous principle can, for some purposes, be extracted by alcohol. Berzelius says that the efflorescences are not acid.

VAPOUR (*Vapeur*, Fr.; *Dampf*, Germ.) is the state of elastic or aëriform fluidity into which any substance, naturally solid or liquid at ordinary temperatures, may be converted by the agency of heat. See Evaporation.

VAPOUR. A *visible* fluid floating on the atmosphere, as distinguished from a gas which is ordinarily — unless it be coloured as chlorine gas — invisible. The vapour of water is Steam, which see.

VAREC. The name of kelp made on the coast of Normandy.

VARNISH (*Vernis*, Fr.; *Firniss*, Germ.) is a solution of resinous matter, which is spread over the surface of any body, in order to give it a shining, transparent, and hard coat, capable of resisting, in a greater or less degree, the influences of air and moisture. Such a coat consists of the resinous parts of the solution, which remain in a thin layer upon the surface after the liquid solvent has either evaporated away, or has dried up. When large quantities of spirit varnish are to be made, a common still, mounted with its capital and worm, is the vessel employed for containing the materials, and it is placed in a steam or water bath. The capital should be provided with a stuffing-box, through which a stirring-rod may pass down to the bottom of the still, with a cross-piece at its lower end, and a handle or winch at its top. After heating the bath till the alcohol boils and begins to distil, the heat ought to be lowered, that the solution may continue to proceed in an equable manner, with as little evaporation of spirit as possible. The operation may be supposed to be complete when the rod can be easily turned round. The varnish must be passed through a silk sieve of proper fineness; then filtered through porous paper, or allowed to clear leisurely in stone jars. The alcohol which has come over should be added to the varnish, if the just proportions of the resins have been introduced at first.

The building or shed wherein varnish is made, ought to be quite detached from any buildings whatever, to avoid accidents by fire. For general purposes, a building about 18 feet by 16 is sufficiently large for manufacturing 4000 gallons and upwards annually, provided there are other convenient buildings for the purpose of holding the utensils, and warehousing the necessary stock.

Procure a copper pan made like a common washing-copper, which will contain from 50 to 80 gallons, as occasion may require; when wanted, set it upon the boiling furnace, and fill it up with linseed oil within 5 inches of the brim. Kindle a fire in the furnace underneath, and manage the fire so that the oil shall gradually, but slowly, increase in heat for the first two hours; then increase the heat to a gentle simmer; and if there is any scum on the surface, skim it off with a copper ladle, and put the skimming away. Let the oil boil gently for three hours longer; then introduce, by a little at a time, one quarter of an ounce of the best calcined magnesia for every gallon of oil, occasionally stirring the oil from the bottom. When the magnesia is all in, let the oil boil rather smartly for one hour; it will then be sufficient. Lay a cover over the oil, to keep out the dust while the fire is withdrawn and extinguished by water; next uncover the oil, and leave it till next morning; and then while it is yet hot, ladle it into the carrying-jack, or let it out through the pipe and cock; carry it away, and deposit it in either a tin or leaden cistern, for wooden vessels will not hold it; let it remain to settle for at least three months. The magnesia will absorb all the acid and mucilage from the oil, and fall to the bottom of the cistern, leaving the oil clear and transparent, and fit for use. Recollect when the oil is taken out not to disturb the bottoms, which are only fit for black paiut.

General Observations and Precautions to be Observed in Making Varnishes.

Set on the boiling-pot with 8 gallons of oil; kindle the fire; then lay the fire in the gum-furnace; have as many 8 lb. bags of gum copal all ready weighed up as will be wanted; put one 8 lb. into the pot, put fire to the furnace, set on the gum-pot; in three minutes (if the fire is brisk) the gum will begin to fuse and give out its gas, steam, and acid; stir and divide the gum, and attend to the rising of it, as before directed. 8 lbs. of copal take in general from sixteen to twenty minutes in fusing, from the beginning till it gets clear like oil, but the time depends very much on the heat of the fire and the attention of the operator. During the first twelve minutes while the gum is fusing, the assistant must look to the oil, and bring it to a smart simmer; for it ought to be neither too hot nor yet too cold, but in appearance beginning to boil, which he is strictly to observe, and when ready to call out, "Bear a hand!" Then immediately both lay hold of a handle of the boiling-pot, lift it right up so as to clear the plate, carry it out and place it on the ash-bed, the maker instantly returning to the gum-pot, while the assistant puts three copper ladlefuls of oil into the copper pouring-jack, bringing it in and placing it on the iron plate at the back of the gum-pot to keep hot until wanted. When the maker finds the gum is nearly all completely fused, and that it will in a few minutes be ready for the oil, let him call out, "ready oil!" The assistant is then to lift up the oil-jack with both hands, one under the bottom and the other on the handle, laying the spout over the edge of the pot, and wait until the maker calls out "oil!" The assistant is then to pour in the oil as before directed, and the boiling to be continued until the oil and gum become concentrated, and the mixture looks clear on the glass; the gum-pot is now to be set upon the brick-stand until the assistant puts three more ladlefuls of hot oil into the pouring-jack, and three more into a spare tin for the third run of gum. There will remain in the boiling-pot still 3½ gallons of oil. Let the maker put his right hand down the handle of the gum-pot near to the side, with his left hand near the end of the handle, and with a firm grip lift the gum-pot, and deliberately lay the edge of the gum-pot over the edge of the boiling-pot, until all its contents run into the boiling-pot. Let the gum-pot be held, with its bottom turned upwards for a minute, right over the boiling-pot. Observe, that whenever the maker is beginning to pour, the assistant stands ready with a thick piece of old carpet without holes, and sufficiently large to cover the mouth of the boiling-pot should it catch fire during the pouring, which will sometimes happen if the gum-pot is very hot; should the gum-pot fire, it has only to be kept bottom upwards, and it will go out of itself; but if the boiling-pot should catch fire during the pouring, let the assistant throw the piece of carpet quickly over the blazing pot, holding it down all round the edges; in a few minutes it will be smothered. The moment the maker has emptied the gum-pot, he throws into it half a gallon of turpentine, and with the *swish* immediately washes it from top to bottom, and instantly empties it into the flat tin jack: he wipes the pot dry, and puts in 8 lbs. more gum, and sets it upon the furnace; proceeding with this run exactly as with the last, and afterwards with the third run. There will then be 8 gallons of oil and 24 lbs. of gum in the boiling-pot, under which keep up a brisk strong fire until a scum or froth rises and covers all the surface of the contents, when it will begin to rise rapidly. Observe, when it rises near the rivets of the handles, carry it from the fire and set it on the ash-bed, stir it down again, and scatter in the driers by a little at a time; keep stirring, and if the frothy head goes down put it upon the furnace, and introduce *gradually* the remainder of the driers, always carrying out the pot when the froth rises near the rivets. In general, if the fire be good, all the time a pot requires to boil from the time of the last gum being poured in, is about three and a half or four hours; but *time* is no criterion for a beginner to judge by, as it may vary according to the weather, the quality of the oil, the quality of the gum, the driers, or the heat of the fire, &c.; therefore, about the third hour of boiling, try it on a bit of glass, and keep it boiling, until it feels strong and stringy between the fingers; it is then boiled sufficiently to carry it on the ash-bed, and to be stirred down until it is cold enough to mix, which will depend much on the weather, varying from half an hour in dry frosty weather to one hour in warm summer weather. Previous to beginning to mix, have a sufficient quantity of turpentine ready, fill the pot, and pour in, stirring all the time at the top or surface, as before directed, until there are 15 gallons, or five tins of oil of turpentine introduced, which will leave it quite thick enough if the gum is good, and has been well run; but if the gum was of a weak quality, and has not been well fused, there ought to be no more than 12 gallons of turpentine mixed, and even that may be too much. Therefore, when 12 gallons of turpentine have been introduced, have a flat saucer at hand, and pour into it a portion of the varnish, and in two or three minutes it will show whether it is too thick; if not sufficiently thin, add a little more turpentine, and strain it off quickly. As soon as the whole is stored away, pour in the turpentine washings with which the gum-pots have been washed, into the boiling-pot, and with the swish quickly wash down all the varnish from the pot sides; afterwards, with a large piece of woollen rag dipped in pumice-powder, wash and polish every part of the inside of the boiling-pot, performing the same operation on the ladle and stirrers; rinse them with the turpentine washings, and at last rinse them altogether in clean turpentine, which also put to the washings; wipe dry with a clean soft rag the pot, ladle, stirrer, and funnels, and lay the sieve so as to be completely covered with turpentine, which will always keep it from gumming up. The foregoing directions concerning running the gum and pouring in the oil, and also boiling off and mixing, are, with very little difference, to be observed in the making of all sorts of copal varnishes, except the differences of the quantities of oil, gum, &c., which will be found under the various descriptions by name, which will be hereafter described.

The choice of linseed oil is of peculiar consequence to the varnish-maker. Oil from fine full-grown ripe seed, when viewed in a phial, will appear limpid, pale, and brilliant; it is mellow and sweet to the taste, has very little smell, is specifically lighter than impure oil, and, when clarified, dries quickly and firmly, and does not materially change the colour of the varnish when made, but appears limpid and brilliant.

Copal varnishes for fine paintings, &c.—Fuse 8 lbs. of the very cleanest pale African gum copal, and, when completely run fluid, pour in two gallons of hot oil, old measure; let it boil until it will string very strong; and in about fifteen minutes, or while it is yet very hot, pour in three gallons of turpentine, old measure, and got from the top of a cistern. Perhaps during the mixing a considerable quantity of the turpentine will escape; but the varnish will be so much the brighter, transparent, and fluid; and will work freer, dry more quickly, and be very solid and durable when dry. After the varnish has been strained, if it is found too thick, before it is quite cold heat as much turpentine, and mix with it, as will bring it to a proper consistence.

Cabinet varnish.—Fuse 7 lbs. of very fine African gum copal, and pour in half a gallon of pale clarified oil; in three or four minutes after, if it feel stringy, take it out of doors, or into another building where there is no fire, and mix with it three gallons of turpentine; afterwards strain it, and put it aside for use. This, if properly boiled, will dry in ten minutes; but if too strongly boiled, will not mix at all with the turpentine; and *sometimes*, when boiled with the turpentine, will mix, and yet refuse to incorporate with any other varnish less boiled than itself: therefore it requires a nicety which is only to be learned from practice. This varnish is chiefly intended for the use of japanners, cabinet-painters, coach-painters, &c.

Best body copal varnish for coach-makers, &c.—This is intended for the body parts of coaches and other similar vehicles, intended for polishing.

Fuse 8 lbs. of fine African gum copal; add two gallons of clarified oil (old measure); boil it very slowly for four or five hours, until quite stringy; mix with three gallons and a half of turpentine; strain off, and pour it into a cistern. As they are too slow in drying, coach-makers, painters, and varnish-makers have introduced to two pots of the preceding varnish, one made as follows:—

8 lbs. of fine pale gum animé;
2 gallons of clarified oil;
3½ gallons of turpentine.
To be boiled four hours.

Quick drying body copal varnish, for coaches, &c.

(1.) 8 lbs. of the best African copal;
2 gallons of clarified oil;
½ lb. of dried sugar of lead;
3½ gallons of turpentine;
Boiled till stringy, and mixed and strained.

(2.) 8 lbs. of fine gum animé;
2 gallons of clarified oil;
¼ lb. of white copperas;
3½ gallons of turpentine.
Boiled as before.

To be mixed and strained while hot into the other pot. These two pots mixed together will dry in six hours in winter, and in four in summer; it is very useful for varnishing old work on dark colours, &c.

Best pale carriage varnish.

(1.) 8 lbs. 2nd sorted African copal;
2½ gallons of clarified oil.
Boiled till very stringy.
¼ lb. of dried copperas;
¼ lb. of litharge;
5½ gallons of turpentine.
Strained, &c.

(1.) 8 lbs. of 2nd sorted gum animé;
2½ gallons of clarified oil;
¼ lb. of dried sugar of lead;
¼ lb. of litharge;
5½ gallons of turpentine.
Mix this to the first while hot.

This varnish will dry hard, if well boiled, in four hours in summer, and in six in winter. As the name denotes, it is intended for the varnishing of the wheels, springs, and carriage parts of coaches, chaises, &c.; also, it is that description of varnish which is generally sold to and used by house-painters, decorators, &c., as from its drying quality and strong gloss it suits their general purposes well.

Second carriage varnish.

8 lbs. of 2nd sorted gum animé;
2¾ gallons of fine clarified oil;
5¼ gallons of turpentine;
¼ lb. of litharge;
¼ lb. of dried sugar of lead;
¼ lb. of dried copperas.
Boiled and mixed as before.

Wainscot varnish.

8 lbs. of 2nd sorted gum animé;
3 gallons of clarified oil;
¼ lb. of litharge;
¼ lb. of dried sugar of lead.
5½ gallons of turpentine.
To be well boiled until it strings very strong, and then mixed and strained.

Mahogany varnish is made either with the same proportions, with a little darker gum; otherwise it is wainscot varnish, with a small portion of gold size.

Axioms observed in the making of copal varnishes.—The more minutely the gum is run, or fused, the greater the quantity, and the stronger the produce. The more regular and longer the boiling of the oil and gum together is continued, the more fluid or free the varnish will extend on whatever it is applied to. When the mixture of oil and gum is too suddenly brought to string by too strong a heat, the varnish requires more than its just proportion of turpentine to thin it, whereby its oily and gummy quality is reduced, which renders it less durable; neither will it flow so well in laying on. The greater proportion of oil there is used in varnishes, the less they are liable to crack, because the tougher and softer they are. By increasing the proportion of gum in varnishes the thicker will be the stratum, the firmer they will set solid, and the quicker they will dry. When varnishes are quite new made, and must be sent out for use before they are of sufficient age, they must always be left thicker than if they were to be kept the proper time. Varnish made from African copal alone possesses the most elasticity and transparency. Too much drier in varnish renders it opaque and unfit for delicate colours. Copperas does not combine with varnish, but only hardens it. Sugar of lead does combine with varnish. Turpentine improves by age; and varnish by being kept in a warm place. All copal or oil varnishes require age before they are used.

All body varnishes are intended and ought to have 1½ lbs. of gum to each gallon of varnish, when the varnish is strained off and cold; but as the *thinning up*, or quantity of turpentine required to bring it to its proper consistence, depends very much upon the degree of boiling the varnish has undergone, therefore, when the gum and oil have not been strongly boiled, it requires less turpentine for that purpose; whereas, when the gum and oil are very strongly boiled together, a pot of 20 gallons will require perhaps 3 gallons above the regular proportionate quantity; and if mixing the turpentine be commenced too soon; and the pot be not sufficiently cool, there will be frequently above a gallon and a half of turpentine lost by evaporation.

All carriage, wainscot, and mahogany varnish ought to have fully 1 pound of gum for each gallon when strained and cold; and should one pot require more than its proportion of turpentine, the following pot can easily be left not quite so strongly boiled; then it will require less turpentine to thin it.

Gold sizes, whether pale or dark, ought to have fully half a pound of good gum copal to each gallon when it is finished; and the best black japan, to have half a pound of good gum, or upwards, besides the quantity of asphaltum.

Pale amber varnish.—Fuse 6 pounds of fine picked very pale transparent amber in the gum-pot, and pour in 2 gallons of hot clarified oil. Boil it until it strings very strong. Mix with 4 gallons of turpentine. This will be as fine as body copal, will work very free, and flow well upon any work it is applied to: it becomes very hard, and is the most durable of all varnishes; it is very excellent to mix in copal varnishes, to give them a hard and durable quality. Observe; amber varnish will always require a long time before it is ready for polishing.

Fine mastic, or picture varnish.—Put 5 pounds of fine picked gum mastic into a new 4-gallon tin bottle; get ready 2 pounds of glass, bruised as small as barley; wash it several times; afterwards dry it perfectly, and put it into the bottle with 2 gallons of turpentine that has settled some time; put a piece of soft leather under the bung; lay the tin on a sack upon the counter, table, or anything that stands solid; begin to agitate the tin, smartly rolling it backward and forward, causing the gum, glass, and turpentine, to work as if in a barrel-churn for at least 4 hours, when the varnish may be emptied out into anything sufficiently clean, and large enough to hold it. If the gum is not all dissolved, return the whole into the bottle, and agitate as before, until all the gum is dissolved; then strain it through fine thin muslin into a clean tin bottle: leave it uncorked, so that the air can get in, but no dust; let it stand for 9 months at least before it is used, for the longer it is kept the tougher it will be, and less liable to chill or bloom. To prevent mastic varnish from chilling, boil 1 quart of river sand with 2 ounces of pearl-ashes; afterwards wash the sand three or four times with hot water, straining it each time; put the sand on a soup-plate to dry, in an oven; and when it is of a good heat, pour half a pint of hot sand into each gallon of varnish, and shake it well for 5 minutes; it will soon settle, and carry down the moisture of the gum and turpentine, which is the general cause of mastic varnish chilling on paintings.

Common mastic varnish.—Put as much gum mastic, unpicked, into the gum-pot as may be required, and to every $2\frac{3}{4}$ pounds of gum pour in 1 gallon of cold turpentine; set the pot over a very moderate fire, and stir it with the stirrer; be careful, when the steam of the turpentine rises near the mouth of the pot, to cover it with the carpet, and carry it out of doors, as the vapour is very apt to catch fire. A few minutes' low heat will perfectly dissolve 8 pounds of gum, which will, with 4 gallons of turpentine, produce, when strained, $4\frac{1}{2}$ gallons of varnish; to which add, while yet hot, 5 pints of pale turpentine varnish, which improves the body and hardness of the mastic varnish.

Crystal varnish may be made either in the varnish-house, drawing-room, or parlour. Procure a bottle of Canada balsam, which can be had at any druggist's; draw out the cork, and set the bottle of balsam at a little distance from the fire, turning it round several times, until the heat has thinned it; then have something that will hold as much as double the quantity of balsam; carry the balsam from the fire, and, while fluid, mix it with the same quantity of good turpentine, and shake them together until they are well incorporated: in a few days the varnish is fit for use, particularly if it is poured into a half-gallon glass or stone bottle, and kept in a gentle warmth. This varnish is used for maps, prints, charts, drawings, paper ornaments, &c.; and when made upon a larger scale, requires only warming the balsam to mix with the turpentine.

White hard spirit-of-wine varnish.—Put 5 pounds of gum sandarac into a 4-gallon tin bottle, with 2 gallons of spirits of wine, 60 over proof, and agitate it until dissolved, exactly as directed for the best mastic varnish, recollecting if washed glass is used that it is convenient to dip the bottle containing the gum and spirits into a copperful of hot water every 10 minutes—the bottle to be immersed only 2 minutes at a time —which will greatly assist the dissolving of the gum; but, above all, be careful to keep a firm hold over the cork of the bottle, otherwise the rarefaction will drive the cork out with the force of a shot, and perhaps set fire to the place. The bottle, every time it is heated, ought to be carried away from the fire; the cork should be eased a little, to allow the rarefied air to escape; then driven tight, and the agitation continued in this manner until all the gum is properly dissolved; which is easily known by having an empty tin can to pour the varnish into until near the last, which is to be poured into a gallon measure. If the gum is not all dissolved, return the whole into the 4-gallon tin, and continue the agitation until it is ready to be strained, when everything ought to be quite ready, and perfectly clean and dry, as oily tins, funnels, strainers, or anything damp, or even cold weather, will chill and spoil the varnish. After it is strained off, put into the varnish 1 quart of very pale turpentine varnish, and shake and mix the two well together. Spirit varnishes should be kept well corked: they are fit to use the day after being made.

Brown hard spirit varnish is made by putting into a bottle 3 pounds of gum sandarac, with 2 pounds of shellac, add 2 gallons of spirits of wine, 60 over proof; proceeding exactly as before directed for the white hard varnish, and agitating it when cold, which requires about 4 hours' time, without any danger of fire; whereas, making any spirit varnish by heat is always attended with danger. No spirit varnish ought to be made either near a fire or by candle light. When this brown hard is strained, add 1 quart of turpentine varnish, and shake and mix it well: next day it is fit for use.

The *Chinese varnish* comes from a tree which grows in Cochin-China, China, and Siam. It forms the best of all varnishes.

Gold lacker.—Put into a clean 4-gallon tin, 1 pound of ground turmeric, 1½ ounces of powdered gamboge, 3½ pounds of powdered gum sandarac, ¾ of a pound of shellac, and 2 gallons of spirits of wine. After being agitated, dissolved, and strained, add 1 pint of turpentine varnish, well mixed.

Red spirit lacker.

2 gallons of spirits of wine;
1 pound of dragon's blood;
3 pounds of Spanish annotto;
3¼ pounds of gum sandarac;
2 pints of turpentine.
Made exactly as the yellow gold lacker.

Pale brass lacker.

2 gallons of spirits of wine;
3 ounces of Cape aloes, cut small;
1 pound of fine pale shellac;
1 ounce gamboge, cut small.
No turpentine varnish. Made exactly as before.

But observe, that those who make lackers frequently want some paler and some darker, and sometimes inclining more to the particular tint of certain of the component ingredients. Therefore, if a 4-ounce phial of a strong solution of each ingredient be prepared, a lacker of any tint can be produced at any time.

Preparation of linseed oil for making varnishes.—Put 25 gallons of linseed oil into an iron or copper pot that will hold at least 30 gallons; put a fire under, and gradually increase the heat, so that the oil may only simmer, for 2 hours; during that time the greatest part of its moisture evaporates; if any scum arises on the surface, skim it off, and put that aside for inferior purposes. Then increase the heat gradually, and sprinkle in, by a little at a time, 3 lbs. of scale litharge, 3 lbs. of good red lead, and 2 lbs. of Turkey umber, all well dried and free from moisture. If any moist driers are added, they will cause the oil to tumefy; and, at the same time, darken it, causing it to look opaque and thick, ropy and clammy, and hindering it from drying and hardening in proper time; besides, it will lie on the working painting like a piece of bladder skin, and be very apt to rise in blisters. As soon as all the driers are added to the oil, keep quietly stirring the driers from the bottom of the pot; otherwise they will burn, which will cause the oil to blacken and thicken before it is boiled enough. Let the fire be so regulated that the oil shall only boil slowly for three hours from the time all the driers were added; if it then ceases to throw up any scum, and emits little or no smoke, it is necessary to test its temperature by a few quill tops or feathers. Dip a quill top in the oil every two minutes, for when the oil is boiled enough the quill top will crackle or curl up quite burnt; if so, draw out the fire immediately, and let the oil remain in the pot at least from 10 to 24 hours, or longer if convenient, for the driers settle much sooner when the oil is left to cool in the pot than when it is immediately taken out.

White spirit varnish.—Sandarach, 250 parts; mastic in tears, 64; elemi resin, 32; turpentine (Venice), 64; alcohol, of 85 per cent., 1000 parts by measure.

The turpentine is to be added after the resins are dissolved. This is a brilliant varnish, but not so hard as to bear polishing.

Varnish for the wood toys of Spa.—Tender copal, 75 parts; mastic, 12·5; Venice turpentine, 6·5; alcohol, of 95 per cent., 100 parts by measure; water ounces, for example, if the other parts be taken in ounces.

The alcohol must be first made to act upon the copal, with the aid of a little oil of lavender or camphor, if thought fit; and the solution being passed through a linen cloth, the mastic must be introduced. After it is dissolved, the Venice turpentine, previously melted in a water-bath, should be added; the lower the temperature at which these operations are carried on, the more beautiful will the varnish be. This varnish ought to be very white, very drying, and capable of being smoothed with pumice-stone and polished.

Varnish for certain parts of carriages.—Sandarach, 190 parts; pale shellac, 95; rosin, 125; turpentine, 190; alcohol, at 85 per cent., 1000 parts by measure.

Varnish for cabinet-makers.—Pale shellac, 750 parts; mastic, 64; alcohol, of 90 per cent., 1000 parts by measure. The solution is made in the cold, with the aid of frequent stirring. It is always muddy, and is employed without being filtered.

With the same resins and proof spirit a varnish is made for the bookbinders to do over their morocco leather.

The varnish of Watin, for gilded articles.—Gum lac, in grain, 125 parts; gamboge, 125; dragon's blood, 125; annotto, 125; saffron, 32. Each resin must be dissolved in 1000 parts by measure of alcohol of 90 per cent.; two separate tinctures must be made with the dragon's blood and annotto, in 1000 parts of such alcohol; and a proper proportion of each should be added to the varnish, according to the shade of golden colour wanted.

For fixing engravings or lithographs upon wood, a varnish called *mordant* is used in France, which differs from others chiefly in containing more Venice turpentine, to make it sticky; it consists of—sandarach, 250 parts; mastic in tears, 64; rosin, 125; Venice turpentine, 250; alcohol, 1000 parts by measure.

Milk of wax is a valuable varnish, which may be prepared as follows:—Melt in a porcelain capsule a certain quantity of white wax, and add to it, while in fusion, an equal quantity of spirit of wine, of sp. gr. 0·830; stir the mixture, and pour it upon a large porphyry slab. The granular mass is to be converted into a paste by the muller, with the addition, from time to time, of a little alcohol; and as soon as it appears to be smooth and homogeneous, water is to be introduced in small quantities successively, to the amount of four times the weight of the wax. This emulsion is to be then passed through canvass, in order to separate such particles as may be imperfectly incorporated.

The *milk of wax*, thus prepared, may be spread with a smooth brush upon the surface of a painting, allowed to dry, and then fused by passing a hot iron (salamander) over its surface. When cold, it is to be rubbed with a linen cloth to bring out the lustre. It is to the unchangeable quality of an encaustic of this nature that the ancient paintings upon the walls of Herculaneum aud Pompeii owe their freshness at the present day.

Black japan is made by putting into the set-pot 48 lbs. of Naples or any other of the foreign asphaltums (except the Egyptian). As soon as it is melted, pour in 10 gallons of raw linseed oil; keep a moderate fire, and fuse 8 pounds of dark gum animé in the gum-pot; mix it with 2 gallons of hot oil, and pour it into the set-pot. Afterwards fuse 10 pounds of dark or sea amber in the 10 gallon iron-pot; keep stirring it while fusing; and whenever it appears to be overheated, and rising too high in the pot, lift it from the fire for a few minutes. When it appears completely fused, mix in 2 gallons of hot oil, and pour the mixture into the set-pot; continue the boiling for 3 hours longer, and during that time introduce the same quantity of driers as before directed: draw out the fire, and let it remain until morning; then boil it until it rolls hard, as before directed: leave it to cool, and afterwards mix with turpentine.

Best Brunswick black.—In an iron pot, over a slow fire, boil 45 pounds of foreign asphaltum for at least 6 hours; and during the same time boil in another iron pot 6 gallons of oil which has been previously boiled. During the boiling of the 6 gallons introduce 6 pounds of litharge gradually, and boil until it feels stringy between the fingers; then ladle or pour it into the pot containing the boiling asphaltum. Let the mixture boil until, upon trial, it will roll into hard pills; then let it cool, and mix it with 25 gallons of turpentine, or until it is of a proper consistence.

Iron-work black.—Put 48 pounds of foreign asphaltum iuto an iron pot, and boil for 4 hours. During the first 2 hours introduce 7 pounds of red lead, 7 pounds of litharge, 3 pounds of dried copperas, and 10 gallons of boiled oil; add 1 eight-pound run of dark gum, with 2 gallons of hot oil. After pouring the oil and gum, continue the boiling 2 hours, or until it will roll into hard pills like japan. When cool, thin it off with 30 gallons of turpentine, or until it is of a proper consistence. This varnish is intended for blacking the iron-work of coaches and other carriages, &c.

A cheap Brunswick black.—Put 28 pounds of common black pitch, and 28 pounds of common asphaltum made from gas tar, into an iron pot; boil both for 8 or 10 hours, which will evaporate the gas and moisture; let it stand all night, and early next morning, as soon as it boils, put in 8 gallons of boiled oil; then iutroduce, gradually, 10 pounds of red lead and 10 pounds of litharge, and boil for 3 hours, or until it will roll very hard. When ready for mixing, introduce 20 gallons of turpentine, or more, until of a proper consistence. This is intended for engineers, founders, ironmongers, &c.; it will dry in half an hour, or less, if properly boiled.

VEGETABLE EXTRACT. In offering anything new, more especially as connected with an art so long practised as that of brewing malt liquors, Mr. Hodge, whose patent we are about to describe, is fully aware that changes in old established methods are never received readily. It is, however, evident that there are certain points to be attained in the production of malt liquors, which, if carried out on scientific principles, would be a great boon to the profession.

The present practice of first making an extract of malt, and then adding the hop-leaves to the wort in the copper, for the purpose of getting out their extractive matter (in a liquid already nearly to the point of saturation) is not in accordance with scientific principles.

It is a well-known fact that, without long boiling, the resin, lupuline, and tannic acid of the hops are not readily disengaged from the leaf; hence we find all brewers say that they *like a good, long, sharp boil to make the beer keep well.*

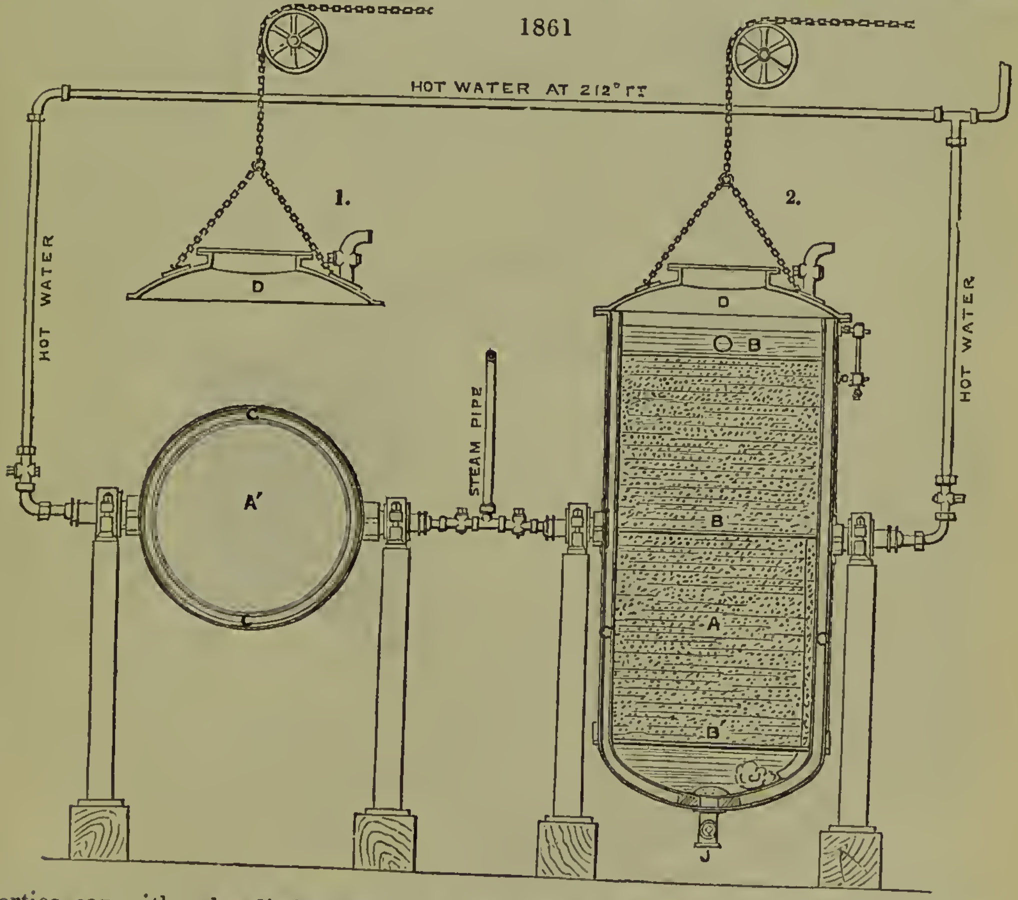
The two most antiputrescent ingredients are the lupuline and tannic acid; but while the long boiling is going on to get these two ingredients liberated, the volatile oil, or that which gives the softening principle, as well as the aroma, to the ales, passes off into the atmosphere and is lost, so that the beer or ale has a nasty, rough, acrid taste, somewhat like gentian root. The great question is, what are the constituents of wort liquor when drawn from the mash tun, what do we want to retain, and what to get rid of. The worts are composed of water, saccharine matter, starch in small quantity, albumen, and gluten. The saccharine matter is the only thing we want to retain, save its proper proportion of water. The other ingredients are nitrogenous, and liable to produce putrid fermentation.

Boiling of the worts is intended to coagulate the nitrogenous matter; two minutes will do this at 200° Fahr. What must now be effected is to bring these particles of coagulated matter into contact with the tanning, resinous, and lupuline properties of hop, rendering them insoluble, which chemical change prevents, in a measure, further decomposition for a time, until they are nearly all got rid of by fermentation or after precipitation.

There cannot be a doubt that boiling worts to a certain extent is necessary, but long boiling is decidedly injurious, as there must be a decomposition of the saccharine matter going on, as well as a reglutinisation of the albumen and other compounds, unless these particles are immediately brought into contact with those properties of the hop to arrest it.

All these difficulties can be prevented by first making an extract of hop in a close digester, as is represented in the enclosed drawing, *fig.* 1861. The most volatile pro-

1861



perties can either be distilled over, or drawn off from the top, and added to the worts after they are cooled, and before fermentation. The keeping principle of the hop will then be drawn off in a strong decoction and added to the worts after they are allowed to boil a few minutes, when the particles of nitrogenous matter will be immediately changed, retaining the aroma and other delicate properties of the hop.

Hence the advantage of the separate extract of hop, in vessels where the temperature can be regulated to the greatest nicety, and where the air cannot come into contact to change the colour of the liquid or lose the aroma.

Another advantage in this process is, not allowing the hop leaf to go into the wort, thereby saving one in every 30 barrels brewed, or 3 per cent. on all malt extract, which to some brewers would amount to 20,000*l.* per annum.

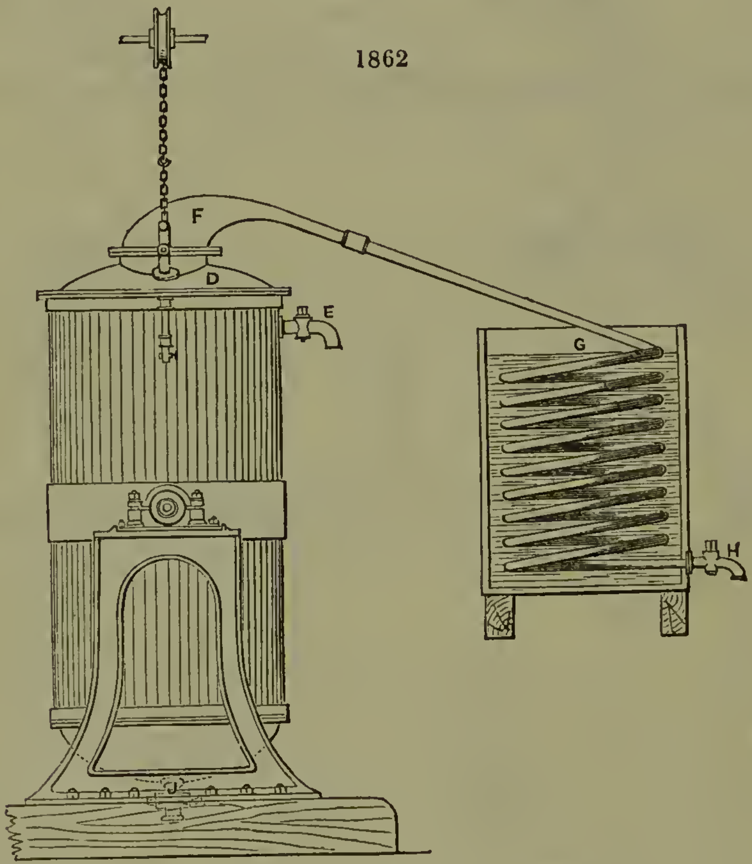
Figs. 1861, 1 and 2 (A and A′), are two digesters, which are supplied with water to the interior at 212° Fahr. This is admitted by the water-pipe passing through the hollow journal, and thence down the side pipe in the interior of the vessel below the perforated platform B′. The hops are placed between these platforms B B and B′. Steam is let on from the steam-pipe, passing through the hollow journal, and into the steam-jacket C, C, C, which keep up the temperature of the mass at or above 212° Fahr., as may be deemed necessary; at the same time no steam is allowed to escape, hence the whole of the aromatic properties of the hop are preserved. This is done in two ways, first by drawing off the top of the extract through the cock E (this is added to the beer after it is cool); or the hop oil is distilled over by means of the hood F, and condenser G, and is run off through the cock H, *fig.* 1862. The cover is then drawn up by the chain and counter-weight. The extract is then drawn off through the bottom cock J, and is added to the boil. The perforated platform is removed, and the vessel, which swings on the trunyons, is turned upside down and the spent hops drop into a press. See BREWING.

Cooling. — The quicker worts are cooled down to the fermenting temperature after being boiled, the better. The less it is exposed to the action of the atmosphere the less liable it is to absorb oxygen, preventing acetous fermentation.

Rapid cooling to all brewers is of vital importance, for if wort be permitted to come into contact with the air during the time its caloric is given off, acidity must set in, especially in summer time.

The best method to cool worts is that which is shown and described in the drawing annexed, *fig.* 1862.

1862



The worts are passed through copper tubes, *thoroughly tinned.* Instead of passing a current of water round these tubes, a dew jet of water is sprinkled all over the outer surface, at the same time a current of cold air is brought into contact with the moist surface of the tube, so that as fast as the molecules of caloric are transmitted to the water through the metal tubes, they are blown away, giving place to others. By this process heat from liquids can be abstracted more rapidly than by any other. In fact, worts can be brought down to freezing temperature, although the water used may be 80° to 100° Fahr. Another great advantage is, that the quantity of water used is about one-half.

These tubes can be cleaned with a brush with perfect ease.

VEGETABLE ETHIOPS. A charcoal prepared by the incineration in a covered crucible of the *fucus vesiculosus*, or common sea wrack.

VEGETABLE PARCHMENT. See Parchment, Vegetable.

VEINS (*Filons*, Fr.; *Gänge*, Germ.) are the fissures or rents in rocks, which are filled with peculiar mineral substances, most commonly metallic ores. See Mines, Mining, &c.

VEIN STONES, or GANGUES, are the mineral substances which accompany, and frequently enclose, the metallic ores. See Mines, Mining, &c.

VELLUM is a fine sort of Parchment, which see.

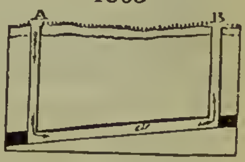
VELVET. (*Velours*, Fr.; *Sammet*, Germ.) A peculiar stuff, the nature of which is explained under Fustian and Textile Fabrics.

VENETIAN CHALK is Steatite.

VENTILATION OF MINES. In our subterranean operations, especially where quantities of carbonic acid are constantly being produced by respiration and combustion, and where, as especially in our coal mines, the workmen are constantly exposed to the efflux of explosive gas—light carburetted hydrogen—it becomes necessary to adopt the means of removing, as rapidly as possible, the air by which the miner is surrounded.

The production of noxious gases renders ventilation a primary object in the system of mining. The most easily managed is the carbonic acid. If an air-pipe has been carried down the engine pit for the purpose of ventilation in the sinking, other pipes are connected with it, and laid along the pavement, or are attached to an angle of the mine next the roof. These pipes are prolonged with the galleries, by which means the air at the forehead is drawn up the pipes and replaced by atmospheric air, which descends by the shaft in an equable current, regulated by the draught of the furnace at the pit mouth. This circulation is continued till the miners cut through upon the second shaft, when the air-pipes become superfluous; for it is well known that the instant such communication is made, as is represented in *fig.* 1863, the air spontaneously descends in the engine pit A, and passing along the gallery *a*, ascends in a steady current in the second pit B. The air, in sinking through A, has at first the atmospheric temperature, which in winter may be at or under the freezing point of water; but its temperature increases in passing down through the relatively warmer earth, and ascends in the shaft B, warmer than the atmosphere. When shafts are of unequal depths, as represented in the figure, the current of air flows pretty uniformly in one direction. If the second shaft has the same depth with the first, and the bottom and mouth of both be in the same horizontal plane, the air would sometimes remain at rest, as water would do in an inverted siphon, and at other times would circulate down one pit and up another, not always in the same direction, but sometimes up the one and sometimes up the other, according to the variations of temperature at the surface, and the barometrical pressures, as modified by winds. There is in mines a proper heat, proportional to their depth, increasing about one degree of Fahrenheit's scale for every 60 feet of descent.

1863



There is a simple mode of conducting air from the pit bottom to the forehead of the mine, by cutting a ragglin, or trumpeting, as it is termed, in the side of the gallery, as represented *fig.* 1864, where A exhibits the gallery in the coal, and B the ragglin, which is from 15 to 18 inches square. The coal itself forms three sides of the air-pipe, and the fourth is composed of thin deals applied air-tight, and nailed to small props of wood fixed between the top and bottom of the lips of the ragglin. This mode is very generally adopted in running galleries of communication, and dip-head level galleries, where carbonic acid abounds, or when from the stagnation of the air the miners' lights burn dimly.

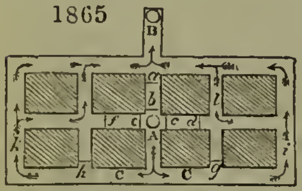
1864

When the ragglin or air-pipes are not made spontaneously active, the air is sometimes impelled through them by means of ventilating fanners, having their tube placed at the pit bottom, while the vanes are driven with great velocity by a wheel and pinion worked with the hand. In other cases, large bellows like those of the blacksmith, furnished with a wide nozzle, are made to act in a similar way with the fanners. But these are merely temporary expedients for small mines. A very slight circulation of air can be effected by propulsion, in comparison of what may be done by exhaustion; and hence it is better to attach the air-pipe to the valve of the bellows than to their nozzle.

Ventilation of collieries has been likewise effected on a small scale, by attaching a horizontal funnel to the top of air-pipes elevated a considerable height above the pit mouth. The funnel revolves on a pivot, and by its tail-piece places its mouth so as to receive the wind. At other times, a circulation of air is produced by placing coal-fires in iron grates, either at the bottom of an upcast pit, or suspended by a chain a few fathoms down.

Such are some of the more common methods practised in collieries of moderate depth, where carbonic acid abounds, or where there is a total stagnation of air. But in all great coal mines the aërial circulation is regulated and directed by double doors, called main or bearing doors. These are true air-valves, which intercept a current of air moving in one direction from mixing with another moving in a different direction. Such valves are placed on the main roads and passages of the galleries, and are essential to a just ventilation. Their functions are represented in the annexed *fig.* 1865, where A shows the downcast shaft, in which the aërial current is made to descend; B is the upcast shaft, sunk towards the rise of the coal; and C the dip-head level. Were the mine here figured to be worked without any attention to the circulation, the air would flow down the pit A, and proceed in a direct line up the rise mine to the shaft B, in which it would ascend. The consequence would therefore be, that all the galleries and boards to the dip of the pit A, and those lying on each side of the pits, would have no circulation of air; or, in the language of the collier, would be laid dead. To obviate this result, double doors are placed in three of the galleries adjoining the pit; viz. at *a* and *b*, *c* and *d*, *e* and *f*; all of which open inwards to the shaft A. By this plan, as the air is not suffered to pass directly from the shaft A to the shaft B, through the doors *a* and *b*, it would have taken the next shortest direction by *c d* and *e f*; but the doors in these galleries prevent this course, and compel it to proceed downwards to the dip-head level C, where it will spread or divide, one portion pursuing a route to the right, another to the left. On arriving at the boards *g* and *h*, it would have naturally ascended by them; but this it cannot do by reason of the building or stopping placed at *g* and *h*. By means of such stoppings placed in the boards next the dip-head level, the air can be transported to the right hand or to the left for many miles, if necessary, providing there be a train or circle of aërial communication from the pit A to the pit B. If the boards *i* and *k* are open, the air will ascend in them, as traced out by the arrows; and after being diffused through the workings, will again meet in a body at *a*, and mount the gallery to the pit B, sweeping away with it the deleterious air which it meets in its path. Without double doors on each main passage, the regular circulation of the air would be constantly liable to interruptions and derangements; thus, suppose the door *c* to be removed, and only *d* to remain in the left-hand gallery, all the other doors being as represented, it is obvious, that whenever the door *d* is opened, the air, finding a more direct passage in that direction, would mount by the nearest channel *l*, to the shaft B, and lay dead all the other parts of the work, stopping all circulation. As the passages on which the doors are placed constitute the main roads by which the miners go to and from their work, and as the corves are also constantly wheeling along all the time, were a single door, such as *d*, so often opened, the ventilation would be rendered precarious or languid. But the double doors obviate this inconvenience; for both men and horses, with the corves, in going to or from the pit bottom A, no sooner enter the door *d*, than it shuts behind them, and encloses them in the still air contained between the doors *d* and *c*; *c* having prevented the air from changing its proper course while *d* was open. When *d* is again shut, the door *c* may be opened without inconvenience, to allow the men and horses to pass on to the pit bottom at A; the door *d* preventing any change in the aërial circulation while the door *c* is open. In returning from the pit, the same rule is observed of shutting one of the double doors before the other is opened.

1865



If this mode of disjoining and insulating air-courses from each other be once fairly conceived, its continuance through a working of any extent may be easily understood.

When carbonic acid gas abounds, or when the fire-damp is in very small quantity, the air may be conducted from the shaft to the dip-head level, and by placing stoppings of each room next the level, it may be carried to any distance along the dip-head levels; and the furthest room on each side being left open, the air is suffered to diffuse itself through the wastes, along the wall faces, and mount in the upcast pit. But should the air become stagnant along the wall faces, stoppings are set up throughout the galleries, in such a way as to direct the main body of fresh air along the wall faces for the workmen, while a partial stream of air is allowed to pass through the stoppings, to prevent any accumulation of foul air in the wastes.

In very deep and extensive collieries more elaborate arrangements for ventilation are introduced. Here the circulation is made active by rarefying the air at the upcast shaft, by means of a very large furnace placed either at the bottom or top of the shaft. The former position is generally preferred. *Fig.* 1866 exhibits a furnace placed at the top of the pit. When it surmounts a single pit, or a single division of the pit, the compartment intended for the upcast is made air-tight at top, by placing strong buntons or beams across it, at any suitable distance from the mouth. On these buntons a close scaffolding of plank is laid, which is well plastered or moated over with adhesive plastic clay. A little way below the scaffold, a passage is previously cut, either in a sloping direction, to connect the current of air with the furnace, or it is laid horizontally, and then communicates with the furnace by a vertical opening. If any obstacle prevent the scaffold from being erected within the pit, this can be made air-tight at top, and a brick flue carried thence along the surface to the furnace.

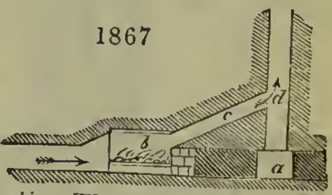
1866

The furnace has a size proportional to the magnitude of the ventilation, and the chimneys are either round or square, being from 50 to 100 feet high, with an inside diameter of from 5 to 9 feet at bottom, tapering upwards to a diameter of from $2\frac{1}{2}$ feet to 5 feet. Such stalks are made 9 inches thick in the body of the building, and a little thicker at bottom, where they are lined with fire-bricks.

The plan of placing the furnace at the bottom of the pit is, however, more advantageous, because the shaft through which the air ascends to the furnace at the pit mouth, is always at the ordinary temperature; so that whenever the top furnace is neglected, the circulation of air throughout the mine becomes languid, and dangerous to the workmen; whereas, when the furnace is situated at the bottom of the shaft, its sides get heated, like those of a chimney, through its total length, so that though the heat of the furnace be accidentally allowed to decline or become extinct for a little, the circulation will still go on, the air of the upcast pit being rarefied by the heat remaining in the sides of the shaft.

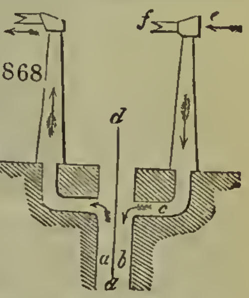
To prevent the annoyance to the onsetters at the bottom from the hot smoke, the following plan has been adopted, as shown in the wood-cut, *fig.* 1867, where *a* represents the lower part of the upcast shaft; *b*, the furnace, built of brick, arched at top, with its sides insulated from the solid mass of coal which surrounds it. Between the furnace wall and the coal beds a current of air constantly passes towards the shaft, in order to prevent the coal catching fire. From the end of the furnace a gallery is cut in a rising direction at *c*, which communicates with the shaft at *d*, about 7 or 8 fathoms from the bottom of the pit. Thus the furnace and furnace-keeper are completely disjoined from the shaft; and the pit bottom is not only free from all incumbrances, but remains comfortably cool.

1867



To obviate the inconveniences from the smoke to the banksmen in landing the coals at the pit mouth, the following plan has been contrived for the Newcastle collieries. *Fig.* 1868 represents the mouth of the pit: *a* is the upcast shaft, provided with a furnace at bottom; *b*, the downcast shaft, by which the supply of atmospheric air descends; and *d*, the brattice carried above the pit mouth. A little way below the settle-boards, a gallery, *c*, is pushed, in communication with the surface from the downcast shaft, over which a brick tube or chimney is built from 60 to 80 feet high, 7 or 8 feet diameter at bottom, and 4 or 5 feet diameter at top. On the top of this chimney a deal funnel is suspended horizontally on a pivot, like a turn-cap. The vane *f*, made also of deal, keeps the mouth of the funnel always in the same direction with the wind. The same mechanism is mounted at the upcast shaft *a*, only here the funnel is made to present its mouth in the wind's eye. It is obvious from the figure, that a high wind will rather aid than check the ventilation by this plan.

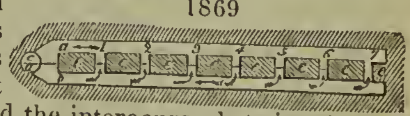
1868



The principle of ventilation being thus established, the next object in opening up a colliery, and in driving all galleries whatever, is the *double mine* or double *headways course*; on the simple but very ingenious distribution of which, the circulation of air depends at the commencement of the excavations.

The double headways course is represented in *fig.* 1869, where *a* is the one heading or gallery, and *b* the other; the former being immediately connected with the upcast side of the pit *c*, and the latter with the downcast side of the pit *d*. The pit itself is made completely air-tight by its division of deals from top to bottom, called the brattice wall; so that no air can pass through the brattice from *d* to *c*, and the intercourse betwixt the two currents of air is completely intercepted by a stopping betwixt the pit bottom and the end of the first pillar of coal; the pillars or walls of coal, marked *e*, are called stenting walls; and the openings betwixt them, walls or thirlings. The arrows show the direction of the air. The headings *a* and *b* are generally made about 9 feet wide, the

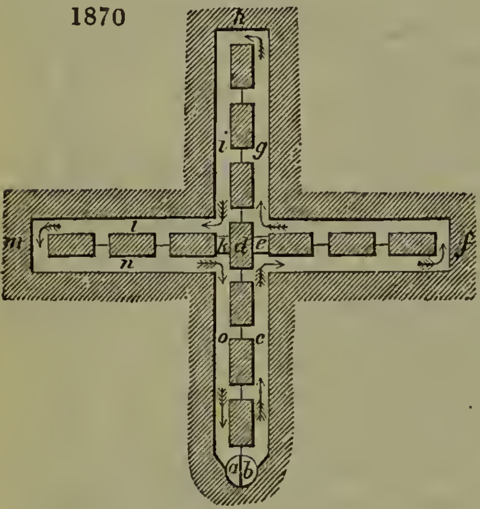
1869



stenting walls 6 or 8 yards thick, and are holed or thirled at such a distance as may be most suitable for the state of the air. The thirlings are 5 feet wide.

When the headings are set off from the pit bottom, an aperture is left in the brattice at the end of the pillar next the pit, through which the circulation betwixt the upcast and downcast pits is carried on; but whenever the workmen cut through the first thirling No. 1, the aperture in the brattice at the pit bottom is shut; in consequence of which the air is immediately drawn by the power of the upcast shaft through that thirling as represented by the dotted arrow. Thus a direct stream of fresh air is obviously brought close to the forehead where the mines are at work. The two headings *a* and *b* are then advanced, and as soon as the thirling No. 2 is cut through, a wall of brick and mortar, 4½ inches thick, is built across the thirling No. 1. This wall is termed a stopping; and being air-tight, it forces the whole circulation through the thirling No. 2. In this manner the air is always led forward, and caused to circulate always by the last-made thirling next the forehead; care being had, that whenever a new thirling is made, the last thirling through which the air was circulated be secured with an air-tight stopping. In the woodcut, the stoppings are placed in the thirlings numbered 1, 2, 3, 4, 5, 6, and of consequence the whole circulation passes through the thirling No. 7, which lies nearest the foreheads of the headings *a*, *b*. By inspecting the figure, we observe that on this very simple plan a stream of air may be circulated to any required distance, and in any direction, however tortuous. Thus, for example, if while the double headways course *a*, *b*, is pushed forward, other double headways courses are required to be carried on at the same time on both sides of the first headway, the same general principles have only to be attended to as shown in *fig.* 1870, where *a* is the upcast and *b* the downcast shaft.

1870

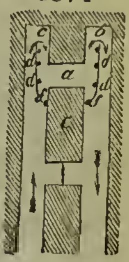


The air advances along the heading *c*, but cannot proceed further in that direction than the pillar *d*, being obstructed by the double doors at *e*. It therefore advances in the direction of the arrows to the foreheads at *f*, and passing through the last thirling made there, returns to the opposite side of the double doors, ascends now the heading *g* to the foreheads at *h*, passes through the last-made thirling at that point, and descends, in the heading *i*, till it is interrupted by the double doors at *k*. The aërial current now moves along the heading *l*, to the foreheads at *m*, returns by the last-made thirling there, along the heading *n*, and finally goes down the heading *o*, and mounts by the upcast shaft *a*, carrying with it all the noxious gases which it encountered during its circuitous journey. This woodcut is a faithful representation of the system by which collieries of the greatest extent are worked and ventilated. In some of these the air courses are from 30 to 40 miles long. Thus the air conducted by the medium of a shaft divided by a brattice wall only a few inches thick, after descending in the downcast in one compartment of the pit at 6 o'clock in the morning, must thence travel through a circuit of nearly 30 miles, and cannot arrive at its reascending compartment on the other side of the brattice, or pit partition, till 6 o'clock in the evening, supposing it to move all the time at the rate of 2½ miles per hour. Hence we see that the *primum mobile* of this mighty circulation, the furnace, must be carefully looked after, since its irregularities may affect the comfort, or even the existence of hundreds of miners spread over these vast subterraneous labyrinths. On the principles just laid down, it appears, that if any number of boards be set off from any side of these galleries, either in a level, dip, or rise direction, the circulation of air may be advanced to each forehead by an ingoing and returning current.

Yet while the circulation of fresh air is thus advanced to the last-made thirling next the foreheads *f*, *h*, and *m*, *fig.* 1870, and moves through the thirling which is nearest to the face of every board and room, the emission of fire-damp is frequently so abundant from the coaly strata, that the miners dare not proceed forwards more than a few feet from that aërial circulation, without hazard of being burned by the combustion of the gas at their candles. To guard against this accident, temporary shifting brattices are employed. These are formed of deal, about ¾ of an inch thick, 3 or 4 feet broad, and 10 feet long; and are furnished with cross-bars for binding the deals together, and a few finger-loops cut through them, for lifting them more expeditiously, in order to place them in a proper position. Where inflammable air abounds, a store of such brattice deals should be kept ready for emergencies.

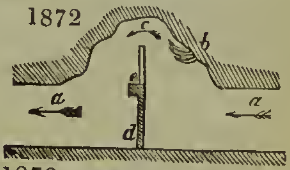
The mode of applying these temporary brattices, or deal partitions, is shown in the accompanying figure (1871), which shows how the air circulates freely through the thirling *d*, *d*, before the brattices are placed. At *b* and *c*, we see two heading boards or rooms, which are so full of inflammable air as to be unworkable. Props are now erected near the upper end of the pillar *e*, betwixt the roof and pavement, about 2 feet clear of the sides of the next pillar, leaving room for the miner to pass along between the pillar side and the brattice. The brattices are then fastened with nails to the props, the lower edge of the under brattice resting on the pavement, while the upper edge of the upper is in contact with the roof. By this means any variation of the height in the bed of coal is compensated by the overlap of the brattice boards; and as these are advanced, shifting brattices are laid close to and alongside of the first set. The miner next sets up additional props in the same parallel line with the former, and slides the brattices forwards to make the air circulate close to the forehead where he is working; and he regulates the distance betwixt the brattice and the forehead by the disengagement of fire-damp and the velocity of the aërial circulation. The props are shown at *d d*, and the brattices at *f f*. By this arrangement the air is prevented from passing directly through the thirling *a*, and is forced along the right-hand side of the brattice, and, sweeping over the wall face or forehead, returns by the back of the brattice, and passes through the thirling *a*. It is prevented, however, from returning in its former direction by the brattice planted in the forehead *c*, whereby it mounts up and accomplishes its return close to that forehead. Thus headways and boards are ventilated till another thirling is made at the upper part of the pillar. The thirling *a* is then closed by a brick stopping, and the brattice boards removed forward for a similar operation.

1871

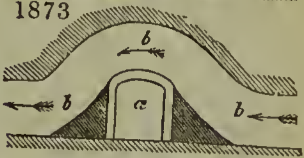


When blowers occur in the roof, and force the strata down, so as to produce a large vaulted excavation, the accumulated gas must be swept away; because, after filling that space, it would descend in an unmixed state under the common roof of the coal. The manner of removing it is represented in *fig.* 1872, where *a* is the bed of coal, *b* the blower, *c* the excavation left by the downfall of the roof, *d* is a passing door, and *e* a brattice. By this arrangement the aërial current is carried close to the roof, and constantly sweeps off or dilutes the inflammable gas of the blower, as fast as it issues. The arrows show the direction of the current; but for which, the accumulating gas would be mixed in explosive proportions with the atmospheric air, and destroy the miners.

1872



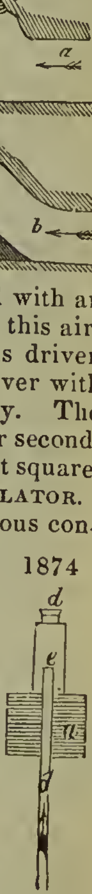
1873



There is another modification of the ventilating system, where the air-courses are traversed across; that is, when one air-course is advanced at right angles to another, and must pass it in order to ventilate the workings on the further side. This is accomplished on the plan shown in *fig.* 1873, where *a* is a main road with an air-course, over which the other air-course *b*, has to pass. The sides of this air-channel are built of bricks arched over, so as to be air-tight, and a gallery is driven in the roof strata as shown in the figure. If an air-course, as *a*, be laid over with planks made air-tight, crossing and recrossing may be effected with facility. The general velocity of the air in these ventilating channels is from 3 to 4 feet per second, or about 2½ miles per hour, and their internal dimensions vary from 5 to 6 feet square, affording an area of from 25 to 36 square feet. See STRUVE'S MINE VENTILATOR.

The hydraulic air-pump, deserves to be noticed among the various ingenious contrivances for ventilating mines, particularly when they are of moderate extent. *a* is a large wooden tub, nearly filled with water, through whose bottom the ventilating pipe *b* passes down into the recesses of the mine. Upon the top of *b* there is a valve *e*, opening upwards. Over *b*, the gasometer vessel is inverted in *a*, having a valve also opening outwards at *d*. When this vessel is depressed by any moving force the air contained within it is expelled through *d*; and when it is raised, it diminishes the atmospherical pressure in the pipe *b*, and thus draws air out of the mine into the gasometer; which cannot return on account of the valve at *e*, but is thrown out into the atmosphere through *d* at the next descent.

1874



The general plan of distributing the air in all cases is to send the first of the current that descends in the downcast shaft among the horses in the stables, next among the workmen in the foreheads, after which the air, loaded with whatever mixtures it may have received, is made to traverse the old wastes. It then passes through the furnace with all the inflammable gas it has collected, ascends the upcast shaft, and is dispersed into the atmosphere. This system, styled *coursing the air*, to be presently described, was invented by Mr. Spedding of Cumberland.

In ventilating the very thick coal of Staffordshire, though there is much inflammable air, less care is needed than in the north of England collieries, as the workings are very roomy, and the air courses of comparatively small extent. The air is conducted down one shaft, carried along the main roads, and distributed into the sides of work. A narrow gallery, termed the air-head, is carried in the upper part of the coal, in the rib walls, along one or more of the sides. Lateral openings, named spouts, are led from the air-head gallery into the side of work; and the circulating stream, mixed with the gas in the workings, enters by these spouts, and returns by the air-head to the upcast pit.

The means adopted in the South Staffordshire coal mines, which have veins varying from 25 to 30 feet in thickness, are well worthy of consideration; since a solid mass of that magnitude must be peculiarly difficult to drain of its imprisoned gas. In excavating such coal large masses must be detached, and pockets or hollows must be formed, which are immediately filled with carburetted hydrogen; whilst a thin vein, for which a level roof can be generally secured, can be kept tolerably free from such accumulations.

Carburetted hydrogen gas, which produces these dreadful explosions, is not explosive until it is united with a certain proportion of ordinary air, say seven to nine times its volume; when this mixture has taken place, it arrives at what is termed its "firing" or explosive point; and in that state, if it come in contact with the flame of a candle, it will instantly explode, with similar rapidity and violence to gunpowder. A considerable volume of this gas is set at liberty in all the thick coal mines, when worked in the usual manner, and as often as fresh masses of coal are cut through. Some coal mines supply a much greater quantity of gas than others, and these are commonly called "fiery mines;" but in nearly all coal mines a sufficient quantity is extricated to produce the most direful consequences, if it be not neutralised, or its escape duly provided for.

The general mode is that of diluting the gas with a quantity of atmospheric air; and a current of air, equal to thirty times the volume of gas yielded by the coal, is the bare limit of safety: that is to say, thirty cubic feet of common air must circulate through the mine in the space of time that the coal will give out one cubic foot of gas; but the quantity of air should very far exceed this, where this mode of ventilation is practised, for a copious supply of fresh air is needful for the numerous workmen, horses, and candles employed in the pit.

Many mechanical plans have been recommended to increase the current of air through the mines; in some, force pumps, and in others, exhaust pumps, have been proposed, to produce an artificial current of air throughout the workings. These plans, theoretically, may be very correct, but, it is to be observed, that the current of air must be constantly maintained; and, in the practical application, the engine that works these pumps, or other mechanical means, may get out of order, and thereby endanger the lives of all the miners.

We should therefore avail ourselves, as far as possible, of the natural powers that are at our command; and, in this instance, the extreme levity of the gas from which we wish to rid the mines, supplies us, to a considerable extent, with the remedy required. But cases may arise where other auxiliaries may be temporarily required, from accidental misplacements of the level of the mine. Under these circumstances, it may be necessary to employ heat, to rarefy the upcast current of air, to make it specifically lighter than the downcast; or mechanical means to force air in, or to extract air from the mines, may be required. Where artificial heat is made use of, a well constructed furnace is the most secure method. If mechanical means should become necessary, Mr. Struve's exhausting cylinders, or Mr. Nasmyth's fan, supply powerful and effective apparatus.

According to the ordinary system adopted in the collieries of the South Staffordshire district, two shafts are sunk, near together, about 7 to 7½ feet in diameter, each to the bottom of the coal, say about 180 yards depth, the two shafts commencing at the same level, and terminating at the same level. One of these becomes the "downcast pit" down which the air descends, and the other the "upcast pit" up which the air ascends, when a communication is made between them at the bottom; but the only determining causes for the motion of the air being accidental, it is unknown beforehand what direction the current will take, and which will become the downcast pit. It is always found that a current of air does take place without any other means being employed; but the determining power is so faint, that, issuing from the upcast pit with such trifling velocity, it is liable to be deranged by the action of the wind, or by atmospheric changes; and it sometimes happens that the air becomes quiescent, or an unsteady column, alternately ascending and descending the same shaft; and then, in miner's language, the pits "fight," and the air will neither ascend nor descend with regularity in one direction.

When the two pits are sunk down through the stratum of coal 30 ft. in thickness, a "gate-road" or horse-way is next driven in the bottom of the coal, from 8 to 9 ft. high, and about the same width, commencing from the bottom of the downcast pit.

At the same time (or rather before, as it should always precede the gate-road), an air-head is driven about the middle of the coal, or 15 feet high from the "floor" or bottom of the coal, commencing from the downcast pit. The gate-road and air-head are then driven in parallel lines, at the same level upon which they commence, for the distance of 100 to 500 yards, or more, according to the quantity of coal intended to be cleared by the pits.

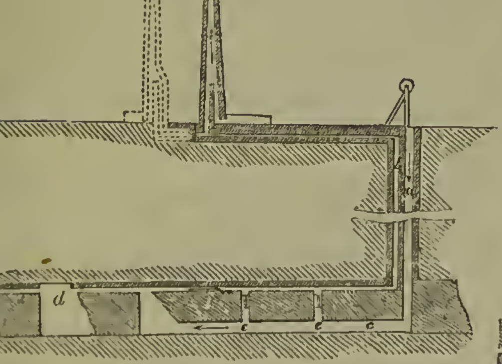
A series of "spouts" or openings are driven upwards from the gate-road into the air-head, at intervals of 10 or 15 yards (as the coal may give out more or less gas), to carry off the gas, and produce a current of air for the workmen,— each spout being closed up when a new one is made in advance. The excavation of the whole thickness of the stratum of coal, 30 feet thick, is then proceeded with, by opening right and left from the end of the gate-road, and excavating a "side of work," which forms a rectangular cavity, say about 90 yards long by 50 yards wide, or about an acre, the whole of the coal being taken away as far as practicable, excepting the pillars of coal (generally 10 yards square and 10 yards distant from each other) which are left to support the superincumbent strata.

The air descending the downcast pit, and travelling along the gate-road into the workings, ascends to the air-head, and traversing that, ascends the upcast pit, carrying with it the gas and impure vapours, as far as such imperfect and interrupted means will effect, and delivering them into the open air.

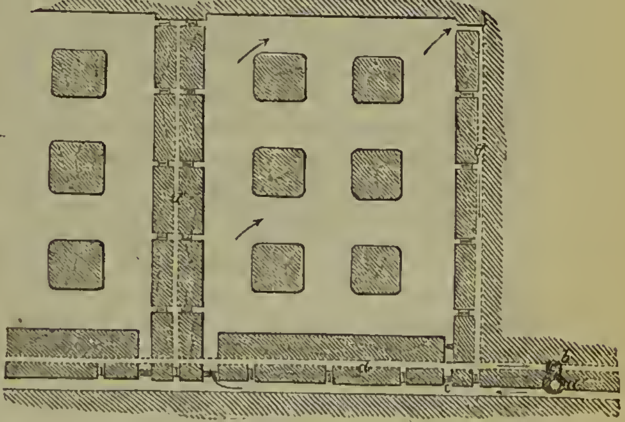
By this plan we ventilate the mine, until the lower 15 feet of the coal is excavated; but where the whole thickness of the coal above the air-head has been removed, by undergoing the coal from the bottom, and dropping it down in large masses, the upper portion of the cavity, being above the level of the air-head, forms a reservoir for gas, which gradually accumulates, and has no means of escape,— a reservoir of the capacity of some hundred thousand of cubic feet, which may be wholly or in part occupied by gas. An accidental change in the direction of the current of air would turn the course of the air along the air-head into this reservoir of gas, and from thence into the gate-road, and render an explosion very probable. After the coal is extracted, a solid wall or "rib" of coal, from 6 to 10 yards thick, which is commonly termed a "fire-rib," is left all round the chamber, separating it from the next workings; and the entrance from the gate-road is securely walled up, to exclude the air, and prevent spontaneous combustion, which would otherwise, in a short period, take place. When an explosion occurs, it is generally followed by a second, or more, as portions of the gas become successively charged with the due proportions of air; and the liability to these terrible explosions will always remain in mines thus worked, till, by some efficient means, the gas can be allowed a continuous escape, and a current of air can be ensured to move always in one direction, with sufficient power to overcome all extraneous disturbing forces, either of the wind or any atmospheric changes.

In *fig.* 1875 the system adopted and carried into operation by Benjamin Gibbons is shown. One pit *a*, is sunk, instead of two; and in the side of the shaft a smaller

1875



1876



shaft *b* is cut, to form an "air-chimney," and is afterwards separated from the main shaft; this air-chimney is circular, and may be made about three feet diameter inside, or more, as may be required. The air-chimney is bricked at the same time with the shaft,— the circular brickwork of each forming a partition of double thickness and secure strength, from the two arches abutting against each other.

The gate-road *c*, is driven from the shaft at the bottom of the coal, as in the ordinary plan; but the air-head *d* is driven from the air-chimney within 2 feet of the top of the coal, or higher if practicable, and runs into the vertical air-chimney. The gate road and air-head are carried forward in a parallel direction to the extent of the work, as before described in the ordinary system; and "spouts" or openings, *e*, are driven upwards to connect them, at about every 15 yards — every spout being bricked up close, in succession, when a fresh one is made in advance, so as to make the current of air traverse the whole extent of the gate-road before it rises up to the air-head and passes away to the air-chimney. These spouts can only be driven perpendicularly upwards from the gate-road to the air-head; and each of them being about 18 feet long in the 30 feet coal, a formidable practical difficulty was experienced by the author in the King's Swinford pits, where the coal being contiguous to a great fault, it abounded in gas to so great a degree, that when a spout was carried up a very few feet, it became so filled with gas that no man could work in it. But this difficulty was overcome by boring upwards from the spout a hole, 4 inches in diameter, into the air-head; the gas then passed off instantly, followed by a stream of air sufficient to ventilate the gate-road, and to enable the men to work with candles in the spout with perfect safety.

The excavation of the coal is commenced in the same manner as in the ordinary system, by driving at right angles from the end of the gate-road, to begin a "side of work;" and the ventilation is carried on completely and continuously from the extremity of the working, whilst the whole of the coal to the top is removed. The whole of the gas is constantly drained off from the upper surface of the coal by the air-head, and the numerous spouts or cross drains, which remain all open to the air-head, by means of a small pipe-hole left in the stopping as they are successively stopped, and which constantly drain off the gas most effectually, by piercing through and cutting the horizontal layers of coal, and thus tapping the several strata at so many different points. By this system the danger of any accumulation of gas in the cavities of the upper part of the workings is effectually prevented.

In the ordinary system of ventilation, it is manifest that only a very slight determining power compels the air to travel constantly in the same direction. Its current is, at all times, weak and insufficient, and liable to be deranged by the action of the wind, or atmospheric changes; and it is under no command whatever. To ensure safety a constant current of air is indispensably necessary; it should be a current, too, maintained by natural causes, as far as possible, and never interrupted, for the reasons already assigned; and should be one that would not vary or fail.

To effect this, the ascending column of air must be rendered specifically lighter than the air of the descending column, which circulates through the workings; and this difference of specific gravity must be maintained constantly free from disturbance by accidental causes, and to such an extent as to produce under all circumstances a total amount of propelling power that is found sufficient for the complete ventilation of the mine. This is accomplished by conducting the whole of the gas in a continuous ascending column, free from interruption or disturbance, up the separate air-chimney; and this ascending power is further increased by erecting a ventilating chimney (shown by dots in the vertical section), of a sufficient height, on the surface of the ground, into the base of which the air-chimney is continued so as to form one uninterrupted air flue, from the top of the ventilating chimney down to the air-head in the seam of coal. By this means a long experience has shown that a constant draught is established and secured, with the occasional aids of a small furnace or steam jet, which is amply sufficient, in all ordinary cases, to defy wind and weather, and also to produce a current sufficiently strong that it may be split, and such portions withdrawn from the main stream of air as may be found requisite to carry on the preparatory work to maintain the get of coal.

The air in the gate-road and workings is warmed above the temperature of the air on the surface, in ordinary mean temperatures, by the heat of the earth, and is consequently rarefied; this is aided much more than would be generally supposed, by the heat proceeding from the numerous workmen, horses, and candles, employed in the mine; and the current is further increased by the escape of the gases, which are specifically lighter than the air,— the air-head forming, with the air-chimney, an uninterrupted and continuous passage from the workings, and delivering the gas into the ventilating chimney: thus a draught is constantly maintained sufficient for all usual purposes.

Ventilation is nowhere exhibited to such advantage as in the coal mines of Northumberland and Durham, where they have carried well nigh to systematic perfection the plan of coursing the air through the winding galleries, originally contrived about the year 1760 by Mr. James Spedding, of Workington, the ablest pitman of his day*; who was also the inventor of the flint wheel formerly used to give light

* Mining engineers use the term *good pitman*, as admirals do *good seaman*, to denote a proficient in his calling.

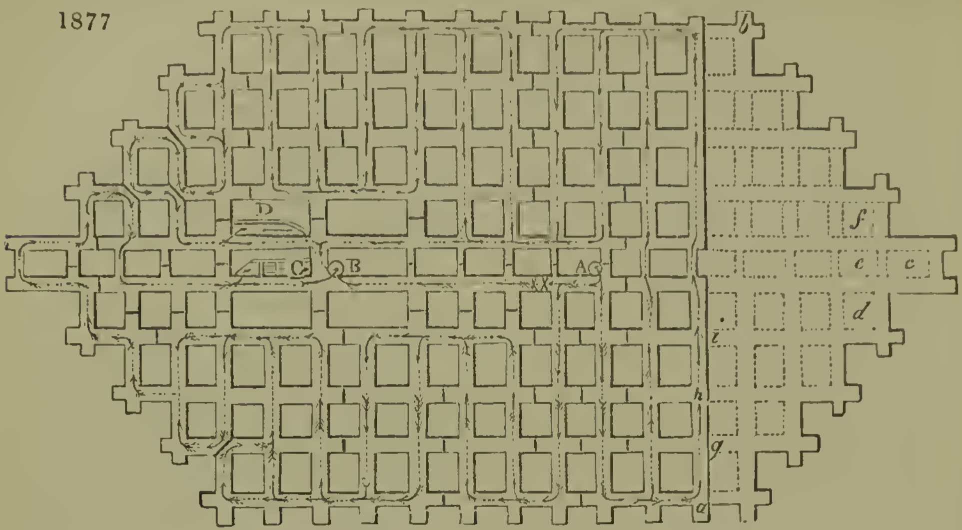
to the miner when working in dangerous situations. He converted the whole of the passages into air-pipes, so to speak, drew the current of air from the downcast pit, then traversed it up and down, and round about, through the several sheaths of the workings, so that no particular gallery was left without a current of air. There is in every coal mine an experienced corps, called wastemen, because they travel over the waste, or the exhausted regions, who can tell at once, by the whistling sound which the air makes at the crevices in certain partitions and doors, whether the ventilation be in good condition or not. They hear these stoppings begin to *sing* or *call*, as they say, whenever an interruption takes place in any point of the labyrinthan line. Another indication of something being wrong, is when the doors get so heavy that the boys in attendance upon them find them difficult to shut or open. The instant such a defect is discovered by any one, he cries aloud, "Halloa, there is something wrong—the doors are calling!"

In Mr. Spedding's system the whole of the return air came in one current to his rarefying furnace (see letter C, *fig.* 1877), whether it was at the explosive point or not. This distribution was often fraught with such danger, that a torrent of water had to be kept in readiness, under the name of the waterfall, to be let down to extinguish the fire in a moment. Many explosions at that time occurred, from the furnaces below, and also down through tubes from the furnaces above ground.

About the year 1807 Mr. Buddle had his attention intensely occupied with this most important object, and then devised his plan of a divided current, carrying that portion of the air which, descending in the downcast pit A, coursed through the *clean* workings, through the active furnace C, *fig.* 1877, and the portion of the air from the *foul* workings up the dumb furnace D, till it reached a certain elevation in B, the upcast pit, above the fireplace. The pitmen had a great aversion, however, at first to adopt this plan, as they thought that the current of air by being split would lose its ventilating power; but they were ere long convinced by Mr. Buddle to the contrary. He divided the main current into two separate streams, at the bottom of the pit A, as shown by darts in the figure; the feathered ones representing that part of the pit in which the course of the current of air is free from explosive mixture, or does not contain above one-thirtieth of carburetted hydrogen, as indicated by its effect upon the flame of a candle. The naked darts denote the portions of the mine where the air, being charged to the firing point, is led off towards D, the dumb furnace, which communicates with the hot upcast shaft, out of reach of the flame, and thence derives its power of draught. By suitable alterations in the stoppings (see the various transverse lines, and the crosses) any portion of the workings may, by the agency of the furnace, be laid out of, or brought within, the course of the vitiated current, at the pleasure of the skilful mine-viewer; so that, if he found it necessary, he could confine, by proper arrangements of his furnace, all the vitiated current to a mere gas-pipe or drift, and direct it wholly through the dumb furnace. During a practice of twenty years Mr. Buddle had not met with any accident in consequence of a defect in the stoppings preventing the complete division of the air. The engineer has it thus within his power to detach or insulate those portions of the mine in which there is a great exudation of gas, from the rest; and, indeed, he is continually making changes, borrowing and lending currents, so to speak; sometimes laying one division or panel upon the one air-course, and sometimes upon the other, just to suit the immediate emergency. As soon as any district has ceased to be dangerous, by the exhaustion of the gas-blowers, it is transferred from the foul to the pure air-course, where gunpowder may be safely used, as also candles, instead of Davy's lamps, which give less light.

Till the cutting out of the pillars commences (see the right end of the diagram), the ventilation of the several passages, boards, &c., may be kept perfect, supposing the working extending no further than *a* or *b*; because, as long as there are pillars standing, every passage may be converted into an air-conduit, for leading a current of air in any direction, either to C, the burning, or D, the dumb furnace. But the first pillar that is removed deranges the ventilation at that spot, and takes away the means of carrying the air into the further recess towards *c*. In taking out the pillars, the miners always work to windward, that is to say, against the stream of air; so that whatever gas may be evolved shall be immediately carried off from the people at work. When a range of pillars has been removed, as at *d*, *e*, *f*, no power remains of dislodging the gas from the section of the mine beyond *a*, *b*; and as the pillars are successively cut away to the left hand of the line *a*, *b*, the size of the *goaf*, or void, is increased. This vacuity, or *goaf*, is a true gas-holder, or reservoir, continually discharging itself at the points *g*, *h*, *i*, into the circulating current, to be carried off by the gas-pipe drift at the dumb furnace, but not to be suffered ever to come in contact with flame of any description. The next range of working is the line of pillars to the left of *a*, *b*; the coal having been entirely cleared out of the space to the right, where the place of the pillars is marked by dotted lines. The roof in the waste soon falls down, and gets fractured up to the next seam of coal, which, abound-

1877



ing in gas, sends it down in large quantities, and keeps the goaf below continually replenished.

Description of the Ventilating Fan at the Abercarn Collieries.—The mode of ventilation that is still generally used in the collieries of this country is the old furnace ventilation, where the required current of air through the mine is maintained by the rarefaction of the column of air in the ascending shaft, by means of a large fire kept constantly burning at the bottom of the shaft. In Belgium and France, on the contrary, this plan is almost superseded by the use of machinery to maintain the current of air; as the furnace ventilation, although possessing the important advantages of great simplicity and freedom from liability to derangement from disturbing causes, has some serious objections and deficiencies, and in some cases becomes so imperfect a provision for ventilation as to render a better system highly desirable and even necessary.

Mr. E. Rogers having occasion to ventilate the workings in some extensive and very fiery coal seams recently won at Abercarn in South Wales, under circumstances where the furnace ventilation could not be applied, after carefully collecting every accessible information as to the ventilating machines used in Great Britain and on the Continent, came to the conclusion that a plan of machine proposed for the purpose some years since by Mr. James Nasmyth would be the most suitable and effective. After consultation with Mr. Nasmyth, it was resolved to test the principle and plan by actual practice; and the ventilating fan described was made at Patricroft by Mr. Nasmyth, and is erected at the Abercarn Collieries.

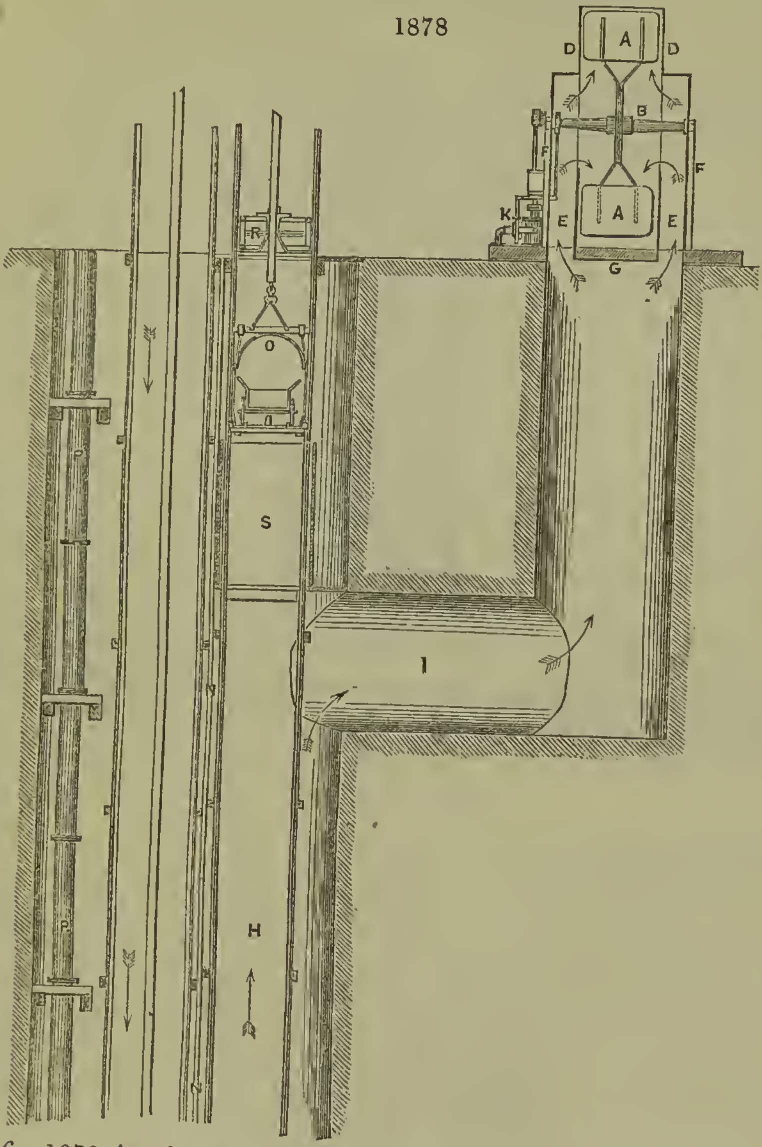
The general arrangements of the top of the shaft and the ventilating fan are shown in *figs.* 1878 and 1879. *Fig.* 1880 is a side elevation of the fan and engine, to a larger scale; and *fig.* 1879 a vertical section of the fan.

The fan A A, *fig.* 1879, is 13½ feet diameter, with 8 vanes, each 3 feet 6 inches wide and 3 feet long. It is fixed on a horizontal shaft B, 8 feet 7 inches in length from centre to centre of the bearings, which are 9 inches long by 4½ inches diameter. The vanes are of thin plate iron, and carried by forked wrought-iron arms secured to a centre disc, C, fixed upon the shaft B. The fan works within a casing, D D, consisting of two fixed sides of thin wrought plate, entirely open round the circumference and connected together by stay rods; the sides are 3 inches clear from the edges of the vanes, and have a circular opening 6 feet diameter in the centre of each, from which rectangular wrought-iron trunks, E E, are carried down for the entrance of the air, the bearings for the fan shaft B being fixed in the outer sides of these trunks, which are strengthened for the purpose by vertical cast-iron standards F bolted to them and resting upon the bottom foundation stone G.

The two air trunks E E join together below the fan, as shown in *fig.* 1878, and communicate with the pit H by means of a horizontal tunnel I, which enters the pit at 21 feet depth from the top.

The fan is driven by a small direct-acting non-condensing engine K, which is fixed upon the face of one of the vertical cast-iron standards F, and is connected to a crank on the end of the fan shaft B. The steam cylinder is 12 inches diameter and 12 inches stroke, and is worked by steam from the boilers of the winding engine of the pit, at a pressure of about 13 lbs. per square inch. The eccentric L for the slide valve is placed just inside the air trunk E, and works the valve through a short weigh shaft M with a lever on the outside.

1878

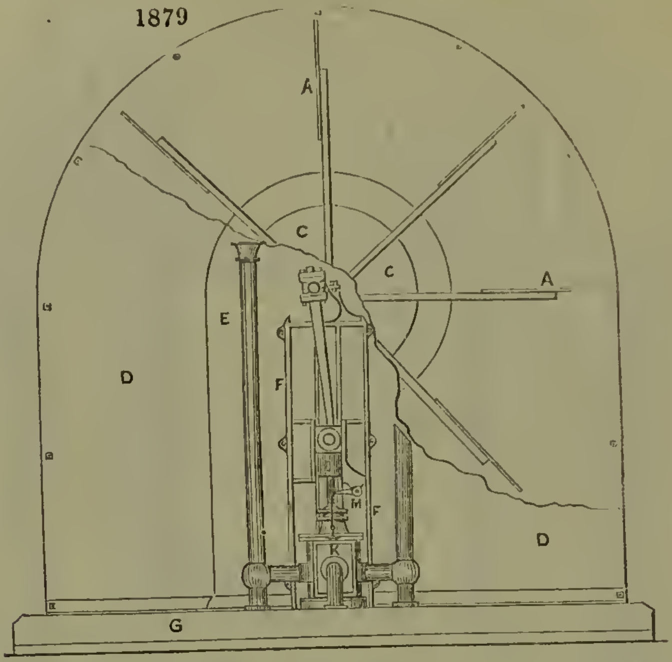


The pit H, *fig.* 1878, is of an oval form, 10 feet by 18 feet, and divided near the centre by a timber brattice N, the one side forming the upcast shaft and the other the downcast. Both of these are used for winding, and the cages O, in which the trucks, &c., are brought up, work between guides fixed to the timbering of the pit. The pumps P are placed in the downcast shaft.

In order to allow of the upcast shaft being used for winding, the top is closed by an air valve R, which is formed by simply boarding up the underside of the ordinary guard upon the mouth of the shaft, leaving only the hole in the centre through which the chain works. This air valve R is carried up by the cage O on arriving at the top of the shaft, as in *fig.* 1878, and then drops down again flat upon the opening when the cage is again lowered. During the time that the valve is lifted, its place is occupied by the close bottom of the cage O, which nearly fills the rectangular opening left at the top of the shaft. By this simple means it is found practically that a complete provision is made for keeping the top of the upcast shaft closed, and maintaining a uniform current of air up the shaft; for the leakage of air downwards through the top whilst the cage is in the act of opening or closing the air valve, and through the small area that always remains open, is found to be quite immaterial, and the surplus ventilating power of the fan is amply sufficient to provide against it.

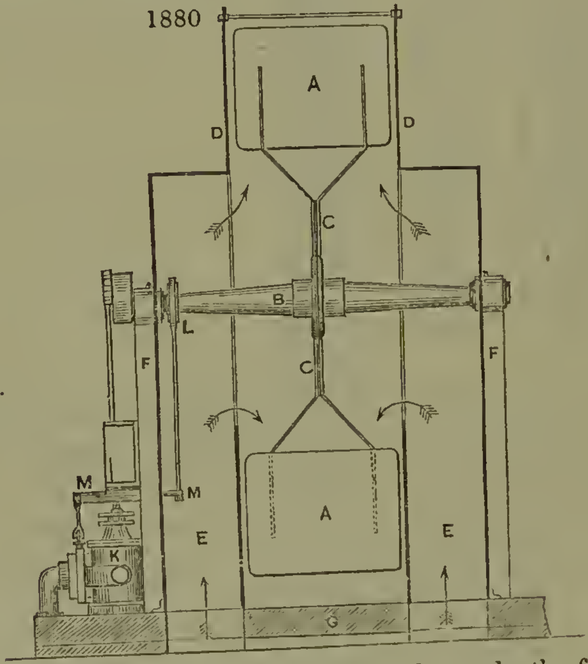
In the original construction a more perfect air valve was supposed to be requisite, and was provided by the inclined flaps S S, which are fixed just above the horizontal tunnel I. These are fitted closely together, leaving only a small opening in the centre for the chain to pass through, and were intended to be opened by the ascending cage coming in contact with them, closing again directly by means of balance weights before the air valve R at the top of the shaft was opened, so as to preserve a thorough closing of the top of the shaft. The flaps were to be opened again by a lever from

1879



the top to allow the cage to descend. However, it was found on trial that the valve R at the top was amply sufficient; and consequently, although the other valves were also provided, they have never been put into use.

1880



The total depth of the pit is nearly 300 yards, and at a depth of 120 yards a split of air is taken off, and coursed through workings from which coal and fire-clay are got; the larger portion of the air descends to the bottom of the pit, and is there split into many courses, to work two separate seams of coal and a vein of ironstone. The total length of road laid with plates or rails in the workings is about 7 miles, and the working faces amount to nearly double that distance. The longest distance that is traversed by any single course or split of air in passing from the downcast to the upcast shaft is nearly 2 miles. The quantity of materials raised from the pit is about 500 tons daily.

The following table gives the results of a series of experiments made with this ventilating fan by Mr. R. S. Roper, showing that the quantity of air delivered at the velocities of 60 and 80 revolutions of the fan per minute is 45,000 and 56,000 cubic feet per minute, with a velocity of current of 782 and 1037 lineal feet per minute respectively, or about 9 and 12 miles per hour; and the degree of vacuum or exhaustion in the upcast shaft is ·5 and ·9 inch of water respectively.

The speed at which the ventilating fan is usually worked is about 60 revolutions per minute, giving a velocity at the circumference of the fan of 2545 feet per minute; 45,000 cubic feet of air per minute are then drawn through the mine, nearly one third of which ventilates the upper workings, and the rest passes through the lower workings.

In these experiments the mode adopted for ascertaining the velocity of the air currents was by calculation from the difference of pressure, as observed by means of a carefully constructed vacuum gauge, the result being checked by the anemometer and by the time of passage of the smoke of powder fired at fixed distances by means of wires from a voltaic battery at the top of the shaft.

VENUS is the mythological name of copper.

VERANTINE. See MADDER.

VERATRINE. $C^{61}H^{52}N^{2}O^{16}$. An alkaloid contained in white hellebore (*Veratrum album*), and in cevadilla (*Veratrum sabadilla*). It is exceedingly poisonous, and if introduced into the nostrils excites violent and prolonged sneezing. In the form of ointment it has been found a valuable remedy in neuralgic disorders.—C. G. W.

VERDIGRIS. (*Vert-de-gris*, Fr.; *Grünspan*, Germ.) The copper used in this manufacture is formed into round sheets, from 20 to 25 inches diameter, by one twenty-fourth of an inch in thickness. Each sheet is then divided into oblong squares, from 4 to 6 inches in length, by 3 broad; and weighing about 4 ounces. They are separately beaten upon an anvil, to smooth their surfaces, to consolidate the metal, and to free it from scales. The refuse of the grapes, after the extraction of their juice, formerly thrown on to the dunghill, is now preserved for the purpose of making verdigris. It is put loosely into earthen vessels, which are usually 16 inches high, 14 in diameter at the widest part, and about 12 at the mouth. The vessels are then covered with lids, which are surrounded by straw mats. In this situation the materials soon become heated, and exhale an acid odour; the fermentation beginning at the bottom of the cask, and gradually rising till it actuates the whole mass. At the end of two or three days the manufacturer removes the fermenting materials into other vessels, in order to check the process, lest putrefaction should ensue. The copper plates, if new, are now prepared, by rubbing them over with a linen cloth dipped in a solution of verdigris; and they are laid up alongside of one another to dry. If the plates are not subjected to this kind of preparation they will become black, instead of green, by the first operation. When the plates are ready, and the materials in a fermenting state, one of them is put into the earthen vessel for 24 hours, in order to ascertain whether it be a proper period to proceed to the remaining part of the process. If, at the end of this period, the plate be covered with an uniform green layer, concealing the whole copper, everything is right; but if, on the contrary, liquid drops hang on the surface of the metal, the workmen say the plates are *sweating*, and conclude that the heat of the fermented mass has been inadequate; on which account another day is allowed to pass before making a similar trial. When the materials are finally found to be ready, the strata are formed in the following manner. The plates are laid on a horizontal wooden grating, fixed in the middle of a vat, on whose bottom a pan full of burning charcoal is placed, which heats them to such a degree that the women who manage this work are obliged to lay hold of them frequently with a cloth when they lift them out. They are in this state put into earthen vessels, in alternate strata with the fermented materials, the uppermost and undermost layers being composed of the expressed grapes. The vessels are covered with their straw mats, and left at rest. From 30 to 40 pounds of copper are put into one vessel.

At the end of 10, 12, 15, or 20 days the vessels are opened to ascertain, by the materials having become white, if the operation be completed.

Detached glossy crystals will be perceived on the surface of the plates; in which case the grapes are thrown away, and the plates are placed upright in a corner of the verdigris cellar, one against the other, upon pieces of wood laid on the ground. At the end of two or three days they are moistened by dipping in a vessel of water, after which they are replaced in their former situation, where they remain seven or eight days, and are then subjected to momentary immersion, as before. This alternate moistening and exposure to air is performed six or eight times, at regular intervals of about a week. As these plates are sometimes dipped into damaged wine, the workmen term these immersions *one wine*, *two wines*, &c.

By this treatment the plates swell, become green, and covered with a stratum of verdigris, which is readily scraped off with a knife. At each operation every vessel yields from five to six pounds of verdigris, in a *fresh* or *humid* state; which is sold to wholesale dealers, who dry it for exportation. For this purpose they knead the paste in wooden troughs, and then transfer it to leathern bags a foot and a half long, and ten inches in diameter. These bags are exposed to the sun and air till the verdigris has attained a sufficient degree of hardness. It loses about half its weight in this operation; and it is said to be knife-proof when this instrument, plunged through the leathern bag, cannot penetrate the loaf of verdigris.

The manufacture of verdigris at Montpellier is altogether domestic. In most wine farm-houses there is a verdigris cellar; and its principal operations are conducted by the females of the family. They consider the forming the strata, and scraping off the verdigris, the most troublesome part. Chaptal says that this mode of making verdigris would admit of some improvements: for example, the acetification requires a warmer temperature than what usually arises in the earthen vessels; and the plates, when set aside to generate the coat of verdigris, require a different degree of heat and moisture from that requisite for the other operations.

Verdigris is a mixture of the crystallised acetate of copper and the sub-acetate, in varying proportions. According to Vauquelin's researches, there are three compounds of oxide of copper and acetic acid; 1, a subacetate, insoluble in water, but decomposing in that fluid, at common temperatures changing into peroxide and acetate; 2, a neutral acetate, the solution of which is not altered at common temperatures, but is decomposed by ebullition, becoming peroxide and superacetate; and, 3, superacetate, which in solution is not decomposed, either at common temperatures or at the boiling point; and which cannot be obtained in crystals, except by slow spontaneous evaporation, in air or *in vacuo*. The first salt, in the dry state, contains 66·51 of oxide; the second, 44·44; and the third, 33·34.

Mr. Phillips has given the following analyses of French and English verdigris; *Annals of Philosophy*, No. 21 :—

	French Verdigris.	English Verdigris.
Acetic acid	29·3	29·62
Peroxide of copper	43·5	44·25
Water	25·2	25·51
Impurity	2·0	0·62
	100·0	100·00

Distilled verdigris, as it was long erroneously called, is merely a *binacetate* or superacetate of copper, made by dissolving, in a copper kettle, one part of verdigris in two of distilled vinegar; aiding the mutual action by slight heat and agitation with a wooden spatula. When the liquor has taken its utmost depth of colour, it is allowed to settle, and the clear portion is decanted off into well glazed earthen vessels. Fresh vinegar is poured on the residuum, and if its colour does not become deep enough, more verdigris is added. The clear and saturated solution is then slowly evaporated, in a vessel kept uniformly filled, till it acquires the consistence of syrup, and shows a pellicle on its surface; when it is transferred into glazed earthen pans, called *oulas* in the country. In each of these dishes two or three sticks are placed, about a foot long, cleft till within two inches of their upper end, and having the base of the cleft kept asunder by a bit of wood. This kind of pyramid is supended by its summit in the liquid. All these vessels are transported into crystallising rooms, moderately heated with a stove, and left in the same state for 15 days, taking care to maintain an uniform temperature. Thus are obtained very fine groups of crystals of acetate of copper, clustered round the wooden rods; on which they are dried, taken off, and sent into the market. They are distinctly rhomboidal in form, and of a lively deep blue colour. Each cluster of crystals weighs from five to six pounds; and, in general, their total weight is equal to about one-third of the verdigris employed.

The crystallised binacetate of commerce consists, by my analysis, of—acetic acid, 52; oxide of copper, 39·6; water, 8·4, in 100.

VERDITER, or BREMEN GREEN. This pigment is a light powder, like magnesia, having a blue or bluish-green colour. The first is most esteemed. When worked up with oil or glue, it resists the air very well; but when touched with lime, it is easily affected, provided it has not been long and carefully dried. A strong heat deprives it of its lustre, and gives it a brown or blackish-green tint.

The following is, according to M. J. G. Gentele, the process of fabrication in Bremen, Cassel, Eisenach, Minden, &c.:—

a. 225 lbs. of sea salt, and 222 lbs. of blue vitriol, both free from iron, are mixed in the dry state, then reduced between mill-stones with water to a thick homogeneous paste.

b. 225 lbs. of plates of old copper are cut by scissors into bits of an inch square, then thrown and agitated in a wooden tub containing 2 lbs. of sulphuric acid, diluted with a sufficient quantity of water, for the purpose of separating the impurities; they are afterwards washed with pure water in casks made to revolve upon their axis.

c. The bits of copper being placed in oxidation-chests, along with the magma of common salt and blue vitriol previously prepared in strata of half an inch thick, they are left for some time to their mutual reaction. The above chests are made of oaken planks joined without iron nails, and set aside in a cellar, or other place of moderate temperature.

The saline mixture, which is partially converted into sulphate of soda and chloride of copper, absorbs oxygen from the air, whereby the metallic copper passes into a hydrated oxide, with a rapidity proportioned to the extent of the surfaces exposed to the atmosphere. In order to increase this exposure, during the three months that the process requires, the whole mass must be turned over once every week, with a copper shovel, transferring it into an empty chest alongside, and then back into the former one.

At the end of three months the corroded copper scales must be picked out, and the saline particles separated from the slimy oxide with the help of as little water as possible.

d. This oxidised *schalm* or mud is filtered, then thrown by means of a bucket containing 30 pounds, in a tub, where it is carefully divided or comminuted.

e. For every six pailfuls of *schalm* thus thrown into the large tub, 12 pounds of muriatic acid, at 15° Baumé, are to be added; the mixture is to be stirred, and then left at rest for twenty-four or thirty-six hours.

f. Into another tub, called the blue back, there is to be introduced, in like manner, for every six pailfuls of the acidified *schalm*, fifteen similar pailfuls of a solution of colourless clear caustic alkali, at 19° Baumé.

g. When the back (*e*) has remained long enough at rest, there is to be poured into it a pailful of pure water for every pailful of *schalm.*

h. When all is thus prepared, the set of workmen who are to empty the back (*e*), and those who are to stir (*f*), must be placed alongside of each. The first set transfer the *schalm* rapidly into the latter back; where the second set mix and agitate it all the time requisite to convert the mass into a consistent state, and then leave it at rest from thirty-six to forty-eight hours.

The whole mass is to be now washed; with which view it is to be stirred about with the affusion of water, allowed to settle, and the supernatant liquor is drawn off. This process is to be repeated till no more traces of potash remain among the blue. The deposit must be then thrown upon a filter, where it is to be kept moist, and exposed freely to the air. The pigment is now squeezed in the filter-bags, cut into bits, and dried in the atmosphere, or at a temperature not exceeding 78° Fahr. It is only after the most complete desiccation that the colour acquires its greatest lustre.

VERDITER, BLUE. This is a precipitate of oxide of copper with lime, made by adding that earth, in its purest state, to the solution of nitrate of copper, obtained in quantities by the refiners, in parting gold and silver from copper by nitric acid. The cupreous precipitate must be triturated with lime, after it is nearly dry, to bring out the fine velvety blue colour. The process is delicate, and readily misgives in unskilful hands.

The *cendres bleues en pâte* of the French, though analogous, are in some respects a different preparation. To make it, dissolve sulphate of copper in hot water, in such proportions that the liquid may have a density of 1·3. Take 240 pound measures of this solution, and divide it equally into four open-headed casks; add to each of these

45 pound measures of a boiling-hot solution of muriate of lime, of spec. grav. 1·317, whereby a double decomposition will ensue, with the formation of muriate of copper and sulphate of lime, which precipitates. It is of consequence to work the materials well together at the moment of mixture, to prevent the precipitate agglomerating in unequal masses. After leaving it to settle for twelve hours, a small quantity of the clear liquor may be examined, to see whether the just proportions of the two salts have been employed, which is done by adding either sulphate of copper or muriate of lime. Should either cause much precipitation, some of the other must be poured in till the equivalent decomposition be accomplished; though less harm results from an excess of sulphate of copper than of muriate of lime.

The muriate of copper is to be decanted from the subsided gypsum, which must be drained and washed in a filter; and these blue liquors are to be added to the stronger; and the whole distributed as before, into four casks; composing in all 670 pound measures of a green liquor, of 1·151 spec. grav.

Meanwhile, a magma of lime is to be prepared as follows: — 100 pounds of quicklime are to be mixed up with 300 pounds of water, and the mixture is to be passed through a wire-gauze sieve, to separate the stony and sandy particles, and then to be ground in a proper mill to an impalpable paste. About 70 or 80 pounds of this mixture (the beauty of the colour is inversely as the quantity of lime) are to be distributed in equal portions between the four casks, strongly stirring all the time with a wooden spatula. It is then left to settle, and the limpid liquor is tested by ammonia, which ought to occasion only a faint blue tinge; but if the colour be deep blue, more of the lime paste must be added. The precipitate is now to be washed by decantation, employing for this purpose the weak washings of a former operation; and it is lastly to be drained and washed on a cloth filter. The proportions of material prescribed above furnish from 500 to 540 pounds of green paste.

Before making further use of this paste, the quantity of water present in it must be determined by drying 100 or 200 grains. If it contain 27 per cent. of dry matter, 12 pounds of it may be put into a wooden bucket (and more or less in the ratio of 12 to 27 per cent.) capable of containing 17½ pints; a pound (measure) of the lime paste is then to be rapidly mixed into it; immediately afterwards, a pint and a quarter of a watery solution of the pearlash of commerce, of spec. grav. 1·114, previously prepared; and the whole mixture is to be well stirred, and immediately transferred to a colour-mill. The quicker this is done, the more beautiful is the shade.

On the other hand two solutions must have been previously made ready, one of sal-ammoniac (4 oz. troy dissolved in 3½ pints of water), and another of sulphate of copper (8 oz. troy dissolved in 3½ pints of water).

When the paste has come entirely through the mill, it is to be quickly put into a jar, and the two preceding solutions are to be simultaneously poured into it, when a cork is to be inserted, and the jar is to be powerfully agitated. The cork must now be secured with a fat lute. At the end of four days this jar and three of its fellows are to be emptied into a large hogshead nearly full of clear water, and stirred well with a paddle. After repose, the supernatant liquid is run off, when it is filled up again with water, and elutriated several times in succession, till the liquid no longer tinges turmeric paper brown. The deposit may be then drained on a cloth filter. The pigment is sold in the state of a paste; and is used for painting, or printing paper-hangings for the walls of apartments.

The above prescribed proportions furnish the superfine blue paste: for the second quality, one-half more quicklime paste is used; and for the third, double of the lime and sal-ammoniac; but the mode of preparation is in every case the same.

This paste may be dried into a blue powder, or into crayons for painters, by exposing it on white deals to a very gentle heat in a shady place. This is called *cendres bleues en pierre.*

VERJUICE. (*Verjus*, Fr.; *Agrest*, Germ.) A harsh kind of vinegar, containing much malic acid, made from the expressed juice of the wild crab apple.

VERMICELLI, a paste of wheat flour, drawn out and dried in slender cylinders, more or less tortuous, like worms — whence the Italian name. The flour of southern countries is best suited for its manufacture.

It may be made economically by the following prescription: —

Vermicelli, or Naples, flour - - - - -	21 lbs.
White potato flour - - - - - -	14
Boiling water - - - - - - -	12
Total - - - - -	47 lbs.

Affording 45 lbs. of dough, and 30 of dry vermicelli. With gluten, made from common flour, the proportions are: —

Flour as above	- - - - - -	30 lbs.
Fresh gluten	- - - - - -	10
Water	- - - - - - - -	7
Total	- - - -	47 lbs.

Affording 30 lbs. of dry vermicelli.

VERMILION, or *Cinnabar*, is a compound of mercury and sulphur in the proportion of 100 parts of the former to 16 of the latter, which occurs in nature as a common ore of quicksilver, and is prepared by the chemist as a pigment, under the name of Vermilion. It is, properly speaking, a bisulphide of mercury. This artificial compound being extensively employed, on account of the beauty of its colour, in painting, for making red sealing-wax, and other purposes, is the object of an important manufacture. When vermilion is prepared by means of sublimation, it concretes in masses of considerable thickness, concave on one side, convex on the other, of a needle-form texture; brownish-red in the lump, but when reduced to powder of a lively red colour. On exposure to a moderate heat, it evaporates without leaving a residuum, if it be not contaminated with red lead; and at a higher heat, it takes fire, and burns entirely away, with a blue flame.

Holland long kept a monopoly of the manufacture of vermilion, from being alone in possession of the art of giving it a fine flame colour. Meanwhile the French chemists examined this product with great care, under an idea that the failure of other nations to rival the Dutch arose from ignorance of its true composition; some, with Berthollet, imagined that it contained a little hydrogen; and others, with Fourcroy, believed that the mercury contained in it was oxidised; but eventually Seguin proved that both of these opinions were erroneous; having ascertained, on the one hand, that no hydrogenous matter was given out in the decomposition of cinnabar, and on the other that sulphur and mercury, by combining, were transformed into the red sulphide in close vessels, without the access of any oxygen whatever. It was likewise supposed that the solution of the problem might be found in the difference of composition between the red and black sulphides of mercury; and many conjectures were made with this view, the whole of which were refuted by Seguin. He demonstrated that a mere change of temperature was sufficient to convert the one sulphide into the other, without occasioning any variation in the proportion of the two elements. Cinnabar, moderately heated in a glass tube, is convertible into Ethiops, which in its turn is changed into cinnabar by exposing the tube to a higher temperature; and thence he was led to conclude that the difference between these two sulphides was owing principally to the state of the combination of the constituents. It would seem to result from all these researches, that cinnabar is only an intimate compound of pure sulphur and mercury, in the proportions pointed out by analysis; and it is therefore reasonable to conclude, that in order to make fine vermilion, it should be sufficient to effect the union of its elements at a high enough temperature, and to exclude the influence of all foreign matters; but, notwithstanding these discoveries, the art of making good vermilion is nearly as much a mystery as ever.

The English vermilion is now most highly prized by the French manufacturers of sealing-wax.

M. Tuckert, apothecary of the Dutch court, published, long ago, in the *Annales de Chimie*, vol. iv., the best account we yet have of the manufacture of vermilion in Holland; one which has been since verified by M. Payssé, who saw the process practised on the great scale with success.

"The establishment in which I saw, several times, the fabrication of sublimed sulphuret of mercury," says M. Tuckert, "was that of Mr. Braud, at Amsterdam, beyond the gate of Utrecht; it is one of the most considerable in Holland, producing annually, from three furnaces, by means of four workmen, 48,000 lbs. of cinnabar, besides other mercurial preparations. The following process is pursued here: —

"The Ethiops is first prepared by mixing together 150 lbs. of sulphur with 1080 lbs. of pure mercury, and exposing this mixture to a moderate heat in a flat polished iron pot, 1 foot deep, and 2½ feet in diameter. It never takes fire provided the workman understands his business. The black sulphuret, thus prepared, is ground, to facilitate the filling with it of small earthen bottles capable of holding about 24 ounces of water; from 30 to 40 of which bottles are filled beforehand, to be ready when wanted.

"Three great subliming pots or vessels, made of very pure clay and sand, have been previously coated over with a proper lute, and allowed to dry slowly. These pots are set upon three furnaces bound with iron hoops, and they are covered with a kind of iron dome. The furnaces are constructed so that the flame may freely circulate and play upon the pots, over two-thirds of their height.

"The subliming vessels having been set in their places, a moderate fire is kindled in the evening, which is gradually augmented till the pots become red. A bottle of the black sulphuret is then poured into the first of the series, next into the second and third, in succession; but eventually, two, three, or even more, bottles may be emptied in at once; this circumstance depends on the stronger or weaker combustion of the sulphuret of mercury thus projected. After its introduction, the flame rises 4 and sometimes 6 feet high; when it has diminished a little, the vessels are covered with a plate of iron, a foot square and an inch and half thick, made to fit perfectly close. In this manner the whole materials which have been prepared are introduced, in the course of 34 hours, into the three pots; being for each pot 360 pounds of mercury, and 50 of sulphur; in all 410 pounds."

The degree of firing is judged of, from time to time, by lifting off the cover; for if the flame rise several feet above the mouth of the pot, the heat is too great; if it be hardly visible the heat is too low; the proper criterion being a vigorous flame playing a few inches above the vessel. In the last of the 36 hours' process, the mass should be dexterously stirred up every 15 or 20 minutes, to quicken the sublimation. The subliming pots are then allowed to cool, and broken to pieces in order to collect all the vermilion encrusted within them; and which usually amounts to 400 lbs., being a loss of only 60 on each vessel. The lumps are to be ground along with water between horizontal stones, elutriated, passed through sieves and dried.

The humid process of Kirchoff has of late years been so much improved, as to furnish a vermilion quite equal in brilliancy to the Chinese. The following process has been recommended:—Mercury is triturated for several hours with sulphur, in the cold, till a perfect ethiops is formed; potash lye is then added, and the trituration is continued for some time. The mixture is now heated in iron vessels, with constant stirring at first, but afterwards only from time to time. The temperature must be kept up as steadily as possible at 130° Fahr., adding fresh supplies of water as it evaporates. When the mixture, which was black, becomes, at the end of some hours, brown-red, the greatest caution is requisite to prevent the temperature from being raised above 114°, and to preserve the mixture quite liquid, while the compound of sulphur and mercury should always be pulverulent. The colour becomes red, and brightens in its hue, often with surprising rapidity. When the tint is nearly fine, the process should be continued at a gentler heat, during some hours. Finally, the vermilion is to be elutriated, in order to separate any particles of running mercury. The three ingredients should be very pure. The proportion of product varies with that of the constituents, as we see from the following results of experiments, in which 300 parts of mercury were always employed, and from 400 to 450 of water:—

Sulphur.	Potash.	Vermilion obtained.
114	75	330
115	75	331
120	120	321
150	152	382
120	180	245
100	180	244
60	180	142

VINE BLACK. A black procured by charring the tendrils of the vine and levigating them.

VINE DISEASE. *Oidium Tuckeri.* See WINES.

VINEGAR. See ACETIC ACID. The gross revenue derived from vinegar manufactured in England in the year 1845, amounted to 284,317*l.*, yielding a net revenue of 57,182*l.* The gross revenue from vinegar manufactured in the United Kingdom, in the same year, amounted to 311,611*l.*, producing a net revenue of 62,936*l.*

Our *importation* of vinegar in the year 1856 was as follows:—

From	In British vessels.	In Foreign vessels.	Total.	Retained for home consumption.	Computed value at 1s.3d. per gall.
	Galls.	Galls.	Galls.	Galls.	£
Hanover	201	955	1,156	579	72
Hans Towns	77	280	357	243	22
Holland	3,675	676	4,351	3,240	272
France	21,647	4,638	26,285	19,482	1,642
Portugal	240	1	241	1,067	15
Spain	197	39	236	1,180	15
Other parts	2,239	651	2,890	2,653	181
	28,276	7,240	35,516	28,444	£2,219

Our *exportation* of vinegar of British manufacture in the same year was 1230 tuns, at the *declared value* of 28,465*l.*; and of foreign vinegar, 8,216 gallons; computed real value, 515*l.*

VIOLET DYE is produced by a mixture of red and blue colouring-matters which are applied in succession. Silk is dyed a fugitive violet with either archil or brazil wood; but a fine fast violet, first by a crimson with cochineal, without tartar or tin mordant, and, after washing, it is dipped in the indigo vat. A finish is sometimes given with archil. A violet is also given to silk, by passing it through a solution of verdigris, then through a bath of logwood, and, lastly, through alum water. A more beautiful violet may be communicated by passing the alumed silk through a bath of brazil wood, and, after washing it in the river, through a bath of archil.

To produce violets on printed calicoes, a dilute acetate of iron is the mordant, and the dye is madder. The mordanted goods should be well dunged.

A good process for dyeing cottons violet, is — first, to gall, with 18 or 20 pounds of nutgalls for every 100 pounds of cotton; second, to pass the stuff, still hot, through a mordant composed of — alum, 10 pounds; iron-liquor, at $1\frac{1}{2}°$ B., and sulphate of copper, each 5 or 6 pounds; water, from 24 to 28 gallons; working it well, with alternate steeping, squeezing, airing, dipping, squeezing, and washing; third, to madder, with its own weight of the root; and fourth, to brighten with soap. If soda be used at the end, instead of soap, the colour called *prune de monsieur* will be produced; and by varying the doses of the ingredients, a variety of violet tints may be given.

The best violets are produced by dyeing yarn or cloth which has been prepared with oil as for the Turkey-red process. See MADDER.

For the violet *pruneau*, a little nitrate of iron is mixed with the alum mordant, which makes a black; but this is changed into *violet pruneau* by a madder-bath, followed by a brightening with soap. See MUREXIDE, PURPLE.

VITRIFIABLE COLOURS. See ENAMELS, PASTES, POTTERY, and STAINED GLASS.

VITRIFIABLE PIGMENTS. The art of painting with vitrifiable pigments has not kept pace with the progress of science, and is far from having attained that degree of perfection of which it is capable. It still presents too many difficulties to prove a fertile field to the artist for his labours; and its products have, for this reason, never held that rank in art which is due to them from the indestructibility and brilliancy of the colours. The reason of this is attributable to the circumstance that the production of good vitrifiable pigments is mere chance work; and notwithstanding the numerous papers published on the subject, is still the secret of the few. The directions given in larger works and periodicals are very incomplete and indefinite; and even in the otherwise highly valuable *Traité des Arts Céramiques* of Brongniart, the chapter on the preparation of colours is far from satisfactory, and is certainly no frank communication of the experience gathered in the Royal Manufactory of Sèvres.

The branch of painting with vitrifiable pigments which has acquired its greatest development is the art of painting on porcelain. The glaze of hard felspar porcelain, owing to its difficult fusion, produces less alteration upon the tone of a colour of the easily fusible pigments than is the case in painting upon glass, enamel, fayence, &c. The colours for painting upon porcelain are all of them, *after* the firing, coloured lead-glasses throughout; but before this operation most of them are mere mixtures of colourless lead-glass, the *flux*, and a pigment. In the so-called gold colours, purple, violet and pink, the pigments are preparations of gold, the production of which has hitherto been considered as especially difficult and uncertain. The following are the processes recommended.

Light Purple. — 5 grammes of tin turnings are dissolved in boiling nitromuriatic acid, the solution concentrated in the water bath until it solidifies on cooling. The perchloride of tin prepared in this manner, and which still contains a slight excess of muriatic acid, is dissolved in a little distilled water, and mixed with 2 grammes of solution of protochloride of tin of 1·700 sp. gr., obtained by boiling tin turnings in excess with muriatic acid to the required degree of concentration. This mixed solution of tin is poured into a glass vessel, and gradually mixed with 10 litres of distilled water. It must still contain just so much acid that no turbidness results from the separation of oxide of tin; this may be ascertained previously by taking a drop of the concentrated solution of tin upon a glass rod, and mixing it in a watch glass with distilled water. A clear solution of 0·5 grammes gold in nitromuriatic acid, which must be as neutral as possible, is poured into the solution of tin diluted with 10 litres of water, constantly agitating the whole time. The gold solution should have been previously evaporated nearly to dryness in the water bath, then diluted with water, and filtered in the dark.

On adding the gold solution, the whole liquid acquires a deep red colour, without, however, any precipitate being formed; this instantly separates upon the addition of 50 grammes of solution of ammonia. But if no precipitate should result, which may happen if the amount of ammonia was too great in proportion to the acid contained in the liquid, and in which case the liquid forms a deep red solution, the precipitate immediately results upon the addition of a few drops of concentrated sulphuric acid. It subsides very quickly. The supernatant liquid should be poured off from it as soon as possible, and replaced 5 or 6 times successively by an equal quantity of fresh spring water. When the precipitate has been thus sufficiently washed, it is collected upon a filter: and as soon as the water has drained off completely, removed while still moist with a silver spatula, and mixed intimately upon a ground plate of a glass by means of a spatula and grinder with 20 grammes of lead glass, previously ground very fine upon the same plate with water. The lead-glass is obtained by fusing together 2 parts of minium with 1 part of quartz sand and 1 part of calcined borax.

The intimate mixture of gold-purple and lead-glass is slowly dried upon the same glass plate upon which it had been mixed in a moderately warm room, carefully protected from dust, and when dry, rubbed to a fine powder, and mixed with three grammes of carbonate of silver.

In this manner we obtain 33 grammes of light purple pigments from 0·5 gramme gold.

The above proportion of lead-glass and carbonate of silver to the gold precipitate holds good only for a certain temperature, at which the colour must be burnt-in upon the porcelain, and which is situated very near the fusing point of silver.

To obtain the colour with a less degree of heat, the amount of lead-glass added to the gold must be greater, but that of the carbonate of silver less. The same holds good with respect to the preparation of the purple pigment for glass painting.

The best purple may be spoiled in the baking in the muffle. When this is done at too low a temperature, the colour remains brown and dull; but if the right degree of temperature has been exceeded, it appears pale and bluish. Reducing, and especially acid, vapours, vapours of oxide of bismuth, &c., have likewise an injurious effect upon it.

Dark Purple. — The clear and neutral solution of 0·5 gramme gold in nitromuriatic acid is diluted in a glass vessel with 10 litres of distilled water, and mixed under constant agitation with 7·5 grammes of the solution of protochloride of tin of 1·700 sp. gr. prepared in the manner described above. The liquid is coloured of a dark brownish-red; but the precipitate is only deposited on the addition of a few drops of concentrated sulphuric acid. The supernatant liquid is poured off, and replaced five or six times successively with an equal amount of spring water. The precipitate, which is sufficiently washed, is collected on a filter; and after the excess of water is drained off, removed while still moist with a spatula, and mixed, exactly as described for the light purple, upon a glass plate with 10 grammes of the above lead-glass, dried, then reduced to a fine powder, and mixed with 0·5 grammes carbonate of silver; it furnishes about 13 grammes of dark purple pigment. The stated proportion of lead-glass and carbonate of silver to the gold is for the same temperature of firing as given for the mixture of light purple; for a lower temperature, and also for painting upon glass, the quantity of lead-glass must be increased and that of the silver salt diminished.

Red Violet.— The gold precipitate from 0·5 gramme gold is prepared in the same manner as for the dark purple, and whilst moist taken from the filter, and mixed intimately upon the plate of glass with 12 grammes of a lead-glass prepared by fusing 4 parts of minium with 2 parts of quartz sand and 1 part calcined borax; it is then dried as above, and reduced to a fine powder upon a plate of glass, but without any addition of silver. The proportion of lead-glass to gold applies likewise for the same degree of temperature as in the case of the light and dark purple pigments; a lower temperature requires a larger proportion of lead-glass. A slight addition of silver to this pigment converts the red violet into a dark purple: and when employed alone for painting upon glass, it gives a very excellent purple.

Blue Violet.— This same gold precipitate of 0·5 grammes gold is mixed, while still moist, upon the glass plate with 10·5 grammes of a lead-glass obtained by fusing 4 parts of minium with 1 of quartz sand, drying it slowly in the manner above mentioned, and then reducing it to a fine powder upon the glass plate. When the pigment is burnt-in at a lower temperature, a larger addition of lead-glass is required. This blue violet pigment is more especially adapted for mixing with blue pigments. It is not applicable to glass painting. The most important requisite in the preparation of good purple and violet vitrifiable pigment is the very minute state of division of the gold in the gold precipitate, and of the latter in the lead-glass, which is accomplished by mixing the moist precipitate with the glass.

By mixing the light purple with the dark purple or with the red violet, or the red violet with the dark purple, in different proportions, the artist is able to produce every possible tint of purple and violet. The light purple, without any additional silver, furnishes an amaranth-red colour, like that seen upon most of the porcelains of the preceding century, when the peculiar property of silver, of converting the amaranth-red into a rose-red colour, does not appear to have been known. Dr. Richter, who at the commencement of this century prepared the pigments for the Royal Berlin manufactory of porcelain, appears, however, to have employed it for his purple, as a very beautiful rose colour may be seen upon the painted porcelain of that time.

Pink. — One gramme of gold is dissolved in nitromuriatic acid; the solution mixed with one of 50 grammes of alum in 20 litres of spring water; then mixed, constantly agitating, with 1·5 gramme solution of protochloride of tin of 1·700 spec. grav., and so much ammonia added until all the alumina is precipitated. When the precipitate has subsided, the supernatant liquid is poured off, and replaced about 10 times successively by an equal amount of fresh spring water; the precipitate is then collected on a filter, and dried at a gentle heat. It weighs about 13·5 grammes; and to prepare the pigment is mixed with 2·5 grammes carbonate of silver, and 70 grammes of the same lead-glass, described under light purple (2 minium, 1 quartz sand, 1 calcined borax), and reduced to a fine powder on the glass plate.

This colour is adapted only for the production of a light pink ground upon porcelain, and must only be applied in a thin layer: when laid on in a thick layer the gold separates in a metallic state, and no colour is produced.

All the gold colours above described do not furnish, when fused alone in a crucible, red or violet glasses, as might be expected, but dirty brown or yellowish glasses, which appear troubled from the separation of metallic gold and silver; this peculiar beautiful tint is only developed when they are fused upon the porcelain glaze in a layer, which must not be too thick; they then colour it through and through, as a piece of porcelain painted with it shows distinctly in the fracture. If the layer exceeds a certain thickness, the gold and silver separate in a metallic state; and they produce either a liver colour, as for instance the purple and violet pigments, or no colour at all, as is the case with the more fusible pink pigment.

Yellow Pigments for painting upon Porcelain. — The yellow vitrifiable pigments are lead-glasses, coloured either by antimonic acid or oxide of uranium. The antimoniate of potash is prepared by igniting 1 part of finely powdered metallic antimony with 2 parts of nitre, in a red-hot Hessian crucible, and washing the residue with water. The oxide of uranium is obtained in the fittest state, by heating the nitrate, until the whole of the nitric acid is expelled.

Lemon Yellow.—8 parts antimoniate of potash, 2½ parts oxide of zinc, 36 parts of lead-glass (prepared by fusing together 5 parts minium, 2 parts of white sand, and 1 part of calcined borax), are intimately mixed, and heated to redness in a porcelain crucible, which is placed in a Hessian crucible, until the mixture forms a paste; it is then taken out with a spatula, pounded after cooling, and ground upon a plate glass. If the pigment is fused longer than requisite for the perfect union of the ingredients, the yellow colour is converted into a dirty grey by the destruction of the antimoniate of lead.

Light Yellow.—4 parts antimoniate of potash, 1 part oxide of zinc, and 36 parts of lead-glass (prepared by fusing together 8 parts of minium and 1 part of white sand), are well mixed, fused in a Hessian crucible, and after cooling, pounded and ground. In the preparation of this colour, long fusion is less injurious than with the preceding one, owing to the absence of the borate of soda in the lead-glass. The colour itself is more intensely yellow than the preceding one, and is extremely well adapted for mixing with red and brown pigments; but it does not furnish such pure tints as that when mixed with green; owing to its higher specific gravity, it flows more freely from the brush, and may be laid on in a thicker layer, without scaling off after the firing.

Dark Yellow, 1.—48 parts minium, 16 parts sand, 8 calcined borax, 16 antimoniate of potash, 4 oxide of zinc, and 5 parts peroxide of iron (*caput mortuum*), are intimately mixed and fused in a Hessian crucible, until the ingredients have perfectly combined, but no longer; otherwise, the golden yellow colour is converted into a dirty grey, as in the case of the lemon-yellow pigment.

Dark Yellow, 2.—20 parts minium, 2½ white sand, 4¼ antimoniate of potash, 1 part peroxide of iron (*caput mortuum*), and 1 part oxide of zinc, are well mixed and fused in a Hessian crucible. Long fusion is less injurious in this case than in the preceding. Iron-red pigment may be laid on and near this dark yellow 2, without its being destroyed, or the harmony of the tints injuriously affected.

For landscape and figure painting, the above-mentioned yellow pigments should be made less readily fusible, in order to paint with them upon or beneath other colours, without any fear of what has been painted being dissolved by the subjacent or superposed pigment. This property is given to it by the addition of Naples yellow, which is best prepared for this purpose by long-continued ignition of a mixture of 1 part tartar-emetic, 2 parts nitrate of lead, 4 parts of dry chloride of sodium, in a Hessian crucible, and washing the pounded residue with water. Very useful yellow colours are likewise obtained by mixing this Naples yellow with lead-glass; they are, however, more expensive than those above given. A very excellent yellow for landscape painting may be prepared, for instance, by mixing 8 parts Naples yellow and 6 parts lead-glass (obtained by fusing 2 parts of minium with 1 of white sand and 1 of calcined borax).

The yellow pigments obtained with antimony, after being burnt-in upon the porcelain, appear under the microscope to be mixtures of a yellow transparent substance (antimoniate of lead ?), and a colourless glass, and not homogeneous yellow glasses.

Uranium Yellow.—1 part oxide of uranium, 4 parts lead-glass (prepared by fusing 8 parts minium with 1 part white sand), are intimately mixed and ground upon a glass plate. This colour is not adapted for mixing with others, with which it produces discordant tints. It may be shaded with dark purple or violet.

Uranium Orange.—2 parts oxide of uranium, 1 part chloride of silver, and 3 parts bismuth glass, (prepared by fusing 4 parts of oxide of bismuth with 1 part of crystallised boracic acid), are intimately mixed and ground upon a plate glass. This orange is not adapted, any more than the yellow pigment, for being mixed with other colours. When examined under the microscope, after being burnt-in upon porcelain, the uranium pigments appear as pale yellow-coloured glasses, in which unaltered oxide of uranium is suspended. Only a small portion, therefore, of the oxide of uranium has dissolved in the fusing.

Green Pigments for painting upon Porcelain. Blue Green.—10 parts of the chromate of protoxide of mercury and 1 part of chemically pure oxide of cobalt are ground upon a glass plate, in order to produce as intimate a mixture as possible; the mixture is then heated in a porcelain tube, open at both ends, until the whole of the mercury is expelled. The beautiful bluish-green powder thus obtained is then transferred into a porcelain crucible, and the lid cemented to it with glaze. The full crucible is exposed to the highest temperature of the porcelain furnace during one firing, the crucible carefully broken after the cooling, and the pigment washed with water, to remove a small quantity of chromate of potash. In this manner a compound of oxide of chromium and oxide of cobalt is obtained in nearly equivalent proportions, which possesses the bluish-green colour of verdigris.

The blue-green pigment consists of a mixture of 1 part of the above compound of oxide of chromium and oxide of cobalt, $\frac{1}{2}$ part of oxide of zinc, and 5 parts of lead-glass (prepared by fusing together 2 parts minium, 1 part white sand, and 1 part calcined borax), which are mixed and ground upon the glass plate. By mixing this blue-green with lemon-yellow, any desired intermediate tint may be produced. 1 part of blue-green to 6 parts of lemon-yellow furnishes a beautiful grass-green.

Dark Green.—The chromate of mercury is treated separately in the same way as the mixture of it with oxide of cobalt for the blue-green; and 1 part of the beautiful green oxide of chromium thus obtained is mixed with 3 parts of the same lead-glass as given under blue-green, and ground upon the glass plate.

Green for shading.—8 parts chromate of mercury and 1 part oxide of cobalt are intimately mixed, and exposed in a shallow dish to the strongest heat of the porcelain furnace, during one of the bakings. In this manner a compound of oxide of chromium and oxide of cobalt is obtained, of a greenish-black colour, which, mixed with twice the weight of the lead-glass directed for the blue-green, furnishes a very infusible blackish-green colour, for shading other green colours.

When thin splinters of the green pigments of chromium, burnt-in upon porcelain, are examined under the microscope, it is distinctly seen that particles of the oxide of chromium, or of the oxide of chromium and cobalt, are suspended, undissolved, in the colourless lead-glass.

Blue Pigments for painting upon Porcelain. Dark Blue.—1 part chemically pure oxide of cobalt, 1 part oxide of zinc, 1 part lead-glass (prepared by fusing together 2 parts of minium and 1 of white sand), are well mixed and fused in a porcelain crucible, for at least 3 hours, at a red heat: then poured out, reduced to powder, and ground upon the glass. When this pigment cools slowly, it solidifies to a mass of acicular crystals. Long-continued fusion, at not too high a temperature, is requisite to obtain a beautiful tint; this is best attained by fusing it, during one of the bakings, in the second floor of the porcelain furnace; this is also the cheapest and best way of fusing the lead-glasses.

Light Blue.—1 part oxide of cobalt, 2 parts oxide of zinc, 6 parts lead-glass (prepared by fusing together 2 parts of minium and 1 of white sand, and $1\frac{1}{2}$ part lead-glass (prepared by fusing together 2 parts of minium, 1 part white sand, and 1 part calcined borax), are well mixed and fused, as directed for the dark blue.

Blue for shading.—10 parts oxide of cobalt, 9 parts oxide of zinc, 25 parts of lead-glass (obtained by fusing 2 parts of minium and 1 of white sand), and 5 parts of lead-glass (prepared by fusing together 2 parts of minium, 1 part of white sand, and 1 part of calcined borax), are mixed and fused, as directed for the dark blue. The colour is only used for shading, or to be applied upon or beneath the two preceding blue pigments, for which purpose it is admirably suited, from its being very difficult of fusion.

Sky Blue.—2 parts of dark blue, 1 part oxide of zinc, and 4 parts of lead-glass (prepared by fusing 4 parts minium with 1 of white sand), are intimately mixed and ground upon the glass plate. This pigment is employed, either alone, or mixed with other colours, only for painting the sky in landscape.

The blue pigments described likewise appear under the microscope, after having been burnt-in upon the porcelain, not to be homogeneous blue glasses, but mixtures of a transparent blue substance (silicate of cobalt and zinc?) and a colourless glass.

Turquoise Blue.—3 parts of chemically pure oxide of cobalt, and 1 part of pure oxide of zinc, are dissolved together in sulphuric acid; then an aqueous solution of 40 parts ammonia-alum added, the mixed solutions evaporated to dryness, and the residue heated to expel the whole of the water; then reduced to a powder, and exposed in a crucible to an intense red heat for several hours. The colour is most beautiful, when it has been exposed, during one firing, to the heat of the porcelain furnace. It is a combination of nearly 4 equivs. alumina, 3 equivs. oxide of cobalt, and 1 equiv. oxide of zinc, and is of a beautiful turquoise-blue colour. When the oxides are mixed in other proportions than those above given, they do not furnish such beautiful coloured compounds. To impart to it a slightly greenish tint, a little moist recently precipitated protochromate of mercury is mixed with the above described solution of ammonia-alum, zinc, and cobalt; with the above quantities, $\frac{1}{10}$ part of the chromate, calculated in the dry state, suffices.

The turquoise-blue vitrifiable pigment is prepared by mixing one part of the compound of alumina-oxide of zinc and cobalt with 2 parts of bismuth glass (prepared by fusing 5 parts of oxide of bismuth with 1 part of crystallised boracic acid).

The receipt for the preparation of the turquoise-blue pigment, communicated in the *Traité des Arts Céramiques* by Brongniart, is incorrect; for a lead-glass of the composition there given (3 parts minium, 1 part sand, 1 part boracic acid) destroys the turquoise-blue pigment entirely on fusion, and only a dirty bluish-grey colour is produced. On examining under the microscope the turquoise-blue pigment burnt-in upon porcelain, it appears to be a mixture of a transparent blue substance and a colourless glass. The transparent blue substance in all probability is the above-described compound of oxide of cobalt and alumina, which is of itself transparent under the microscope, but the transparency of which is increased by the surrounding fused glass of bismuth, just like the fibres of paper by oil. This is probably the case also with the microscopic blue constituent of the other blue vitrifiable pigments, and which is probably silicate of zinc and cobalt; for this, when prepared separately, forms a pure blue transparent powder.

Black and grey colours for painting upon porcelain.—Iridium Black.—Iridium, as obtained in commerce from Russia in the state of a fine grey powder, is mixed with an equal weight of calcined chloride of sodium, and heated to a faint red in a porcelain tube, through which a current of chlorine is passed. In this manner a portion of the iridium is converted into the bichloride of iridium and sodium, which is dissolved out with water from the ignited mass. The aqueous solution of the double salt is evaporated to dryness with carbonate of soda, and then extracted with water, which furnishes black sesquioxide of iridium. This is dried and mixed with twice its weight of lead-glass (prepared by fusing together 12 parts of minium, 3 parts of white sand, and 1 part of calcined borax), and ground upon a plate of glass. The iridium, which remained undecomposed in the first treatment with sea-salt and chlorine, is again submitted to the same treatment.

Iridium Grey.—1 part of the sesquioxide of iridium, 4 parts of oxide of zinc, and 22 parts of lead-glass (prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax) are intimately mixed and ground fine upon a plate of glass. On microscopical examination of the iridium pigments after they have been burnt-in upon porcelain, the sesquioxide of iridium is seen to be suspended in the transparent fused lead-glass. It is owing to the unalterability of the sesquioxide of iridium that it admits of being mixed with all other vitrifiable colours without injuriously affecting the tints, as is the case with all the other vitrifiable grey and black pigments.

Black from cobalt and manganese.—2 parts of sulphate of cobalt deprived of its water of crystallisation, 2 parts of dry protosulphate of manganese, and 5 parts of nitre, are intimately mixed, and heated to redness in a Hessian crucible until the whole of the nitre is decomposed. The calcined mass, exhausted with boiling water, furnishes a deep black powder, which consists of a combination of oxide of cobalt and oxide of manganese. 1 part of this compound is mixed with 2½ parts of lead-glass (prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part calcined borax), and ground fine upon a plate of glass.

Grey from cobalt and manganese. — 2 parts of the above compound of the oxide of cobalt and manganese, 1 part oxide of zinc, and 9 parts of lead-glass (prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax) are mixed and ground fine.

These black and grey pigments are far less expensive to prepare than those from iridium, and are not inferior to them in colour ; but they do not mix so well with other colours, and when baked several times they vary their tint somewhat, which renders their application less certain. When these colours burnt-in upon porcelain are examined under the microscope, it is seen that the oxide of cobalt and manganese is not dissolved by the lead-glass, but merely suspended in it.

Besides these colours a very infusible black is used in painting, which is not acted upon by the superposed colours in the fusion; it is the

Ground Black, which consists of 5 parts of blue violet (gold purple), 1⅔ part of oxide of manganese and cobalt, and 1⅔ part of oxide of zinc ; these are intimately mixed and ground fine upon a plate of glass.

White for covering. — 1 part minium, 1 part white sand, and 1 part crystallised boracic acid, are well mixed, and fused in a porcelain crucible. This white enamel has the peculiarity of forming a colourless clear glass when quickly cooled, for instance, when poured into water ; while, when slowly cooled, it remains perfectly white and opaque. On heating the clear glass to its melting point, it loses its transparency, aud becomes opaque as before. This property it possesses in common with the enamels, the opacity of which is produced by arsenic or tungstic acid; probably the opacity in the present case is produced by the separation of silicate of lead, as in the white enamels by arseniate or tungstate of potash, or by oxide of zinc. It is, however, of excessive minuteness ; for under the microscope, even with the highest power, the glass merely exhibits a yellowish turbidness, and no individual particles are visible.

This white serves for marking the lightest part of the pictures, where it is impossible to produce them by exposing the bare surface of the white porcelain; it is also frequently mixed in small quantity with the yellow and green pigments, to make them cover well.

Lead Flux.—A colourless lead-glass for touching-up those parts of the painting which have remained dull, and for mixing with those pigments which are not easy of fusion, is obtained by mixing together 5 parts of minium, 2 parts of white sand, and 1 part of calcined borax.

Red and Brown vitrifiable Pigments derived from Peroxide of Iron for painting upon Porcelain.—Yellow Red.—Anhydrous sulphate of the peroxide of iron is heated to redness on a dish in an open muffle, and constantly stirred with an iron spatula until the greater portion of the sulphuric acid has been expelled, and a sample mixed with water upon a glass-plate exhibits a beautiful yellowish-red colour; after cooling. the peroxide of iron is freed by washing with water from any undecomposed sulphate, and dried. To prepare the pigment, 7 parts of the yellowish-red peroxide of iron are well mixed with 24 parts of lead-glass (prepared by fusing together 12 parts of minium, 3 parts of sand, and 1 part of calcined borax), and ground fine upon a plate of glass.

Brown Red.—When the persulphate of iron is heated to redness until the whole of the sulphuric acid is expelled, and a sample exhibits a dark red colour, the peroxide of iron is well suited for a brownish red pigment, which is prepared in the same manner as directed for the yellowish red.

Bluish Red (Pompadour).—When the persulphate is heated still more strongly, it is deprived of its loose consistence, becomes heavier, and acquires a bluish-red colour. To hit this point exactly when the oxide of iron has assumed the desired carmine tint is not so easy, as it changes very rapidly at these temperatures.

The pigment is prepared by mixing 2 parts of the purple-coloured peroxide of iron with 5 parts of lead-glass, obtained by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax.

Chestnut Brown.—This colour of various shades, even to black, is acquired by the peroxide of iron, at still higher degrees of heat than required for the preparation of red colours; the pigments are prepared by mixing 2 parts of the chestnut-brown peroxide of iron with 5 parts of lead-glass, prepared by fusing together 12 parts of minium, 3 parts of sand, and 1 part of calcined borax.

Chamois.—1 part of the hydrate of the peroxide of iron, prepared by precipitating the peroxide of iron with ammonia, is mixed with 4 parts of the lead-glass, described in the preceding, and the mixture ground fine on a plate of glass. This colour is laid on very thin, and serves to produce a yellowish-brown ground.

Flesh colour.—1 part red peroxide of iron, 4 parts of dark yellow 2, and 10 parts of lead-glass, prepared as described under chestnut-brown, are well mixed and ground fine upon a plate of glass. This colour can also only be employed in a thin layer. Various tints may be given to it by mixing it with a red peroxide of iron, sky-blue, or dark yellow 2. The red of the cheeks and lips are painted upon it with Pompadour red.

When the above colours are burnt-in upon porcelain, it is distinctly seen under the microscope that the peroxide of iron is suspended unaltered in the clear lead-glass; at least the quantity dissolved by the fused lead-glass is so small that it is not perceptibly coloured.

Various Brown Pigments for painting upon Porcelain.—Light Brown, 1.—6 parts of dry protosulphate of iron, 4 parts of dry sulphate of zinc, and 13 parts of nitre are well mixed, and heated to redness in a Hessian crucible, until the whole of the nitre is decomposed. When cold, the crucible is broken, the residue removed, and separated by boiling with water from soluble matters. A yellowish-brown powder remains, which is a combination of oxide of zinc with peroxide of iron. The pigment is made by mixing 2 parts of this compound with 5 parts of lead-glass, prepared by fusing together 12 parts of minium, 3 parts of sand, and 1 part of calcined borax.

Light Brown, 2.—2 parts of dry sulphate of iron, 2 parts of dry sulphate of zinc, and 5 parts of nitre, are treated in the same manner as described for light brown 1. The resulting compound of oxide of zinc and iron is of a lighter tint; the pigment is prepared from it as above.

Light Brown, 3.—1 part of dry sulphate of iron, 2 parts of dry sulphate of zinc, and 4 parts of nitre are treated as directed for 1 and 2.

The light brown colours, after having been burnt-in upon porcelain, exhibited under the microscope the transparent particles of the yellowish oxide of iron and zinc suspended in the colourless lead-glass.

Bistre Brown, 1.—1 part dry sulphate of manganese, 8 parts of dry sulphate of zinc, 12 parts dry sulphate of iron, and 26 parts nitre, are treated as directed for light brown 1, and the resulting dark brown powder (a combination of the oxides of zinc, iron, and manganese), mixed with $2\frac{1}{2}$ times its weight of lead-glass of the same composition as for light brown 1.

Bistre Brown, 2.—1 part dry sulphate of manganese, 4 parts dry sulphate of iron, 4 parts dry sulphate of zinc, 12 parts nitre, are treated as for bistre brown 1. The colour is somewhat darker.

Sepia Brown, 1.—1 part dry sulphate of iron, 1 part dry sulphate of manganese, 2 parts dry sulphate of zinc, and 5 parts nitre, are treated as directed for light brown 1, and the greyish brown pigment thus obtained mixed with $2\frac{1}{2}$ times its weight of lead-glass of the above composition.

Sepia Brown, 2.—1 part calcined sulphate of iron, 2 parts calcined sulphate of manganese, 6 parts calcined sulphate of zinc, and 10 parts nitre, are treated as for sepia 1.

Dark Brown.—1 part dry sulphate of cobalt, 4 parts dry sulphate of zinc, 4 parts dry sulphate of iron, and 10 parts of nitre, are mixed and treated as directed for light brown 1. The resulting beautiful dark reddish brown combination of the oxides of cobalt, zinc, and iron is mixed with $2\frac{1}{2}$ times its weight of the same lead-glass as for the preceding colours.

Chrome Brown.—1 part of hydrated peroxide of iron is intimately mixed with 2 parts of the chromate of the protoxide of mercury, and then heated to redness in a dish, in an open muffle, to expel the whole of the mercury. The dark reddish brown compound of the oxides of chromium and iron is mixed with 3 times its weight of lead-glass, prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax.

When examined under the microscope, after being burnt-in upon porcelain, these different brown colours also show that the dark compounds are merely suspended in the lead-glass, and not, or merely to a small extent, dissolved. The direction above given for preparing the coloured combinations of the oxides in the dry way, for the bodies which constitute the different brown pigments, is cheaper and more certain than the precipitation of the mixed solutions by carbonate of soda and calcination of the washed precipitate, which also answers. If, however, the several oxides were to be mixed with the lead-glass separately, instead of combined, the colours would not be pure, that is to say they would exhibit after the firing different tints in a thick and thin layer; they would moreover possess a totally different colour before the burning from that which they acquire after that operation, and would thus contribute to deceive the artist.

Gold purple is obtained, according to the process of Ladersdorff, by mixing a solution of 1 part ducat gold, in 4 parts *aqua regia*, with 1 drachm of tin salt dissolved in 4 oz. distilled water, and a solution of 1 drachm of gum in 3 oz. of water in the following proportions:—

Distilled water	3	oz.
Solution of gum arabic	28	grs.
do of tin salt	14	„
do of gold	23	„

and adding alcohol of 0·863 spec. grav., until the liquid begins to grow turbid. The purple is deposited and washed with spirit of 0·958. The dried precipitate has a brownish colour, and furnishes, when all the gum has been carefully removed by washing, a very beautiful purple after the firing.

According to Fuchs, 1 oz. *liq. ferri muriat. oxydati*, Ph. bor., is mixed with 3 oz. of distilled water, and a solution of 1 oz. protochloride of tin in 6 oz. distilled water, and 10 drops of muriatic acid added until the whole has acquired a greenish colour, when a further addition of 16 oz. of distilled water is made.

On the other hand, some ducat gold is heated to boiling with pure nitric acid, until all the gold is dissolved. An excess of acid should be avoided. 360 parts of distilled water are added to this solution of gold; and then the above solution of iron and tin gradually poured into it until the whole of the purple is precipitated. This precipitate has likewise a brownish tint after drying, but furnishes a beautiful purple after burning.

It has been found, however, that gold purple prepared according to the following process is preferable, especially as regards the external appearance. A mixture of 4 parts pure nitric acid of 1·24 spec. grav., and 1 part pure muriatic acid, which is mixed with half as much pure alcohol of 0·863, and chemically pure tin, gradually added in small portions until no more is dissolved; the solution must be effected slowly, on which account the vessel containing the mixture should be placed in snow or cold water. The carefully decanted solution is diluted with 80 times its weight of distilled water, and mixed with a solution of gold, prepared according to the above directions. The precipitate is purple-red, and remains so after drying. The tin solution for this purpose cannot be preserved long, otherwise nitric ether is formed; and the higher oxidation of the tin salt no longer furnishes such beautiful precipitates with gold as the recently prepared solution.

For mixing with the purple in order to produce a rose colour, the author does not employ carbonate of silver, but the metal in a very minute state of division, obtained by mixing the finest silver leaf with honey and a few drops of ether, and well grinding it, when the honey is washed out with water. Mr. Waechter uses as a flux for the purple colours a lead-glass, consisting of 6 parts minium, 2 parts silica, and 2 parts calcined borax.

With respect to the chrome colours, he observes, that the expensive method for their preparation by means of the chromate of the protoxide of mercury is still the only one by means of which a fine colour can be obtained.

Cobalt colours.—In purifying the cobalt for porcelain colours, the removal of the whole of the arsenic is of less consequence than that of the iron. Cobalt ores from various localities, Tunaberg, Saxony, and Thuringia, are treated in the following manner. The mineral is reduced to a fine powder in an iron mortar, kept for the purpose, and mixed with $\frac{1}{5}$ its weight of charcoal powder; then exposed in Hessian crucibles to a red heat under a chimney with a good draught or in the open air, and roasted as long as arsenical vapours escape, a very disagreeable operation, which lasts several hours. The ore thus prepared is now boiled over the fire with a mixture of 4 parts nitre, and 1 part muriatic acid, 1 part of which is diluted with 3 parts of water. This operation is repeated about 3 times, with less acid. The liquids are allowed to settle, the clear portion decanted, the remainder diluted with water and filtered, and the solution evaporated to dryness. The dry mass is mixed with some water, heated, and separated by filtration from the residue of arseniate of iron. The green liquid, which now contains more or less cobalt, iron, nickel, and manganese, is mixed with a filtered solution of pearlash, until the dirty reddish precipitate begins to turn blue. Care and experience in this operation are requisite, otherwise a loss of cobalt might result. The precipitate of arseniate and carbonate of iron, which at the same time contains nickel and manganese, is separated by filtration, and the beautiful red liquid mixed with more of the solution of pearlash until the whole of the cobalt is precipitated; the precipitate is carefully washed and dried. This hydrated oxide of cobalt is sufficiently pure for technical purposes, and answers just as well as that prepared from oxalate of cobalt or by caustic ammonia.

For painting, the oxide of cobalt is heated in a Hessian crucible with 1 part silica, and 1½ part oxide of zinc for two hours in a blast furnace, then reduced to a fine powder in a porcelain mortar, and mixed with an equal weight of lead-glass.

Yellow colour.—A beautiful yellow is obtained from 2 oz. minium, ½ oz. *Stib. oxydat. alb. abl.*, 2 drms. oxide of zinc, 2 drms. 2 scruples calcined borax, ½ oz. silica, ½ drm. dry carbonate of soda, and 1 scruple *ferr. oxydat. fuscum*, which are well mixed, fused in a crucible, and then ground fine.—*Waechter.*

VITRIOL, from *vitrum*, glass, is the old chemical, and still the vulgar appellation of sulphuric acid, and of many of its compounds, which in certain states have a glassy appearance; thus: —Vitriolic acid, or oil of vitriol, is sulphuric acid ; blue vitriol, is sulphate of copper; green vitriol, is green sulphate of iron ; vitriol of Mars, is red sulphate of iron; and white vitriol, is sulphate of zinc.

VORTEX WATER-WHEEL. See TURBINE.

W.

WACKE is a massive mineral, intermediate between claysalt and basalt. It is of a greenish-grey colour; vesicular in structure ; dull, opaque; streak shining; soft, easily frangible ; spec. grav. 2·55 to 2·9 ; it fuses like basalt.

WADD is the provincial name of plumbago in Cumberland ; and also of an ore of manganese in Derbyshire, which consists of the peroxide of that metal, associated with nearly its own weight of oxide of iron.

WADDING (*Ouate*, Fr.; *Watte*, Germ.) is the spongy web which serves to line ladies' pelisses, &c. *Ouate*, or *Wat*, was the name originally given to the glossy downy tufts found in the pods of the plant commonly called *Apocyn*, and by botanists *Asclepias Syriaca*, which was imported from Egypt and Asia Minor for the purpose of stuffing cushions, &c. Wadding is now made with a lap or fleece of cotton prepared by the carding-engine (see *Carding*, COTTON MANUFACTURE), which is applied to tissue paper by a coat of size, made by boiling the cuttings of hare-skins, and adding a little alum to the gelatinous solution. When two laps are glued with their faces together, they form the most downy kind of wadding.

WALNUT OIL. See OILS.

WAFERS. There are two manners of manufacturing wafers: 1, with wheat flour and water, for the ordinary kind ; and 2, with gelatine. 1. A certain quantity of fine flour is to be diffused through pure water, and so mixed as to leave no clotty particles. This thin pap is then coloured with one or other of the matters to be particularly described under the second head; and which are, vermilion, sulphate of indigo, and gamboge. The pap is not allowed to ferment, but must be employed immediately after it is mixed. For this purpose a tool is employed, consisting of two plates of iron, which come together like pincers or a pair of tongs, leaving a certain small definite space betwixt them. These plates are first slightly heated, greased with butter, filled with pap, closed, and then exposed for a short time to the heat of a charcoal fire. The iron plates being allowed to cool, on opening them, the thin cake appears dry, solid, brittle, and about as thick as a playing-card. By means of annular punches of different sizes, with sharp edges, the cake is cut into wafers. 2. The transparent wafers are made as follows: —

Dissolve fine glue, or isinglass, in such a quantity of water that the solution, when cold, may be consistent. Let it be poured hot upon a plate of mirror glass (previously warmed with steam, and slightly greased), which is fitted in a metallic frame with edges just as high as the wafers should be thick. A second plate of glass, heated and greased, is laid on the surface, so as to touch every point of the gelatine, resting on the edges of the frame. By this pressure, the thin cake of gelatine is made perfectly uniform. When the two plates of glass get cold, the gelatine becomes solid, and may easily be removed. It is then cut with proper punches into discs of different sizes.

The colouring matters ought not to be of an insalubrious kind.

For red wafers, carmine is well adapted, when they are not to be transparent ; but this colour is dear, and can be used only for the finer kinds. Instead of it, a decoction of brazil wood, brightened with a little alum, may be employed.

For yellow, an infusion of saffron or turmeric has been prescribed ; but a decoction of weld, fustic, or Persian berries, might be used.

Sulphate of indigo, partially saturated with potash, is used for the blue wafers ; and it is mixed with yellow, for the greens. Some recommend the sulphate to be nearly neutralised with chalk, and to treat the liquor with alcohol, in order to obtain the best blue dye for wafers.

Common wafers are, however, coloured with the substances mentioned at the beginning of the article ; and for the cheap kinds, red lead is used instead of vermilion, and turmeric instead of gamboge.

Three new methods of manufacturing wafers were made the subject of a patent by Peter Armand Le Comte de Fontainemoreau, in April 1850 ; the chief feature of which is a layer of metal foil. In the first of the three forms described, the metal slip or band is to be coated with the ordinary farinaceous paste used for making wafers, for which purpose the slip is laid on one of the jaws of the ordinary iron mould, then a spoonful of paste is poured on it, the mould is shut, and the paste baked as usual. The metal band is lastly punched into wafers, either plain or ornamental.

The second method is to stick these slips to paper with paste, then to dry and punch them out.

By the third plan, strips of gummed paper are fixed to the slips, and a resinous cement is put on the other side. The first two methods require moistening, the third heating. This contrivance is susceptible of much variety of decoration.

WALNUT HUSKS, or PEELS (*Brout des noix*, Fr.), are much employed by the French dyers for rooting or giving dun colours.

WANGHEES, or JAPAN CANES. A cane imported from China.

WARP (*Chaine*, Fr.; *Kette*, *Anschweif*, *Zettel*, Germ.) is the name of the longitudinal threads or yarns, whether of cotton, linen, silk, or wool, which being decussated at right angles by the woof or weft threads form a piece of cloth. The warp yarns are parallel, and continuous from end to end of the web. See WEAVING, for a description of the *warping-mill*.

WASH is the fermented wort of the distiller.

WASHING COAL. M. Berard is the inventor of a very successful apparatus for purifying small coal. He exhibited his arrangement at the Great Exhibition of 1851, receiving the council medal. The decoration of the Legion of Honour and a gold medal was also awarded to him at the Paris Exhibition in 1855. This apparatus, to be presently described, effects, without any manual labour, the following operations: —

1st. The sorting the coal by throwing out the larger pieces.

2nd. Breaking the coal, which is in pieces too large to be subjected to the operation of washing.

3rd. Continuous and perfect purification of the coal.

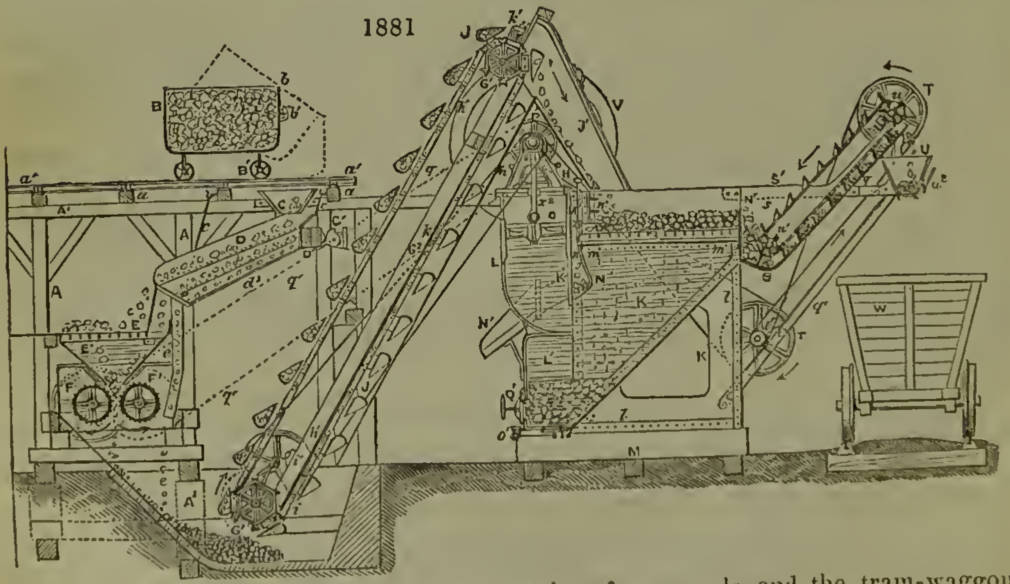
4th. Loading the purified coal into waggons.

5th. Loading the refuse (pyrites or schist) into waggons for removal.

The power required for the apparatus is that of from four to five horses, and the machine can operate upon from 80 to 100 tons of coal in about twelve hours, if fitted up near the colliery. The expense of the operation of purifying is stated to consist solely in the wages of the workmen charged to conduct the labour of the machine.

The following description of the *figs.* 1881 and 1882, will render the arrangements of M. Berard's machine readily intelligible.

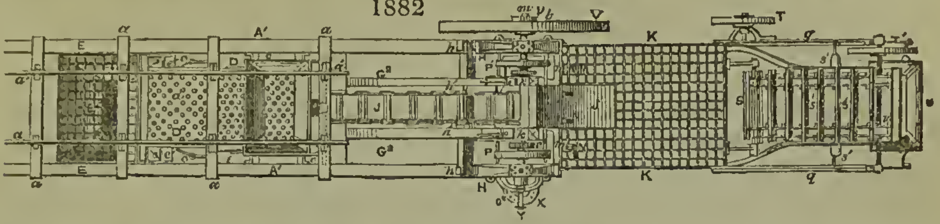
1881



The coal is carried from the mine on a staging, for example, and the tram-waggon

B is unloaded into a hopper, C, either by opening the bottom or by tilting it (as in the position represented by the dotted lines *b*), by means of a lever. It falls afterwards

1882



either on to a table or a movable grating, D, formed of frames, or of a series of stages, of sloping perforated plates, which immediately sorts it into as many sizes as there are perforated plates.

This grating is suspended out of perpendicular by four chains or iron rods, C C, fixed to the framework of the staging, A. It is moved by means of a cam motion (an arrangement of a cam and tongue mentonnet), C′, and falls back by its own weight against the stops, which produce concussions or vibrations favourable to the clearing out of the holes and to the descent of the materials. The motion communicated to the grating admits of a much less inclination being given to it than would be the case if it were fixed: the sorting is effected quicker and more perfectly, besides which the differences of level which it is necessary to preserve are maintained.

The larger pieces rejected by the first plate reach the picking table E, where a labourer picks out the largest stones and extraneous substances as fragments of castings, iron, &c.

The fragments which have passed through the upper plate, and are retained by that below, descend direct to the crushers F F′, situated below. Lastly, the fine portions of the coal which have passed through the second perforated plate fall on to a solid bottom, A′, whence they are thrown, delivered direct into the pit by means of a fixed shoot, *e*.

The crushing cylinders, F F′, are made with a covering of cast-iron, mounted on an iron shaft. This covering can be easily replaced when worn out. It has on its surface small grooves, which are usually placed longitudinally, parallel with the axis of the cylinder, in order to avoid the slipping of the substances operated on. But it is also necessary to crush fragments of slate which gain admission with the coal, and these consisting of thin, flattened laminæ, it would be necessary to bring the crusher closer than would be required to reduce the coal which is of a more cubical form to the proper size.

In order to obviate this difficulty another series of grooves are formed on the surfaces of the crusher transversely to those already described, the intersection of the two producing projections in the form of quadrangular pyramids, with slightly rounded tops. In coming between the projections of the crushers the fragments of slate, being unable to pass, are broken up without reducing the coal to a smaller size than is required.

When the coal has undergone a preliminary sifting, which has removed all the pieces exceeding 6 or 7 centimetres in size, one pair of crushers is sufficient. In that case the grating may be dispensed with altogether by discharging the coal direct into the pit, and returning from the sifter to the washer the pieces of coal which have not been able to pass beyond the first perforated plate.

The small coal resulting from the washer, or from the sifter, by means of the jigger, is delivered into a common pit placed under the washers. The pit is shaped like an inverted quadrangular pyramid, the three faces of which are inclined to one another at an angle of 45°, to facilitate the descent of the substance, and the fourth is usually vertical. It is on the latter that an opening is made, which is regulated by a flood-gate.

An elevator, formed of an endless chain, with buckets, raises the coal from the bottom of the pit, places itself sufficiently high to allow of the final discharge, which may take place into the waggon.

The rate of ascent of the buckets and their capacities are calculated so as to raise 160 to 200 tons of coal in the working hours; but this quantity may be diminished by means of the flood-gate in the pit.

The coal discharged by the elevator falls on the sorter, which ought immediately to divide it, according to size, and distribute it to the ferry-boats.

The classifier is formed of a kind of oblong rectangular chest, made of iron plates, in the inside of which are placed stages of perforated plates, the apertures in which decrease in a downward direction. Sufficient space is allowed between each plate for the motion of the materials. At the bottom of the perforated plates are disposed inclined planes for throwing on one side the product of the sifting, which escapes through a slope made on the side of the sifter. A bottom fixed to the classifier itself, and like it movable, receives the dust in the finest numbers, if the sifting has been effected in the dry way, or else this bottom is immovable and fixed to longerons which support the classifier, if the sifting take place in water, as we are about to point out.

The classifier is suspended by two or three pairs of articulated handles turning on axles fixed to longerons: by that means it enjoys an extreme freedom of motion in a longitudinal direction. A rapid reciprocating motion is communicated by a "*bielle*," which receives the action of a bent axle firmly established on a foundation fixed on the principal wall of the chamber of the machine. The motion of rotation is communicated to the axle by the disposition of an iron pinion *d'angle* working into *a*.

The *bac* is formed of a rectangular chest in cast-iron, L′, one part of the bottom of which is inclined at 45°, the other lower parts remaining horizontal.

Opposite one of the lesser sides of the rectangle is placed a cylinder O, opening into the oblong chest at about half its height. The chest L′ is prolonged under the cylinder, in order to increase the stability of the system and the capacity of the drain-well (puisard).

A cast-iron box, M M′, is firmly fixed in the interior of the bac, on flanges of cast-iron with vertical faces. This box has a slight inclination from M towards M′. It is covered with a perforated plate, usually of copper, fastened to the frame by a number of iron pins or bolts easy of replacement. The size of the holes varies according to that of the matters brought into the bac.

A cast-iron door, N, traverses, opening outward, is fixed at a slight height above the frame, serving as a kind of partition dividing the materials in the bac, and against it a flood-gate N′, by means of which the opening beneath the cast-iron door may be closed at pleasure.

A counter floodgate, N′, is placed at the lower extremity of the frame; in raising it a barrier is formed of variable height, by means of which the substances between the floodgate and counter floodgate may be arrested.

A piston, C, receives from the machine a sufficiently rapid reciprocating motion.

Everything being thus arranged, if the bac is supposed to be filled with water to the level of the front face at N′, and that the substances to be washed fill the space in the bac between this level and the perforated plate of the frame, the piston working upwards and downwards will press the water in the body of the cylinder, and will force it by its incompressibility to pass through the holes in the perforated plate; it will establish above this plate an ascending current, which, if of sufficient power, will raise the substances submerged.

The resistance to the rise of each body will be in proportion to its specific gravity, and the height it will be carried will follow an inverse law, supposing the fragments to be of nearly equal sizes.

The slates which fall over the counter floodgate fall into a pocket or reservoir N, whence they are discharged on opening a floodgate K′. Pressed by the upper column of water, they slide with a slight admixture of water on the inclined plane K′ N′, which can be pierced with holes; the water escapes, and the slate only falls directly into the waggon of discharge.

The bent axle of transmission S S, moves in a groove turning on a pivot at its extremity. The rotation of the axle communicates an oscillating motion to it.

The deposit formed in the drain-well is emptied through an opening of the floodgate placed at the lower part. An opening serving as a man hole is reserved for effecting internal repairs without the necessity of raising the frame.

All coal contains a portion of earthy matters or impurities which, in the form of bands or scales, are generally in some degree apparent to the eye, and constitute the ashes and clinker left by combustion. The small coal which is sent out of mines necessarily contains a still larger proportion, frequently exceeding 10 per cent., consisting chiefly of shale and iron pyrites derived from the roof or floor of the seam of coal, or from the bands of impurities interstratified with it. Generally these impurities are so incorporated with the mass of the coal that it must be crushed in order sufficiently to detach them. The pyrites, which contains nearly the whole of the sulphur found in coal seams, is well known to be very injurious either in a heating or smelting furnace, in the manufacture or working of iron, in gas-making, in coking, and other processes.

Many seams of coal already sunk to, or portions of seams in work, are left underground as unsaleable in consequence of the impurities they contain. Small coal sells at a low price chiefly in consequence of its impurities and the defective coking property which they occasion. It has been estimated that an amount not far short of the quantity of coal sold is sacrificed in producing a commercial article of adequate quality and description. The enormous consumption of coal in this country, amounting to 70 millions of tons per annum, renders the utilisation of a larger portion of the more valuable seams now in course of being exhausted, and the bringing into the market of other seams, objects of national importance.

The differences between the specific gravities of coal and its impurities, allow of their being separated by the action of water when sufficiently crushed. The water process hitherto most commonly adopted is that known as "jigging," which consists in forcing the water alternately up and down through the mass of coal. The downward current of water in "jigging" is prejudicial, and entails a large sacrifice of the finer particles of the best coal; whilst the upward current, from its rapidity and irregularity, is costly both in time and power, besides failing to effect the more perfect separation which is obtained by a slow, continuously ascending or pulsating current, regulated to the proportion of shale in the coal, and to the size of the particles to be acted upon.

Mackworth's patent coal purifier.— In the late Mr. Herbert Mackworth's purifier, *fig.* 1883, the water ascends with a velocity of an inch or two in a second. It is sufficient to keep the particles in constant agitation, and the area of the separator can be reduced to a small fraction of its former size. The coal is supplied into the machine in a uniform stream, and as it is purified is raised out of the water on to a perforated plate, and delivered by the coalsweep into a long perforated shoot, down which it descends into the tram or waggon placed to receive it. The purified coal is thus obtained for coking and other purposes in a comparatively drier state. The shale, which has during the separation accumulated in the shalebox, will discharge itself into another tram without stopping the machine, if the shale valves are first closed by the valve lever before throwing open the shale door. The pump, or agitator, is capable of throwing from 50 to 200 gallons of water per minute, according to the size of the machine. The endless band raises or lowers the coal from the hopper into which the coal trams are tipped.

The advantages of the machine may be thus summed up:—

1st. The more perfect separation of the impurities. If the coal is not sufficiently crushed, even the fragments of coal containing shale or pyrites can be separated as well as the shale, by regulating the velocity of the water. By increasing the speed of the machine and the velocity of the water, the separation of the impurities may be limited to any extent desired.

2nd. The saving of coal. This may be estimated at from 6*d.* to 1*s.* 6*d.* per ton. The ordinary washing processes sacrifice more than 20 per cent. in weight, of which more than one half is the best coal. In this machine the water does not pass out, but is used over and over again in a continuously circulating stream. The loss of coal does not exceed 2 per cent., and is generally under 1 per cent.

3rd. The economy in the power required to work the machine. 1-horse power will suffice to work a machine with pump and elevator capable of purifying 50 tons of coal per day.

4th. The saving in manual labour.

5th. The quantity of water required is comparatively insignificant. A small supply of water is required to replace that absorbed by the wetting of the shale and coal.

6th. The coal is delivered drier than by any other existing process.

7th. The largest machine stands in an area of 9 feet square, and motion can be given off any existing engine by a strap to a pulley making 40 revolutions per minute, at a height of about 12 feet above the ground. The height given to the machine is for the purpose of passing trams underneath it to receive the purified coal and shale as they are delivered. The machine requires no foundation, and is easily removable.

8th. The great economy of the process in every point of view is important to —

The coke trade.—Many coals when deprived of their impurities will coke which never coked before, and the quality of every description of coke may be greatly improved. In coals above the average in quality, it has been found that the clinker may by water purification be reduced by four-fifths in quantity. The two principal sources of clinker—the whitish scales of carbonate of lime and the iron pyrites—are removed. A coke more uniform in texture and better in appearance is produced, and different descriptions of coal may be simultaneously *mixed* and purified by this machine. A cost of 3*d.* per ton on the coke will remove those impurities for which the consumer now pays at the same rate as the coke itself. An increase in the make and quality of the iron results from using purified coke *in blast furnaces.*

Persons using steam.—The amount of ash and clinker from a coal, by no means represents the full amount of loss and waste occasioned by them. The coal is imperfectly burnt, and the fire bars are injured. By removing the impurities, much of the labour in attending *boiler fires* may be spared, and the steam kept up more regularly. In *steamers*, and whenever the freight of coal is heavy, these advantages are peculiarly important.

Gas companies.—Gas may be produced comparatively free from sulphur, as well as a purer and more valuable coke. By a small addition to the cost of the machine the coal may be delivered in a dry state.

Smiths and workers in metal.—A coal purer than the large coal is produced. Better work and metal and cleaner hearths are the results. Smiths are paying in several instances nearly double the former prices for coals which have been purified. In puddling-and other furnaces the advantages of pure coal have been well ascertained.

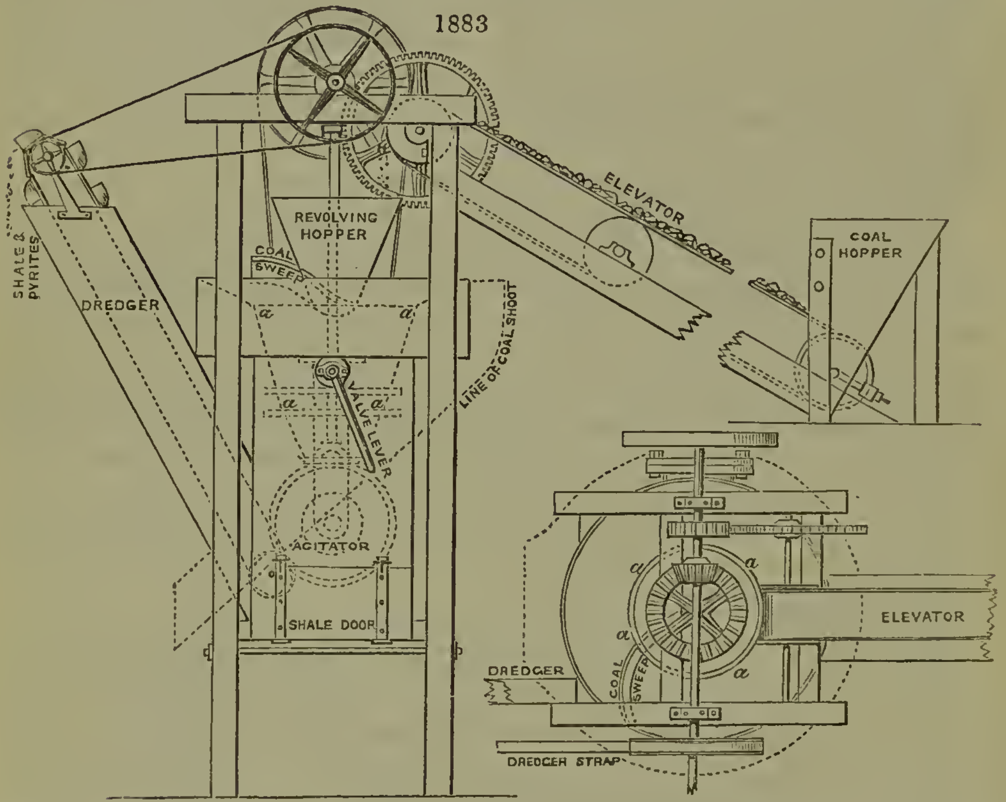
Patent fuel companies.—In all cases where freights are heavy and the manipulation of the fuel costly, purity in the raw material is essential.

Colliery owners.—Coal and shale in lieu of being thrown into the gob can be brought out of the mine and separated for from 1*s.* to 2*s.* per ton, including haulage, &c. Crop coal, old pillars, and creeps, may be turned to account.

The spontaneous combustion in the wastes of some mines may be prevented by bringing out the whole of the small coal and pyrites at a now remunerative price. New coal seams may be brought into the market, to the benefit both of the producer and consumer.

In working this machine the coal tram is tipped into the coal hopper; it is thence conveyed by the elevator in a continuous stream into the machine, and the purified

1883



coal is delivered continuously into a tram whilst the shale and pyrites are delivered in a continuous manner by the dredger, or Jacob's ladder. The workman has only to attend to the placing of these waggons and regulating the amount of opening of the valves which allow the shale to descend into the shale box after it is separated.

The revolving hopper allows the coal to descend gradually into the separator where a slow current of water is driven upwards through the mass of shale and coal, at a velocity of from 4 to 5 feet per minute, by the agitator or screw. This water passes back again by the finely perforated plate, and with the fine silt suspended in it, is again driven upwards by the screw to undergo a repetition of the process. The gentle agitation produced by this current separates the shale and pyrites from the coal in the separator, the two latter descend through the valves and are taken up by the dredger, whilst the former is pushed upwards out of the water by the curved arm; and as soon as the water has drained off, the coal falls on to the shoot, which conducts it to the tram. A brush following the arm helps to keep the holes in the perforated plate open. The valves remain constantly more or less open, according to the indications given by the dredger, and are regulated by the valve lever. The water required to replace that absorbed by the dry coal and shale enters by the hopper and flows slightly inwards through the shale valves as the shale is coming out.

The objects said to be attained by the machine are, 1st, a more perfect separation of the impurities than by the jigging or buddling processes; 2nd, a saving of from 5 to 15 per cent of coal; 3rd, economy of power and manual labour; 4th, saving of water and the delivery of the coal in a drier state.

Machines have been established in Scotland, Cumberland, Derbyshire, Gloucestershire, and Wales, to purify from 20 to 100 tons of coal per day, at a cost not exceeding 3*d.* per ton, and with a loss not exceeding 2 per cent. of coal.

WATER. (*Eau*, Fr.; *Wasser*, Germ.) There is no substance, not even including air, or oxygen itself, which is so extensively used in the operations of nature on our globe, as well as in the workshops of men, as water. To speak of its numerous relationships, even briefly, would demand too much space, and it will be needful to confine ourselves strictly to a consideration of its physical conditions.

Rain is the probable source of all water. It is almost absolutely pure water if it falls through uncontaminated air. Water is almost colourless, brilliant, without taste or smell, and very transparent. When seen through great depths it has a slightly blue shade of colour. It weighs 252·45 grains per cubic inch at 60° Fahr. in the air. The specific gravity of all substances liquid and solid are taken by their relation to water, which is called 1·000 or 1. Its boiling point at 29·92 bar. pressure is 212° Fahr.; it freezes at 32°, and it evaporates at all temperatures. Its boiling point at 760 metres pressure is called 100° Cent.; freezing point 0°. It assumes, therefore, the gaseous, liquid, and solid states with great facility. The specific heat of water at 32° F. is taken as 1000. Water is taken to measure amounts of heat also. The heat required to raise 1 gramme of water 1° Cent. is a unit of heat. The amount of heat required to raise 1 lb. of water, one degree of Fahr., requires for its evolution the expenditure of a mechanical force equal to the fall of 772 lbs. through the space of 1 foot. Or 1 gramme of water is heated 1° (Cent.) by an amount of heat represented by the fall of 423·55 grammes through the space of 1 metre. The latent heat of water and the amount required to convert ice at the freezing point into water is 144°, or 144·6 F. (80—80·34 Cent.) The refractive power of water, or its index of refraction of light, is 133·6; that is, the sine of the angle of incidence is to the sine of the angle of refraction as 1·336 to 1. Refractive power increases below 39·, although density diminishes. Water expands when heated or cooled beyond 39° Fahr., or 3·9 Centigrade; Playfair and Joule give 39·1; Fraukenhein, 38·95; Plücker and Gessler, 38·8; Hope, who discovered the property, gave 39·5. Water freezes in crystals, one form is not unlike Iceland spar, a rhomboid. Hail crystallises in six-sided pyramids, base to base; snow frequently with various stellar radiations.

Specific gravity of the vapour of water is 0·622; it is nine times heavier than hydrogen. Water itself is 812 times heavier than the atmospheric air. Water expands by heat, between 32° and 212°, 1 in 21·3 volumes. It expands in cooling below 32°, even if it be not allowed to crystallise. The expansion may be prevented by using smooth vessels and preventing disturbance. It may be cooled in this way to about 7° F. A slight agitation, or the presence of a rough substance, rapidly causes it to shoot out crystals in all directions. The spec. gr. of ice is 0·916, it therefore floats on water. It expands with irresistible force, bursting asunder iron vessels, however strong, in which it may be confined, water-pipes of whatever substance, porous stones which may have absorbed it, and vegetable cells in which it may be enclosed. By this simple act it performs a great part in breaking up the rocks, so as to renew the soil, and in defacing beautifully polished stones, causing an early decay.

Water heated to 212° F. boils. Long before this period, and even in heating it only a few degrees, it gives off bubbles, which are those of air, from which it is never found free in nature. At 212° the bubbles are distinctly formed of water; in vapour they rise to the surface. These bubbles form more readily on certain surfaces; on metals easily, especially if they are not polished. Gay-Lussac gave the difference of the boiling point in metal and glass as two degrees. Scrymgeour found it raised in any kind of vessel when there was oil present. M. Marcet found it raised to 221° when a glass flask had its inner surface coated with a thin film of shell-lac. When water has ceased to boil in a glass or porcelain vessel, it will begin again instantly if a metallic wire is introduced. Platinum wire is very well suited to this purpose. It is used for other liquids also. Rough glass and porcelain vessels allow water to boil better than smooth. Water thrown on red-hot surfaces is known not to touch the surface. Boutigny found that it may assume this state at any temperature above 340°. When it falls to 288° it touches the surface and commences boiling. In this state of separation from the surface it assumes a globular form; it seems suspended on a film of steam. The condition is called the *spheroidal*. The boiling of water depends on the pressure of the air as well as temperature, as the following shows:—

Barometer, inches.	Water boils at degs. Fahr.
27·74	208°
28·29	209°
28·84	210°
29·41	211°
29·92	212°
30·6	213°

This change of boiling point is used to ascertain the height of mountains, 550 feet making a difference of 1 degree. In a vacuum water will boil at 67°. In a Papin's digester it is raised to 300 or 400 without boiling.—R. A. S.

WATERING OF STUFFS (*Moirage*, Fr.) is a process to which silk and other textile fabrics are subjected, for causing them to exhibit a variety of undulated reflections and plays of light. See MOIRE.

WATER PRESSURE MACHINERY FOR MINES. Considerable attention has been given to the construction of pressure engines by Mr. Darlington, who was actively engaged some years since in effecting the drainage of the Alport Mines, in Derbyshire. *See fig.* 1884.

The first engine erected by him had a cylinder 50 inches diameter, and a stroke of 10 feet; the piston-rod passed through the bottom of the cylinder and formed a continuation with the pump-rod, whilst the valve and cataract gearing was worked by a rod connected with the top of the piston, which gave motion to a beam and plug-rod gearing. The column of water was 132 feet high, affording a pressure on the piston of about 58 pounds per square inch, or more than 50 tons on its area. The water was raised from a depth of 22 fathoms, by means of a plunger 42 inches diameter, and in very wet seasons it discharged into the adit nearly 5000 gallons of water per minute. Water was admitted only on the under side of the piston, and in order to avoid violent concussion in working; two sets of valves were employed, the larger being cylindrically shaped, 22 inches diameter; and the smaller 5 inches diameter. In making the upstroke of the engine the cylindrical valves admitted a full flow of water for about $\frac{7}{8}$ths of the stroke, and then commenced closing, but at this stage the small valve opened, through which passed sufficient water to terminate the stroke. In this way the flow of water in the column was gradually slackened, and finally brought to a state of rest without imparting impact to the machinery. The speed of the engine was regulated by sluice valves, one fixed between the engine and the pressure column, and the other upon the discharge-pipe.

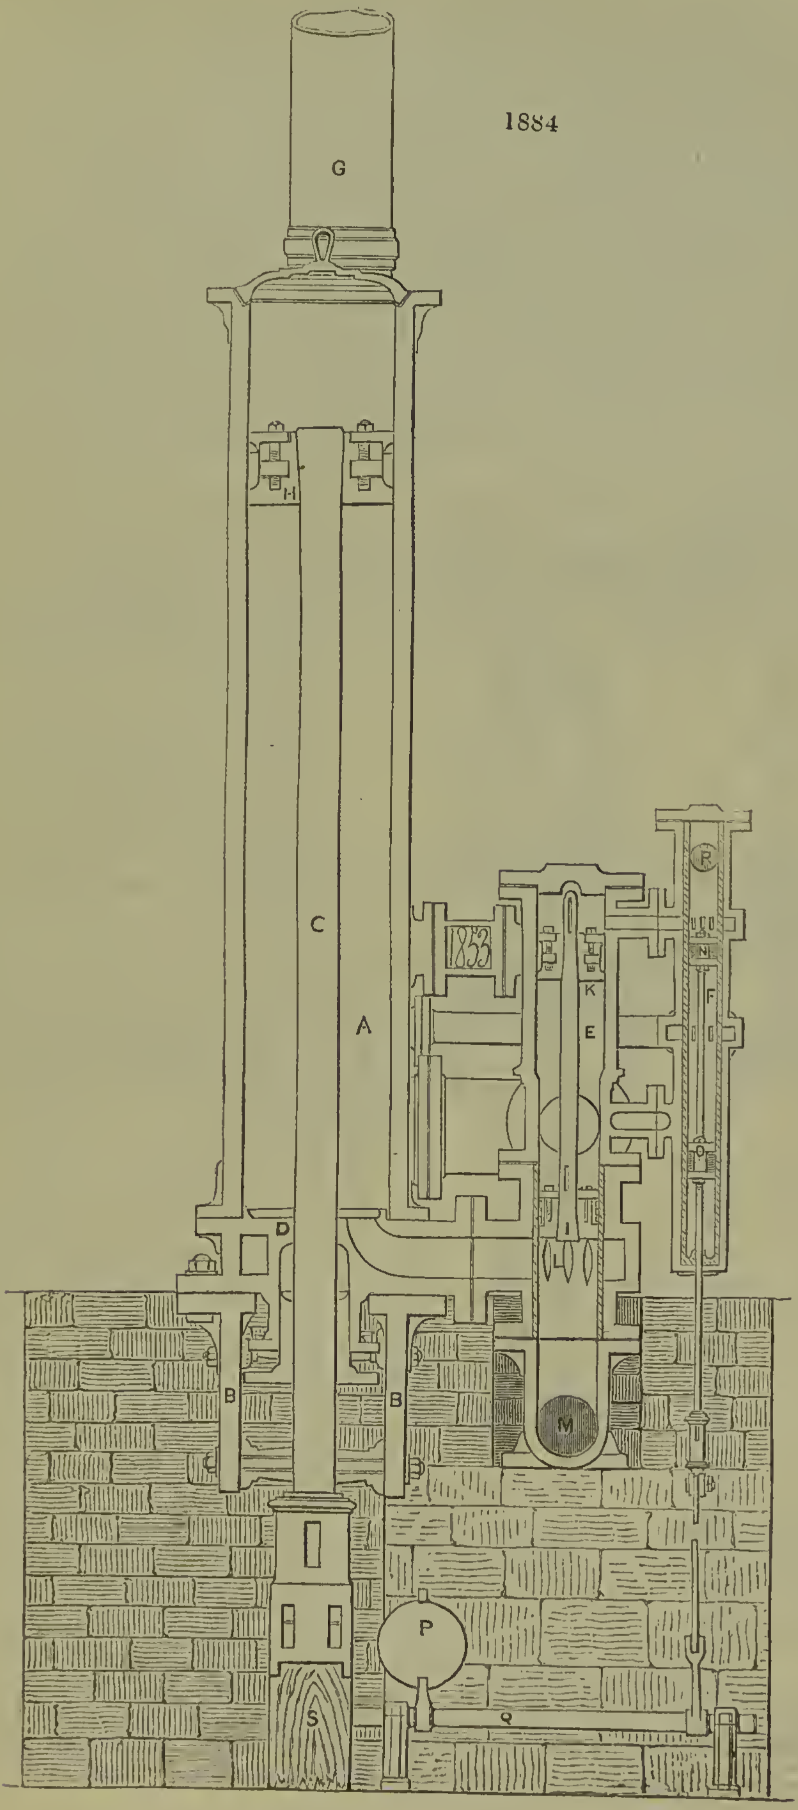
The cylindrical valves were made of brass with a thin feather-edged beat, and kept tight by a concentric boss, projecting from the nozzle, upon which hemp packing was laid. This was pressed down by a projection in the under surface of the valve bonnet. The water thus acted on the exterior of the valves between the zone of packing and the seatings, and when opened passed through the latter. Besides this engine, others of a different construction were designed and erected by Mr. Darlington, but the one to which he gave preference for simplicity, cheapness, and smoothness of action, is illustrated in the following woodcut.

This engine has one main cylinder A, resting on strong cast-iron bearers B B, fixed across the shaft. The piston-rod C, is a continuation of the pump-rod S, and works through the cylinder bottom D. In front of the cylinder A, is a smaller one E, with differential diameters for the admission and emission of water, and right and left are sluice valves not shown for regulating the speed of the engine. Connected with the second cylinder is a small 3-inch auxiliary cylinder F, provided with inlet and outlet regulating cocks.

In starting this engine the sluice valves and regulating cocks are opened, the water then flows from the pressure-column G, into the main cylinder A, through the nozzle cylinder E, and acts under the piston H, until the upstroke is completed. The piston I, has a counter piston K, of larger diameter, and when relieved from pressure on its upper surface, the water acting between them forces it upwards, in which case the pressure is cut off from the main piston, and the water contained in the cylinder A, is free to escape under the piston I, through the holes L. With the emission of water from the main cylinder through M, the downstroke is effected. The downward displacement of the pistons I and K, is performed by the auxiliary cylinder F, and pistons N, O; the pressure column is continually acting between these pistons, and by their alternate displacement by the fall-bob P, and canti-arbor Q. The water is either admitted or prevented from operating on the upper surface of the piston K. The water from the top of piston K, escapes through the aperture R. The motion of the canti-arbor Q, is effected by tappets fixed on the pump-rod S.

One of these engines was recently in operation at the Minera Mines, in North Wales. The cylinder was 35 inches diameter; stroke 10 feet, pressure column 227

1884



feet high. Its average speed was 80 feet, and maximum speed 140 feet per minute. The pressure of water under the piston was 98 pounds per square inch, giving a total weight on its area of about 40 tons. This machine required no personal attendance, the motion being certain and continuous, as long as the working parts remained in order, consequently the cost of maintaining it was of the most trifling character.

In 1803, Trevithick erected an engine at the Alport Mines which worked continuously for a period of forty-seven years, or until 1850, when the mines ceased working. The water from the pressure-column acted on alternate sides of the main piston, by means of two piston valves, displaced by a heavy tumbling beam, and tilted by a projection from the pump-rod. The construction and action of this machine will be best understood by the accompanying illustration, *fig.* 1885.

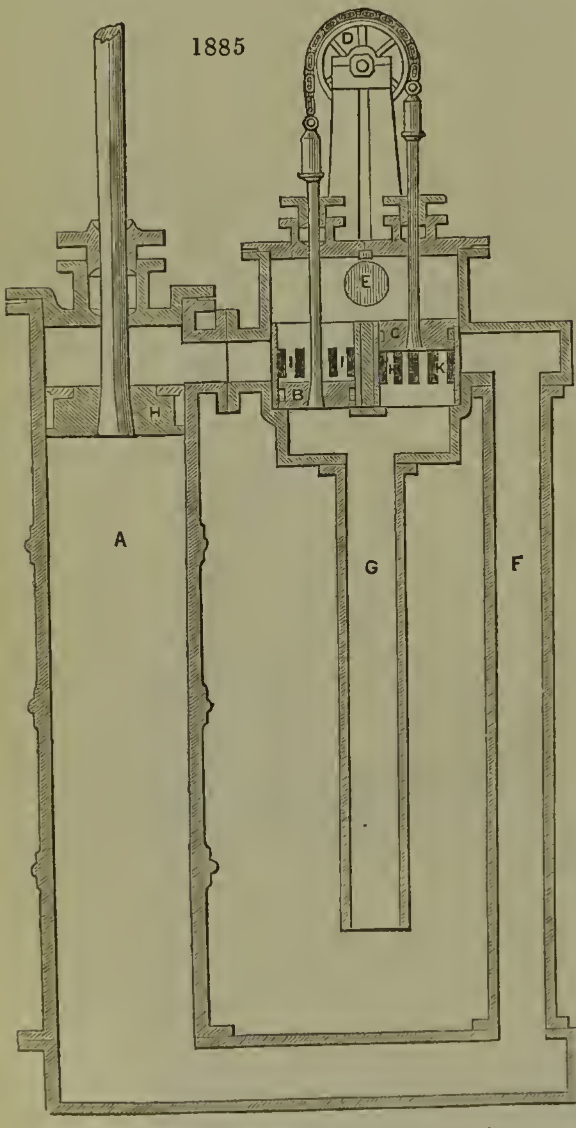
A, main cylinder, B and C, valve pistons; D, chain wheel upon the axis of which is fixed a lever not shown, in connection with a tumbling beam; E, aperture through which water enters from pressure column; F, pipe in communication with main cylinder A, and G, pipe for discharging the water admitted both above and under the main piston H. The position of the valve pistons in the woodcut shows that the pressure column is supposed to be flowing through the holes I, upon the piston H, producing a down stroke, and that the water which has been introduced under this piston in order to make the upstroke is leaving through the pipe F, holes K, and outlet pipe G.

By referring to HYDRAULIC CRANES, the principles adopted by Sir Wm. Armstrong will be understood.

It is not necessary to repeat that part of the subject in this place, but it remains to notice the applications made of the pressure derived from natural falls.

When the moving power consists of a natural column of water, the pressure rarely exceeds 250 or 300 feet; and in such cases he has employed to produce rotary motion, in preference to the original scheme of a rotary engine, a pair of cylinders and pistons, with slide valves resembling in some degree those of a high-pressure engine, but having relief valves to prevent shock at the return of the stroke, as shown in *fig.* 982, already described. Where the engine is single-acting, with plungers instead of pistons, as in the water pressure engine already described, the relief valves are greatly simplified, and in fact are reduced to a single clack in connection with each cylinder, opening against the pressure, which is the same as the relief valve in the valve chest of the hydraulic crane. The water pressure engines erected at Mr. Beaumont's lead mines, at Allenheads in Northumberland, present examples of such engines applied to natural falls. They were there introduced under the advice of Mr. Sopwith, and are now used for the various purposes of crushing ore, raising materials from the mines, pumping water, giving motion to machinery for washing and separating ore, and driving a saw-mill and the machinery of a workshop. In all these cases nature, assisted by art, has provided the power. Small streams of water, which flowed down the steep slopes of the adjoining hills, have been collected into reservoirs at elevations of about 200 feet, and pipes have been laid from these to the engines.

1885



Another application of hydraulic machinery at the same mines is now being made in situations where falls of sufficient altitude for working such engines cannot be obtained, which from its novelty deserves special notice. For the purpose of draining an extensive mining district and searching for new veins, a drift or level nearly six miles in length is now being executed. This drift runs beneath the valley of the Allen nearly in the line of that river, and upon its course three mining establishments are being formed. At each of these power is required for the various purposes above mentioned, and it was desired to obtain this power without resorting to steam engines. The river Allen was the only resource, but its descent was not sufficiently rapid to permit of its being advantageously applied to water pressure engines. On the other hand, it abounded with falls suitable for overshot wheels, but these could not be applied to the purposes required without provision for conveying the power to many separate places. Under these circumstances it was determined to employ the stream through the medium of overshot wheels in forcing water into accumulators, and thus generating a power capable of being transmitted by pipes to the numerous points where its agency was required. In this arrangement intensity of pressure takes the place of magnitude of volume, and the power derived from the stream assumes a form susceptible of unlimited distribution and division, and capable of being utilised by small and compact machines.

A somewhat similar plan is also adopted at Portland Harbour, in connection with the coaling establishment there forming for the use of the navy. The object in that case is to provide power for working hydraulic cranes and hauling machines, and more particularly for giving motion to machinery arranged by Mr. Coode, the present engineer of the work, for putting coal into war steamers. A reservoir on the adjoining height affords an available head of upwards of 300 feet; but in order to diminish the size of the pipes, cylinders, and valves connected with the hydraulic machinery, and also with a view of obtaining greater rapidity of action, a hydraulic pumping engine and accumulator are interposed, for the purpose of intensifying the pressure and diminishing the volume of water acting as the medium of transmission.

WATER-PROOF CLOTH. See Caoutchouc.

WATER, SEA — *rendered fresh.* (*Communicated by Dr. Normandy.*) The analyses of sea water which have been made at various times, and the results of which will be found elsewhere, prove that that liquid contains from 3½ to 4 per cent. of saline substances, two-thirds at least of which are common salt, and also a certain quantity of organic matters, all of which substances impart to it its well-known taste and odour, and render it unfit for drinking or other domestic purposes.

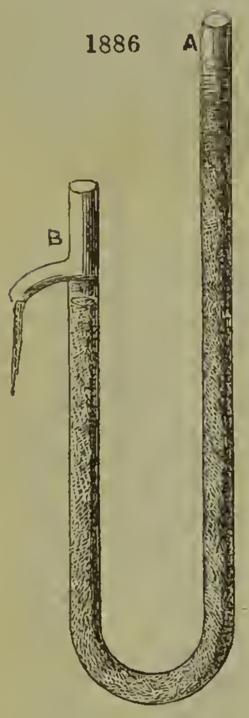
To render sea water drinkable, and thus avoid the accidents resulting from an insufficient supply, or from an absolute want of fresh water, in sea voyages, is a

* Rotary Engines

problem which may be said to have engaged the attention of men from the very moment they ventured to lose sight of the friendly shore and became navigators; gradually, as the enlargement of commercial operations extended the length of sea voyages, the difficulty of preserving in a pure state the fresh water taken in store, the necessity of putting up at stations for procuring a fresh supply of it when it is exhausted, the great gain to be realised by being enabled to devote to the stowage of cargo the valuable space occupied by water-tanks and water-casks, have induced many people at various times, and for many years past, to contrive apparatus by means of which sea water would be rendered fit to drink, or by means of which good fresh water could be obtained therefrom.

Fresh water can be obtained from sea water in two ways; the one by distillation, the other by passing it through a layer or column of sand, or of earth, of sufficient thickness or length. In effect, if sea water be poured at A, in a pipe 15 feet high, and full of clean dry sand, the water, which will at first flow at B, will be found pretty fresh and drinkable, but as the operation is continued, the water which flows at B soon becomes brackish; the brackishness gradually augmenting, until, in a very short time, the water which flows at B is actually more salted than that poured at A; because the latter dissolves the salt which had been first retained by the sand, which must then be renewed, or washed with fresh water, a process evidently useless for the purpose in question. This phenomenon, according to Berzelius, is due to the interstices between the grains of sand acting as capillary tubes; and as, at the beginning of the operation, the effect depends more on the attraction than on the pressure of the liquid poured in one of the branches of the tube, the salt is partly separated from the water which held it in solution, the latter lodging itself into the interstices of the sand, and filling them; if, when the mass of the sand is completely wetted, a greater quantity of sea water is poured upon it, the weight of the said sea water first displaces and expels the fresh water; but as soon as the interstices of the sand have thus been forcibly filled up with sea water, the water flowing at B becomes more and more salted; wherefore this filtration cannot yield more fresh water than can be contained in the interstices of a column of sand of a certain length and proportionate to the saltness of the sea water.

1886



Howbeit, the removal of the salt from sea water, so as to obtain fresh water therefrom, is, practically speaking, an impossibility, except by evaporation.

At first sight one would think that it is sufficient to submit sea water to distillation to convert it into fresh water, and that the solution of the problem is altogether dependent upon a still constructed so as to produce, by evaporation, a great quantity of distilled water, with a consumption of fuel sufficiently small to become practicable.

Distillation at a cheap rate is doubtless an important item, and fuel being a cumbrous and expensive article *on board ship*, it is superabundantly evident that, supposing all the apparatus which have hitherto been contrived for the purpose to answer equally well, that one would clearly merit the preference which would produce most at least cost; but there are, besides, other desiderata of a no less primary importance, and it is from having neglected, ignored, or been unable to realise them, that all the apparatus for obtaining fresh water from sea water, which have been from time to time brought before the public, have hitherto, without exception, proved total failures, or, after trial, have been quite discarded, or fulfil the object in view in a way so imperfect or precarious, that, practically speaking, the manufacture of fresh water at sea, or from sea water, may be said to have been, until quite lately, an unaccomplished feat. In order to understand the nature of the difficulties which stood in the way of success, a few words of explanation become necessary.

When ordinary water, whether fresh or salt, is submitted to distillation, the condensed steam, instead of being, as might be supposed, pure, tasteless, and odourless, yields on the contrary a liquid free from salt, it is true, but of an intolerably nauseous and empyreumatic taste and odour which it retains for many weeks; it is, moreover, insipid, flat, and vapid, owing to its want of oxygen and carbonic acid, which water in its natural state possesses, and of which it has been deprived by the process of distillation. In the absence of ordinary fresh water, this distilled water, however disagreeable and objectionable it may be, is of course of use so far as it is fresh, but the crews invariably refuse it as long as they can obtain a supply from natural sources, even though this may be of so bad a quality as to endanger their health or their lives, as evidenced by the report of *The Times'* Own Correspondent in reference to the water supplied to the crews of our ships in the Baltic during the Crimean war.

With a view to remedy the defects just alluded to, various means have from time to time been proposed and employed; such as the addition of alum, sulphuric and other acids, chloride of lime, &c.; but it is evident that chemical reagents cannot effect the object; but if even they did, their use is always unsafe, for their continuous and daily absorption might, and doubtless would, cause accidents of a more or less serious nature, not to speak of the trouble and care required in making such additions. Liebig said with both authority and reason, that, as a general rule, the use of chemicals should never be recommended for culinary (or food) purposes, for chemicals are seldom met with in commerce in a state of purity, and are frequently contaminated by poisonous substances. On the other hand, the percolation through perforated barrels or coarse sieves, porous substances, plaster, chalk, sand, &c., the pumps, ventilators, bellows, agitators, which have been proposed to aërate the distilled water obtained, and render it palatable, are slow in their action, of a difficult, inconvenient, or impossible application; and as to leaving the distilled water to become aërated by the agitation imparted to it in tanks or casks by the motion of the ship, this must be continued for a length of time, proportioned of course to the vigour of the oscillations imparted to the ship by the violence of the waves, and the time thus required is always considerable; yet in this way, and finally by pouring the water several times from one glass to another before drinking it, it may become fully aërated, but without entirely losing its vapid and nauseous taste and odour, and in fact the report of the correspondent of *The Times*, above alluded to, shows that this method is attended with but indifferent success. I shall presently explain why no system or method of aëration whatever could be attended with success, in the production of *perfect* fresh water from salt water, notwithstanding the great ingenuity displayed in their endeavours to realise the object in view by persons who, some of them at least, though of consummate skill as engineers or philosophers, or as men of general knowledge, were not, it would appear, sufficiently well acquainted with the exact nature of the difficulties which stood in the way, or were not fitted for the investigation and conquest thereof. In reality the failures in this respect have been due to the fact that the aëration of the distilled water, instead of being, as everybody thought, the whole problem, is only a part of it; and we shall see, moreover, that the said aëration, to be effective, must be practised under certain conditions, in a certain manner, and is only a preparatory step though an all-important one, to the final production of *perfect* fresh water.

But before proceeding further, it may not be amiss to say a few words respecting another condition in the construction of marine condensing machines, which, from not being sufficiently taken into account, frequently puts them suddenly out of service, or necessitates constant repairs. I am alluding to those condensers the joints of which are made by soldering or brazing, for the different rates of expansion and contraction of metals by heat and by cold, during the intervals of work and of rest of the apparatus, would be sure eventually to cause the soldered parts to crack and give way, an effect which the motion of the ship would of course greatly promote. This in fact was the cause of the accident which about thirty-five years ago put the lives of Captain Freycinet and of his crew in fearful jeopardy. On the other hand, the electro-chemical action which sets up between the metals of the solder and that of the condenser, corrodes the latter, and in either case a leak being started, the sea water penetrates through it into the apparatus, which may thus be at once put out of service after a few months' working, its unsoundness thus creating the most distressing sufferings, and putting the lives of all on board in imminent peril. It may therefore be most truly asserted that any fresh-water distilling apparatus, for marine purposes, in any part of which solder is employed, is *ipso facto* defective, and ought not to be trusted, the soldered parts being sure to give way from the causes just alluded to. Lastly, another condition often lost sight of (although of extreme importance), in the endeavours which have been made to accomplish the object in question, is to obviate or prevent the deposit of saline matter which takes place when the limit of saturation has been attained, and which in a short time interferes, temporarily at least, and often permanently, with the working of the apparatus, renders frequent repairs necessary, and in all cases eventually destroys it.

The question which had hitherto been left unanswered, and yet which must be integrally solved before success could be hoped for, is the following:—

To obtain, with a small proportion of fuel, large quantities of fresh, inodorous, salubrious, aërated water, without the help of chemical reagents, by means of a self-acting and compact apparatus capable of being worked at all hours, under all latitudes, in all weathers and conditions compatible with the existence of the ship itself, and incapable of becoming incrusted, or of otherwise going out of order.

How this complex and difficult problem has been solved I will now proceed to explain:—

It is a known property of steam that it becomes condensed into water again, whenever it comes in contact with water at a temperature lower than itself, no matter how high the temperature of that condensing water may be.

It is known that the sea and other natural waters are saturated with air containing a larger proportion of oxygen and of carbonic acid than the air we breathe. In effect, 100 volumes of the air held in solution in water contain from 32 to 33 volumes of oxygen, whereas 100 volumes of ordinary atmospheric air contain only 24 volumes of oxygen. Again, ordinary atmospheric air contains only $\frac{1}{4000}$ of carbonic acid, whereas the air held in solution in water contains from 40 to 42 per cent. of carbonic acid. The experiments which I undertook in 1849–50, with a view to determine the amount of these gases present in water, showed me that this amount varied with the state of purity of the water; that whilst ordinary rain-water contains, on an average, 15 cubic inches of oxygenised air per gallon constituted as follows:—

Carbonic acid	6·26
Oxygen	5·04
Nitrogen	3·70
	15·00;

sea water, owing to the various substances which it holds in solution, contains only on an average 5 cubic inches of gases, more than one half of which is carbonic acid; or, in other words, 1 gallon of sea water contains about two-thirds less gases than ordinary rain water, and one half less gases than river water.

I have also ascertained that air begins to be expelled from such natural waters when the temperature reaches about 130° Fahr.; and we know that when the temperature reaches 212° Fahr., all the air which it contained has been expelled, and it is for this reason that distilled water contains no air.

At that time I shared the prevalent opinions of all who had interested themselves on the subject, namely, that the flat, disagreeable, and mawkish taste and odour of distilled water were due to its having been deprived of air, and knowing that the various methods adopted or resorted to for aërating distilled water by forcing atmospheric air into it had failed, and that the distilled water thus aërated spontaneously or by mechanical means, retained the abominable taste and odour just alluded to, and remained for a long time almost undrinkable, I thought that the defect was possibly owing to the air mixed with it not being of a suitable quality, the experiments which I have related having indeed shown that the composition of air contained naturally in water differed essentially from atmospheric air; and that consequently if I could reintroduce into the distilled water the carbonic acid and oxygen of which ebullition had deprived it, it would then become as sweet as good ordinary water. With this view I contrived the apparatus which forms the subject of the present article.

The apparatus is represented in *figs.* 1887, 1888. It consists of three principal parts, an evaporator, A, a condenser, B, and a refrigerator, C, joined so as to form one compact and solid mass, screwed and bolted, without soldering or brazing of any kind. The evaporator is a cylinder, partly filled with sea-water, into which a sheaf of pipes are immersed, so that on admitting steam at a certain pressure into these pipes it is condensed into fresh, though non-aërated water by the sea water by which the pipes are surrounded, that sea water being thus heated and a portion of it evaporated at the same time; for it is one of the properties of steam to be condensed by water, no matter how high the temperature of that water may be, if it be only inferior to that of the steam. This non-aërated water becomes aërated, as I shall explain presently:—On board steamers, the steam is obtained directly from the boilers of the ship; in sailing vessels it is procured from a small boiler which may, or may not be connected with the hearth, galley, or caboose.

The steam at a pressure being, of course, hotter than ordinary boiling water, serves to convert a portion of the water contained in the evaporator into ordinary or no-pressure steam, which, as it reaches the pipes in the condenser, B, is resolved therein into fresh aërated water. The manner in which it becomes aërated will be explained presently. By thus evaporating water under slight pressure, one fire performs double duty, and thus the first condition, that of economy, is completely fulfilled, for while, in the usual way, 1 lb. of coal evaporates at most 6 or 7 lbs. of water, the same quantity of coals, burnt under the same boiler, but in connection with my apparatus, is thus made to evaporate 12 or 14 lbs. of water, or, in other words, from the same amount of coals or of steam employed, the machine which I am describing will produce double the quantity of fresh water that can be obtained by simple or ordinary distillation; that is to say, double the quantity obtained by the ordinary condensers.

The comparative trials made in 1859 on board H. M. ships the Sphynx, Erebus, and Odin, at Portsmouth, before the Commissioners of the Admiralty, have most conclusively proved the perfect accuracy of that statement.

The steam issuing from the evaporator, and which is condensed by the water in the condenser, imparts, of course, its heat to the sea water in it; and as this water is admitted cold at the bottom, whilst the steam of the evaporator is admitted at the top of the condenser, the water therein becomes hotter and hotter gradually as it ascends, and when it finally reaches the top its temperature is about 208° Fahr.

I have already stated that water begins to part with its air at a temperature of about 130° Fahr., therefore the greater portion of the air contained in the water which flows constantly and uninterruptedly through the condenser is thus separated, and led through a pipe into the empty space left for steam-room within the evaporator, where it mixes with the steam.

Now, as about six gallons of sea water must be discharged for every gallon of fresh water which is condensed, and as each gallon of sea water contains, as we said before, 5 cubic inches of air, and whereas the utmost quantity of it that fresh water can naturally absorb is 15 cubic inches per gallon, it follows that the steam in the evaporator, before it is finally condensed, has been in contact with twice as much air as water can take up, the result being a production of fresh water to the maximum of aëration, that is, containing as much air as in pure rain water.

This aëration of the water to the maximum and with the air naturally contained in the water in its original state, though a condition of the utmost importance, as will be seen presently, having, to my extreme surprise, failed in removing the detestable odour and taste in question, it became necessary to try to discover whence came that flavour which no means of aëration could destroy, except after a considerable length of time, and even then never perfectly. With that view I took 25 gallons of distilled water, possessing the characteristic empyreumatic odour and taste, and having evaporated them slowly at a temperature much below the boiling point, I found, at the end of six weeks, the inside of the little platinum dish into which the experiment had finally been carried, covered with a thin oily film of a most disagreeable odour, and upon rinsing the little dish in 25 gallons of excellent ordinary fresh water, the latter immediately acquired the empyreumatic odour and flavour peculiar to distilled water, which odour and flavour are evidently due to the destructive action of the heated surface of the vessels in which the water is boiled on the organic substances which are always floating in the air, on those indescribable particles of dust which are seen playing or moving about in a sunbeam, and which have been dissolved or taken up by the water before its distillation. That water has the power of absorbing and dissolving organic matter in this way is, of course, well known, but it may be illustrated in a very simple manner, as follows:—If water, from whatever source, be distilled, the distillate will, of course, be fresh water, pure fresh water, but it will have a peculiar, nauseous, and empyreumatic taste and odour, stronger in proportion as the heat applied to evaporate it has been more elevated; it is that smell and taste which render it undrinkable for a while. If, when it has become sweet again by long standing, which period may be hastened by agitation in the atmosphere; if, I repeat it, that distilled water be then re-distilled, the distillate will be found to have acquired again the same empyreumatic taste and odour as when it was first distilled. How is this?—Because it will, by standing or agitation, have re-dissolved a portion of the air in the room in which it was kept, and along with that air it will have absorbed whatever substances were present, dissolved or suspended in it, and those substances by their contact with the heated surfaces of the still, yield an empyreumatic product, which taints the distillate. On board ships, the water which is stored in for the use of crews in the usual way, in the course of about a fortnight becomes putrid and almost undrinkable, because the organic matter which that water contains is undergoing putrefactive fermentation. But about a month or so afterwards the water gradually becomes sweeter and sweeter, until at last it becomes drinkable again; because, eventually, all the organic matter which it contained becomes decomposed, carbonic acid and water being the result, and although the air of the ship's hold is none of the sweetest, such water, as just said, generally remains afterwards perfectly good and palatable; because, the tanks in which it is kept being covered up, it is sheltered from fresh pollutions, and because it is now saturated with pure air, and therefore cannot absorb that of the atmosphere.

When the natural waters supplied to our habitations are obtained from impure sources, as is unfortunately too often the case, the evils resulting from their use may in some degree be remedied by putting in practice the recommendation which has been sometimes made, of boiling such water previous to employing it as a beverage; unfortunately the water being thereby deprived of air is, like distilled water, though in a less degree, unpalatable and vapid and heavy; it is, in fact, of difficult digestion; but there is something worse than that; water which has been boiled, or which has been distilled, by reason of its containing *no air*, has a great tendency to absorb or to take that of the media where it is kept, so that if distilled water which contains no air be kept in a ship's hold, or in an impure and confined place, it will absorb precisely the quantity of air which it can absorb, namely, 15 cubic inches per gallon, and if that air be loaded with organic particles or impure emanations, it will soon become fetid and putrid. The experiments of Dr. Angus Smith have proved that if a stream of air which has already been breathed be passed through water, the latter will retain a peculiar albuminoid matter which undergoes putrefaction with extraordinary rapidity; and the water which condenses on the cold exterior surfaces of vessels in crowded rooms possesses the same character, and acquires in a short time an offensive odour; now this is to a great extent the case with the water of ordinary condensers when allowed to become spontaneously aërated on board ship. Thus water, though distilled, if kept in tainted rooms, will soon become foul. The only condition necessary for distilled water not to become putrid or offensive is to saturate it with *pure air*, because in that case there is no room left for other gases to impregnate it (at least, practically speaking, and in the ordinary conditions of domestic or of ship economy) and to keep it in covered vessels or tanks.

Now, although aëration alone is, as I have just said, powerless to destroy the nauseous odour of distilled water within a time practically useful, this aëration, when effected in the manner which I have described, is of the utmost importance; since if even all the other conditions of the problem had been complied with—all, except that one, the apparatus, economical and perfect though it might have been in all other respects, would have been comparatively useless. I would strongly urge the importance of *aërating the fresh water in the manner which I have described*—that is to say, not with ordinary atmospheric air, but with that which was naturally contained in the water before its distillation; because aërating it mechanically with ordinary atmospheric air, by simple ventilation or agitation, is far from answering the purpose so well, for the reasons which I have already stated. Having thus found that the cause of the odour and taste was due to the presence of empyreumatic products, it became evident that, whereas the fresh water produced by my apparatus was aërated in the same manner and to the same extent as that obtained from the very best sources, and equal to it in every other respect, the removal of these ill-smelling and ill-tasting principles was the last obstacle to the entire success of the operation.

Now, if a tree, for example, after having been cut down, is left exposed to the action of the air on the spot on which it lies, we know that, in the course of time, its exterior becomes soft and friable, and that it gradually crumbles into dust. The tree, in that case, is said to be decaying; and, in effect, after a greater or less number of years, it will be found to have completely disappeared; all its combustible parts, that is to say, all those parts which would have been burnt off if the tree had been set fire to, have vanished, and been volatilised, nothing being left behind but the incombustible parts, that is to say, the earthy constituents of the tree. Whether the tree is destroyed by actual burning or by *spontaneous decay*, the result is the same; the only difference is, that in the first case the combustion is rapid, and is energetically accomplished, with disengagement of heat and of light, in a few hours; in the second case, the combustion is slow, without sensible elevation of temperature, and a period of thirty, or perhaps forty years may be required to accomplish it, and for the tree to disappear completely: it is only a question of time; whether the tree is burnt in a fire, or allowed to decay in the air, the final result is the same; the carbon and hydrogen of its wood being oxidised, or burnt by the oxygen of the air, give, the one carbonic acid, the other water, both of which disappear, and a fixed residue, namely, *ashes*. But if, instead of leaving the tree whole, it be cut into pieces, into shavings, into fragments of shavings, into shreds—then its combustion in a fire will be completed in a few moments; or spontaneously in a few months, as indeed is the case with farm-yard manures, which are spread on the ground, and of which nothing remains in the ensuing year—nothing but the incombustible part thereof—the earthy portion, *the ashes*, mixed with the soil.—How is it that a corpse which, while putrefying, evolves a revolting odour, becomes inodorous when it is put into a hole in the ground, covered with earth, wherein it continues nevertheless to decay and to rot, so entirely and effectually, that after a certain time nothing remains but bones, or the earthy matter of those bones?—What has become of the muscles, of the fat, of the nerves, tendons, tissues of all kinds?—They have been burnt, oxidised, converted into carbonic acid and water; the sulphur thereof has been converted into sulphuretted hydrogen, and that again into sulphuric acid and water; the nitrogen has been converted into ammonia, &c. &c. Whence it is seen, that all dead organic matter is eventually burnt up by the oxygen of the air; and that this combustion, whether rapid or slow, is accelerated by the greater or less degree or state of division in which it is exposed to the action of that gas.

Now, Dr. Stenhouse several years ago, I believe, found that the power which charcoal possesses of purifying *tainted air* is owing to its burning in an insensible manner the substances to which the bad odour was due; and acting, therefore, upon this discovery, I conceived that in order to burn a substance spontaneously in that manner, it mattered not whether the oxygen of the medium into which the said substance was placed was a mixture of oxygen and nitrogen, (atmospheric air,) or a mixture of oxygen and water, (water aërated by my process,) since *oxygen alone* was the supporter of combustion, the *nitrogen* having nothing to do with the burning of the substance, any more than the *water* of the aërated water. And accordingly, on experimenting in that direction, I found that charcoal has the power of destroying the empyreuma of distilled water *when such water is* AERATED, that is to say, when it contains free oxygen. I found by experiments, performed on a somewhat extensive scale for many months, that two cubic feet of charcoal are sufficient to remove entirely the empyreumatic odour and taste of distilled water, produced at the rate of 500 gallons per diem, and that the charcoal *never wants renewing*, because it does not act as a *filter*, but as a *fire grate*, the substance burnt being the empyreumatic product, and the result of the slow combustion thereof being the ordinary products of combustion, to wit, carbonie aeid and water. I have every reason to believe, from the length of time during which several of my apparatus have been in operation, both on board a large number of ships and on land, that such a filter once made will last for ever, because the charcoal disinfects the water, so to speak, as it does air, not by mechanical separation, but by actual, though insensible combustion. The water as it issues from the apparatus is perfectly sweet, tasteless, inodorous, and saturated with its proper and normal quantity of oxygenised air and carbonic acid; it is of sparkling clearness, and being refrigerated in traversing the sheaf of pipes of the refrigerator, C, surrounded by cold sea water at the lower part of the apparatus, it is fit for immediate use.

These qualities I sincerely affirm are not in the slightest degree exaggerated, and a multitude of testimonials establish in an incontrovertible manner that such is truly the case.

And thus is the second condition that of aëration, of digestibility, of wholesomeness accomplished, whereby the fresh water produced is rendered *at once* not only drinkable, but so sweet, limpid, and fresh, that it cannot be distinguished from the very best spring water.

During the experiments or comparative trials which took place at Portsmouth in 1859 before the Committee of the Admiralty, between my apparatus and that of the late Sir Thomas Grant, with which all H. M steam ships were then provided, a very curious phenomenon took place, which corroborated in a startling manner the explanation which I have given of the nauseous odour of ordinary distilled water. The circumstances under which the phenomenon was produced were as follows:—

On the 20th of October, 1859, steam having been got up in one of the boilers of H. M. ship "Odin, that steam was turned in precisely equal quantity to each of the apparatus under trial (Sir T. Grant's and mine). The first experiment was completed about 3·30 of the ensuing morning. The fire was then "banked up" for the rest of the night; the general steamcock supplying the steam to both apparatus was turned off; both apparatus of course became quite cold, and the residuary steam in the boiler was used by the engineer for working his donkey-pump. Towards 12 o'clock of the ensuing day the experiments were resumed; steam again got up for the purpose, and an equal quantity of it turned as before into each apparatus.

When, however, a boiler is not at work, or has been even a few hours without working, its steam room as well as the steam pipe is of course filled with common air instead of with steam; wherefore the steam which is *at first* generated in the said boiler instead of being steam only, is a mixture of steam and air. Accordingly when steam is at first turned into my apparatus, a small cock with which the latter is provided is simultaneously opened for the purpose of allowing an escape for that air which otherwise would to a certain extent interfere with the condensation of the steam, and retard the boiling of the sea water in my evaporator. In conformity with this practice, as soon as the steam from the ship's boiler was turned into both apparatus (Sir T. Grant's and mine), the small cock above alluded to was opened, whereupon a rush of air escaped through it as usual, but I then observed for the first time that this air escaping from my *cold* apparatus (for no steam had as yet come into it), instead of being merely atmospheric air, was an inflammable gas, which being brought in contact with a lighted lamp burnt with a thin bluish flame, due evidently to the presence of carburetted gases resulting from the decomposing action exercised by the heated surfaces of the boiler, not only on the organic matters naturally contained in all natural waters, as discovered by the experiments which I made in 1850, and to which I have already alluded, but also on the fatty matters of the packings of the pistons, and introduced into the boiler by the feed pump, but in all probability principally from the decomposition of the melted tallow which is generally forced into it by means of a syringe *ad hoc*, for the purpose of preventing "priming," which introduction, in my humble judgment, is not under certain circumstances altogether free from danger.

I believe that most of the boiler explosions unsatisfactorily explained or absolutely unaccounted for are referable to the presence of the gases above alluded to, and of atmospheric air in such proportions as to form a detonating mixture, which is then inflamed *possibly* by the unduly heated surfaces of the boiler *above* the water level, but in my opinion much more probably by the electricity resulting from the friction of the vesicular steam against the steam pipe and other surfaces. In effect it is well known that the steam which issues from a boiler is always highly charged with electricity, and that electric sparks several inches in length may and have been drawn from it, especially when the boiler happens accidentally or otherwise to be isolated. On the other hand, a mixture of these gases may be exploded when mixed with atmospheric air in certain proportions varying between 1 of the former and from 6 to 16 of the latter, the maximum effect being when 1 of carburetted hydrogen is mixed with 8 of atmospheric air. Given, therefore, the conditions of a sufficiently insulated boiler, and a mixture therein of the above-mentioned gas and atmospheric air in proportions ranging between one of the first, and six, seven, eight, or nine of the second, an explosion of the boiler, of a more or less formidable nature, may take place.

I have already stated that sea water contains salt in the proportion of about 1 lb. to 33 lbs. of water. Now when sea water is evaporated, all the steam produced therefrom being of course fresh water, all the salt which that water contained is left behind, that is to say, the salt previously contained in the evaporated portion is left in that portion which is not yet evaporated, and which is therefore more impregnated with salt than before. If this salt be not removed, and the evaporation is continued, it goes on accumulating, furring and incrusting the vessel, and very soon destroys it. This is, in fact, an inconvenience common not only to all the sea-water stills hitherto contrived, but to the boilers of marine engines; for no boiler is safe from incrustation as soon as about one-half of the sea water admitted into it has been evaporated; that is, as soon as the sea water has been saturated by concentration so as to contain 1 lb. of salt in about 16 lbs. of water.

My apparatus is not liable to these incrustations or deposits of salt, because the sea water circulates in it in a constant and uninterrupted manner, a discharge taking place at the same time through cock 45 (see *fig.* 1887) so as to leave the sea water in the apparatus superabundantly diluted to hold in perfect solution the whole of its salt; in fact the sea water discharged through that cock contains only about one-half per cent. more salt than it did when it first entered the apparatus, which is a perfectly insignificant increase.

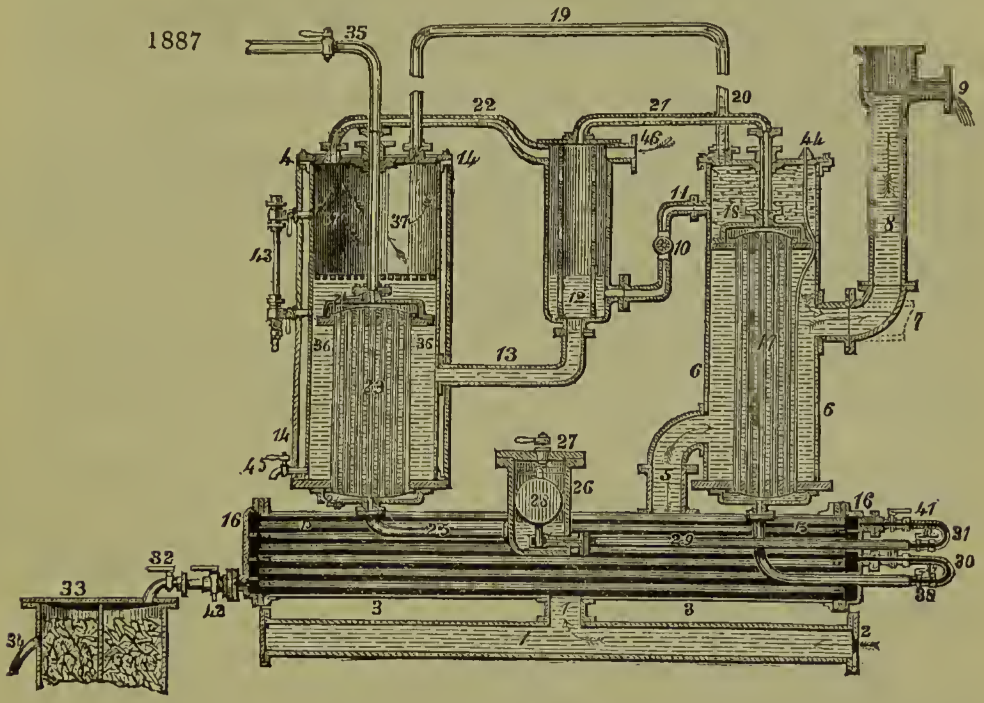
The different parts of the apparatus being made of sheet, riveted, galvanised iron plates and of cast iron, connected in a substantial manner by screws and bolts, without soldering or brazing of any kind or in any part, it is perfectly impossible that it should go out of order by any accident short of those cases of *force majeure* which, unfortunately, are too often the cause of the ruin or wreck of the ship itself.

I shall now give a description of the *figs.* 1887 and 1888, in which the same numbers represent the same organs. *Fig.* 1887 is a section on the same plane, showing the mode of action of the apparatus, without reference to the real position of its constituent parts. *Fig.* 1888 is a correct front elevation of the apparatus.

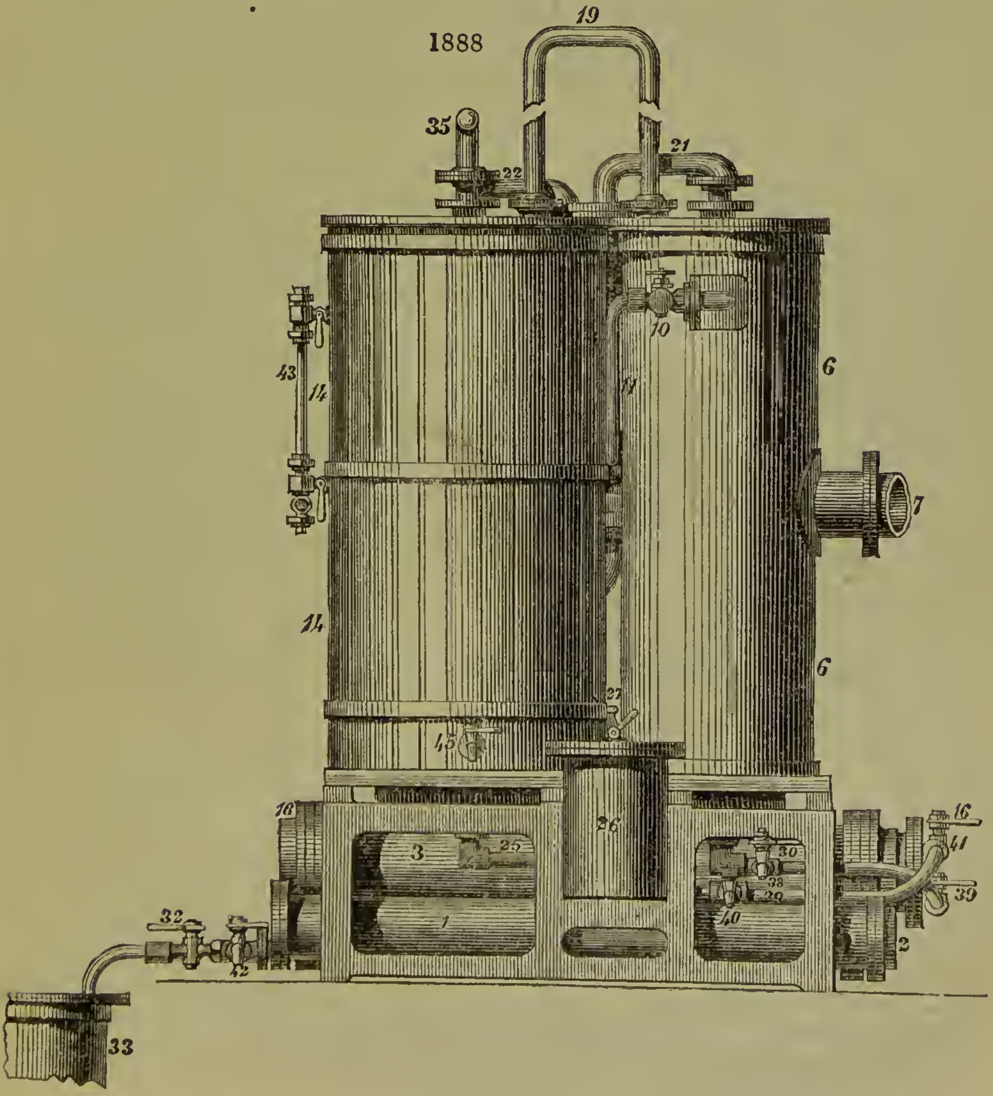
1 shows the large entrance tube for the sea water: this tube is connected to a large cock, communicating with the sea through the side or bottom of the ship; or else flanged to a much smaller pipe connected with a pump, by means of which the apparatus is supplied with water from the sea, which thus penetrates into the refrigerator 3, through the tube of communication 4, and thence passes round the sheaf of pipes 15, in the said refrigerator, through another communication tube 5, into the condenser 6, as shown by the arrows, and up the large vertical tube 8, whence the surplus sea water pumped up flows away through the pipe 9, in the direction indicated by the arrows. The condenser, 6, being thus completely filled up with sea water, on opening the cock 10, the sea water passing through pipe 11 falls into the feed and priming box 12, and thence through pipe 13 into the evaporator 14, filling it up to a certain level, regulated by opening or shutting the cock 10 so as to maintain the sea water at the proper level in the evaporator 14.

3, *Refrigerator.* It is a horizontal case pervaded with pipes 15, placed horizontally in it. The sea water being introduced into this refrigerator, circulates round a sheaf of pipes 15, held between the caps 16, at each end of the said refrigerator, so that the fresh water which has been condensed in the pipes 23, of the evaporator 14, and in the pipes 17 of the condenser 6, is thereby cooled down to the temperature of the sea water outside.

1887



1888



4, large pipe connecting the pipe 1 with the refrigerator 3.
5, large pipe connecting the refrigerator 3 with the condenser 6.
6, *Condenser.* It is a cylinder containing a sheaf of pipes 17, into which the non-aërated steam from the evaporator is condensed by the sea-water which surrounds them.
7, large outlet tube, used only when the apparatus is put below the level of the sea.
8, large upright tube, which, when the apparatus is placed on deck is turned upwards, and is of such a length that the sea water which is forced through the apparatus by means of the pump, or otherwise, may be raised a few feet above the whole apparatus, so that there may be in the large tube 8, a column of sea water higher than the condenser 6, in order to keep it quite full.
9, overflow pipe for the escape of the excess of sea water.
10, cock of the feed pipe.
11, feed pipe, one end of which is inserted in the condenser 6, and the other end in the feed and priming box 12. It is through this feed pipe 11, that the sea water is led from the top of the condenser into the feed and priming box 12, by opening the cock 10 to a suitable degree, as said before, 1.
12, feed and priming box. It is a box into which, on opening the cock 10, the sea-water supplied from the condenser 6, by pipe 11, passes through pipe 13 into the evaporator 14, which is thus fed with the proper quantity of sea water. This feed box receives also any priming which might be mechanically projected by or carried along with the steam through pipe 22. In such a case the priming is then returned to the evaporator 14, through pipe 13.
13, feed-pipe leading to the sea-water to be evaporated into the evaporator 14.
14, evaporator. It is a cylinder containing a sheaf of pipes 23, with their caps, 24, at each end, immersed in the sea-water, part of which is to be evaporated.
15, sheaf of pipes of the refrigerator 3, for the purpose of cooling the fresh water produced; has already been described under No. 3.
16, caps of the refrigerator 3, so arranged that by means of the divisions reserved in the said caps, the steam from the boiler, and that evolved from the evaporator 14, are both made to travel to and fro through the different pipes 15 consecutively, so as eventually to flow out in a mixed and cold state through the cock 32 into the filter 33, and finally through the tube 34 in a perfect state.
17, sheaf of pipes placed between the two caps 18 of the condenser 6, for the purpose of condensing the aërated steam from the evaporator 14.
18, caps covering the ends of the sheaf of pipes 17 placed in the condenser 6.
19, aërating pipe leading the air which separates from the sea water round the pipes 17 of the condenser 6 into the steam-room or chamber of the evaporator 14. It is by means of this aërating pipe that the fresh water condensed in the condenser 6 becomes aërated, and this aëration is accomplished as follows:—

As the steam from the evaporator 14 enters the pipes within the condenser 6 at the top thereof, through the pipe 21, it follows that the sea water at the top of the condenser 6 is brought, as was already said under No. 11, to a temperature which, at the top of the said condenser, is as high as 206° or 208° Fahr.; this temperature, as we also said, No. 11, gradually diminishes from the top downwards, but at a zone corresponding to about the point marked by No. 7, the temperature of the sea-water round the sheaf of pipes 17 is reduced to about 140° Fahr. As the air naturally contained in sea-water begins to separate therefrom at about 130° Fahr., that in the sea water round the sheaf of pipes 17, between No. 7 and the top of the condenser, becoming entirely liberated, ascends, by virtue of its lighter weight, to the top of the said condenser 6; it then passes through the aërating pipe 19, and is then poured into the steam-room 37 of the evaporator 14, wherein it mixes with the secondary steam therein produced by the evaporating pipes 23. This mixture of air and steam passes then through pipes 22 into the feed and priming-box 12, and thence through pipe 21 into the sheaf of pipes 17. The air being there absorbed during the condensation of this secondary steam, with which it was mixed, the condensed fresh water resulting therefrom becomes thus super-aërated, and in passing subsequently through the cock 39 of pipe 30 into a portion of the pipes 15 of the refrigerator 3, it mixes there with the non-aërated fresh water, resulting from the steam of the boiler, which has condensed in the pipes 23 of the evaporator 14, which condensed water flows through pipe 25 into the steam-trap 26, thence along pipes 29 and 31, and through the cock 41, into the other portion of pipes 15 of the refrigerator 3. The condensed water from the pipes 23 of the evaporator 14 becomes aërated by the excess of air contained in the condensed water of the pipes 17 of the condenser, in its passage with the latter through the pipes 15 of the refrigerator 3, in traversing which the combined waters are cooled down to the temperature of the sea water round the said sheaf of pipes in the refrigerator. And the result is, that after passing through the filter it flows at 34 in the state of perfectly cold fresh water, thoroughly aërated, and of matchless quality.

20, level to which the sea water rises in the aërating pipe 19.

21, pipe conducting the mixture of steam and air from the feed and priming-box 12 into the sheaf of pipes 17 of the condenser 6.

22, pipe leading the mixture of steam and air from the evaporator 14 into the feed and priming-box 12, where any salt water, with which it may be mixed, is arrested and returned to the evaporator 14, through pipe 13, while the pure steam, passing through pipe 21, is next condensed in the sheaf of pipes 17 of the condenser 6.

23, sheaf of pipes immersed in the sea water 36 of the evaporator 14, and in which pipes the steam coming from the boiler through the steam-pipe 35 is condensed, after which it flows as distilled but *non-aërated* fresh water into the lower cap 24, and thence through pipe 25 into the steam-trap 26, thence through pipes 29 and 31 and cock 41 into the sheaf of pipes 15 of the refrigerator 3.

24, upper and lower caps covering the two extremities of pipes 23 of the evaporator 14, into which pipes the steam from the boiler diffuses itself, and is condensed, after which it flows in the state of distilled but non-aërated fresh water, through pipe 25 into the steam-trap 26, and thence through pipes 29 and 31 into the pipes 15 of the refrigerator 3, in which it mixes with the *aërated* water coming through pipe 30, and passing through pipe 32 into the filter 33, finally issues at pipe 34 in the state of cold, matchless, aërated fresh water, *immediately fit for consumption.*

25, pipe for the exit of the condensed non-aërated fresh water from the sheaf of pipes 23, of the evaporator 14, which water, after entering the steam trap 26, issues therefrom through pipe 29, and then enters the refrigerator as already said.

26, steam trap. It is a box containing a float 28, provided with a plunger acting in such a way that when the box contains only steam, or a quantity of condensed water, not sufficient to buoy the float, it (the plunger) closes the exit pipe 29; but as soon as the condensed water has accumulated in quantity sufficient to buoy the float up, the plunger, of course, rising with the float, no longer obstructs the exit pipe 29, and accordingly the condensed water may then escape as fast as it is produced.

27, small pet cock on the top of the cover of the steam trap 26.

28, float already described (26).

29, pipe leading the condensed non-aërated water from the steam trap 26, through pipe 31, into the pipes 15 of the refrigerator 3, in which it mixes with the aërated fresh water from the condenser.

30, pipes leading the condensed aërated water from the pipes 17 of the condenser 6, into the pipes 15 of the refrigerator 3, in which it mixes with the non-aërated water from the steam trap 26. This pipe is provided with two cocks, 38 and 39, for the purpose of cleaning the condenser 6.

31, pipe leading the condensed non-aërated water from pipe 29 into the pipes 15 of the refrigerator, in which it mixes with the aërated water from the condenser.

32, exit-pipe and cock, through which the mixed distilled waters (aërated and non-aërated), after passing through the pipes of the refrigerator, enter the filter, 33.

33, filter for receiving the condensed water from both the evaporator and the condenser, as they issue in a mixed and cold state from the pipes 15 of the refrigerator 3, through cock and pipe 32.

34, pipe for the final exit of the perfect aërated fresh water.

35, steam pipe and cock leading the steam more or less under pressure from any description of boiler to the pipes 23 of the evaporator 14. It is connected at one end with the steam boiler, and at the other with the upper cap 24, of the evaporating pipes 23.

36, sea water, to be evaporated by the steam-pipes 23, of the evaporator 14.

37, steam room, or space into which the air naturally contained in the sea water used for condensation in the condenser 6, is poured through the aërating pipe 19, so as to mix with the steam generated by the pipes 23 of the evaporator.

38 and 39, two cocks on pipe 30, placed between the condenser 6 and the refrigerator 3, for the purpose of clearing the pipes 17 of the condenser 6.

40 and 41, two cocks placed on pipe 31, for the purpose of clearing the pipes 23 of the evaporator 14 and steam trap 26.

42, cock placed between the cap 16 of the refrigerator 3, and the cock 32, for the purpose of cleaning the pipes 15 of the refrigerator 3.

43, glass water-gauge.

44, breathing-pipe. It is a small pipe, one end of which is in communication with the lower cap 18 of the condensing-pipes 17, and the other end is open to the atmosphere. The object of this pipe is not only to remove pressure from the cylinders, but likewise to afford an exit for the excess of air generated.

45, brine cock.

46, opening reserved in the feed and priming-box.

The first thing to be done is, of course, to charge the apparatus with sea water. This is done by establishing a communication between the apparatus and the sea water round the ship. This is easily done by turning on the large cocks, or Kingston valves, connected with the large orifices 2 and 7 (see the figures), whereupon the salt water immediately fills up both the refrigerator 3 through the passage 4 and the condenser 6 through the passage 5, up to a certain point 20 of the aërating pipe.

Opening now the cock 10 of the feed pipe 11 the sea water will pass from the condenser 6 into the feed and priming box 12 and thence through pipe 13 into the evaporator 14, where it should be allowed to rise up to about one-third of the glass gauge, 43, when the cock 10 should be shut up. The apparatus being thus charged with its proper quantity of sea water; the steam-boiler being ready to furnish the necessary steam; and admitting, of course, that the steam pipe 35 is in communication with the said boiler, the next thing to be done is to open the steam cock, 35, shutting at the same time the cocks 39, 41, and 32, and opening cocks 38, 40, and 42, and likewise the small pet cock 27 of the steam trap 26. On opening this small pet cock 27 nothing but air will at first rush out; but, presently, steam will issue from it; it should then be closed more and more gradually as the steam is seen issuing from it with rapidity; and it should eventually be left *almost*, but not altogether, shut up, so as to leave only room for the smallest possible wreath of steam slowly to issue from it. As soon as the steam-cock 35 is open, the steam from the boiler will rush through that cock into the sheaf of pipes 23 of the evaporator 14, in which pipes it will be condensed by the sea water which surrounds them, and it will then flow in the state of condensed non-aërated distilled water through the pipe 25 into the steam trap 26; lift up the float 28, and passing through pipe 29, will flow through cock 40, its further progress being intercepted by cock 41, which is shut, as said before. As soon as the condensed water flows out in a clear state from cock 40, shut it, and open cock 41, so that it may pass into the pipes 15 of the refrigerator 3, and out at cock 42. In a few moments the condensed water will flow out in a clear state from that cock, 42, which should then be closed, opening at the same time cock 32, so that it may pass into the filter 33.

But the steam within the sheaf of pipes 23 of the evaporator 14 soon brings the sea water round them to the boiling point, and converts part of it into steam. This pure secondary steam from the evaporator, issuing then from the priming-box 12, passes through pipe 21 into the pipes 17 immersed in the salt water of the condenser 6, and being condensed in the said pipes, is allowed to flow out at the cock 38 (which has been opened at starting), as long as it is not clear. In a short time, however, it will flow out from that cock, 38, in a perfectly clear state; when this takes place shut this cock 38, and open cock 39, whereupon it will flow into the pipes 15 of the refrigerator 3, in which pipes it will mix with that coming from the pipes 23 of the evaporator 14, and flow with it through the said pipes 15, and thence into the filter 33 through the cock 32, the whole issuing finally from the filter 33 through pipe 34, in the state of perfect aërated fresh water.

From this brief description of my marine fresh-water apparatus it may be seen that a quantity of fresh water is produced *always double* that which can be evaporated from any boiler whatever, and indeed by increasing the number of evaporators 1 lb. of coals may thus be made to yield 30 or 40 lbs. of fresh water of matchless quality. That the small volume of the apparatus, the large quantity of fresh aërated water which it produces*, at an extremely small cost, its perfect safety, permanent order, and the ease with which it can be disconnected and all its parts reached, not only render it pre-eminently suited to naval purposes, but likewise to such stations or places as are deficient in one of the first necessaries of life, salubrious fresh water, or where it cannot be obtained at all, or only in an insufficient, precarious, or expensive manner.—A. N.

The following letters were addressed to the Editor in reply to an inquiry made by him as to the value of Dr. Normandy's invention.

"Government Emigration Board,
"8, Park Street, Westminster, 1st March, 1860.

"Sir,—I am directed by the Emigration Commissioners to acknowledge the receipt of your letter of the 28th ultimo, requesting to be furnished with any evidence they may possess as to the good or ill effects of the use of Dr. Normandy's distilled water on board emigrant ships.

"In reply, I am to acquaint you that the Commissioners have placed on board several of their emigrant ships Dr. Normandy's apparatus for distilling fresh from salt water, and that the reports which

---

* An apparatus 4 ft. 6 in. high, 5 ft. long, and 2 ft. wide, produces at least 24 gallons of fresh water per hour.

they have as yet received from their surgeons in those vessels (who are instructed to pay particular attention to the matter) are uniformly of a favourable character — one gentleman only having mentioned that the water had at first an insipid taste which subsequently went off. This probably arose from some accidental circumstance in the particular machine, as freedom from insipidity is one of the main characteristics of the water.

"I enclose, for your information, extracts from the official reports made to this Board by their surgeons and the colonial emigration agents, respecting the quality of the water and its effects.

"I have the honour to be, sir,
"Your obedient servant,
"S. WALCOTT, *Secretary*."

"Robert Hunt, Esq."

Extract from the report of Dr. Duncan, Immigration Agent, on the ship "*Confiance*" *dated Port Adelaide*, 10*th Jan.* 1859:—

"A distilling apparatus, invented by Dr. Normandy, was sent out in the 'Confiance' to test its efficiency.

"There are two great objections to water distilled in the ordinary manner; the first is, that water thus obtained is without air, is unpalatable and indigestible; the second is, that it contracts, while in the process of distillation, an empyreumatic odour and taste; in fact, ordinary distilled water is said to be indigestible and nauseous.

"These two objections appear to be perfectly met by Dr. Normandy's invention; the water obtained by his process is perfectly palatable, well aërated, and devoid of smell.

"During the passage of the 'Confiance,' nearly eleven thousand gallons of water were distilled, and is reported by the surgeon superintendent to have been of most excellent quality, and preferred by the emigrants to the water shipped on board in casks."

Extract from the Report of Dr. Carroll on the ship "*Conway*," *dated Melbourne*, 20*th Sept.* 1858:—

"The quality of the water produced was, in my opinion, excellent, and most agreeable in taste; and, so far as my observation went, most wholesome; in fact, during the hot weather I considered it quite a luxury; and I regretted much that the quantity produced was not greater. It was also preferred by the passengers to ship's water."

Extract from the Report of Dr. Crane on the ship "*Forest Monarch*," *dated Sydney, Jan.* 5*th*, 1859:—

"The condensed water was very good, excelling in clearness and purity, and much more palatable than any water I had ever previously seen on board ship, being not unlike the rain-water so much esteemed in the West Indies. The water, as it came from the apparatus, possessed a slight peculiar taste, which varied in degree with the purity of the sea water employed in its production, and which disappeared on exposure to the air. This peculiar taste I attribute partly to the excessive aëration of the condensed water, as I have noticed a similar taste in soda-water that has been adulterated for cheapness' sake, with common air, and partly to empyreumatic products obtained from the destructive distillation of organic impurities contained in the sea water subjected to distillation."

Extract from the Report of Dr. Rivers on the "*Morayshire*," *dated Calcutta*, 18*th May*, 1859:—

"The emigrants did not at first like the distilled water, but gradually got accustomed to it, and afterwards to prefer it to the ordinary water. Those drinking it seemed better in health than the people using the other water, and more free from bowel complaints. I would, therefore, strongly recommend that the water prepared from Dr. Normandy's apparatus be generally used in all ships carrying Coolies, as, in my opinion, it is not only wholesome, but perfectly free from all impurities, besides not so liable to disorder the bowels as the common water."

Extract from the Report of Mr. James Crosby, Immigration Agent at British Guiana, on the ship "*Queen of the East*," *dated British Guiana*, 19*th Oct.* 1859: —

"I found also Dr. Normandy's admirable distilling apparatus in full operation. It is almost impossible to speak in too favourable terms of this apparatus, capable of producing five hundred gallons a day—with the consumption, I think, of only eight bushels of coals—of water apparently as pure and wholesome as could be drunk, and taken from alongside the ship, from the muddy and impure water of the Demerara river."

Extract of a letter from Dr. L. S. Crane, surgeon superintendent of the ship "*Devonshire*," *dated Coconada*, 27*th December*, 1859:—

The "Devonshire" was dismasted in a hurricane, by which the apparatus on deck was injured.

"Since the water apparatus was broken, the health of the Coolies has deteriorated. After careful observation I can find no other cause for the dysentery and diarrhœa prevailing than the water they drink. The ventilation is excellent, the between-decks have been kept beautifully clean and dry—the food is good and well cooked. The rice, cargo, has been steaming to a certain extent, but the diseases that arise from bad air,—low fevers and cholera,—have not made their appearance. Besides the crew have suffered very much more than the Coolies, and the only condition common to both is the water they drink."

Extract of a letter from Mr. C. Chapman, surgeon superintendent of the ship "*Euxine*," *to S. Walcott, Esq., dated Madras*, 23*rd January*, 1860:—

"In my opinion, the water it (Dr. Normandy's apparatus) produces is perfectly sweet and wholesome; is far preferable, and preferred by all hands, to the water in tanks or casks."

WAX (*Cire*, Fr.; *Wachs*, Germ.) is the substance which forms the cells of bees. It was long supposed to be derived from the pollen of plants, swallowed by these insects, and merely voided under this new form; but it has been proved by the experiments, first of Mr. Hunter, and more especially of M. Huber, to be the peculiar secretion of a certain organ, which forms a part of the small sacs situated on the sides of the median line of the abdomen of the bee. On raising the lower segments of the abdomen these sacs may be observed, as also scales or spangles of wax, arranged in pairs upon each segment. There are none, however, under the rings of the males and the queen. Each individual has only eight wax sacs, or pouches; for the first and the last ring are not provided with them. M. Huber satisfied himself by precise experiments that bees, though fed with honey or sugar alone, produced nevertheless a very considerable quantity of wax; thus proving that they were not mere collectors of this substance from the vegetable kingdom. The pollen of plants serves for the nourishment of the larvæ.

But wax exists also as a vegetable product, and may, in this point of view, be regarded as a concrete fixed oil. It forms a part of the green fecula of many plants, particularly of the cabbage; it may be extracted from the pollen of most flowers, as also from the skins of plums and many stone fruits. It constitutes a varnish upon the upper surface of the leaves of many trees, and it has been observed in the juice of the *cow-tree* The berries of the *Myrica angustifolia*, *latifolia*, as well as the *cerifera*, afford abundance of wax.

Bees' wax, as obtained by washing and melting the comb, is yellow. It has a peculiar smell, resembling honey, and derived from it, for the cells in which no honey has been deposited yield a scentless white wax. Wax is freed from its impurities, and bleached, by melting it with hot water or steam, in a tinned copper or wooden vessel, letting it settle, running off the clear supernatant oily-looking liquid into an oblong trough with a line of holes in its bottom, so as to distribute it upon horizontal wooden cylinders made to revolve half immersed in cold water, and then exposing the thin ribbons or films thus obtained to the blanching action of air, light, and moisture. For this purpose the ribbons are laid upon long webs of canvas stretched horizontally between standards, two feet above the surface of a sheltered field, having a free exposure to the sunbeams. Here they are frequently turned over; then covered by nets to prevent their being blown away by winds, and watered from time to time, like linen upon the grass field in the old method of bleaching. Whenever the colour of the wax seems stationary, it is collected, re-melted, and thrown again into ribbons upon the wet cylinder, in order to expose new surfaces to the blanching operation. By several repetitions of these processes, if the weather proves favourable, the wax eventually loses its yellow tint entirely, and becomes fit for forming white candles. If it be finished under rain, it will become grey on keeping, and also lose in weight.

In France, where the purification of wax is a considerable object of manufacture, about four ounces of cream of tartar or alum are added to the water in the first melting-copper, and the solution is incorporated with the wax by diligent manipulation. The whole is left at rest for some time, and then the supernatant wax is run off into a settling cistern, whence it is discharged by a stopcock or tap over the wooden cylinder revolving at the surface of a large water-cistern, kept cool by passing a stream continually through it.

The bleached wax is finally melted, strained through silk sieves, and then run into circular cavities in a moistened table, to be cast or moulded into thin disc pieces, weighing from two to three ounces each, and three or four inches in diameter.

Neither chlorine nor even the chlorides of lime and alkalies can be employed with any advantage to bleach wax, because they render it brittle and impair its burning quality.

Wax purified as above is white and translucent in thin segments; it has neither taste nor smell; it has a specific gravity of from 0·960 to 0·966; it does not liquefy till heated to 154½° Fahr.; but it softens at 86°, becoming so plastic that it may be moulded by the hand into any form. At 32° it is hard and brittle.

It is not a simple substance, but consists of two species of wax, which may be easily separated by boiling alcohol. The resulting solution deposits, on cooling, the waxy body called *cerine*. The undissolved wax being once and again treated with boiling alcohol, finally affords from 70 to 90 per cent. of its weight of cerine. The insoluble residuum is the *myricine* of Dr. John, so called because it exists in a much larger proportion in the wax of the *Myrica cerifera*. It is greatly denser than wax, being of the same specific gravity as water; and may be distilled without decomposition, which cerine undergoes. Professor B. C. Brodie has made an extensive series of researches into the constitution of wax. He applies the name cerotic acid to cerine, and represents its formula as $C^{54}H^{54}O^{4}$. Pure myricine he considers to be represented by $C^{92}H^{92}O^{4}$.

Wax is adulterated sometimes with starch; a fraud easily detected by oil of turpentine, which dissolves the former and leaves the latter substance; and more frequently with mutton suet. This fraud may be discovered by dry distillation; for wax does not thereby afford, like tallow, sebacic acid (benzoic), which is known by its occasioning a precipitate in a solution of acetate of lead. It is said that 2 per cent. of a tallow sophistication may be discovered in this way.

Wax is sometimes adulterated with stearine, which can be detected, according to Lebel, even when only in 1-20th part. It may be recognised by dissolving the specimens in two parts of oil, agitating with water, and adding acetate of lead. The precipitate thus obtained is said to exhibit a very high degree of solidity.

WAX CANDLES.—Wax contains 81·75 parts of carbon in 100, which generate by combustion 300 parts of carbonic acid gas. Now, since 125 grains of wax constitute the average consumption of a candle per hour, these will generate 375 grains of carbonic acid; equivalent in volume to 800 cubic inches of gas. According to the most exact experiments on respiration, a man of ordinary size discharges from his lungs 1632 cubic inches of carbonic acid gas per hour, which is very nearly the double of the quantity produced from the wax candle. Hence the combustion of two such candles vitiates the air much the same as the breathing of one man. A tallow candle, three or four in the pound, generates nearly the same quantity of carbonic acid as the wax candle; for though tallow contains only 79 per cent. of carbon, instead of 81·75, yet it consumes so much faster, as thereby to compensate fully for this difference.

When a tallow candle of 6 to the lb. is not snuffed, it loses in intensity, in 30 minutes, 80 hundredths, and in 39 minutes 86 hundredths; in which dim state it remains stationary, yet still consuming nearly the same proportion of tallow. A wax candle attains to its greatest intensity of light when its wick has reached the greatest length, and begins to bend out of the flame. The reason of this difference is, that only the lower part of the wick in the tallow candle is charged with the fat, so as to emit luminiferous vapour, while the upper part remains dry; whereas, in the wax candle the combustible substance being less fusible and volatile, allows a greater length of the wick to be charged by capillary attraction, and of course to emit a longer train of light.

WAX, MINERAL, or *Ozocerite*, is a solid, of a brown colour, of various shades, translucent and fusible like bees' wax; slightly bituminous to the smell, of a foliated texture. Its specific gravity varies from 0·94 to 0·97. Candles have been made of it which give a tolerable light. It occurs at the foot of the Carpathians near Slanik, beneath a bed of bituminous slate-clay, in masses of from 80 to 100 pounds weight. It is associated with variegated sandstone, rock salt, and beds of coal (lignite?). It is analogous to *hatchetine*. Ozocerite has been discovered at Urpeth colliery, near Newcastle, 60 fathoms beneath the surface.

WEAVING (*Tissage*, Fr.; *Weberei*, Germ.) is performed by the implement called *loom* in English, *métier à tisser* in French, and *weberstuhl* in German. The process of warping must always precede weaving. Its object is to arrange all the longitudinal threads, which are to form the chain of the web, alongside of each other in one parallel plane. Such a number of bobbins, filled with yarn, must therefore be taken as will furnish the quantity required for the length of the intended piece of cloth. One-sixth of that number of bobbins is usually mounted at once in the warp mill, being set loosely in a horizontal direction upon wire skewers, or spindles, in a square frame, so that they may revolve, and give off the yarn freely. The warper sits at A,

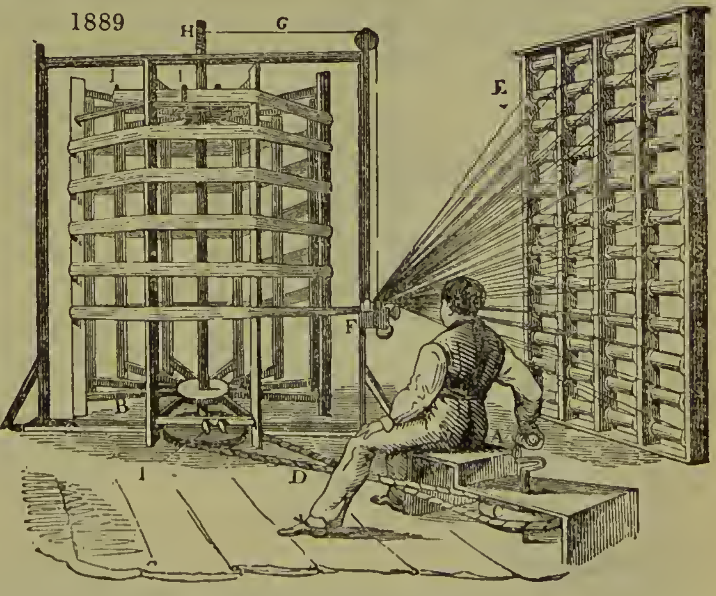

fig. 1889, and causes the reel B to revolve, by turning round with his hand the wheel C, with the endless rope or band D. The bobbins filled with yarn are placed in the frame E. There is a sliding pieee at F, ealled the *heck* box, whieh rises and falls by the eoiling and uneoiling of the cord G, round the eentral shaft of the reef H. By this simple eontrivanee the band of warp-yarns is wound spirally from top to bottom upon the reel. I, I, I, are wooden pins which separate the different bands. Most warping mules are of a prismatic form, having twelve, eighteen, or more sides. The reel is eommonly about six feet in diameter and seven feet in height, so as to serve for measuring exaetly upon its periphery the total length of the warp. All the threads from the frame E pass through the heek F, whieh eonsists of a series of finely-polished, hard-tempered steel pins, with a small hole at the upper part of eaeh to reeeive and guide one thread. The heek is divided into two parts, either of which may be lifted by a small handle below, while their eyes are plaeed alternately. Henee, when one of them is raised a little, a vaeuity is formed between the two bands of the warp; but when the other is raised the vaeuity is reversed. In this way the lease is produeed at eaeh end of the warp, and it is preserved by appropriate wooden pegs. The lease being earefully tied up affords a guide to the weaver for inserting his lease-rods. The warping mill is turned alternately from right to left, and from left to right, till a suffieient number of yarns are eoiled round it to form the breadth that is wanted; the warper's prineipal eare being to tie immediately every thread as it breaks, otherwise defieiencies would be oeeasioned in the ehain, injurious to the appearanee of the web, or produetive of much annoyance to the weaver.

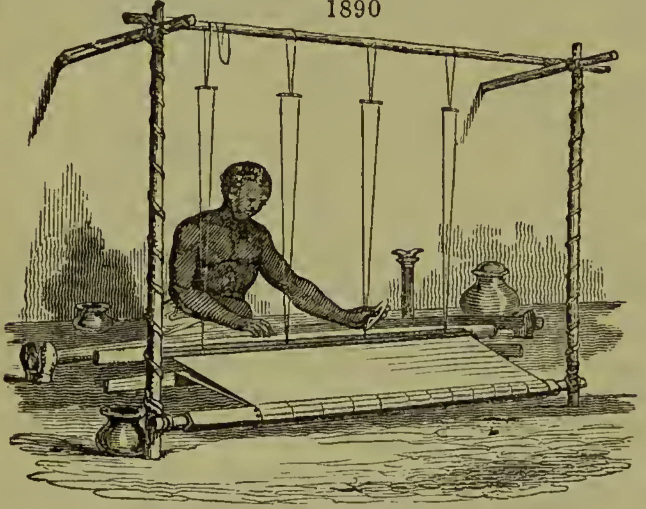
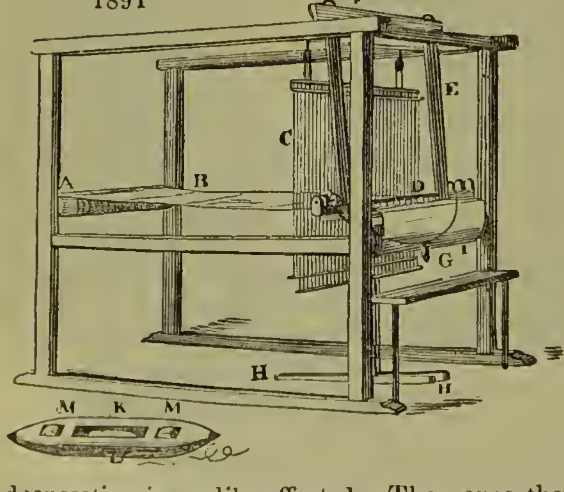
The simplest and probably the most aneient of looms now to be seen in aetion is that of the Hindu tanty, shown in *fig.* 1890. It consists of two bamboo rollers; one for the warp, and another for the woven eloth; with a pair of heddles, for parting the warp, to permit the weft to be drawn aeross between its upper and under threads. The shuttle is a slender rod, like a large netting needle, rather longer than the web is broad, and is made use of as a batten or lay, to strike home or eondense eaeh sueeessive thread of weft, against the elosed fabrie. The Hindu earries this simple implement, with his water pitcher, riee pot, and hooka, to the foot of any tree whieh ean afford him a eomfortable shade; he there digs a large hole, to reeeive his legs, along with the treddles or lower part of the harness; he next extends his warp, by fastening his two bamboo rollers at a proper distanee from eaeh other, with pins, into the sward; he attaehes the heddles to a convenient braneh of the tree overhead; inserts his great toes into two loops under the gear, to serve him for treddles; lastly, he sheds the warp, draws through the weft, and beats it elose up to the web with his rod shuttle or batten.

1890



1891



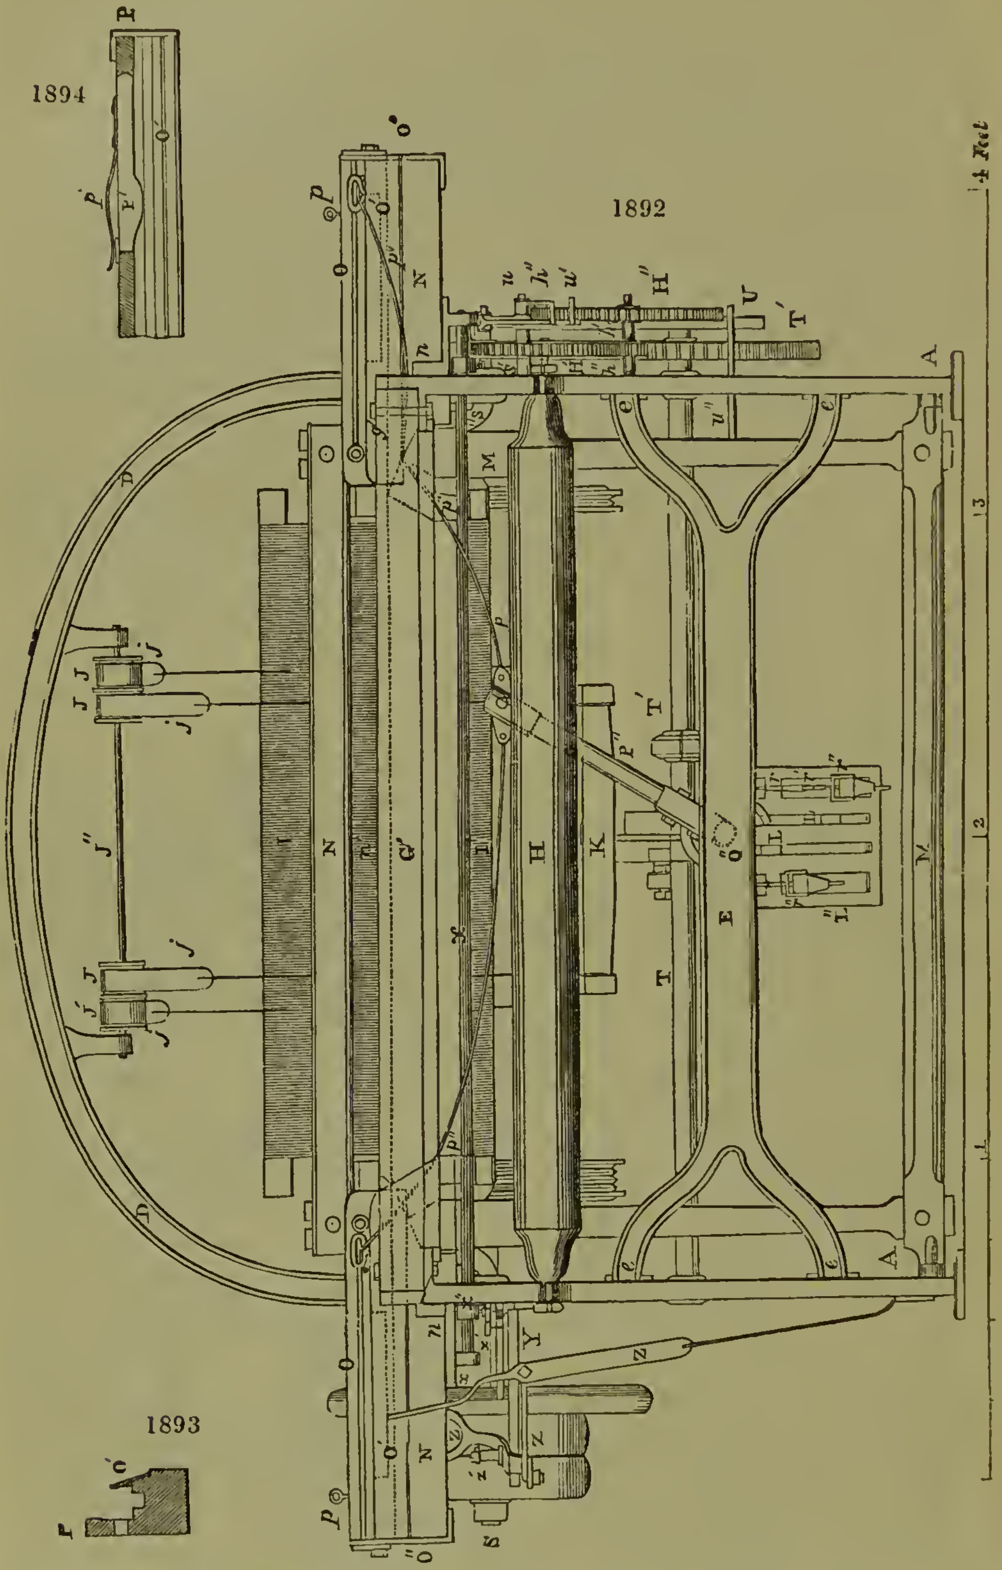
The European loom is represented in its plainest state, as it has existed for several eenturies, in *fig.* 1891. A is the warp-beam, round whieh the ehain has been wound; B represents the flat rods, usually three in number, whieh pass across between its threads, to preserve the lease, or the plane of deeussation for the weft; C shows the heddles or healds, eonsisting of twines looped in the middle, through which loops the warp yarns are drawn, one half through the front heddle, and the other through the baek one; by moving whieh, the decussation is readily effeeted. The yarns then pass through the dents of the reed under D, which is set in a movable swing-frame E, ealled the lathe, lay, and also batten, because it *beats* home the weft to the web. The lay is freely suspended to a cross-bar F, attached by rulers, called the *swords*, to the top of the lateral standards of the loom, so as to oscillate upon it. The weaver, sitting on the bench G, presses down one of the treddles at H, with one of his feet, whereby he raises the corresponding heddle, but sinks the alternate one; thus sheds the warp, by lifting and depressing each alternate thread through a little space, and opens a pathway or race-course for the shuttle to traverse the middle of the warp, upon its two friction rollers M M. For this purpose, he lays hold of the picking-peg in his right hand, and with a smart jerk of his wrist drives the fly-shuttle swiftly from one side of the loom to the other, between the shed warp yarns. The shoot of weft being thereby left behind from the shuttle pirn or cop, the weaver brings home, by pulling the lay with its reed towards him by his left hand, with such force as the closeness of the texture requires. The web, as thus woven, is wound up by turning round the cloth beam I, furnished with a ratchet-wheel, which takes into a holding tooth. The plan of throwing the shuttle by the picking-peg and cord, is a great improvement upon the old way of throwing it by hand. It was contrived upwards of a century ago, by John Kay, of Bury, in Lancashire, but then resident in Colchester, and was called the fly-shuttle from its speed, as it enabled the weaver to make double the quantity of narrow cloth, and much more broad cloth, in the same time.

The cloth is kept distended during the operation of weaving, by means of two pieces of hard wood, called a templet, furnished with sharp iron points in their ends, which take hold of the opposite selvages or lists of the web. The warp and web are kept longitudinally stretched by a weighted cord, which passes round the warp-beam, and which tends continually to draw back the cloth from its beam, where it is held fast by the ratchet tooth. See FUSTIAN, JACQUARD LOOM, REED, and TEXTILE FABRICS.

The greater part of plain weaving, and much even of the figured, is now performed by the power loom, called *métier mécanique à tisser* in French. *Fig.* 1892, represents the cast-iron power loom of Sharp and Roberts. A, A′, are the two side uprights, or standards, on the front of the loom. D, is the great arch of cast-iron, which binds the two sides together. E, is the front cross-beam, terminating in the forks *e*, *e*; whose ends are bolted to the opposite standards A, A′, so as to bind the framework most firmly together. G′, is the breast beam of wood, nearly square; its upper surface is sloped a little towards the front, and its edge rounded off for the web to slide smoothly over it in its progress to the cloth beam. The beam is supported at its end upon brackets, and is secured by the bolts *g*′, *g*′. H, is the cloth beam, a wooden cylinder mounted with iron gudgeons at its ends, that on the right hand being prolonged to carry the toothed winding wheel H′. *k*′, is a pinion in geer with H′. H″, is a ratchet wheel, mounted upon the same shaft *h*‴, as the pinion *h*′. *h*′, is the click of the ratchet wheel H″. *h*‴, is a long bolt fixed to the frame, serving as a shaft to the ratchet wheel H″, and the pinion *h*′. I, is the front heddle-leaf, and I′, the back one. J, J, J′, J′, jacks or pulleys and straps for raising and depressing the leaves of the heddles. J″, is the iron shaft which carries the jacks or system of pulleys J, J, J′, J′. K, a strong wooden ruler, connecting the front heddle with its treddle. L, L′, the front and rear marches or treddle pieces for depressing the heddle leaves alternately, by the intervention of the rods *k*, (and *k*′, hid behind *k*). M, M, are the two swords (swing bars) of the lay or batten. N, is the upper cross-bar of the lay, made of wood, and supported upon the squares of the levers *n*, *n*′, to which it is firmly bolted. N′, is the lay-cap, which is placed higher or lower, according to the breadth of the reed; it is the part of the lay which the hand-loom weaver seizes with his hand, in order to swing it towards him. *n*′, is the reed contained between the bar N, and the lay-cap N′. O, O, are two rods of iron, perfectly round and straight, mounted near the ends of the batten-bar N, which serve as guides to the drivers or peckers *o*, *o*, which impel the shuttle. These are made of buffalo hide, and should slide freely on their guide-rods. O′, O′, are the fronts of the shuttle-boxes; they have a slight inclination backwards; P is the back of them. See *figs.* 1893 and 1894. O″, O″, are iron plates, forming the bottoms of the shuttle-boxes. *p*, small pegs or pins, planted in the posterior faces P (*fig.* 1892) of the boxes, round which the levers P′ turn. These levers are sunk in the substance of the faces P, turned round pegs *p*, being pressed from without inwards, by the springs *p*′. P″, *fig.* 1892, (to the right of K,) is the whip or lever, (and Q″, its centre of motion, corresponding to the right arm and elbow of the weaver,) which serves to throw the shuttle by means of the pecking-cord *p*″, attached at its other end to the drivers *o*, *o*.

On the axis of Q″, a kind of eccentric or heart wheel is mounted, to whose concave part, the middle of the double band or strap *r*, being attached, receives impulsion; its two ends are attached to the heads of the bolts *r*′, which carry the stirrups *r*″, that may be adjusted at any suitable height, by set screws.

S (see the left-hand side of *fig.* 1892) is the moving shaft of wrought iron, resting on the two ends of the frame. s′ (see the right-hand side), is a toothed wheel, mounted exteriorly to the frame, upon the end of the shaft s. s″ (near s′), are two



1894 1892 1893

equal elbows in the same direction, and in the same plane, as the shaft s, opposite to the swords M, M, of the lay.

z, is the loose, and z′, the fast pulley, or riggers, which receive motion from the steam-shaft of the factory. z″, a small fly wheel, to regulate the movements of the main shaft of the loom.

T, is the shaft of the eccentric tappets, cams, or wipers, which press the treddle levers alternately up and down; on its right end is mounted T′, a toothed wheel in gear with the wheel s′, of one half its diameter. T″, is a cleft clamping collar, which serves to support the shaft T.

U, is a lever which turns round the bolt *u*, as well as the clink *h*″. U′, is the click of traction, for turning round the cloth beam, jointed to the upper extremity of the lever U; its tooth *u*′, catches in the teeth of the ratchet wheel H″. *u*″, is a long slender rod, fixed to one of the swords of the lay M, serving to push the lower end of the lever U, when the lay retires towards the heddle leaves.

X, is a wrought-iron shaft, extending from the one shuttle-box to the other, supported at its ends by the bearings *x*, *x*.

Y, is a bearing, affixed exteriorly to the frame, against which the spring bar Z rests near its top, but is affixed to the frame at its bottom. The spring falls into a notch in the bar Y, and is thereby held at a distance from the upright A, as long as the band is upon the loose pulley *z*′; but when the spring bar is disengaged, it falls towards A, and carries the band upon the fast pulley *z*, so as to put the loom in gear with the steam-shaft of the factory.

Weaving, by this powerful machine, consists of four operations: 1, to shed the warp by means of the heddle leaves, actuated by the tappet wheels upon the axis Q′, the rods *k*, *k*′, the cross-bar E, and the eyes of the heddle leaves I, I′; 2, to throw the shuttle (see *fig.* 1891), by means of the whip lever P″, the driver cord *p*, and the peeker *o*; 3, to drive home the weft by the batten N, N′; 4, to unwind the chain from the warp beam, and to draw it progressively forwards, and wind the finished web upon the cloth beam H, by the click and toothed wheel mechanism at the right-hand side of the frame.

See COTTON, FLAX, TEXTILE FABRICS, &c.

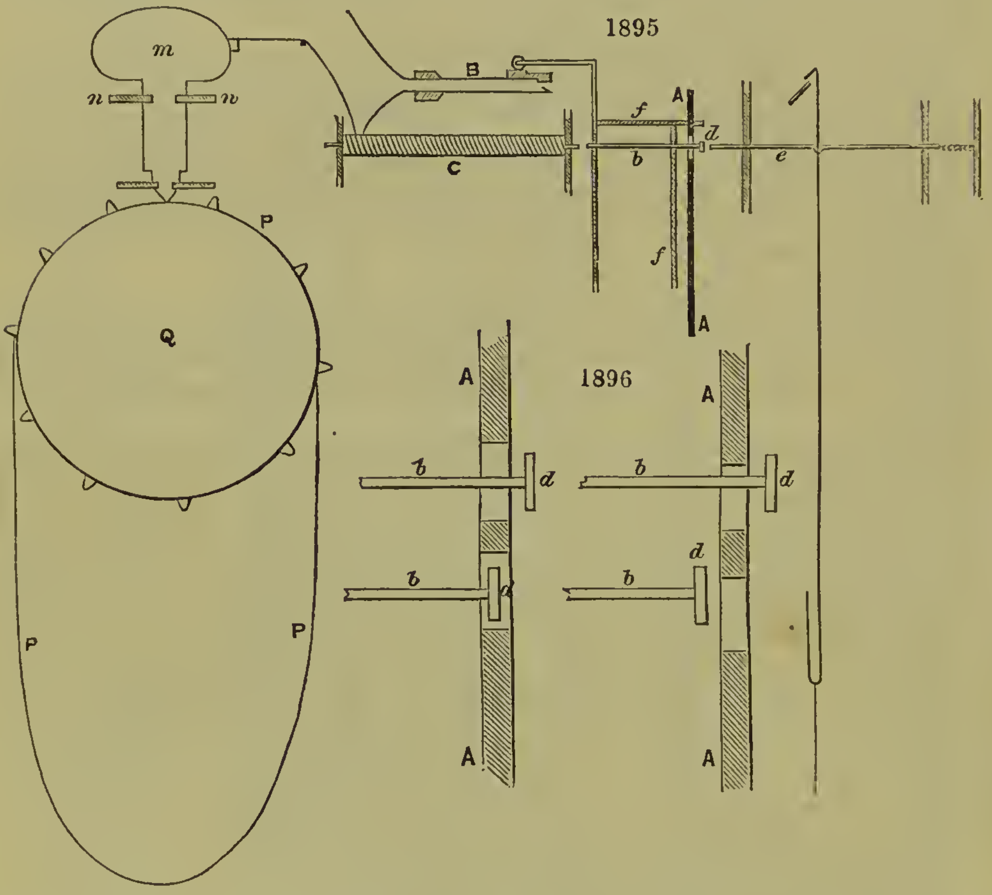
WEAVING BY ELECTRICITY. The article weaving, and those referred to from it, together with the article on the Jacquard loom, will render the conditions necessary to the production of figures in any textile fabric tolerably familiar. A brief notice of a new invention for employing electricity in weaving cannot fail to be interesting.

So long ago as 1852, M. Bonelli constructed an electric loom, which was exhibited at that time in Turin, but the first trial to which the machine was submitted gave but small hope to those who saw it that the inventor would succeed in his object. The public trial at Turin, in 1853, in the presence of manufacturers, was not so successful as to remove all doubts as to the merits of the novel apparatus. In the following year it was submitted to the judgment of the Academy of Sciences at Paris, who appointed a committee to examine it, but it is believed that no report was ever made. In 1855, a model of the loom had a place at the Universal Exhibition at Paris, but the lateness of its arrival there prevented any official report being made in reference to its merits. Since then, M. Bonelli has devoted much time and attention in endeavouring to remedy its defects and to perfect its working, so as to render it capable of holding its place in the factory. This M. Bonelli believes he has at last accomplished, and he has brought over to this country not merely a model, but a loom in complete working order, which he is prepared with confidence to submit to the judgment of manufacturers, as a machine which, from its economy and efficiency, may be put in favourable comparison with the Jacquard loom.

In the first place, it must be understood that the special object of M. Bonelli's machine is to do away with the necessity for the Jacquard cards used to produce the pattern at the present time, the source of delay and very considerable cost, more especially in patterns of any extent and variety of treatment. M. Bonelli uses an endless band of paper, of suitable width, the surface of which is covered with tin-foil. On this metallised surface, the required pattern is drawn, or rather painted with a brush in black varnish, rendering the parts thus covered non-conducting to a current of electricity. This band of paper, bearing the pattern, being caused to pass under a series of thin metal teeth, each of which is in connection with a small electro-magnet, it will readily be conceived that as the band passes under these teeth, a current of electricity from a galvanic battery may be made to pass through such of the teeth as rest on the metallised or conducting portion of the band, and from such teeth, through the respective coils, surrounding small bars of soft iron, thus rendering them temporary magnets, whilst no current passes through those connected with the teeth resting on the varnished portions. Thus, at every shift of the band, each electro-magnet in connection with the teeth becomes active or remains inactive according to the varying portion of the pattern which happens to be in contact with the teeth. In a movable frame opposite the ends of the electro-magnets, which, it should be stated, lie in a horizontal direction, are a series of small rods or pistons, as M. Bonelli terms them, the ends of which are respectively opposite to the ends of the electro-magnets. These pistons are capable of sliding horizontally in the frame, and pass through a plate attached to the front of it. When this frame is moved so that the ends of the pistons are brought into contact with the ends of the electro-magnets they are seized by such of them as are in an active state, and on moving the frame forward, those are retained while the others are carried back with it, and, by means of a simple mechanical arrangement, become fixed in their places; thus there is in front of the frame a plate, with holes, which are only open where the pistons have been withdrawn, and this plate, as will be readily understood, acts the part of the Jacquard card, and is suitable for receiving the steel needles which govern the hooks of the Jacquard in connection with the warp threads as ordinarily used.

The ordinary Jacquard cards are shown in the following wood-cut, *fig.* 1895.

Instead of this arrangement, which will be understood by reference to the article JACQUARD, M. Bonelli, as we have said, instead of the cards prepares his design on metal foil, in a resinous ink, which serves to interrupt the current, and thus effect the object of the machine.



Figs. 1895 and 1896 explain generally the arrangements by which the process is effected.

A, *fig.* 1896, represents the plate pierced with holes, which plays the part of the card. Each of the small pistons or rods, *b*, forming the armatures of the electro-magnets C, have a small head, *d*, affixed to the end, exactly opposite the needles, *e*, *fig.* 1895, of the Jacquard, and are capable of passing freely through the holes of the plate, A, *fig.* 1896. At a given moment the plate is slightly lowered, which prevents the heads of the pistons passing, and the surface of the plate then represents a plain card. The pistons are supported on a frame, *f f*, which allows them to move horizontally in the direction of their length. At each stroke of the shuttle, the frame, carrying with it the plate, A, has, by means of the treddle, a reciprocating motion backwards and forwards, and in its backward movement presents the ends of the pistons to one of the poles of the electro-magnets, and, by means of certain special contrivances, contact with the magnets is secured. When the frame, *f f*, returns with the plate A towards the needles of the Jacquard, the electro-magnets, which become temporarily magnetised by the electric current, hold back the pistons, the heads of which pass through the plate A, and rest behind it. On the other hand, the electro-magnets which are not magnetised, owing to the course of the current being interrupted, permit the other pistons to be carried back, their heads remaining outside the plate and in front of it. At this moment, the plate, by means of an inclined plane beneath it, is lowered slightly, thus preventing the heads of the pistons passing through the holes, by the edges of which they are stopped, so as to push against the needles of the Jacquard;

on the other hand, the heads of the pistons which have passed within and to the back of the plate, leave the corresponding holes of the plate free, and the needles of the Jacquard which are opposite to them are allowed to enter.

The electro-magnets are put into circuit in the following manner: One of the ends of the wire forming the coil of each of the magnets is joined to one common wire in connection with one of the poles of a galvanic battery. The other end of the coil wire of each magnet is attached to a thin metallic plate, *m*, having a point at its lower extremity. All these thin metallic plates are placed side by side, with an insulating material between them, formed like the teeth of a comb, *n n*. At a given time these thin plates rest with their lower extremities on the sheet bearing the design P, which, in the form of an endless band, is wrapped round and hangs upon the cylinder, Q, and according as the thin metal plate rests on a metallised or on a non-conducting portion of the design, the corresponding electro-magnet is or is not magnetised, and its corresponding piston does not or does press against the needle of the Jacquard. The wire from the other pole of the battery of course communicates with the band bearing the design, by being attached to a piece of metal, which lies in constant contact with the metallic edge of the band. At B is a contact-breaker, which is put in motion by the movement of the frame. Besides this, by means of a mechanical arrangement connected with the treddle, which raises or depresses the griff frame, the band bearing the design is carried forward at each stroke, and the rapidity with which it is made to travel can readily be regulated, by means of gearing, at the will of the workman. By regulating the speed of the band, and by the use of thicker or thinner weft, an alteration in the character of the woven material may be made, whilst the same design is produced, though in a finer or coarser material.

Such are the arrangements by which the loom will produce a damask pattern, or one arising from the use of two colours, one in the warp and the other in the weft. I will now shortly explain the method adopted by M. Bonelli for producing a pattern where several colours are required.

The design is prepared on the metallised paper, so that the coloured parts are re presented by the metallised portion of the band, but each separate colour is, by removing a very thin strip of the foil at the margin, insulated from its neighbouring colour. Then all the pieces of foil thus insulated, which represent one colour or shade, are connected with each other by means of small strips of tinfoil, which pierce through the paper and are fastened at the back, and are conducted to a strip of tinfoil which runs along the edge of the band, there being as many such strips of tinfoil as there are colours. Thus each special colour of the pattern, in all its parts, is connected by a conductor with its own separate strip of tinfoil, and by bringing the wire from the pole of the battery successively into contact with the several strips, a current of electricity may be made to pass in succession through the several parts of the design on the band representing the separate colours of the design. Thus, assuming four colours, 1, 2, 3, 4, there would be four strips of tinfoil running the length of the band, insulated from each other, each of which would be in connection with its own separate colour only. At any given moment, the thin plates of metal resting on the pattern would touch it in a line which, as it passes over the width of the pattern, would run through all, or any one or more of the colours, but the electric current would pass only through those plates which rest on the one colour represented by the strip with which the pole of the battery at that instant happened to be in contact.

The inventor claims the following as the results of his invention:—

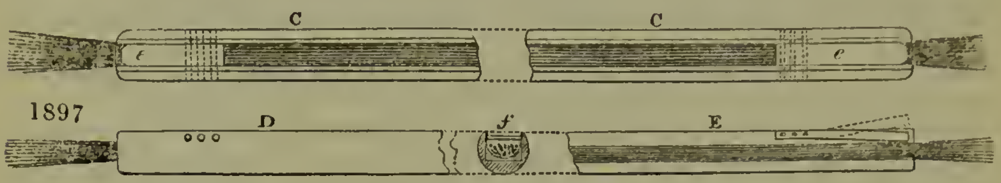
First.—The great facility with which in a very short time, and with precision, reductions of the pattern may be obtained on the fabric by means of the varying velocity with which the pattern may be passed under the teeth.

Second.—That without changing the mounting of the loom or the pattern, fabrics thinner or thicker can be produced by changing the number of the weft, and making a corresponding change in the movement of the pattern.

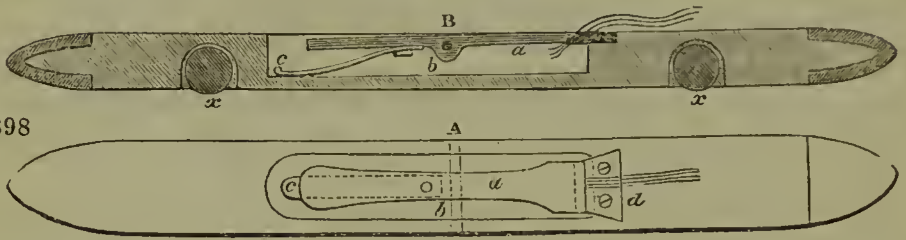
Third.—The loom and its mounting remaining unchanged, the design may be changed in a few minutes by the substitution of another metallised paper having a different pattern.

Fourth.—The power of getting rid of any part of the design if required, and of modifying the pattern.

WEAVING OF HAIR CLOTH, In addition to the description of this art under HAIR, a short notice is required of the best kind of shuttle for weaving hair. *Fig.* 1898 shows in plan A, and in longitudinal section B, a shuttle which differs from that of the common cloth weaver only in not having a pirn enclosed in the body of the box-wood, but merely an iron trap *a*, which turns in the middle upon the pin *b*. This trap-piece is pressed up at the one end, by the action of the spring *c*, so as to bear with its other end upon the cleft of the iron plate *d*, which is intended to hold fast the ends of the hair-weft: *d* and *c* together are called the jaw or mouth, whence the popular name of this shuttle. The workman opens this jaw by the pressure of his thumb upon the spring end of the trap *a*, introduces with the other hand one or more hairs (according to the description of hair cloth) into the mouth, and removing his thumb, lets the hairs be seized by the force of the spring. The hairs having one end thus made fast are passed across the warp by the passage of the shuttle, which is received at the other end by the weaver's left hand. The friction rollers, *x*, *x*, are like those of fly-shuttles, but are used merely for convenience, as the shuttle cannot be thrown swiftly from side to side. The hand which receives the shuttle opens at the same time the trap, in order to insert another hair, after the preceding has been



1897



1898

drawn through the warp on both sides and secured to the list. A child attends to count and stretch the hairs. This assistant may, however, be dispensed with by means of the following implement, represented in *fig.* 1897. C, C is the view of it from above or the plan; D is a side view; E a longitudinal section, and *f* an oblique section across. The chief part consists in a wooden groove, or chamfered slip of wood, open above, and rounded on the sides. It is about twenty-one inches in length, about as long nearly as the web is broad, therefore a little shorter than the horse hairs inserted in it, which project about an inch beyond it at at each end. They are herein pressed down by elastic slips, *e*, of indiarubber, so that the others remain, when one or more are drawn out by the ends. The ends of the grooves are flat where the indiarubber spring exerts its pressure, as shown by the dotted line *f*. The spring is formed by cutting out a double piece from the curvature of the neck of a caoutchouc bottle or flask, fastening the one end of the piece by a wire staple in the groove of the shuttle, whereby the other end, which alone can yield, presses upon the inlaid hairs. Wire staples like *f* (in the section E) are passed obliquely through two places of the groove or gutter, to prevent the hairs from springing up in the middle of the shuttle, which is suitably charged with them. The workman shoves the tool across the opened warp with the one hand, seizes with the other the requisite number of hairs by the projecting ends, and holds them fast while he draws the shuttle once more through the warp. The remaining hairs are retained in the groove by the springs, and only those for the single decussation remain in the web, to be secured to the list on either side. A weaver with this tool can turn out a double length of cloth of what he could do with the mouth-shuttle.

WEFT (*Trame*, Fr.; *Eintrag*, Germ.) is the name of the yarns or threads which run from selvage to selvage in a web.

WELD, or DYER'S WEED (*Gande*, Fr.; *Wau*, Germ.) A biennial plant, native of Britain, Italy, and various parts of Europe; the *Reseda luteola* of Botanists. Weld is preferred to all other substances in giving the lively green lemon yellow to silk. Although the quercitron bark has almost superseded it in calico printing, weld is still largely used in dyeing silk a golden yellow, and in paper staining.

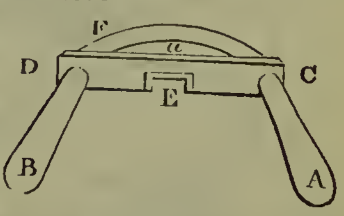
WELDING (*Souder*, Fr.; *Schweissen*, Germ.) is the property which pieces of wrought iron possess when heated to whiteness of uniting intimately under the hammer without any appearance of junction. See IRON.

WELLS, ARTESIAN. See ARTESIAN WELLS.

WHALEBONE (*Baleine*, Fr.; *Fischbeine*, Germ.) is the name of the horny laminæ, consisting of fibres laid lengthways, found in the mouth of the whale, which, by the fringes upon their edges, enable the animal to allow the water to flow out, as through rows of teeth (which it wants), from between its capacious jaws, but to catch and detain the minute creatures upon which it feeds. The fibres of whalebone have little lateral cohesion, as they are not transversely decussated, and may, therefore, be readily detached in the form of long filaments or bristles. The *blades*, or scytheshaped plates, are externally compact, smooth, and susceptible of a good polish. They are connected, in a parallel series, by what is called the *gum* of the animal, and are arranged along each side of its mouth, to the number of about 300. The length of the longest *blade*, which is usually found near the middle of the series, is the gauge adopted by the fishermen to designate the size of the fish. The greatest length hitherto known has been 15 feet, but it rarely exceeds 12 or 13. The breadth, at the root end, is from 10 to 12 inches; and the average thickness, from four to five tenths of an inch. The series, viewed altogether in the mouth of the whale, resemble, in general form, the roof of a house. They are cleansed and softened before cutting, by boiling for two hours in a long copper.

Whalebone, as brought from Greenland, is commonly divided into portable junks or pieces, comprising ten or twelve blades in each; but it is occasionally subdivided into separate blades, the gum and the hairy fringes having been removed by the sailors during the voyage. The price of whalebone fluctuates from 50*l* to 150*l*. per ton. The blade is cut into parallel prismatic slips, as follows: — It is clamped horizontally, with its edge up and down, in the large wooden vice of a carpenter's bench, and is then planed by the following tool, *fig.* 1899. A, B, are its two handles; C, D, is an iron plate, with a guide-notch E; F, is a semicircular knife, screwed firmly at each end to the ends of the iron plate C D, having its cutting edge adjusted in a plane, so much lower than the bottom of the notch E, as the thickness of the whalebone slip is intended to be for different thicknesses: the knife may be set by the screws at different levels, but always in a plane parallel to the lower guide surface of the plate C D. The workman, taking hold of the handles A, B, applies the notch of the tool at the end of the whalebone blade furthest from him, and with his two hands pulls it steadily along, so as to shave off a slice in the direction of the fibres; being careful to cut none of them across. These prismatic slips are then dried, and planed level upon their other two surfaces. The fibrous matter detached in this operation, is used, instead of hair, for stuffing mattresses.

1899



From its flexibility, strength, elasticity, and lightness, whalebone is employed for many purposes; for ribs to umbrellas or parasols; for stiffening stays; for the framework of hats, &c. When heated by steam, or a sand bath, it softens, and may be bent or moulded, like horn, into various shapes, which it retains if cooled under compression. In this way, snuff-boxes, and knobs of walking-sticks, may be made from the thicker parts of the blade. The surface is polished at first with ground pumice-stone, felt, and water; and finished with dry quicklime spontaneously slaked, and sifted.

A patent was granted to Mr. Laurence Kortright in March, 1841, for improvements in the treatment of whalebone, which consist in compressing the strips in width to increase their thickness, so as to render the material applicable for forming walking-sticks, whip handles, parasol and umbrella sticks, ramrods, archery bows, &c. He accomplishes this by bending the strips together, introducing them into a steam chest, thereby softening them, and in that state compressing them into a compact mass by appropriate machinery.

Although all the species of Balæna possess this substance, it is furnished in the largest quantities, and of the finest quality, by the *Balæna mysticetus*, which is the object of incessant and eager pursuit, not only for the value of this substance, but for the immense supply of oil which is obtained from the thick layer of blubber, or cutaneous fat, in which the body is enveloped. The length of the largest piece of baleen in a whale 60 feet long, is frequently as much as 12 feet, and the laminæ are arranged in two series, each containing about 300 in number.

WHALE OIL. See OILS.

WHEAT. (*Triticum vulgare*, Linn.; *Froment*, Fr.; *Waizen*, Germ.) See BREAD, GLUTEN, and STARCH.

WHEAT FLOUR; *to detect adulteration of.* Potato starch is insoluble in cold water, unless it be triturated in thin portions in a mortar. If pure wheat flour be thus triturated, it affords no trace of starch to iodine, as the former does, because the particles of wheat starch are very minute, and are sheathed in gluten.

Bean flour digested with water at a heat of 68° Fahr., and triturated, affords on filtration a liquid which becomes milky on the addition of a little acetic acid, by its reaction on the legumine present in the beans.

WHEEL CARRIAGES. Though this manufacture belongs most properly to a treatise upon mechanical engineering, we shall endeavour to describe the parts of a carriage, so as to enable gentlemen to judge of its make and relative merits. The external form may vary with every freak of fashion; but the general structure of a vehicle, as to lightness, elegance, and strength, may be judged of from the following figure and description.

Fig. 1900, shows the body of a chariot, hung upon an iron carriage, with iron wheels, axletrees, and boxes; the latter, by a simple contrivance, is close at the out-head, by which means the oil cannot escape; and the fastening of the wheel being at the in-head, as will be explained afterwards, gives great security, and prevents the possibility of the wheel being taken off by any other carriage running against it.

Fig. 1901, shows the arm of an axletree, turned perfectly true, with two collars in the solid, as seen at G and H. The parts from G to B are made cylindrical. At K is a screw nail, the purpose of which will be explained in *fig.* 1905.

1900

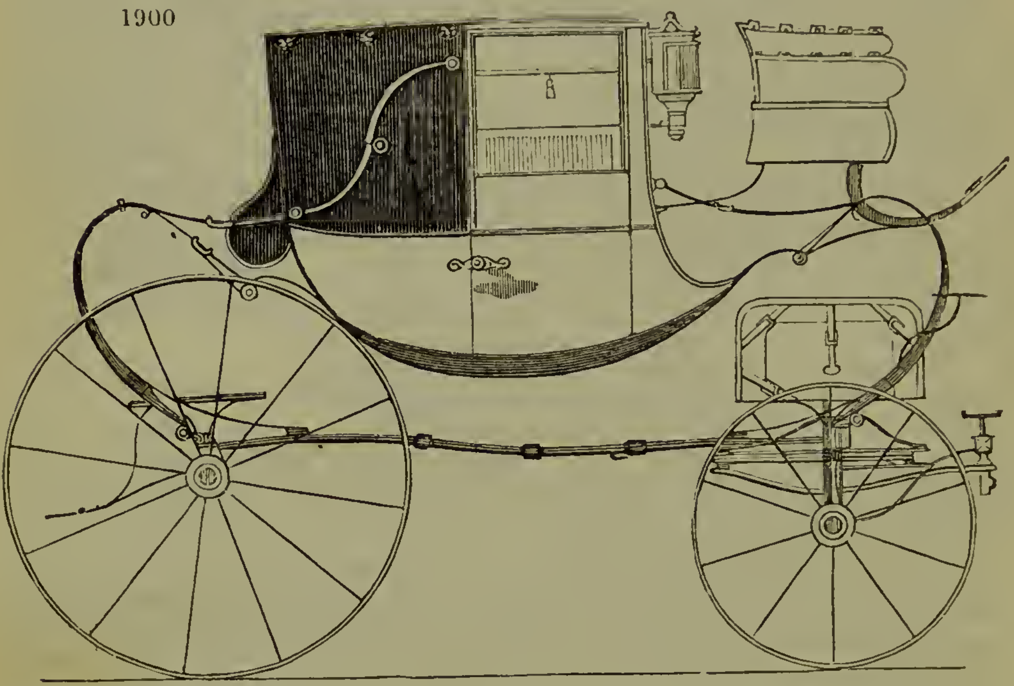


Fig. 1902 is a longitudinal section of a metal nave, which also forms the bush, for the better fitting of which to the axletree, it is bored out of the solid, and made quite air-tight upon the pin; and for retaining the oil it is left close at the out-head D.

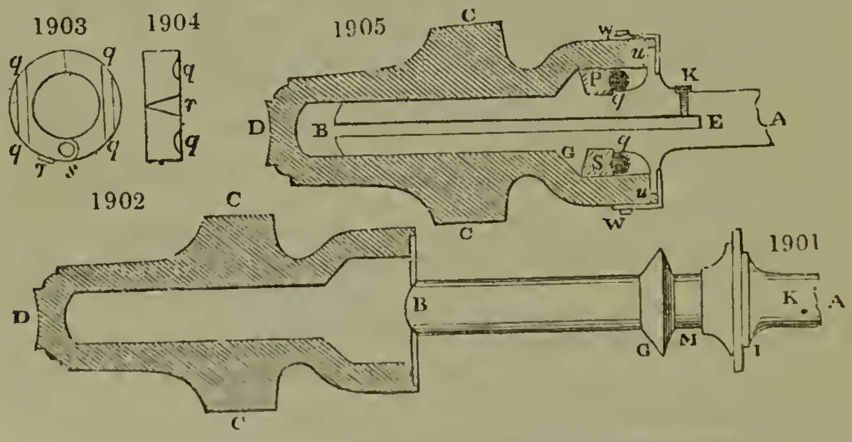
Fig. 1903, represents a collet made of metal, turned perfectly true, the least diameter of which is made the same with that part of the axletree M, *fig.* 1901, and its greatest diameter the same with that of the solid collar G, *fig.* 1901. This collet is made with a joint at S, and opens at P. Two grooves are represented at *q q*, *q q*, which are seen at the same letters in *fig.* 1904, as also the dovetail *r*, in both figures.

Fig. 1904 is an edge view of the collet, *fig.* 1903.

Fig. 1905 is a longitudinal section of an axletree arm, nave, or bush, and fastening. A B, is the arm of the axletree, bored up the centre from B to E. C C D, the nave



which answers also for the bush. P S, the collet (see *figs.* 1903 and 1904) put into its place; *q*, *q*, two steel pins passing through the in-head of the bush, and filling up the grooves in the collet; W, W, a caped hoop, sufficiently broad to cover the ends of said pins, and made fast to the bush by screws. This hoop, when so fastened to the bush, prevents the possibility of the pins *q*, *q*, from getting out of their places. *u*, *u*, is a leather washer, interposed betwixt the in-head of the bush and the larger solid collar of the axletree, to prevent the escape of oil at the in-head. K, is a screw, the head of which is near the letter K, in *fig.* 1901. This screw being undone, and oil poured into the hole, it flows down the bore in the centre of the axletree arm, and fills the space B, left by the arm being about 1 inch shorter than the bore of the bush, and the screw, being afterwards replaced, keeps all tight. In putting on the wheel, a little oil ought to be put into the space betwixt the collet P, S, and the larger collar. The collet P, S, being movable round the axletree arm, and being made fast to the bush by means of the two pins *q*, *q*, revolves along with the bush, acting against the solid collar G, of the arm, and keeps the wheel fast to the axletree, until by removing the caped hoop W, W, and driving out the pins *q*, *q*, the collet becomes disengaged from the bush.

The dovetail, seen upon the collet at *r*, *fig.* 1904, has a corresponding groove cut in the bush to receive it, in consequence of which the wheel must of necessity be put on so that the collet and pins fit exactly. These wheels very rarely require to be taken off, and they will run a thousand miles without requiring fresh oiling.

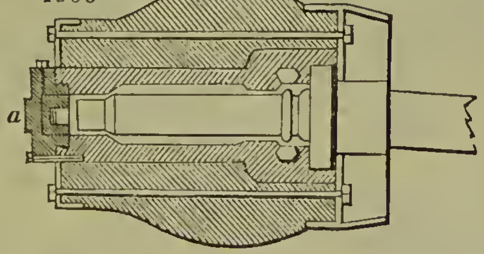
The spokes of the wheel, made of malleable iron, are screwed into the bush or nave at C, C, *figs.* 1902, 1905, all round. The felloes, composed merely of two bars of iron bent into a circle edgeways, are put on, the one on the front, the other on the back of the spokes, which have shoulders on both sides to support the felloes, and all three are attached together by rivets through them. The space between the two iron rings forming the felloes, should be filled up with light wood, the tire then put on, and fastened to the felloes by bolts and glands clasping both felloes.

This is a carriage without a mortise or tenon, or wooden joint of any kind. It is, at an average, one-seventh lighter than any of those built on the ordinary construction.

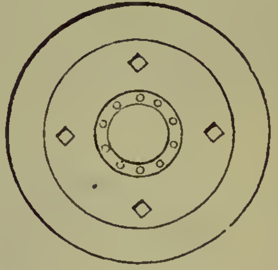
The design of Mr. W. Mason's patent invention, of 1827, is to give any required pressure to the ends of what are called mail axletrees, in order to prevent their shaking in the boxes of the wheels. This object is effected by the introduction of leather collars in certain parts of the box, and by a contrivance, in which the outer cap is screwed up so as to bear against the end of the axletree with any degree of tightness, and is held in that situation, without the possibility of turning round, or allowing the axletree to become loose.

Fig. 1906 shows the section of the box of a wheel, with the end of the axletree secured in it. The general form of the box, and of the axle, is the same as other mail axles, there being recesses in the box for the reception of oil. At the end of the axle a cap *a*, is inserted, with a leather collar enclosed in it, bearing against the end of the axle, which cap, when screwed up sufficiently tight, is held in that situation by a pin or screw passed through the cap *a*, into the end of the iron box; a representation of this end of the iron box being shown at *fig.* 1907.

1906



1907



In the cap *a*, there is also a groove for conducting the oil to the interior of the box, with a screw at the opening, to prevent it running out as the wheel goes round.

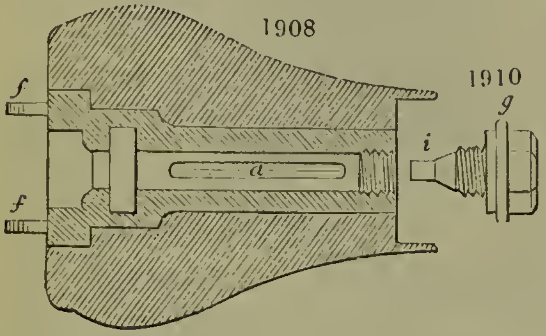
The particular claims of improvement are, the leather collar against the end of the axle; the pin going through one of the holes in the end of the box, to fix it; and the channel for conducting the oil.

Mr. Mason's patent, of August 1830, applies also to the boxes and axles of that construction of carriage wheels which are fitted with the so-called mail-boxes; but part of the invention applies to other axles.

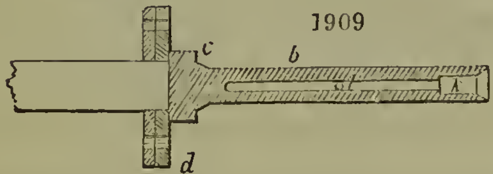
Fig. 1908 represents the nave of a wheel, with the box for the axle within it, both shown in section longitudinally; *fig.* 1909 is a section of the axle, taken in the same direction; and *fig.* 1910 represents the screw cap and oil-box, which attaches to the outer extremity of the axle-box. Supposing the parts were put together, that is, the axle inserted into the box, then the intention of the different parts will be perceived.

The cylindrical recess *a*, in the box of the nave, is designed to fit the cylindrical part of the axle *b*; and the conical part *c*, of the axle, to shoulder up against a corresponding conical cavity in the box, with a washer of leather to prevent its shaking. A collar *d*, formed by a metallic ring, fits loosely upon a cylindrical part of the axle, and is kept there by a flange or rim, fixed behind the cone *c*. Several strong pins, *f*, *f*, are cast into the back part of the box; which pins, when the wheel is attached, pass through corresponding holes in the collar *d*; and nuts being screwed on to the ends of the pins *f*, behind the collar, keep the wheel securely attached to the axle. The screw-cap *g*, is then inserted into the recess *h*, at the outer part of the box, its conical end and small tube *i*, passing into the recess *k*, in the end of the axle.

The parts being thus connected, the oil contained within the cap *g*, will flow through the small tube *i*, in its end, into the recess or cylindrical channel *l*, within the axle, and will thence pass through a small hole in the side of the axle, into the cylindrical recess *a*, of the box; and then lodging in the groove and other cavities within the box, will lubricate the axle as the wheel goes round. There is also a small groove cut on the outside of the axle, for conducting the oil, in order that it may be more equally distributed over the surface and the bearings. This construction of the box and axle, as far as the lubrication goes, may be applied to the axles of wheels in general; but that part of the invention which is designed to give greater security in the attachment of the wheel to the carriage applies particularly to mail axles.



1908 1910



1909

Mr. William Mason's patent invention for wheel carriages, of August 1831, will be understood by reference to the annexed figures. *Fig.* 1911 is a plan showing the four-axletree bed *a*, *a*, of a four-wheeled carriage, to which the axletrees *b*, *b*, are jointed at each end; *fig.* 1912 is an enlarged plan; and *fig.* 1913 an elevation, or side view of one end of the said fore-axletree bed, having a Collinge's axletree jointed to the axletree bed, by means of the cylindrical pin or bolt *e*, which passes through and turns in a cylindrical hole *d*, formed at the end of the axletree bed, shown in the plan view *fig.* 1914, and section, *fig.* 1915.

1923

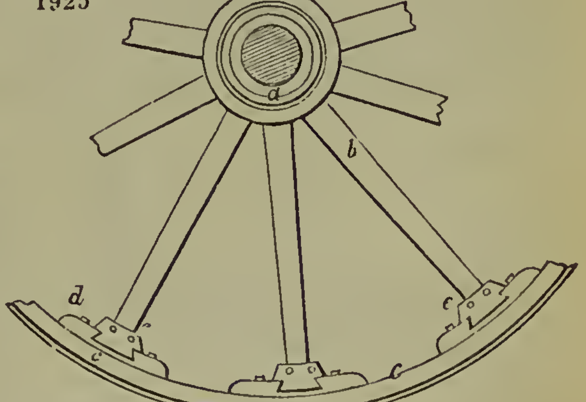
The axletree *b*, is firmly united with the upper end *c*, of the pin or bolt *c*; and to the lower end of it, which is squared, the guide piece *f*, is also fitted, and secured by the screw *g*, and cap or nut *h*, seen in *fig.* 1913, and in section in *fig.* 1916. There are leather washers *i*, *i*, let into recesses made to receive them in the parts *a*, *b*, and *f*, the intent of which is to prevent the oil from escaping that is introduced through the central perpendicular hole seen in *fig.* 1916, which hole is closed by means of a screw inserted into it. The oil is diffused, or spread over the surface of the cylinder *c*, by means of a side branch leading from the bottom of the hole into a groove formed around the cylinder, and also by means of two longitudinal gaps or cavities made within the hole, as shown in *figs.* 1914 and 1915. The guide piece *f*, is affixed at right angles with the axletree *b*, as shown in *fig.* 1912, and turns freely and steadily in the cylindrical hole *d*, made to receive one end of the iron fore-axletree bed *a*. In like manner, the opposite fore-axletree *b*, *fig.* 1911, is jointed to the other end of the iron fore-axletree bed. The outer ends of the guide pieces *f*, *f*, are jointed to the splinter-bar *n*, *fig.* 1915, as follows: — *Fig.* 1917 is a plan, and *fig.* 1918 a section of the joint *o*, in *fig.* 1911, shown on an enlarged scale; a cylindrical pin or bolt *c*, is firmly secured in the splinter-bar, and round the lower part of the said pin or bolt the guide piece *f*, turns, and is made fast in its place by the screw *g*, and screwed nut *h*.

Oil is conveyed to the lower part of the cylindrical pin *c*, in a similar manner to that already described, and two leather washers are likewise furnished, to prevent its escape. The connecting joint at the opposite end of the splinter bar *n*, is constructed in a similar manner. The futchel or socket *p*, *p*, for the pole of the carriage, must also be jointed to the middle of the fore-axletree bed and splinter-bar, in a similar manner. The swingletrees *q*, *q*, *fig.* 1911, are likewise jointed in the same way to the splinter-bar. *Fig.* 1919 is a side view of these parts. The fore-wheels of the carriage, *fig.* 1911, are furnished with cast-iron boxes, as usual. The dotted lines show the action of the pole *p*, *p*, upon the splinter-bar *n*, and as communicated through the latter to the guide pieces *f*, *f*, connected with the axletrees *b*, *b*, so as to lock the wheels *r*, *r*, as shown in that figure.

The axletree may be incased in the woodwork of the fore-bed of the carriage, as usual, as and shown by dotted lines in the back end view thereof, *fig.* 1920; and the framing *s*, *fig.* 1921, may be affixed firmly upon the said woodwork, in any fit and proper manner, as well as the fore springs *t*, *t*, shown in *figs.* 1920 and 1921, and likewise in the side view, *fig.* 1922. In certain cases it may be desirable to fix the cylindrical pin or bolt *c*, firmly in the splinter-bar *n*, in the manner shown in *figs.* 1923 and 1924; the swingletrees *q*, *q*, and guide pieces *f*, *f*, turning above and below upon the said pin or bolt, and secured in their places thereon by screws and screwed nuts, oil being also supplied through holes formed in both ends of the said pin or bolt, and leather washers provided, as in the above-described instances.

Mr. Gibbs, engineer, and Mr. Chaplin, coach-maker, obtained a patent, in 1832, for the construction of a four wheeled carriage which shall be enabled to turn within a small compass, by throwing the axles of all the four wheels simultaneously into different positions. They effect this object by mounting each wheel upon a separate jointed axle and by connecting the free ends of the four axles by jointed rods or chains, with the pole and splinter-bar in front of the carriage.

1925



To fix the ends of the spokes of wheels to the felloe or rim with greater security than had been effected by previous methods is the object of a contrivance for which William Howard obtained a patent in February 1830. *Fig.* 1925 shows a portion of a wheel constructed on this new method; *a*, is the nave, of wood; *b*, *b*, *b*, wooden spokes, inserted into the nave in the usual way; *c*, *c*, is the rim or felloe, intended to be formed by one entire circle of wrought iron; *d*, and *e*, *e*, are the shoes or blocks, of cast iron, for receiving the ends of the spokes, which are secured by bolts to the rim on the inner circumference. The cap of the block *d* is removed for the purpose of showing the internal form of the block; *e*, *e*, have their caps fixed on, as they would appear when the spokes are fitted in. One of the caps or shoes is shown detached, upon a larger scale, at *fig.* 1926, by which it will be perceived that the end of the spoke is introduced into the shoe on the side. It is proposed that the end of the spoke shall not reach quite to the end of the recess formed in the block, and that it shall be made tight by a wedge driven in. The wedge piece is to be of wood, as *fig.* 1927, with a small slip of iron within it; and a hole is perforated in the back of the block or shoe, for the wedge to be driven through. When this is done the ends of the spokes become confined and tight; and the projecting extremities of the wedges being cut off, the caps are then attached on the face of the block, as at *e*, *e*, by pins riveted at their ends, which secures the spokes, and renders it impossible for them to be loosened by the vibrations as the wheel passes over the ground. One important use of the wedges is to correct the eccentric figure of the wheel, which may be readily forced out in any part that may be out of the true form, by driving the wedge up further; and this it is considered will be a very important advantage, as the nearer a wheel can be brought to a true circle the easier it will run upon the road. The periphery of the wheel is to be protected by a tyre, which may be put on in pieces, and bolted through the felloe; or it may be made in one ring, and attached, while hot, in the usual way.

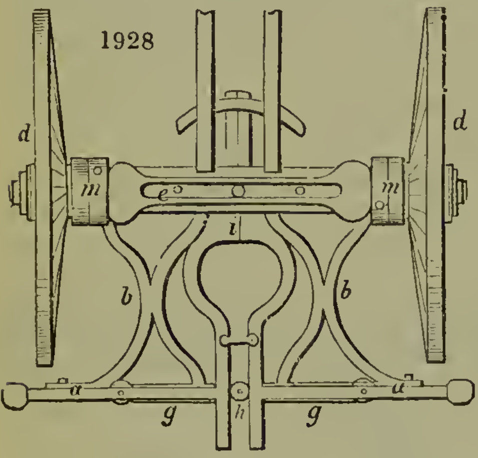
1926

1927

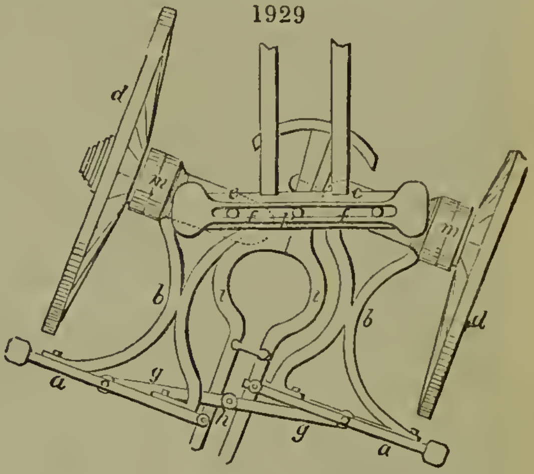
Mr. Reedhead's patent improvements in the construction of carriages are represented in the following figures. They were specified in July, 1833.

Fig. 1928 is a plan or horizontal view of the fore part of a carriage intended to be drawn by horses, showing the fore wheels in their position when running in a straight course; *fig.* 1929 is a similar view, showing the wheels as locked, when in the

1928

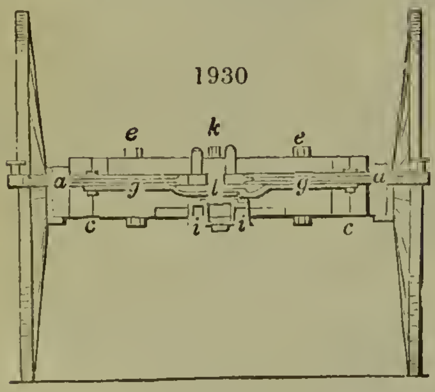


1929

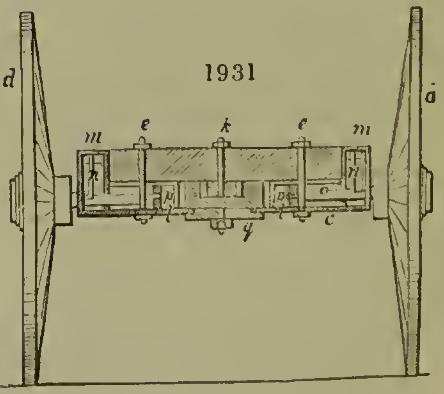


act of turning; *fig.* 1930 is a front end elevation of the same; *fig.* 1931 is a section taken through the centre of the fore axletree; and *fig.* 1932 is a side elevation of the general appearance of a stage coach, with the improvements appended; *a*, *a*, are two splinter-bars with their roller-bolts, for connecting the traces of the harness; these splinter-bars are attached by the bent irons *b*, *b* to two short axletrees or axle-boxes *c*, *c*, which carry the axles of the fore wheels *d*, *d*, and turn upon vertical pins or bolts *e*, *e*, passed through the fore axletree *f*, the splinter-bars and axle-boxes being mounted so as to move parallel to each other, the latter partaking of any motion given to the splinter-bars by the horses in drawing the carriage forward, and thereby producing

1930



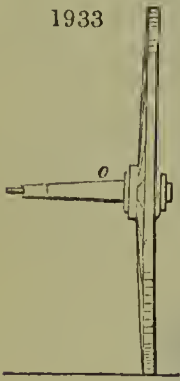
1931



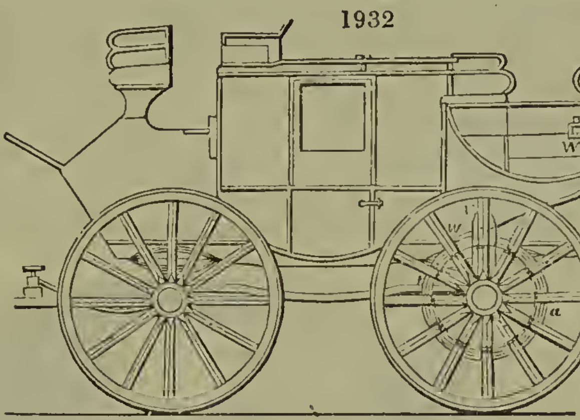
the locking of the wheels, as shown in *fig.* 1929; and in order that the two wheels and their axles and axle-boxes, together with the splinter-bars *a*, *a*, may move simultaneously, the latter are connected by pivots to the end of the links or levers *g*, *g*, which are attached to the arms *i*, *i*, which receive the pole of the coach by a hinge-joint or pin *h*; the arms *i*, *i*, turning on a vertical fulcrum-pin *k*, passed through the main axletree *f*, as the pole is moved from one side to the other.

The axles *o*, *o*, are firmly fixed into the nave of the wheels, as represented in the side view of a wheel detached, at *fig.* 1934, the axles being mounted so as to revolve within their boxes in the following manner:—The axle-boxes, which answer the purpose of short axletrees, are formed of iron, and consist of one main or bottom plate *l*, seen best in *figs.* 1934 and 1933; upon this bottom plate is formed the chamber *m*, *m*, carrying the two anti-friction rollers *n*, *n*, which turn on short axles passed through the sides and partition at the upper part of the chambers. These anti-friction

1933

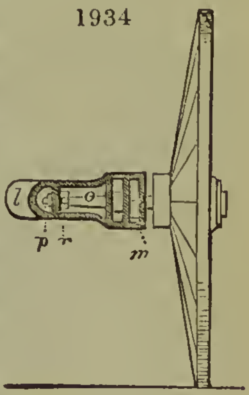


1932



rollers bear upon the cylindrical parts of the axle *o*, of each wheel, and support the weight of the coach; *p* is a bearing firmly secured in the axle-box to the plate *l*, for the end of the axle *o* to run in, the axle being confined in its proper situation by a collar and screw-nut on its end; *e* is the vertical pin or bolt before mentioned, upon which the axle-bar turns when the wheels are locking, which bolt is enlarged within the box, and has an eye for the axle to pass through, being firmly secured to the plate *l*, and also to the sides of the box. *Fig.* 1934 is a plan or horizontal view of an axle and its box belonging to one of the fore wheels; a piece *q* is attached to the under side of the main axletree, which supports the ends of the plates *l*, and thereby relieves the pins *e*, *e* of the strain they would otherwise have to withstand. The axles of the hind wheels are mounted upon similar plates *l*, *l*, with bearings and chambers with anti-friction rollers; but as these are not required to lock, the plates *l l* are fixed on to the under side of the hind axletree by screw-nuts; there are small openings or doors, which can be removed for the purpose of unscrewing the nuts and collars of the bearings *p* when the wheel is required to be taken off the carriage, when the axle can be withdrawn from the boxes. If it should be thought necessary, other chambers with friction rollers may be placed on the under side of the plate *l*, to bear up the end of the axles, and relieve the bearing *p*. In order to stop or impede the progress of a carriage in passing down hills, there is a grooved friction or brake wheel *t*, fixed, by clamps or otherwise, on to the spokes of one of the hind wheels; *u* is a brake-band or spring, of metal, encircling the friction wheel, one end of which band is fixed into the standard *v*, upon the hind axletree, and the other end connected by a joint to the shorter end of the lever *w*, which has its fulcrum in the standard *v*; this lever extends up to the hind seat of the coach, as shown in *fig.* 1932, and is intended to be under the command of the guard or passengers of the coach, and when descending a hill, or on occasion of the horses running away, the longer end of the lever is to be depressed, which will raise the shorter end, and consequently bring the band or spring *u* in contact with the surface of the friction wheel, and thereby retard its revolution, and prevent the coach travelling too fast; or, instead of attaching the friction brake to the hind wheel, as represented in *fig.* 1932, it may be adapted to the fore wheels, and the end of the lever brought up to the side of the foot-board, or under it, and within command of the coachman, the standard which carries the fulcrum being made to move upon a pivot, to accommodate the locking of the wheels. It will be observed that by these improved constructions of the carriage and mode of locking, the patentee is enabled to use much larger fore wheels than in common, and that the splinter-bars will always be in the position of right angles with the track or way of

1934



the horses in drawing the carriage, by which they are much relieved, and always pull in a direct and equal manner.

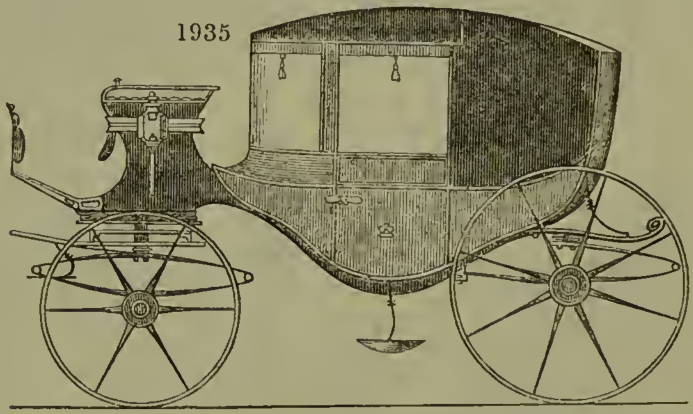
The advantages of these carriages may be thus summed up: — A great diminution of the total weight; a diminution of resistance in draught equal to about one-third; increase of safety to the riders; increased durability of the vehicle; absence of noise and vibration; absence of oscillation.

To these qualities, so desirable to all, and especially those of delicate nervous temperament, may be added — greater economy, both in the first cost and maintenance.

The *whirling* public so blindly follows fashionable caprice in the choice of a carriage, as to have hitherto paid too little attention to this fundamental improvement; but many intelligent individuals have fully verified its practical reality. Having inspected various forms of two-wheeled and four-wheeled carriages in the patentee's premises in Drury Lane, I feel justified in recommending them as being constructed on the soundest mechanical principles; and have no doubt, that if reason be allowed to decide upon their merits, they will ere long be universally preferred by all who seek for easy-moving, safe, and comfortable vehicles.

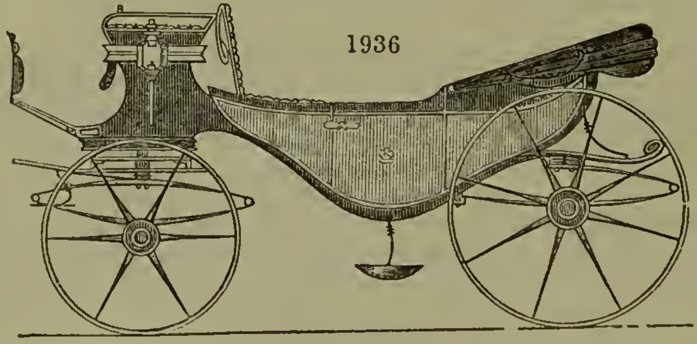
Among the wheel carriages displayed in the Exhibition, one of the most remarkable was the *amempton* (*unblamable*), of E. Kesterton, Long Acre. It is a close double-seated carriage, which by a simple contrivance can be converted into a light, open, step-piece barouche, adapted for summer and winter. *Fig.* 1935, represents the carriage

1935



closed, or what is termed the amempton, which can be readily converted into a step-piece barouche. *Fig.* 1936, is the carriage thrown completely open, and constructed

1936



as an ordinary open carriage, with a half head, which is raised and lowered in the usual manner, with a solid folding knee flap. The front portion of the amempton is formed of a framework with circular front glasses, and furnished with doors. The door glasses and front glasses are made to rise and fall at pleasure, and are furnished with silk spring curtains, the whole being surmounted or covered with a roof. This framework is secured to the head with a new kind of fastening; the door glasses when down are received into the lower part of the doors; the back, instead of being flat, is of a curved form.

WHETSLATE, is a massive mineral of a greenish-grey colour; feebly glimmering; fracture, slaty or splintery; fragments tabular; translucent on the edges; feels rather greasy; and has a spec. grav. of 2·722. It occurs in beds, in primitive and transition slates. Very fine varieties of whetslate are brought from Turkey, called *hones*tones, which are in much esteem for sharpening steel instruments.

WHEY (*Petit lait*, Fr.; *Molken*, Germ.) is the greenish-grey liquor which exudes from the curd of milk. Scheele states, that when a pound of milk is mixed with a spoonful of proof spirit, and allowed to become sour, the whey filtered off, at the end of a month or a little more, is a good vinegar, devoid of lactic acid.

WHISKY. A spirit obtained by distillation from corn, sugar, or molasses, though generally from the former. It is extensively manufactured and used in Scotland and in Ireland.

WHITE LEAD, *Carbonate of lead, or Ceruse.* (*Blanc de plomb*, Fr.; *Bleiweiss*, Germ.) This is the principal preparation of lead in general use for painting wood and the plaster walls of apartments white. It mixes well with oil, without having its bright colour impaired, spreads easily under the brush, and gives a uniform coat to wood, stone, metal, &c. It is employed either alone, or with other pigments, to serve as their basis, and to give them body. This article has been long manufactured with much success at Klagenfurth in Carinthia, and its mode of preparation has been described with precision by Marcel de Serres. The great white-lead establishments at Krems, whence, though incorrectly, the term *white of Kremnitz* became current, on the continent, have been abandoned.

In Germany the manufacture of white lead is conducted as follows:—

1. The lead mostly comes from Bleyberg; it is very pure, and particularly free from contamination with iron, a point essential to the beauty of its factitious carbonate. It is melted in ordinary pots of cast iron, and cast into sheets of varying thickness, according to the pleasure of the manufacturer. These sheets are made by pouring the melted lead upon an iron plate placed over the boiler; and whenever the surface of the metal begins to consolidate, the plate is slightly sloped to one side, so as to run off the still liquid metal, and leave a lead sheet of a desired thinness. It is then lifted off like a sheet of paper; and as the iron plate is cooled in water, several hundred weight of lead can be readily cast in a day. In certain white-lead works these sheets are one twenty-fourth of an inch thick; in others half that thickness; in some, one of these sheets takes up the whole width of the conversion-box; in others, four sheets are employed. It is of consequence not to smooth down the faces of the leaden sheets; because a rough surface presents more points of contact, and is more readily attacked by acid vapours than a polished one.

2. These plates are now placed so as to expose an extensive surface to the acid fumes, by folding each other over a square slip of wood. Being suspended by their middle, like a sheet of paper, they are arranged in wooden boxes, from 4½ to 5 feet long, 12 to 14 inches broad, and from 9 to 11 inches deep. The boxes are very substantially constructed; their joints being mortised; and whatever nails are used, being carefully covered. Their bottom is made tight with a coat of pitch about an inch thick. The mouths of the boxes are luted over with paper in the works where fermenting horse-dung is employed as the means of procuring heat, to prevent the sulphuretted and phosphuretted hydrogen from injuring the purity of the white-lead. In Carinthia it was formerly the practice, as also in Holland, to form the lead sheets into spiral rolls, and to place them so coiled up in the chests; but this plan is not to be recommended, because these rolls present obviously less surface to the action of the vapours, are apt to fall down into the liquid at the bottom, and thus to impair the whiteness of the lead. The lower edges of the sheets are suspended about two inches and a half from the bottom of the box; and they must not touch either one another or its sides, for fear of obstructing the vapours in the first case, or of injuring the colour in the second. Before introducing the lead, a peculiar acid liquor is put into the box, which differs in different works. In some, the proportions are four quarts of vinegar, with four quarts of wine-lees; and in others a mixture is made of 20 pounds of wine-lees, with 8½ pounds of vinegar, and a pound of carbonate of potash. It is evident that in the manufactories where no carbonate of potash is employed in the mixture, and no dung for heating the boxes, it is not necessary to lute them.

3. The mixture being poured into the boxes, and the sheets of lead suspended within them, they are carried into a stove-room, to receive the requisite heat for raising round the lead the corrosive vapours, and thus converting it into carbonate. This apartment is heated generally by stoves, is about 9 feet high, 30 feet long, and 24 feet wide, or of such a size as to receive about 90 boxes. It has only one door.

The heat should never be raised above 86° Fahr.; and it is usually kept up for 15 days, in which time the operation is, for the most part, completed. If the heat be too high, and the vapours too copious, the carbonic acid escapes in a great measure, and the metallic lead, less acted upon, affords a much smaller product.

When the process is well managed, as much carbonate of lead is obtained as there was employed of metal; or, for 300 pounds of lead, 300 of ceruse are procured, besides a certain quantity of metal after the crusts are removed, which is returned to the melting-pot. The mixture introduced into the boxes serves only once; and if carbonate of potash has been used, the residuary matter is sold to the hatters.

4. When the preceding operation is supposed to be complete, the sheets, being removed from the boxes, are found to have grown a quarter of an inch thick, though previously not above a twelfth of that thickness. A few crystals of acetate of lead are sometimes observed on their edges. The plates are now shaken smartly, to cause the crust of carbonate of lead formed on their surfaces to fall off. This carbonate is put into large cisterns, and washed very clean. The cistern is of wood, most commonly of a square shape, and divided into from seven to nine compartments. These are of equal capacity, but unequal height, so that the liquid may be made to overflow from one to the other. Thereby, if the first chest is too full, it decants its excess into the second, and so on in succession.

The water poured into the first chest passes successively into the others, a slight agitation being meanwhile kept up, and there deposits the white lead diffused in it proportionally, so that the deposit of the last compartment is the finest and lightest. After this washing, the white lead receives another, in large vats, where it is always kept under water. It is lastly lifted out in the state of a liquid paste, with wooden spoons, and laid on drying-tables to prepare it for the market.

The white lead of the last compartment is of the first quality, and is called on the continent silver white. It is employed in fine painting.

When white lead is mixed in equal quantities with ground sulphate of barytes, it is known in France and Germany by the name of Venice white. Another quality, adulterated with double its weight of sulphate of barytes, is styled Hamburgh white; and a fourth, having three parts of sulphate to one of white lead, gets the name of Dutch white. When the sulphate of barytes is very white, like that of the Tyrol, these mixtures are reckoned preferable for certain kinds of painting, as the barytes communicates opacity to the colour, and protects the lead from being speedily darkened by sulphureous smoke or vapours.

The high reputation of the white lead of Krems was by no means due to the barytes, for the first and whitest quality was mere carbonate of lead. The freedom from silver of the lead of Villach, a very rare circumstance, is one cause of the superiority of its carbonate; as well as the skilful and laborious manner in which it is washed, and separated from any adhering particle of metal or sulphide.

In England, lead is converted into carbonate in the following way:—The metal is cast into the form of a network grating, in moulds about 20 inches long, and 8 or 9 broad. Several rows of these are placed over cylindrical glazed earthen pots, about 6 or 7 inches in diameter, containiug some wood-vinegar, which are then covered with planks and spent tan; above these pots another range is piled, and so in succession, to a convenient height. The whole are imbedded iu spent bark from the tan-pit, brought into a fermenting state by being mixed with some bark used in a previous process. The pots are left undisturbed under the influence of a fermenting temperature for 8 or 9 weeks. In the course of this time the lead gratings become, generally speaking, converted throughout into a solid carbonate, which, when removed, is levigated in a proper mill, and elutriated with abundance of pure water. The plan of inserting coils of sheet lead into earthenware pipkins containing vinegar, and imbedding the pile of pipkins in fermenting horsedung and litter, has now ceased to be used; because the coil is not uniformly acted on by the acid vapours, and the sulphuretted hydrogen evolved from the dung is apt to darken the white lead.

In the above processes, the conversion of lead into carbonate seems to be effected by keeping the metal immersed iu a warm humid atmosphere, loaded with carbonic and acetic acids.

Another process has lately been practised to a considerable extent in France, though it does not afford a white lead equal in body and opacity to the products of the preceding operations. M. Thenard first established the principle, and MM. Brechoz and Leseur contrived the arrangements of this new method, which was subsequently executed on a great scale by MM. Roard and Brechoz.

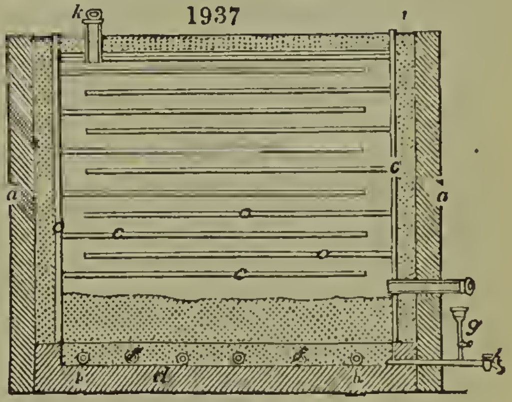
A subacetate of lead is formed by digesting a cold solution of uncrystallised acetate, over litharge, with frequent agitation. It is said that 65 pounds of purified pyroligneous acid, of specific gravity 1·056, require, for making a neutral acetate, 58 pounds of litharge; and hence, to form the subacetate, three times that quantity of base, or 174 pounds, must be used. The compound is diluted with water, as soon as it is formed, and being decanted off quite limpid, is exposed to a current of carbonic acid gas, which, uniting with the two extra proportions of oxide of lead in the subacetate, precipitates them in the form of a white carbonate, while the liquid becomes a faintly acidulous acetate. The carbonic acid may be extricated from chalk, or other compounds, or generated by combustion of charcoal, as at Clichy; but in the latter case it must be transmitted through a solution of acetate of lead before being admitted into the subacetate, to deprive it of any particles of sulphuretted hydrogen. When the precipitation of the carbonate of lead is completed and well settled down, the supernatant acetate is decanted off, and made to act on another dose of litharge. The deposit being first rinsed with a little water, this washing is added to the acetate; after which the white lead is thoroughly elutriated. This repetition of the process may be indefinitely made; but there is always a small loss of acetate, which must be repaired, either directly or by adding some vinegar.

It is customary on the continent to mould the white lead into conical loaves, before sending it into the market. This is done by stuffing well-drained white lead into unglazed earthen pots, of the requisite size and shape, and drying it to a solid mass by exposing these pots in stove-rooms. The moulds being now inverted on tables, discharge their contents, which then receive a final desiccation; and are afterwards put up in pale-blue paper, to set off the white colour by contrast.

It has been supposed that the differences observed between the ceruse of Clichy and the common kinds, depend on the greater compactness of the particles of the latter, produced by their slower aggregation; as also, according to M. Robiquet, on the former containing considerably less carbonic acid. See *infrâ.*

Mr. Ham proposed, in a patent dated June, 1826, to produce white lead with the aid of the following apparatus. *a, a, fig.* 1937, are the side-walls of a stove-room constructed of bricks; *b* is the floor of bricks laid in Roman cement; *c, c,* are the side-plates, between which and the walls a quantity of refuse tanner's bark, or other suitable vegetable matter, is to be introduced. The same material is to be put also into the lower part at *d* (upon a false bottom of grating?). The tan should rise to a considerable height, and have a series of strips of sheet lead *e, e, e,* placed upon it, which are kept apart by blocks or some other convenient means, with a space open at one end of the plates, for the passage of the vapours; but above the upper plates, boards are placed, and covered with tan, to confine them there. In the lower part of the chamber, coils of steam-pipe *f, f,* are laid in different directions to distribute heat; *g* is a funnel-pipe, to conduct vinegar into the lower part of the vessel; and *h* is a cock to draw it off, when the operation is suspended. The acid vapours raised by the heat pass up through the spent bark, and on coming into contact with the sheets of lead, corrode them. The quantity of acid liquor should not be in excess; a point to be ascertained by means of the small tube *i*, at top, which is intended for testing it by the tongue. *k* is a tube for inserting a thermometer, to watch the temperature, which should not exceed 170° Fahr. We are not aware of what success has attended this patented arrangement. The heat prescribed is far too great.

1937



A factory was some years since erected at West Bromwich, near Birmingham, to work a patent lately granted to Messrs. Gossage and Benson, for making white lead by mixing a small quantity of acetate of lead in solution with slightly damped litharge, contained in a long stone trough, and passing over the surface of the trough currents of hot carbonic acid, while its contents are powerfully stirred up by a travelling-wheel mechanism. The product is afterwards ground and elutriated, as usual. The carbonic acid gas is produced from the combustion of coke. This factory has since proved abortive.

Messrs. Button and Dyer obtained a patent, a few years ago, for making white lead by transmitting a current of purified carbonic acid gas, from the combustion of coke, through a mixture of litharge and nitrate of lead, diffused and dissolved in water, which is kept in constant agitation and ebullition by steam introduced through a perforated coil of pipes at the bottom of the tub. The carbonate of lead is formed here upon the principle of Thenard's old process with the subacetate; for the nitrate of lead forms with the litharge a subnitrate, which is forthwith transformed into carbonate and neutral nitrate, by the agency of the carbonic acid gas. It is known that all sorts of white lead produced by precipitation from a liquid, are in a semi-crystalline condition; appear, therefore, semi-transparent, when viewed in the microscope; and do not cover so well as white lead made by the process of vinegar and tan, in which the lead has remained always solid during its transition from the blue to the white state; and hence consists of opaque particles.

A patent was obtained in December 1833, by John Baptiste Constantine Torassa, and others, for making white lead by agitating the granulated metal or shot, in trays or barrels, along with water, and exposing the mixture of lead-dust and water to the air, to be oxidised and carbonated. It is said that upwards of 100,000*l.* were expended at Chelsea, by a joint-stock company, in a factory constructed for executing the preceding most laborious and defective process; which had been many years before tried without success in Germany. The whole of these recent projects for preparing white lead are inferior in economy and quality of produce to the old Dutch process, which may be so arranged as to convert sheets of blue lead thoroughly into the best white lead, within the space of ten weeks, at less expense of labour than by any other plan.

The composition of the different varieties of white lead has been carefully examined by J. Arthur Phillips.* The result of this investigation shows that those specimens, which are obtained by precipitation from solutions of the nitrate by means of an alkaline carbonate, contain very variable quantities of oxide of lead, whilst in white lead prepared by the ordinary Dutch process, the relations existing between the amounts of carbonate and oxide, although definite, is usually very simple. The most usual composition of the white lead of commerce is represented by the formula $2PbO.CO^2 + PbO.HO$., although specimens represented by the formulæ $3PbO.CO^2 + PbO.HO$, and $5PbO.CO^2 + PbO.HO$ are also occasionally met with.

On examining the ordinary corroded leads in a finely divided state, by the aid of a powerful microscope, no traces of a crystalline structure will be perceived, but when precipitated specimens are subjected to a power of 300 diameters, distinct hexagonal plates become visible. These vary from $\frac{1}{5000}$th to $\frac{1}{10000}$th of an inch in diameter, and appear slightly yellow by transmitted light.

Mr. Thomas Richardson, of Newcastle, obtained a patent in December 1839, for a preparation of sulphate of lead, applicable to some of the purposes to which the carbonate is applied. His plan is to put 56 pounds of flake litharge into a tub, to mix it with 1 pound of acetic acid (and water) of spec. grav. 1·046, and to agitate the mixture till the oxide of lead becomes an acetate. But whenever this change is partially effected, he pours into the tub, through a pipe, sulphuric acid of spec. grav. 1·5975, at the rate of about 1 pound per minute, until a sufficient quantity of sulphuric acid has been added to convert all the lead into a sulphate; being about 20 parts of acid to 112 of the litharge. The sulphate is afterwards washed and dried in stoves for the market, but is very inferior to ordinary white lead.

Mr. Leigh, surgeon in Manchester, prepared his patent white lead by precipitating a carbonate from a solution of the chloride of the metal by means of carbonate of ammonia. On this process, in a commercial point of view, no remarks need be made.

A patent was granted to Mr. Hugh Lee Pattinson, in September 1841, for improvements in the manufacture of white lead, &c. This invention consists in dissolving carbonate of magnesia in water impregnated with carbonic acid gas, by acting upon magnesian limestone, or other earthy substances containing magnesia in a soluble form, or upon rough hydrate of magnesia in the mode hereafter described, and in applying this solution to the manufacture of magnesia and its salts, and the precipitation of carbonate of lead from any of the soluble salts of lead, but particularly the chloride of lead; in which latter case the carbonate of lead so precipitated is triturated with a solution of caustic potash or soda, by which a small quantity of chloride of lead contained in it is converted into hydrated oxide of lead, and the whole rendered similar in composition to the best white lead of commerce. The manner in which these improvements are carried into effect is thus described by the patentee:—I take magnesian limestone, which is well known to be a mixture of carbonate of lime and carbonate of magnesia in proportions varying at different localities; and on this account I am careful to procure it from places where the stone is rich in magnesia. This I reduce to powder, and sift it through a sieve of forty or fifty apertures to the linear inch. I then heat it red-hot, in an iron retort or reverberatory furnace, for two or three hours, when the carbonic acid being expelled from the carbonate of magnesia, but not from the carbonate of lime, I withdraw the whole from the retort or furnace, and suffer it to cool. The magnesia contained in the limestone is now soluble in water impregnated with carbonic acid gas, and to dissolve it I proceed as follows:—I am provided with an iron cylinder lined with lead, which may be of any convenient size, say 4 feet long by $2\frac{1}{2}$ feet in diameter; it is furnished with a safety valve and an agitator, which latter may be an axis in the centre of the cylinder, with arms reaching nearly to the circumference, all made of iron and covered with lead. The cylinder is placed horizontally, and one extremity of this axis is supported within it by a proper carriage, the other extremity being prolonged and passing through a stuffing-box at the other end of the cylinder, so that the agitator may be turned round by applying manual or other power to its projecting end. A pipe, leading from a force-pump, is connected with the under side of the cylinder, through which carbonic acid gas may be forced from a gasometer in communication with the pump, and a mercurial gauge

* Journal of the Chemical Society, vol. iv. p. 145.

is attached, to show at all times the amount of pressure within the cylinder, independently of the safety-valve. Into a cylinder of the size given I introduce from 100 to 120 lbs. of the calcined limestone with a quantity of pure water, nearly filling the cylinder; I then pump in carbonic acid gas, constantly turning the agitator, and forcing in more and more gas, till absorption ceases under a pressure of five atmospheres. I suffer it to stand in this condition three or four hours, and then run off the contents of the cylinder into a cistern, and allow it to settle. The clear liquor is now a solution of carbonate of magnesia in water impregnated with carbonic acid gas, or, as I shall hereafter call it, a solution of bicarbonate of magnesia, having a spec. grav. of about 1·028, and containing about 1600 grains of carbonate of magnesia to the imperial gallon.

I consider it the best mode of obtaining a solution of bicarbonate of magnesia from magnesian limestone, to operate upon the limestone after being calcined at a red-heat in the way described; but the process may be varied by using in the cylinder the mixed hydrates of lime and magnesia, obtained by completely burning magnesian limestone in a kiln, as commonly practised, and slaking it with water in the usual manner: or, to lessen the expenditure of carbonic gas, the mixed hydrates may be exposed to the air a few weeks till the lime has become less caustic by the absorption of carbonic acid from the atmosphere. Or the mixed hydrates may be treated with water, as practised by some manufacturers of Epsom salts, till the lime is wholly or principally removed; after which the residual rough hydrate of magnesia may be acted upon in the cylinder, as described; or hydrate of magnesia may be prepared for solution in the cylinder, by dissolving magnesian limestone in hydrochloric acid, and treating the solution, or a solution of chloride of magnesium, obtained from sea-water by salt-makers in the form of bittern, with its equivalent quantity of hydrate of lime, or of the mixed hydrates of lime and magnesia, obtained by completely burning magnesian limestone, slaking it as above. When I use this solution of bicarbonate of magnesia for the purpose of preparing magnesia and its salts, I evaporate it to dryness, by which a pure carbonate of magnesia is at once obtained, without the necessity of using a carbonated alkali, as in the whole process; and from this I prepare pure magnesia by calcination in the usual manner; or, instead of boiling to dryness, I merely heat the solution for some time to the boiling point, by which the excess of carbonic acid is partly driven off, and pure carbonate of magnesia is precipitated, which may then be collected, and dried in the same way as if precipitated by a carbonated alkali. If I require sulphate of magnesia, I neutralise the solution of bicarbonate of magnesia with sulphuric acid, boil down, and crystallise; or I mix the solution with its equivalent quantity of sulphate of iron, dissolved in water, heated to the boiling point, and then suffer the precipitated carbonate of iron to subside; after which I decant the clear solution of sulphate of magnesia, boil down, and crystallise as before. When using this solution of bicarbonate of magnesia for the purpose of preparing carbonate of lead, I make a saturated solution of chloride of lead in water, which at the temperature of 50° or 60° Fahr., has a specific gravity of about 1·008, and consists of 1 part of chloride of lead dissolved in 126 parts of water. I then mix the two solutions together, when carbonate of lead is immediately precipitated; but in this operation I find it necessary to use certain precautions, othewise a considerable quantity of chloride of lead is carried down along with the carbonate. These precautions are, first, to use an excess of the solution of magnesia; and secondly, to mix the two solutions together as rapidly as possible. As to the first, when using a magnesian solution containing 1600 grs. of carbonate of magnesia, per imperial gallon, with a solution of chloride of lead saturated at 55° or 60° Fahr., 1 measure of the former to 8½ of the latter is a proper proportion; in which case there is an excess of carbonate of magnesia employed, amounting to about an eighth of the total quantity contained in the solution. When either one or both the solutions vary in strength, the proportions in which they are to be mixed must be determined by preliminary trials. It is not, however, necessary to be very exact, provided there is always an excess of carbonate of magnesia amounting to from one-eighth to one-twelfth of the total quantity employed. If the excess is greater than one-eighth, no injury will result, except the unnecessary expenditure of the magnesian solution. As to the second precaution, of mixing the two solutions rapidly together, it may be accomplished variously; but I have found it a good method to run them in two streams, properly regulated in quantity, into a small cistern, in which they are to be rapidly blended together by brisk stirring, before passing out, through a hole in the bottom, to a large cistern or tank, where the precipitate finally settles. The precipitate thus obtained is to be collected, washed and dried in the usual manner. It is a carbonate of lead, very nearly pure, and suitable for most purposes; but it always contains a small portion of chloride of lead, seldom less than from 1 to 2 per cent., the presence of which, even in so small a quantity, is somewhat injurious to the colour and body of the white lead. I decompose this chloride, and convert it into a hydrated oxide of lead by grinding the dry precipitate with a solution of caustic alkali, in a mill similar to the ordinary mill used in grinding white lead with oil, adding just so much of the lye as may be required to convert the precipitate into a soft paste. I allow this paste to lie a few days, after which, the chloride of lead being entirely, or almost entirely, decomposed, I wash out the alkaline chloride formed by the reaction, and obtain a white lead, similar in composition to the best white lead of commerce. I prepare the caustic alkaline lye by boiling together, in a leaden vessel, for an hour or two, 1 part by weight of dry and recently-slaked lime, 2 parts of crystallised carbonate of soda (which, being cheaper than carbonate of potash, I prefer) and 8 parts of water. The clear and colourless caustic lye, obtained after subsidence, will have a specific gravity of about 1·090, and when drawn off from the sediment, must be kept in a close vessel for use.

As we have before hinted, the manufacture of white lead by the Dutch process is one the nature of which seems yet enveloped in considerable obscurity. So far as appearances go, the action would seem to consist; first, in the oxidation of metallic lead by the atmosphere, under the influence of the vapour of acetic acid; secondly, in the production of acetate of lead, by the combination of the oxide of lead with the acetic acid; and, thirdly, in the displacement of the acetic acid from its union with the oxide of lead, by the action of carbonic acid, and the consequent formation of white lead. But this in no way accounts for the fact, that, when acetate of lead is decomposed by carbonic acid, it is carbonate of lead, and not white lead, which is formed. Nor can we conceive how an acid like the acetic is capable of being wholly expelled from a metallic oxide by a quantity of another acid incapable of completely saturating the oxide. In other words, as white lead contains free or uncombined oxide of lead, how happens it that the free acetic acid does not remain united to this? We confess our inability to reconcile the facts of the case with the preceding hypothesis, and therefore pass on to another, in which we will assume that acetate of lead, but not the neutral acetate, is formed as we have already supposed. Now there are two subacetates; one composed of six atoms of oxide of lead to one atom of acetic acid; and the other consisting of three atoms of oxide of lead to one of acetic acid. We select, in preference the former, as it is the one which forms naturally when acetic acid acts, at common temperatures, on an excess of oxide of lead. The composition of this salt is such, that, if we can conceive slow combustion to take place, or that its acetic acid combining with the oxygen of the air is resolved into water and carbonic acid, then the carbonic acid produced would be exactly sufficient to saturate four atoms of the oxide of lead, and leave a compound of the precise composition of white lead. On this view, the first action in a white lead stack would be the production of sexbasic acetate of lead; and the next would be the destruction of this by eremacausis, and the formation of white lead.

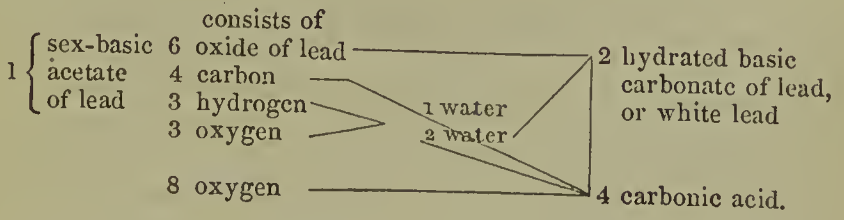
The apparatus employed in the manufacture of white lead is extremely simple, and consists merely of certain large enclosures or spaces, called beds, in which the stacks are built up, together with the earthenware pots needed for holding the vinegar, and the machinery used in casting the lead and grinding the white lead, so as to fit it for the market. The metallic lead was formerly used in the shape of sheets or coils, which were placed perpendicularly over the vinegar pots; but this practice has been almost everywhere abandoned, and at present the lead is generally cast into what are called "crates" or "grates," and having the appearance of lattice-work; the object being to expose as large a surface as possible of metallic lead to the action of the vapour of the vinegar. The beds are of considerable size; and, in this respect, some diversity of opinion prevails amongst practical men; but it seems pretty certain that no advantage is gained when the area of a bed comes to exceed 300 square feet; and there are many reasons for believing, that, with beds of twice this area, the gain, in point of diminished labour, is much more than compensated for by the reduced produce in white lead. Nevertheless, each manufacturer seems to entertain an opinion of his own in respect to this matter; and there are even some pretensions to secresy concerning it. In fact, everything depends upon the construction of the bed, for it is this which regulates the production of white lead; and, as a proof of the great importance connected with this circumstance, we may here mention, that, whilst one manufacturer has produced as much as 65 per cent. of corrosion during a long course of years, another in his immediate neighbourhood has never been able to exceed 52 per cent. The beds of the former are 16 feet square, whilst those of the latter are 19½ feet square; and, in dwelling upon the details of this operation, we shall find that theoretically, a bed may be too large, as the above practical fact indicates.

In forming a stack, it is necessary to begin by laying, in the first instance, a bed of spent tanner's bark, 3 feet in thickness, over the surface of the bed; and upon this are placed the earthenware pots containing the vinegar. These are arranged side by side, and filled to about one-third of their contents with vinegar, of a strength equal to 6 per cent. of anhydrous acetic acid. Upon these pots are placed the crates of lead, and over all a series of boards are arranged, which form a floor for the next layer of spent tan. Such an arrangement as we have described is denominated "a bed," but there is this difference between the beds, viz. that the lowest or bottom bed has a bed of tan 3 feet in thickness, whereas but one foot only is needed in the others. Having finished the lowest bed, 12 inches of spent tan are now placed upon the boards, and a similar arrangement of pots, crates, and boards takes place, which constitutes the second bed; this is followed by a third, a fourth, and so on, until at last the uppermost bed is finished; when a layer of spent tan, 30 inches in thickness, is placed over the whole, and the operation may be said to commence. In six or eight days the tan begins to ferment and evolve heat; and this goes on increasing for some weeks, when it gradually diminishes, and at the end of about three months the whole has become cool, and the stack is fit to be taken down. When examined, the pots, which formerly contained vinegar, will now be found to be quite empty, or to hold a little water merely, but no acetic acid; the leaden crates will be discovered to have increased sensibly in bulk, to have become coated with a thick and dense incrustation of white lead, and in some places even to have become altogether converted into this substauce; whilst the tan, haviug lost its fermentative quality, is now useless, except as fuel.

The successive beds constituting the entire stack are next carefully removed, so as to obtain the white lead with the least possible admixture of the tan; and as a portion of this substance always adheres to the crates, these are washed in a kind of wear or trough, by which the whole of the tan is thoroughly separated. When this is seen to be complete, the corroded part of the plate or "white lead" is detached from the uncorroded or "blue lead," either by means of rollers or with a mallet. The blue lead is weighed, and, for the most part, remelted and again cast into crates; whilst the white lead is first crushed, and afterwards ground in water into a fine powder, when it is eollected by elutriation and deposition, and dried in stoves, a little below the boiling point of water. Formerly this grinding was performed in the dry way, and much injury to the health of the workmen thus resulted; but during the last 30 years the wet mode of grinding has become general, and is greatly to be preferred.

The conversion of white lead into paint is a simple mechanical operation, though, as we have before remarked, it is followed by chemical results; for there can be no doubt that the surplus oxide in the white lead combines with part of the oil employed to form the paint, and gives rise to a true plaster or metallic soap. The proportions of oil and white lead vary with different manufacturers; nor does it much matter what these proportions are: the principal point is to obtain a thorough intermixture of the two ingredients; and this is done by grinding them together beneath heavy stones or "runners" for several hours, at the end of which time the mixture will be found homogeneous.

If we examine the process of white lead making with a view to discover its chemical peculiarities, we perceive at once that it presents no salient feature to guide our inquiry. The most probable explanation is certainly that before given, aud which supposes the pre-existence of sex-basic acetate of lead. At the same time there are no experiments which prove that this substance is capable of undergoing the slow combustion requisite to complete the argument. But then this is precisely the question which now calls for solution; and there are many analogous facts in chemistry that warrant the kind of eremacausis or combustion here hinted at. And presuming this to be correct, then one atom of the sex-basic of lead and eight atoms of atmospheric oxygen, would unite as in the following diagram, and produce two atoms of white lead, and three atoms of water, two atoms of which would remain united to the white lead thus: —



It remains, however, to be demonstrated, whether this kind of sub-acetate of lead, and which is readily formed by boiling acetic acid with a large excess of litharge, can, under the influence of a gentle heat, become thus converted into white lead.

Connected with this subject is the fabrication of an article called the sub-chloride of lead, or oxychloride, which is now sometimes employed as a substitute for white lead. The oyxchloride is so constituted, that if for two atoms of carbonate of lead in white lead we substitute two atoms of chloride of lead, the result will be the new compound, and which was made the subject of a patent by the late Mr. H. L. Pattinson, of Newcastle-upon-Tyne. Now it is a very remarkable fact, and strongly corroborative of the views which we have here advanced, that the new paint "covers" equally well with the best white lead, just as its basic composition would indicate; and the probability is, that the oxide of lead contained in it unites to part of the oil of the paint, forming as before a metallic soap, whilst the chloride of lead remains interspersed in the mass, and communicates opacity and whiteness. An observation made, we believe, in the first instance by Dr. Ure, shows the correctness of such a conclusion; for, although, when alone, the oxychloride of lead be quite insoluble in water, yet, after admixture with oil, boiling water readily dissolves from the mass the chloride of lead, and leaves the oxide combined with the oil. This circumstance, which can be easily demonstrated, seems also to show, that paint made with an insoluble salt, like carbonate of lead, is preferable to one made with a soluble salt, like the chloride.

WHITING *exported* in 1858:—Cwts. 1485. Declared real value, 6850*l.*

WICK (*Mèche*, Fr.; *Docht*, Germ.) is the spongy cord, usually made of soft spun cotton threads, which by capillary action draws up the oil in lamps, or the melted tallow or wax in candles, in small successive portions, to be burned. In common wax and tallow candles, the wick is formed of parallel threads; in the stearine candles the wick is plaited upon the braiding machine, moistened with a very dilute sulphuric acid, and dried, whereby as it burns it falls to one side and consumes without requiring to be snuffed; in the patent candles of Mr. Palmer one-tenth of the wick is first imbued with subnitrate of bismuth ground up with oil; the whole is then bound round in the manner called *gimping;* and of this wick, twice the length of the intended candle is twisted double round a rod, like the *caduceus of Mercury.* This rod with its coil being inserted in the axis of the candle mould is to be enclosed by pouring in the melted tallow; and when the tallow is set the rod is to be drawn out at top, leaving the wick in the candle. As this candle is burned, the ends of the double wick stand out sideways beyond the flame; and the bismuth attached to the cotton being acted on by the oxygen of the atmosphere causes the wick to be completely consumed, and therefore saves the trouble of snuffing it.

WINCING MACHINE is the English name of the dyer's reel, which he suspends horizontally, by the ends of its iron axis in bearings, over the edge of his vat, so that the line of the axis, being placed over the middle partition in the copper, will permit the piece of cloth which is wound upon the reel to descend alternately into either compartment of the bath, according as it is turned by hand to the right or the left. For an excellent self-acting or mechanical wince, see Dyeing.

WINE is the fermented juice of the grape. This beverage has been in use from the earliest periods of man's history. We have, however, only space to deal with wine in its modern relations.

In the reign of Elizabeth the wines chiefly in use in England were those of Gascony, Burgundy, and Guienne, which with Canary, Cyprus, Grecian Malmsey, Italian Vernage, Rhenish Tent, Malaga, and others, were "accompted of, because of their strength and valure."

In the time of Charles II. "the consumption of French wines was two-fifths that of the whole of England." The favourite wines were then Bordeaux, Burgundy, and hermitage. Champagne, although known in England in the reign of Henry VIII., did not come into use till that of Charles II.

The strong wines of Burgundy, the white wines of Spain (*Sherris-sack* or *Sec*), and the red wines of Portugal, first came into use about 1690 A.D. Port wine was at first a much lighter wine than it afterwards became. According to Baron Forrester the first port wine introduced into this country was not from the Douro, or even shipped at Oporto. It was a wine resembling claret of Burgundy, from the Minho, shipped at Vienna.

The wine-growing countries are especially the more southern states of Europe, where the grapes, being more saccharine, afford a more abundant production of alcohol, and stronger wines, as exemplified in the best Port, Sherry, and Madeira. In the more temperate climates, such as the district of Burgundy, the finer flavoured wines are produced; and there the vines are usually grown upon hilly slopes fronting the south, with more or less of an easterly or westerly direction, as on the Côte d'Or, at a distance from marshes, forests, and rivers, whose vapours might deteriorate the air. The plains of this district, even when possessing a similar or analogous soil, do not produce wines of so agreeable a flavour. The influence of temperature becomes very manifest in countries further north, where, in consequence of a few degrees of thermometric depression, the production of generous, agreeable wine becomes impossible.

The land most favourable to the vine is light, easily permeable to water, but somewhat retentive by its composition ; with a sandy subsoil, to allow the excess of moisture to drain readily off. Calcareous soils produce the highly esteemed wines of the Côte d'Or ; a granitic debris forms the foundation of the lands where the Hermitage wines are grown; siliceous soil interspersed with flints furnishes the celebrated wines of Château-Neuf, Ferté, and La Gaude ; schistose districts afford also good wine, as that called *la Malgue.* Thus we see that lands differing in chemical composition, but possessed of the proper physical qualities, may produce most agreeable wines ; and so also may lands of like chemical and physical constitution produce various kinds of wine, according to their varied exposure. As a striking example of these effects, we may adduce the slopes of the hills which grow the wines of Montrachet. The insulated part towards the top furnishes the wine called *Chevalier Montrachet,* which is less esteemed, and sells at a much lower price, than the delicious wine grown on the middle height called *true Montrachet.* Beneath this district and in the surrounding plains the vines afford a far inferior article called *bastard Montrachet.* The opposite side of the hills produces very indifferent wine. Similar differences, in a greater or less degree, are observable relatively to the districts which grow the Pomard, Volnay, Beaune, Nuits, Vougeot, Chambertin, Romanée, &c. Everywhere it is found that the reverse side of the hill, the summit and the plain, although generally consisting of like soils, afford inferior wine to the middle southern slopes. In an essay on the soil and climate of the province of Biscay, by Don L. de Olazabal, an analysis of the soil of the left bank of the Nervion, in the district of Abando, is given.

Argil (silex, alumina, and oxide of iron) - - -	35·15
Broken and small flints - - - - - -	14·20
Carbonate of lime - - - - - -	40·09
Manure and vegetable soil - - - - -	10·16
	100·00

This analysis represents the general character of all the best wine growing districts; and when the vine lands are too light or too dense they may be modified, within certain limits, by introducing into them either argillaceous or siliceous matter. Marl is excellent for almost all grounds, which are not previously too calcareous, being alike useful to open dense soils and to render porous ones more retentive.

For the vine, a manure supplying azotised or animal nutriment may be used with great advantage, provided care be taken that it may not, by absorption in too crude a state, impart any disagreeable odour to the grape, as sometimes happens to the vines grown in the vicinity of great towns, like Paris, and near Argenteuil. There is a compost used in France called *animalised black,* of which from $\frac{1}{3}$ to $\frac{1}{2}$ of a litre (old English quart) serves sufficiently to fertilise the root of one vine when applied every year or two years. An excess of manure, in rainy seasons especially, has the effect of rendering the grapes large and insipid.

The ground is tilled at the same time as the manure is applied, towards the month of March; the plants are then dressed, and the props are inserted. The weakness of the plants renders this practice useful; but in some southern districts the stem of the vine, when supported at a proper height acquires after a while sufficient size and strength to stand alone. The ends of the props or poles are either dipped in tar, or charred, to prevent their rotting. The bottom of the stem must be covered over with soil, after the spring rains have washed it down. The principal husbandry of the vineyard consists in digging or ploughing to destroy the weeds, and to expose the soil to the influence of the air during the months of May, June, and occasionally in August.

The fruit of the same plant when transferred to a different soil loses its peculiar characteristics ; thus one and the same vine produces Hock upon the Rhine, Bucellas in Portugal, and Sercial at Madeira. It has been found that vines from Germany, France, Portugal, and Spain transplanted to the Cape of Good Hope and Australia have in no one instance produced wine assimilating to the peculiarities of the original plant ; and no European vine has hitherto succeeded when transplanted to the United States, although wine is made at Cincinnati from American grapes.

The finest known wines are the produce of soils the combination and proportions of whose ingredients are extremely rare and exceptional; and co-operating with these they require the agency of peculiar degrees of light, moisture, and heat. The richest wines of France, Italy, Hungary, Madeira, and Teneriffe are grown on the sites of extinct volcanoes. The district of Xeres, which has so long supplied us with Sherry, is mapped out so accurately by the line of its peculiar soil that its dimensions are known by the acre. The vine which produces Port on the hills above the Douro yields a totally different wine in the vicinity of the Tagus. The wine district of the Rhingau, between Mayence and Rudesheim, is but nine miles in length by half as much broad. The south side of a single hill produces Johannisberg; and Steinberg is the vineyard of a suppressed monastery. The numerous wines of Burgundy and the Garonne take their names respectively from circumscribed spots,h and so narrow and apparently so capricious are the respective limits, that a dite divides portions which from time immemorial have been sought with avidity, from others which in the market will uniformly bring but one-fifth the price. The produce of the celebrated vineyard of Lafitte, near Bordeaux, for the year 1848, was sold at 4000 francs per tun, while the wines of the immediate neighbourhood realised only 200 francs. The proprietor of a vineyard which is only separated from that of Lafitte by a narrow gully, a few years since expended a large sum of money in endeavouring, by improved cultivation, to assimilate his wines to that of Lafitte. To some extent he improved the quality, but the wines never approached the peculiar character of the Lafitte, while the expense incurred was so enormous that the enterprising proprietor was ruined. The costly *Clos Vougeot* grows in a farm of eighty acres. *Romanée Conti* is but six and a half, and the famous *Mont Rachet* of the Côte d'Or is distinguished into three classes, of which one sells at one-third less than the other two, "yet these qualities are produced from vineyards only separated from one another by a footpath; they have the same aspect, and apparently the same soil, in which the same vines are cultivated and managed in precisely the same manner."—(*Henderson on Wines.*) One small valley in Madeira alone produces the finest *Malmsey.* See Sir Emerson Tennent *On wine, its uses and taxation.* Art and horticultural science have, he remarks, been applied to extend the limits thus circumscribed by nature, but with such unsatisfactory results, that, as a rule, it may be stated that the higher class wine of any known district has not been successfully reproduced beyond it. The red wines of Portugal grown in the Alto Douro can no more be made in the adjoining provinces of the Minho or Beira than the white wines of Spain could be successfully imitated on the Rhine.

The vine disease.—The *Oidium Tuckeri* is the name given to this disease, Mr. Tucker having first carefully observed the growth of this destructive microscopic fungus. In connection with the cultivation of the vine, and the manufacture of wine, it is necessary that the peculiar characteristics of this disease should be described.

It is stated that the epidemic first showed itself in a hothouse in England in 1845. White efflorescences were remarked, which covered the vine; the grapes were soon after attacked, and, hindered from swelling, the skin burst, and at last they became rotten and fell off. In 1847 it appeared in France; attacking first the hothouses, it spread rapidly to the trellised vines, and to those cultivated near the ground. It then invaded Spain, which it devastated; and finally, in 1851, made its appearance in Italy. This fungus attacks the hinder parts of the vine, and rarely the stems. The leaves and tendrils also become more or less affected, the green colour of those parts becoming paler, and marked with a dark yellow, as if burnt, and emitting an offensive smell. It was fancied at first that the fungus was produced by the puncture of an insect, and its presence was actually ascertained in the seed of the grape, and on the hinder side of the leaf. This insect established itself on the leaves, and formed a cobweb-like film, rising like a blister on the upper part of the leaf. The birth of it is, however, now generally admitted to be posterior to the invasion of the *oidio.*

The *Reports of her Majesty's Secretaries of Embassy and Legation on the Effects of the Vine Disease on the Commerce of the Countries in which they reside,* all point to sulphur as the only reliable remedy for this disease. The most practical method of applying sulphur to the vines was that introduced by Dr. Ashby Price. By boiling sulphur and lime together in water we obtain a brilliant yellow solution, which is a sulphide of lime (*the quadrisulphuret of Dr. Dalton*); with a diluted solution of this the vines are washed over every part. By the action of the carbonic acid of the plant it is speedily decomposed, and over every part a thin white film of sulphur is produced, which effectually destroys the parasite without injuring the vine. See Forrester *on the Vine Disease in the Port-wine Districts of the Alto Douro,* in the *Transactions of the Royal Society for* 1854.

The vintage, in the temperate provinces, generally takes place about the end of September, and it is always deteriorated whenever the fruit is not ripe enough before the 15th or 20th of October; for, in this case, not only is the must more acid and less saccharine, but the atmospherical temperature is apt to fall so low during the nights, as to obstruct more or less its fermentation into wine. The grapes should be plucked in dry weather, at the interval of a few days after they are ripe; being usually gathered in baskets, and transported to the vats in dorsels, sufficiently tight to prevent the juice from running out. Whenever a layer about 14 or 15 inches thick has been spread on the bottom of the vat, the treading operation begins, which is usually repeated after macerating the grapes for some time, when an incipient fermentation has softened the texture of the skin and the interior cells. When the whole bruised grapes are collected in the vat, the juice, by means of a slight fermentation, reacts, through the acidity thus generated, upon the colouring-matter of the husks, and also upon the tannin contained in the stones and the fruit-stalks. The process of fermentation is suffered to proceed without any other precaution, except forcing down from time to time the pellicles and pedicles floated up by the carbonic acid to the top; but it would be less apt to become acetous were the mouths of the vats covered. With this view, M. Sebille Augur introduced with success his elastic bung in the manufacture of wine in the department of the Maine-et-Loire.

With whatever kind of apparatus the fermentation may have been regulated, as soon as it ceases to be tumultuous, and the wine is not sensibly saccharine or muddy, it must be racked off from the lees, by means of a spigot, and run into the ripening tuns. The marc being then gently squeezed in a press, affords a tolerably clear wine, which is distributed among the tuns in equal proportions; but the liquor obtained by stronger pressure is reserved for the casks of inferior wine.

In the south of France the fermentation sometimes proceeds too slowly, on account of the must being too saccharine; an accident which is best counteracted by maintaining a temperature of about 65° or 68° Fahr. in the tun-room. When the must, on the other hand, is too thin, and deficient in sugar, it must be partially concentrated by rapid boiling before the whole can be made to ferment into a good wine. By boiling up a part of the must for this purpose, the excess of ferment is at the same time destroyed. Should this concentration be inconvenient, a certain proportion of sugar must be introduced, immediately after racking it off.

The specific gravity of must varies with the richness and ripeness of the grapes which afford it; being in some cases so low as 1·0627, and in others so high as 1·283. This happens particularly in the south of France. In the district of the Necker in Germany, the spec. grav. varies from 1·050 to 1·090; in Heidelberg, from 1·039 to 1·091; but it varies much in different years.

After the fermentation is complete, the vinous part consists of water, alcohol, a colouring-matter, a peculiar aromatic principle, a little undecomposed sugar, bitartrate and malate of potash, tartrate of lime, muriate of soda, and tannin; the latter substances being in small proportion.

It is known that a few green grapes are capable of spoiling a whole cask of wine, and therefore they are always allowed to become completely ripe, and even sometimes to undergo a species of slight fermentation before being plucked, which completes the development of the saccharine principle. At other times the grapes are gathered whenever they are ripe, but are left for a few days on wicker-floors, to sweeten, before being pressed.

In general the whole vintage of the day is pressed in the evening, and the resulting must is received in separate vats. At the end usually of six or eight hours, if the temperature be above 50° Fahr., and if the grapes have not been too cold when plucked, a froth or scum is formed at the surface, which rapidly increases in thickness. After it acquires such a consistence as to crack in several places, it is taken off with a skimmer, and drained; and the thin liquor is returned to the vat. A few hours afterwards another coat of froth is formed, which is removed in like manner, and sometimes a third may be produced. The regular vinous fermentation now begins, characterised by air-bubbles rising up the sides of the staves, with a peculiar whizzing as they break at the surface. At this period all the remaining froth should be quickly skimmed off, and the clear subjacent must, be transferred into barrels, where it is left to ripen by a regular fermentation.

The white wines, which might be disposed to become stringy, from a deficient supply of tannin, may be preserved from this malady by a due addition of the footstalks of ripe grapes. The tannin, while it tends to preserve the wines, renders them also more easy to clarify, by the addition of white of egg or isinglass.

The white wines should be racked off as soon as the first frosts have made them clear, and at the latest by the end of the February moon. By thus separating the wine from the lees, the fermentation which takes place on the return of spring, and which, if too brisk, would destroy all its sweetness by decomposing the remaining portion of sugar, is avoided or rendered of little consequence.

The characteristic odour possessed by all wines, in a greater or less degree, is produced by a peculiar substance, which possesses the characters of an essential oil. As it is not volatile, it cannot be confounded with the aroma of wine. When large quantities of wine are distilled, an oily substance is obtained towards the end of the operation. This may also be procured from the wine lees which are deposited in the casks after the fermentation has commenced. It forms one 40,000th part of the wine.

and consists of a peculiar new acid, and ether, each of which has been called the *œnanthic*. The acid is analogous to the fatty acids, and the ether is liquid, but insoluble in water. The acid is perfectly white when pure, of the consistence of butter at 60°, melts with a moderate heat, reddens litmus, and dissolves in caustic and carbonated alkalies, as well as in alcohol and ether. Œnanthic ether is colourless, has an extremely strong smell of wine, which is almost intoxicating when inhaled, and a powerful disagreeable taste.—*Liebig and Pelouze.*

PORTUGAL.— Port wine is the produce of a single well-defined district in the north of Portugal, extending 8 leagues west and east from the Serra do Marão, an elevation of 4400 feet above the level of the sea, to the Quinta da Baleira, near San Joao da Pesqueira, and 4 leagues north and south between Villa Real and Lamego. The return of the vintages in this area, known as the Alto Douro, from 1843 to 1851, show the average production of qualities fit for use in ordinary years to be 63,568 pipes, in addition to which there are 20,633 pipes of refuse, fit only for distillation; in all 84,211 pipes.

The alcoholic contents of port wine, as given by Brande, are:—

Port wine, maximum - - - -	23·92 alcohol.
,, minimum - - - -	19·82 ,,

Christison gives the alcoholic contents in volume as:—

Port wine, weak - - - - - -	18 alcohol.
,, average of seven kinds - - -	20 ,,
,, strong - - - - - - -	21 ,,

Red wine of a good character is grown in the vicinity of Figueira, and sometimes, in peculiar years, shipments have taken place from that port and from Aveiro for the English market.

Portugal, in addition to port wine and its congeners, yields a variety of other wines of a sound and good character; and at one time England consumed, though never very largely, the white wines of *Lisbon* and *Bucellas*, and the red wines of the Minho and Beira; but the taste for them changed; it was transferred to the drier and stronger-bodied wines of Spain, and their importation came to an end.

SPAIN.—The sherries of Spain have long been favourite wines in England and the United States. In 1840, Sir E. Tennent informs us, the consumption attained an average of 2,500,000 gallons, and in 1854 it had risen to 2,741,230 gallons.

Exports of wine from Spain to England.

	Pipes.	Value.		Pipes.	Value.
1850	39,407	£811,841	1854	42,062	£1,192,498
1851	39,493	750,360	1855	38,835	1,149,496
1852	2,809	14,935	1856	42,710	1,217,587
1853	44,943	1,283,316	1857	42,853	1,164,861

In the United States the consumption of sherry is rapidly increasing; and this is the case also in Russia. To meet this demand efforts have of late years been made to introduce Sicilian Marsala.

In the *Basque Provinces* a light wine, called *chacoli*, is produced, but not in large quantities. Mr. Lumley gives the value of the wines of this district as £17,072.

Alicante produced about 21,118 pipes of wine in 1857.

Valencia produced about 150,000 pipes of 100 gallons each.

Cadiz produces annually from 60,000 to 70,000 butts of new wine (*Mosto*) at about £7 per butt. The sherries exported from this district are never under three to four years old.

Barcelona is stated to produce 85,000,000 gallons.

Tarragona exports by sea about 35,000 butts, and a large portion is consumed in the province.

Malaga. Many kinds of grapes are cultivated in this province. The Pedro Ximen, Doradillo, and Don Bueno are cultivated entirely for the manufacture of wine. The Uvas de Parra or trellis vine, the Passa larga or bloom raisin grape, and the Loja, which is shipped green for England for table use, are cultivated for exportation as fruit. Of Malaga wine the annual produce is on the average about 20,000 butts. Three butts of Malaga wine yield one of brandy, while ten butts of French wine are required to produce the same quantity of spirit. This brandy is used to cure the wines.

Aragon produces a large quantity of wine, those which are most preferred being the wines of Campo de Cariñena. Many of the wine districts of Old Castile produce also large quantities of wine.

"At present many of the Spanish wines are not only so badly made that they will not keep for two years, but their quality is much injured from their being kept and transported in pig-skins."—*Correspondent of the Secretary of Legation at Madrid.*

In 1857 the total exportation of Spanish wines was as follows:—

	Pipes.	Value.	
England	42,853	£1,164,861	of which £647,467 was for common wine.
France	100,392	663,661	
Tuscany	22,410	114,285	
Sardinia	3,715	25,535	
Portugal	2,351	17,445	
Total	216,829	£2,602,876	

Spain produces an enormous quantity of wine which is not suitable for the English market. Mr. Porter estimated that, good, passable, and bad, it amounted to 120,000,000 gallons; but (says Sir E. Tennant) the testimony is concurrent that, except in Andalusia and a few other minor localities, its manufacture is so imperfect, its qualities so peculiar, and its flavour so extraordinary, from carelessness, dirt, and other causes, that it is not presentable in the English market. Dr. Gorman, in his evidence before the House of Commons Committee, says:—"No natural sherry comes to this country; no wine house will send it; the article you get is a mixed article; if they gave you the natural produce of Xeres it would not suit you; in all probability you would say it was an inferior wine; our taste is artificial, because we are not a wine-drinking people."

Brande gives the alcohol in sherry 18·37 the maximum, and 17·00 the minimum, while Christison gives the following result from his examination:—

Sherry, weak - - - - - - -	17 in volume.
„ average of 13 old wines - -	18 „
„ strong - - - - - -	20 „
„ Madre de Xeres - - - - -	21 „

The *Montillado* of Spain is a wine which appears to depend for its character on the soil, which is a white soil called *albariza*, containing 70 per cent. of carbonate of lime, with alumina, silica, and a little magnesia. The *Manzanilla* is the produce of the terrains rouges, or red earths, somewhat sandy.

Sicily, as producing the celebrated *Sicilian Marsala*, is perhaps next in importance. Marsala resembles ordinary sherry in many respects; it is, when good, a wholesome, and, as it is technically described in the trade, a *clean* wine. Of Marsala, Sicily produces not less than 2,143,370 gallons. Sicily also produces red wine, but of a very coarse quality.

Madeira and the Canaries produce a wine, the former under the name of the place of its production, being well known. Its consumption has never, however, been very large. The produce of the island has rarely exceeded 25,000 pipes. In 1854 we imported 42,874 gallons.

Cape of Good Hope.—*Cape wine* has never found much favour in this country. In 1854 we imported 275,382 gallons, whereas in 1825 we obtained 670,000 gallons. This wine is used to some extent in the manufacture of "British wines."

African port and sherry have lately been introduced to the English market; and, as the price has been remarkably low as compared with the Portuguese and Spanish wines, a large demand has been created; but there appears to be but little chance of any of those South African wines holding a place amongst us.

Before we proceed to the more important wines of France and Germany, we must say a few words on

The Catawba wine of the United States.—About the year 1826, "the Catawba," a native American grape, was first brought into notice by Major Adlum, who had found it growing in a garden at Georgetown, near Washington. This vine, which is derived from the wild fox grape, has gradually supplanted all others, and is now adopted, almost universally, throughout the United States for making wine. It imparts a very peculiar musty flavour to the wine, displeasing when first tasted to many palates; but this dislike is easily removed by habit, and the wine is much relished in Ohio and Missouri, where it sells readily at good prices.

About 3000 acres are cultivated as vineyards in the state of Ohio; 500 in Kentucky; 1000 in Indiana; 500 in Missouri; 500 in Illinois; 100 in Georgia; 300 in North Carolina, and 200 in South Carolina. It is calculated that at least 2,000,000 gallons of wine are now raised in the United States, the value of which may be taken at a dollar and half the gallon.

In the United States the wine-press is constructed much on the same principle as the ordinary screw cider-press. It has an iron screw 3 or 4 inches in diameter, in a strong, upright frame. A box platform, 6 or 7 feet square, of 3-inch plank, is wedged into heavy timbers, and in this a box to contain the mashed grapes is placed, the box being perforated with holes. Bands to fit loosely inside the box, and pieces of scantling to receive the pressure, complete the implement. The power is applied by a strong lever, and the juice runs out through a hole in the floor, and is led into the cellar beneath by means of india-rubber pipes. Before being subjected to pressure, the grapes are bruisedin a small wooden mill. When it is intended to make red wine, the grapes mashed by this process are allowed to stand for two or three days, and are then pressed, in order that the colouring matter in the skins may be absorbed by the grape juice or "must." An analysis of good Catawba wine by Dr. Chapman gave:—

Alcohol	11·5
Water	88·5
	100·0

Large quantities of sparkling wine are made at Cincinnati, and at St. Louis, in imitation of Champagne, and sold as sparkling Catawba.

Germany.—Bavaria, Wurtemburg, and Baden each produce wine in the utmost abundance. Prussia and Nassau supply us with *Rhenish* and *sparkling Moselle*. Hungary has been ever famed for *Tokay* and *Vins de liqueur*; Germany imports for her own use a larger quantity of wine of all sorts than she exports to all the rest of the world.—*Tennent.*

Austria.—The total average vintage in Austria is estimated at 158,986,000 florins =£3,974,650, while the value of the wine production amounts only to 40,000,000 florins, or about £1,000.000 sterling.

The exportations of wine from Austria were as follows for the years named:—

1850	109,713 eimers.	1854	107,803 eimers.
1851	78,840 „	1855	134,921 „
1852	81,793 „	1856	142,991 „
1853	94,329 „	1857	210,214 „

The Vienna eimer is equal to 56·6052 litre, or 1·760 pints English measure.

The Austrian wines are on the average but of middling quality, but there are some which can bear comparison with all but the very best Rhine, French, and Spanish wines. Of Hungarian wine a considerable quantity is sold in England as port wine. The principal wines of Austria are—

"*Red wines*," grown at Erlan, Carlowitz, Szeksard, Buda, Adelsberg, Villau, and St. André;

"*Schiller wines*," a pale, reddish-coloured wine, grown at Erlan and Carlowitz;

"*White wines*," grown at Pesth, Steinbruch-Berg, Totfaln, Moor, Teting, Vöslan, and Rust;

"*Wines of the first press*," grown at Rust and Oedenburg.

France. — The chief wine-growing districts of France are Provence, Languedoc, Roussillon, Auvergne, Bourgogne, Saintonge, and Champagne, the rich valleys of the Gard, Hérault, Garonne, Dordogne, the Loire and the Rhone, and the neighbouring departments as far as the Pyrénées, the Hautes Pyrénées, and the Pyrénées Orientales.

The average production of wine per annum is between 40,000,000 and 42,000,000 hectolitres (of 22·0096 gallons English).

Vinage means in French a certain quantity of brandy added to wine in its natural state: this being necessary to enable wines to resist the effect of removal for exportation, the law allows the addition of 5 litres of brandy to each hectolitre of wine, provided the alcoholic strength of the latter after the mixture does not exceed 21 per cent.; whatever there is above this limit is liable to the scale of taxation applicable to spirits. From experiments made with a view to prevent fraud, it has been ascertained that wines usually furnished to private consumers do not average more than 10 or 11 per cent. of alcohol; that those in the hands of the retail dealer average 16 or 17, while those delivered to wholesale firms contain from 22 to 24 per cent. In order to put a stop to this system, which defrauds both the Government and the consumer, the commissioners proposed to limit the alcoholic force of wines to 18 degrees only, and to authorise the operation of "vinage" only in the Departments of the Pyrénées Orientales, Aude, Hérault, Gard Bouches du Rhone, and Var.

As our Treaty of Commerce with France promises to open out a large trade in French wines, we think the remarks of Sir Emerson Tennent, although made five years since, bear strongly on the probable results of the present:—

"From Bordeaux, it is well known that little or no increase is to be looked for of claret, or of the more generous wines of the Gironde. The strong wines of Burgundy have long since ceased to be brought to England, among other causes from their inability to bear the sea voyage; and even in France their use has been gradually declining from a similar reason. They are easily injured by removal; and a damp cellar, or even the agitation occasioned by the rolling of a carriage along the streets, is sometimes sufficient to turn them sour. The produce of Champagne does not enter into calculation; and on the whole, the portion of France which is most relied on to meet the newly-created demand, is the district of Roussillon, including the departments of the Pyrénées Orientales and Hérault; whence of late years the Masdew, or spurious port, and Picardan, for adulterating sherry, have been imported into England. The vine on this northern side of the Pyrenees seems to participate in the character of the vintages of Portugal and Spain on their southern aspect; and the similarity has suggested the attempt to obtain a place for them in the English market; but failing to establish them in public favour, they have been gradually withdrawn from consumption under their own name, but continue to be introduced for the purpose of *blending* with other wines more familiar and popular.

"Very ample details of those endeavours to bring Masdew into use in this country were given by some wine merchants of experience who were examined as witnesses by the Committee of the House of Commons in 1852. The attempt was first made as a substitute for port-wine, at a moment when the exports were interrupted during the siege of Oporto in 1832; it was taken a little at first, but it obtained no permanent footing, and soon ceased to sell for domestic use.

"Those who have travelled in the south of France, pleased with the abundance of its ordinary wines, and the lowness of their cost, and amused by the novelty of drinking them on the place of growth, frequently return with an impression in their favour, and a supply for future use. But whether it be that they overlook the difference between tasting these low wines at home and under the charming climate in which they ripen, or whether the change which they perceive in their flavour is the result of a sea voyage, the taste proves but transient; their guests do not approve of the new wine; the fancy is soon satisfied; the adventure is not repeated; and the traveller relapses into his accustomed round of stronger wines.

"The evidence taken by the Committee of 1852 abounds in examples of the difficulty before adverted to of introducing a new wine, especially of a light and thin description, into use in the United Kingdom; and the most striking illustrations have been drawn from the wines of France. It was attested by some merchants of large experience that *every attempt made within the last half century to introduce a new wine of this character into use in these countries, has been an almost total failure;* although the experiment has been made with sound and pure wines at a cost greatly below the prevailing prices of port and sherry.

"One gentleman, Mr. Gassiot, stated that in 1825, on the reduction which then took place in the duty, he, firmly relying on the effect of that measure in leading to a consumption of light wines, imported low-priced wines from France, Figueiras and Colares from Portugal, Spanish red wine from Barcelona, and others from Italy and Sicily: but the entire speculation ended in failure and loss.

"Mr. Maxwell, another extensive importer, stated that in 1841 his house had made a large importation of light French wines on speculation; they were sent to Calais, 'after being a long while in the docks, thinking that as the English would not drink them, the French would; but it was a total loss; and the importers did not even get the price of the casks.'

"Mr. Carbonell tried to bring Masdew into use, but failed; and numerous other examples are recorded in the evidence, each singularly unsuccessful, the taste of this country hitherto being decidedly averse from all but wines of high flavours, full body, and strong spirituous character."

Sir E. Tennent concludes his remarks thus: —

"Bearing in mind the very limited area within which the existence of a suitable climate and soil permits the cultivation of those finer wines to be carried on, looking to the comparatively small supply which is capable of being produced, and the increasing demand, not only from the growing population of the old world, but amongst the 23,000,000 of North American citizens, and the new communities which the discovery of gold is distributing over the coasts of the Pacific, and the Continent and Islands of Australia, it is scarcely to be hoped that the reduction of duty in England will lead to a very large increased supply of wines *at present* shipped to us from France."

The following account of the principal French wines is condensed from Viscount Chelsea's Report on the *Effects of the Vine Disease.* He divides France into six principal districts.

1st. The southern, including Corsica, Roussillon, Languedoc, and Provence.

(*a.*) *Corsican.* Corsica produces both dry and sweet wines, but in quantities too small for exportation.

(*b.*) *Roussillon.* These wines are produced exclusively in the Department of the Pyrénées Orientales, which contains about 125,000 acres of vineyards. Sweet, dry, and ordinary wines are equally abundant. Strong, rich in colour, and being generous, they keep long, travel well, and are good for mixing with others. There are three recognised varieties, 1st, those of Banyuls, of Collioure, and of Port Vendres, red wines which generally improve with age; 2nd, those of Rivesaltes; the greater portion being ordinary wines of commerce, deep and brilliant in colour; 200 acres alone produce fine wines, as *Muscat, Manabes, Grenache, Malvoisie,* and *Rancio*; 3rd, Perpignay—the wines of this district will keep an indefinite time, and are sent to North and South America.

(*c.*) *Languedoc.* Under this name are included all the wines of the Hérault, Aude, and a part of Gard. The most important of these districts is that of Hérault, producing two kinds of wine—those for conversion into spirit and ordinary wines, which may be subdivided into red and white ordinary wines, fine red wine, white wines, dry and sweet, and Muscats.

Aude. This district produces a red wine at Limoux, and a white wine known by the name of Blanquette, which is nearly double the value of the preceding. Hérault is the most important wine country in the south of France; it is the largest producer of raw spirits in Europe. The red wines of Hérault are produced in the vineyards of St. George's d'Orques; these are generally heady.

The white wines of Picardan include both dry and sweet.

Muscat, Frontignan, and *Lunel.* The cultivation of these wines has considerably diminished of late years; they have less flavour and do not keep so well as those of Rive-saltes.

The vineyards of St. Gilles (Gard) produce a less delicate wine than those of Roussillon, but which serves to bring up the colour of other wines.

(*d.*) *Provence.* The wines of Provence have not the importance of those of Roussillon or of Languedoc. The chief growths of the region are—

1st. In the Var, that of *Gande* producing a fine wine, at first highly coloured and heady, but becoming dry with age.

2nd. That of Malgue, producing a wine which does not mature, but that bears the sea well.

3rd. That of Bandol, an excellent wine for export, improving much with age: it is sent to India, Brazil, and California.

In the Basses Alpes, the vineyards of Mécs yield a generous wine. In the Bouches du Rhône, Cassis produces the finest wines in the region, both red and white, much sought after by foreigners. The sour and flat wines of Roquevaire are little appreciated. The methods of cultivation are nearly the same in all the districts of the south of France. The soil is generally dug up before the vines are planted; in Roussillon only is this omitted, when the ground has been previously cultivated. In the latter, the operation of planting is carried on in January and February; in Languedoc it is put off until April.

With those varieties of the vine which produce the Muscat, it is the custom to rub off part of the buds. The vines are dressed four times during the first year, but afterwards only twice. They commence bearing in from three to four years. The grapes are pressed by the feet or between channelled rollers without being picked off the bunches. The wine is slightly sprinkled with lime or plaster of Paris when it is intended for commerce. It is allowed to ferment for ten, twenty, or even thirty days.

2nd. The south-eastern region, including Gard, Vancluse, Ardeche, Drôme, and Rhone. This region embraces all the lower part of the basin of the Rhone; the wines produced are generally known as wines of the Côte du Rhône.

(*a.*) That part of *Gard* which is included in this region produces, 1st, the red wine of *Tavel*—very dry and improving much by age—and the red wine of Lirac. 2nd. The sweet wines of *Chuselan*, wines of the finest quality, and those of *Orsan* and *St. Geniez*, of the second. The Gard also produces the ordinary wines of *St. Laurent-des-Arbres* and *Roquemaure.*

(*b.*) *Vaucluse.* The chief growths are the *Châteauneuf-du-Pape*, a very celebrated wine, and the growth of *La Nerthe*, which is decreasing both in quality and quantity; it is sent to Bordeaux and Burgundy, for the purpose of colouring other wines. In Vaucluse also are the vineyards of the *Château-Vieux*, of *Nettes*, and of *Etrel.*

(*c.*) *Ardeche* includes the famous vineyards of *St. Peray.* This white wine, when in a state of effervescence, almost equals Champagne, which, however, has more lightness, delicacy, and softness. It is sent to England, Germany, Belgium, and Holland. The best sparkling sort sells at 2 francs 50 centimes the bottle. There are also the vineyards of St. Jean, Comas, and St. Joseph. The sparkling wine of St. Peray is produced in the same way as Champagne.

(*d.*) *Drôme*. The *Hermitage*, the most famous vineyard in the Côte du Rhône, consists of only 140 hectares. It produces red wine, white wine, and "vins de paille" (straw-coloured); the other vineyards are *Larnage*, *Rochegude*, *Crozes*, and *Mercurol*, all of which wines are esteemed.

(*e.*) *Rhone*. The southern part of the Rhone produces wines very similar to the preceding. The best known are those of *Condrieux* and *St. Michel*.

The vineyards of the Hermitage are managed with great care; the soil is dry to the depth of a metre (39 inches); the leaves are picked off the vine, and it is dressed and tended five times a year during the first two years; the grapes are stripped off the stalks, and the fermentation lasts from fifteen to twenty days.

3rd. The eastern region is formed principally of the valley of the Saône.

(*a.*) *Beaujolais*, the *Mâconnais*, and the *Côte Chalonnaise*. These wines are delicate, light, well-flavoured, but not highly coloured; they are principally consumed in the interior of France. The principal growths are of *Chênas* and that of *Fleury*. The *Mâconnais* produces the highly esteemed white wine of *Ponilly*, a dry wine which keeps badly, and the red wine of *Romanèche*. The wines of *Côte Chalonnaise* are common wines, amongst which the *Mercurey* alone is remarkable.

(*b.*) *Haute Bourgogne*, consisting of the Côte d'Or, produces the most famous wines in Burgundy. The white wines of the Côte d'Or most known are those of *Montrachet*, very superior wines; of *Memsault*, very delicate, light, and with a delicious "bouquet;" and those of Blaquy. It is the red wines, however, which give preeminence to this district. Here grows the renowned *Volnay*, *Pomard*, *Beaune*, *Nuits*, more spirituous than the others, and which require to be kept five or six years in the wood; *Vosne*, *Romanée*, *Clos Vougert*, and *Chambertin*.

(*c.*) *Basse Bourgogne*. The wines of Lower Burgundy are brisk, delicate, and light, but too spirituous. The *Tonnerre* is fit for drinking after the third year, and the wines of *Auxerrois*, which are sooner matured. In Auxerrois also are the vineyards of *Chablis;* these white wines, so much esteemed for their lightness, are made in the early part of October, under the name of *Chablis*. A large quantity of other white wine from the neighbouring vineyards finds its way into the market. The wines of *Avallonais* and those of Joigny are sent into Flanders and Belgium.

(*d.*) *Jura*. The wines of this district are in general dry, heady, brisk, but with some acidity, which arises from their bad cultivation and the unskilful mixture of the vines, and reduces their reputation. In addition to the inferior wines the Jura produces also rose-coloured wines ("*Vins Rosés*"); these are sparkling wines, and the luscious wine known under the name of "*Vin de Garde du Château Chalons*." This vineyard only comprises 96 hectares. The wines produced there require to be kept from twelve to fifteen years in the cask. All these wines are consumed where they are grown, or sent to Switzerland.

(*e.*) *Alsace* produces only common wine, with the exception of the *Turchemi* and *Ribeauviller*.

(*f.*) *Lorraine*. The principal growths are those of *Thiancourt*, *Pagny*, and *Sey*.

(*g.*) *Champagne*. The wines of the Department of the Marne, known under the name of *Champagne*, have a universal reputation, and form one of the principal products of France.

Champagne Wines are divided into four categories —

Sparkling Granot.	*Half Sparkling.*
Ordinary Sparkling.	*Tisane de Champagne.*

The following are the principal growths: —

On the Marne.	By the Avise.	On the Mountains of Rheims.
Mareuil.	*Avise.*	*Bowzy.*
Ay.	*Cramant.*	*Ambonnay.*
Hautvillers.	*Oger.*	*Mailly.*
Epernay.	*Mesnil.*	*Sillery.*
		Romont.

The most esteemed kinds are the *Sillery*, *Ay*, *Cramant*, and *Bowzy*. In good seasons this district does not produce less than 15,000,000 bottles of white wine. The average produce is 7,000,000, of which 6,000,000 are sent to England, Russia, and Germany.

The methods employed in Lower Burgundy and Champagne are nearly the same. It is not as respects the cultivation of the plant, but in the methods adopted in making the wine, that the latter is remarkable.

In the manufacture of Champagne black grapes of the first quality are usually employed, especially those gathered upon the vine called by the French *noirien*, cultivated on the best exposures. As it is important, however, to prevent the colouring matter of the skin from entering into the wine, the juice is squeezed as gently and rapidly as possible. The liquor obtained by a second and third pressing is reserved for inferior wines, on account of the reddish tint which it acquires. The marc is then mixed with the grapes of the red-wine vats.

The above nearly colourless must is immediately poured into tuns or casks, till about three-fourths of their capacity are filled, when fermentation soon begins. This is allowed to continue for about 15 days, and then three-fourths of the casks are filled up with wine from the rest. The casks are now closed by a bung secured with a piece of hoop iron nailed to two contiguous staves. The casks should be made of new wood, but not of oak; though old white wine casks are occasionally used.

In the month of January the clear wine is racked off, and is fined by a small quantity of isinglass dissolved in old wine of the same kind. Forty days afterwards a second fining is required. Sometimes a third may be useful, if the lees be considerable. In the month of May the clear wine is drawn off into bottles. Viscount Chelsea says, "The wine is bottled between April and August. Warm weather is necessary to produce the sparkling wine. The effervescence is the result of carbonic acid gas produced by fermentation, which being interrupted in the cask, reproduces and developes itself in the bottles. For this a temperature of from 70° to 75° Fahr. are required. The bottles, as soon as they are filled, which process is effected by women, are handed over to men called 'boucheurs,' who add a certain quantity of a mixture of brandy and sugar candy (in the proportion of 15 to 16 per cent. for those wines intended for the English market), taking care to leave about 2½ to 3 inches space between the cork and the wine; they then introduce by a machine a moistened cork, and pass the bottle on to other men called 'maillochers,' whose business it is to drive the cork home with a mallet, who again transfer them to those who fasten them with a string or wire; sometimes this is done by a machine. It takes an hour to bottle a tun of 88 gallons. The bottles are ranged against the cellar walls in horizontal layers, each being reversed as it regards the previous layer. Eight or ten days afterwards a deposit called '*griffe*' is found at the bottom of the bottle. This indicates the time for removing the bottles to the second or permanent cellar; this is the period also when breakage commences. This loss can neither be foreseen nor prevented, and is often dangerous; it happens mostly at the season when the vine blossoms. The bottles are first placed in the coldest cellars and afterwards removed to warmer temperatures. In the second winter means are taken to remove the deposit formed in the summer; the bottles are placed with their mouths downwards, and are shaken for twenty days, to cause the sediment to fall into the neck. At the end of this time the bottle is uncorked, the sediment thrown out, and a fifth part of the contents replaced by the sweetened liquor, when the bottles are again corked, tied, and stacked as before." The bottles being filled, and their corks secured by packthread and wire, they are laid on their sides, in this month, with their mouths sloping downwards at an angle of about 20 degrees, in order that any sediment may fall into the neck. At the end of 8 or 10 days the inclination of the bottles is increased, when they are slightly tapped, and placed in a vertical position; so that after the lees are all collected in the neck, the cork is partially removed for an instant, to allow the sediment to be expelled by the pressure of the gas. If the wine be still muddy in the bottles, along with a new dose of *liquor*, a small quantity of fining should be added to each, and the bottles should be placed again in the inverted position. At the end of two or three months the sediment collected over the cork is dexterously discharged; and if the wine be still deficient in transparency, the same process of fining must be repeated.

Sparkling wine (*vin mousseux*), prepared as above described, is fit for drinking usually at the end of from 18 to 30 months, according to the state of the seasons. It is in Champagne that the lightest, most transparent, and most highly flavoured wines have been hitherto made. The breakage of the bottles in these sparkling wines amounts frequently to 30 per cent., a circumstance which adds greatly to their cost of production.

(4.) *Central Region.* In the five departments comprised in this district the common wines alone are produced; the white wine of *Pouilly* being the only celebrated one.

(5.) *Western Region.* The two departments lying on the banks of the Loire, Indre and Loire, and Maine and Loire, possess 40,000 hectares of vineyards; the principal growths are those of *Joué*, *Bourgueil*, *Vouvray*, and the white wine of *Saumur*. More than 2,000,000 hectolitres of wine are annually devoted in Aunis, Saintonge, and Angoumis, to the distillation of brandy, so well known as *Cognac*. Of the 200,000 hectares of vineyards in the Charente and Charente Inferior, only one third is cultivated for home consumption or exportation, the remaining two-thirds is employed in making brandy. This is divided into two classes, that which is produced in the plain of Champagne in the arrondissement of Cognac, which is again divided according to quality into *Champagne* fine and common *Champagne de Bois*, and *Eau de Vie de Bois*, and that of Annis, produced from the vines on the banks of the river.

(6.) *South-Western District.* The Gironde and Jurançon are the only localities of any special interest. Although the wines of the Gironde have a common origin, they are divided in commerce into five great classes, *Medoc, De Graves, Des Côtes, Palus*, and "*D'Entre Deux-mer.*"

Medoc is the name given to a tongue of land to the north-west of Bordeaux, and lying between Gironde and the ocean. Of all kinds of *Medoc* wines, about 40,000 tuns are made annually: 4500 tuns of superior quality, 4500 tuns of fine wines, 31,000 of common wines. They are distinguished as choice ("grand vins," or "vins classés"), "*Bourgeois,*" and "*Paysan.*"

The "grand vins" are subdivided into five classes, according to their different degrees of delicacy and quality.

The 1st of these comprises only the three famous growths of *Château Margaux, Château Lafitte*, and *Château Latour.*

Medoc wines are sent to all parts of Europe, but chiefly to England and Russia; the first growths are reserved for England, but are mixed before exportation with Hermitage.

The 2nd, "*Vins de Graves,*" produced on the plains around Bordeaux. These wines are more powerful, more highly coloured, and more spirituous than the growths of Medoc; they have a different flavour, and less "bouquet." The white wines of the district have a universal reputation. The principal growth of red wine is *Château-haut-Brion*, which comes immediately after Château Margaux, Lafitte, &c., for richness; *Barjac, Beaumes*, and *Sauterne* are fine transparent white wines much in demand abroad. *Sauterne* produces from 500 to 800 tuns; *Château Yguem* is its best growth.

The 3rd, "*Vins de Côtes,*" is the name given to the wines grown on the left bank of the Garonne.

The most celebrated wine is *St. Emilion.*

The 4th, "*Vins de Palus,*" grown in the moist sands of the Gironde, are very highly coloured and spirituous, but wanting in body and briskness.

The other wines, *Bergerac*, "*Vin de tables,*" the wines of Jurançon, and the red wines of *Gaillac* and "Cahors," require only to be enumerated.

The red wines of Gaillac are high coloured, strong, and spirituous, and are much in demand for mixing with other wines; the red wines of Cahors are used principally for the same purpose.

Such is a somewhat concise statement of the varieties of wines known in commerce. It is not possible to enter into all the details of the manufacture, varying as it does in every locality,—the numerous peculiarities being due in some cases to the conditions of the grape itself, and in others to the methods pursued with regard to the fermentation and the subsequent treatment of the wine.

There are many persons who confound the "flavour" of wine with the "bouquet." The differences are well determined by the writer on wine in the *Penny Cyclopedia.* "The flavour of wine, called by the French *sève*, indicates the vinous power and the aromatic savour which are felt in the act of swallowing the wine, embalming the mouth, and continuing to be felt after the passage of the liquor. It seems to consist of the impression made by the alcohol and the aromatic particles which are liberated and volatilised as soon as the wine receives the warmth of the mouth and stomach. The sève differs from the *bouquet*, inasmuch as the latter declares itself the moment the wine is exposed to the air; it is no criterion of the vinous force or quantity of alcohol present (being in fact greatest in weak wines), and influences the organ of smell rather than of taste."

The *bouquet* of wine is a new product, and in no way dependent on the perfume of the grape from which the wine is made. Red wines scarcely ever retain a trace of the odour of the grapes; the white muscadine wines do in some degree, especially *Frontignan.*

Liebig, in his *Organic Chemistry*, has the following remarks on the *bouquet.* "It is well known that wine and fermented liquors generally contain, in addition to alcohol, other substances which could not be detected before their fermentation, and which must therefore have been formed during that process. The smell and taste which distinguish wine from all other fermented liquids are known to depend upon an ether of a volatile and highly combustible acid, which is of an oily nature, and to which the name of *Œnanthic Æther* has been given." (See *Chemistry of Wine*, by G. J. Mulder, edited by H. Bence Jones, M.D. F.R.S.; and *Ure's Dictionary of Chemistry.*)

On the Rhine an artificial *bouquet* is often given to wine for fraudulent purposes, by hanging orris-root in the casks, or by the use of aromatic herbs.

The volatile substance existing in wine which imparts to it, conjointly with œnanthic ether, its vinous aroma, is partly alcohol. There are other odoriferous substances developed in the course of time; these are compounds of oxide of ethyl, amyl, or propylene, with acetic, propionic, pelargonic, butyric, caproic, caprylic or capric acids.

Acetic ether is present in all aromatic wines, and fraudulent dealers will add acetic ether in small quantities to their artificial compounds.

Butyric ether is much used by confectioners, who call it pine-apple oil. *Caprylic ether* has a similar flavour; these are slowly developed in some wines by time. In Ure's *Dictionary of Chemistry* the other chemical compounds will be fully described. For a very clear account of the processes by which these odoriferous substances are formed in wine, *The Chemistry of Wine*, by G. J. Mulder, edited by Bence Jones, should be consulted.

Wine produced from grape juice alone is perfectly colourless or white; but as the whole mass of the grapes is pressed together, it is impossible but that some admixture of the components of the grape skins should occur. White wine may be prepared from purple grapes, but if the skins are allowed to ferment, red or yellow wine will be obtained. The Italian wine, *Vino Cebedino*, is about the most colourless of wines.

The colour in wines appears to be due to the presence of extractive matter, which, when oxidised, assumes a red or brown colour. This colouring matter has been called *apothema* by Berzelius, but it is, in fact, humic acid, retaining traces of the substance from which it has been derived. Müller supposes the humic acid of the grape to be apocrenic acid. If wine be evaporated before fermentation, apothema will form in it very quickly, and the colour of the wine become actually brown. Boiled wines—so called on account of the evaporation they undergo—such as Malaga, Tinto, &c., are thus rendered brown.

Whilst the juice of grapes ferments, the skins being present, the wine which is in process of formation extracts tannic acid from the skins, and this gives the yellow colour —when by oxidation it is converted into apothema—to Muscadel, Champagne, Teneriffe, and Madeira.

What we call red wines are prepared from either black, purple, or red grapes, the juice of which is colourless, and the skins of which are allowed to ferment. During fermentation the weak spirit which is formed extracts not only tannic acid but blue colouring matter from the skins. This blue colouring matter is tinged more or less red by the tartaric acid of the wine, and may afterwards be rendered more decidedly red by the formation of acetic acid. In the change of colour undergone by red wine, five periods, according to Mulder, must be distinguished. As soon as alcoholic liquid is formed during fermentation, blue colouring matter begins to be extracted from the skins. As the small amount of blue colouring matter is brought into contact with grape juice, which has an acid reaction, it becomes red. The fermentation and formation of alcohol proceed, as does also the solution of blue colouring matter, and the young wine is rather blue than red, and may be called dark violet. This new wine now undergoes fermentation, during which a great deal of colouring matter and red tartar, as well as apothema of tannin and albumen, is precipitated. The loss of the colouring matter causes the wine to become lighter. In the meantime the formation of acetic acid begins, and at a later period increases; the amount of colouring matter is not thereby diminished, but the larger proportion of acid in the liquid reddens its colour. Another period now begins, during which the tannic acid is slowly converted into apothema, whereby red colouring matter is again precipitated out of the liquid, for example, in Port wine; it thus gradually diminishes, and finally, after a length of time, disappears entirely from the wine, which then remains what is called yellow. This will explain the alterations produced by keeping wines.

According to the character of the wine, as already stated, is its power of enduring unchanged, or of improving by age.

Weak wines of bad growths ought to be consumed within 12 or 15 months after being manufactured; and should be kept meanwhile in cool cellars. White wines of middling strength ought to be kept in casks constantly full, and carefully excluded from contact of air, and the racking off should be done as quickly as possible. As the most of them are injured by too much fermentation, this process should be so regulated as always to leave a little sugar undecomposed. It is useful to counteract the absorption of oxygen, and the consequent tendency to acidity, by burning a sulphur match in the casks into which they are about to be run. This is done by hooking the match to a bent wire, kindling and suspending it within the cask through the bung-hole. Immediately on withdrawing the match, the cask should be corked, if the wine be not ready for transfer. If the burning sulphur be extinguished on plunging it into the cask, it is a proof of the cask being unsound, and unfit for receiving the wine; in which case it should be well cleansed, first with lime-water, then with very dilute sulphuric acid, and lastly with boiling water.

Wine-cellars ought to be dry at bottom, floored with flags, have windows opening to the north, be so much sunk below the level of the adjoining ground as to possess a nearly uniform temperature in summer and winter; and be at such a distance from a frequented highway or street as not to suffer vibration from the motion of carriages.

Wines should be racked off in cool weather; the end of February being the fittest time for light wines. Strong wines are not racked off till they have stood a year or eighteen months upon the lees, to promote their slow or insensible fermentation. A siphon well managed serves better than a faucet to draw off wine clear from the sediment. White wines, before being bottled, should be fined with isinglass; red wines are usually fined with whites of eggs beat up into a froth, and mixed with two or three times their bulk of water. But some strong wines, which are a little harsh from excess of tannin, are fined with a little sheep or bullock's blood. Occasionally a small quantity of sweet glue is used for this purpose.

The following maladies of wines are certain accidental deteriorations, to which remedies should be speedily applied:—

La-pousse (pushing out of the cask), is the name given to a violent fermentative movement, which occasionally supervenes after the wine has been run off into the casks. If these have been tightly closed, the interior pressure may increase to such a degree as to burst the hoops, or cause the seams of the staves or ends to open. The elastic bungs already described will prevent the bursting of the casks; but something must be done to repress the fermentation, lest it should destroy the whole of the sugar, and make the wine unpalatably harsh. One remedy is, to transfer the wine into a cask previously fumigated with burning sulphur; another is, to add to it about 1000th part of sulphite of lime; and a third, and perhaps the safest, is to introduce $\frac{1}{2}$ a lb. of mustard-seed into each barrel. At anyrate the wines should be fined whenever the movements are allayed, to remove the floating ferment which has been the cause of the mischief.

Turning sour.—The production of too much acid in a wine is a proof of its containing originally too little alcohol, of its being exposed too largely to the air, or to vibrations, or to too high a temperature in the cellar. The best thing to be done in this case is, to mix it with its bulk of a stronger wine in a less advanced state, to fine the mixture, to bottle it, and to consume it as soon as possible, for it will never prove a good keeping wine. This *distemper* in wines formerly gave rise to the very dangerous practice of adding litharge as a sweetener; whereby a quantity of acetate or sugar of lead was formed in the liquor, productive of the most deleterious consequences to those who drank of it. In France, the regulations of police, and the enlightened *surveillance* of the Council of Salubrity, have completely put down this gross abuse. The saturation of the acid by lime and other alkaline bases has generally a prejudicial effect, and injures more or less the vinous flavour and taste.

Ropiness or viscidity of wines.—The cause of this phenomenon, which renders wine unfit for drinking, was altogether unknown, till M. François, an apothecary of Nantes, demonstrated that it was owing to an azotised matter, analogous to *gliadine* (gluten); and in fact it is the white wines, especially those which contain the least tannin, which are subject to this malady. He also pointed out the proper remedy, in the addition of tannin under a rather agreeable form, namely, the bruised berries of the mountain-ash (*sorbier*) in a somewhat unripe state; of which 1 lb., well stirred in, is sufficient for a barrel. After agitation, the wine is to be left in repose for a day or two and then racked off. The tannin by this time will have separated the azotised matter from the liquor, and removed the ropiness. The wine is to be fined and bottled off.

The taste of the cask, which sometimes happens to wine put into casks which had remained long empty, is best remedied by agitating the wine for some time with a spoonful of olive oil. An essential oil, the chief cause of the bad taste, combines with the fixed oil, and rises with it to the surface.

The quantity of alcohol contained in different wines has been made the subject of elaborate experiments by Brande and Fontenelle, and several others; but as it must evidently vary with different seasons, the results can be received merely as approximate. The only apparatus required for this research is a small still and refrigeratory, so well fitted up as to permit none of the spirituous vapours to be dissipated. The distilled liquor should be received in a glass tube, graduated into 100 measures, of such capacity as to contain the whole of the alcohol which the given measure of wine employed is capable of yielding. In the successive experiments, the quantity of wine used, and of spirit distilled over, being the same in volume, the relative densities of the latter will show at once the relative strengths of the wines. A very neat small apparatus has been contrived for the purpose of analysing wines in this manner, by M. Gay-Lussac. It is constructed, and sold at a moderate price, by M. Collardeau, No. 56, Rue Faubourg St. Martin, Paris. The proportion given by Brande (Table I.), has been reduced to the standard of absolute alcohol by Fesser; and that by Fontenelle (Table II.), to the same standard by Schubarth, as in the following tables. Table III. on page 1037 gives the alcoholic strength of the Rhine wines.

From the known prices of these wines, it is obvious that the proportion of alcohol, although one factor in determining the value of a wine, is not the only absolute one, nor does it stand in any fixed relation to the commercial value of the wine. It is remarkable that the finest sorts of wine contain a much greater proportion of solid substances in solution than the inferior sorts; and that the weight of the residue, which the Rhenish wines yield on evaporation, offers a safer criterion for determining their commercial value than the proportion of alcohol. These solids disguise the acid, take off the acrid taste, and at the same time impart body, mellowness, and oiliness. Among the extractive matters of new wines are sugar, which gradually disappears by keeping; and also some imperfectly known gummy substances, which become brownish when the wine is submitted to evaporation. The presence of these in wine appears chiefly to be determined by the soil, and the condition and locality of the vineyard; and it is obvious that the qualities dependent upon these extractive matters cannot be replaced by sugar.

It is of importance that the free acid be not removed before the fermentation, because on its presence during this proeess, as well as during the storing, depend the taste aud principal qualities.

Port is one of the wines which is richest in alcohol. Ginjal has stated that genuine port wines never contain more than 12·75 per cent. of pure alcohol, and is of opinion that those who discover more in such wines, either analysed a wine which had been adulterated with alcohol, or were unable to determine accurately the strength of the alcohol. It is difficult to pronouuce on this opinion out of Portugal. How is it that all who have analysed port wine have found from 17 to 21 per cent. of alcohol? Is there no wine but such as is adultcrated with alcohol exported from Portugal? and does port wine, which is recognised as the strongest wine in the eountry which produces it, really belong to those not very strong wines which only eontain 13 per cent. alcohol?

With regard to alcoholic contents, Madeira ranks next to port wine, in which respect they differ but little from each other. Liquor wines are as a rule stronger than red wines. Jurançon, Lachrymæ Christi, Benicario, and Santerne, all contain from 12 to 15 per cent. alcohol and more. Red French wines eontain less—from 9 to 14 per cent. Good Bordeaux contains 10, 11, 12 per cent. Burgundy 9, 10, 11 per cent. Champagne 10, 11 per eent. Rhine wine from 6 to 12 per cent., generally from 9 to 10 per cent.—*Mulder.*

Under the title of the deacidification of wines, Professor Liebig published in his *Annalen* a proeess for effecting that valuable object on old stored (*alte abgelagerte*) Rhine wines. "Most of these wines," he says, "even of the most propitious growths, and in the best condition, contain a eertain quantity of free tartaric acid, on whose presence many of their essential properties depend. The juice of all sorts of grapes contains bitartrate of potash, and that of those of the young shoots, in good years, is saturated with it. When the must of these sorts of grapes becomes fermented, the tartar diminishes in solubility proportionally as the alcohol increases, and a part of it falls along with the yeast. This deposit of tartar increases during the first years of the vatting; the sides of the casks becoming encrusted more and more with its crystals, in consequence of the continual addition of the new wine to replace what of the liquid is lost by evaporation, so as to keep the casks full, and prevent the destruction of the whole. But this deposition has a limit. By the filling up, the wine receives a certain quantity of free tartaric aeid, and thereby acquires, at a certain point of concentration, the faculty of re-dissolving the deposited tartar. In the storing of many of the finer wines, the tartar again disappears at a certain period. By progressive filling up, the proportion of acid proportionally augments, the taste and flavour of the wine are exalted, but the acid contents make the wine less agreeable in use. Amateurs and manufacturers should therefore welcome a mean of taking away the free tartaric acid without altering in any respect the quality of the wine. This mean is pure neutral tartrate of potash. When this salt, in concentrated solution, is added to such a fluid as the above, there results the sparingly soluble tartar (one part of whieh requires from 180 to 200 parts of water of ordinary temperature for its solution), the free aeid combines with the neutral salt, and separates as bitartrate from the liquid. If we add to 100 parts of a wine which contains one part of free tartaric acid, one and a half parts of neutral tartrate of potash, there will separate by rest at 18°

— 10° C., 2 parts of crystalline tartar, and the wine contains now one half part of tartar dissolved, in which there are only 0·2 parts of the original free acid. In this case, 0·8 of the free acid has been withdrawn from the wine."

WINES, BRITISH, are made either from infusions of dried grapes (raisins) or from the juices of native fruits, properly fermented. These wines are called *sweets* in the language of the Excise, under whose superintendence they were placed till 1834, when the duties upon them were repealed, as onerous to the trade and unproductive to the revenue. The raisins called Lexias are said to produce a dry flavoured wine; the Denias a sweet wine; the black Smyrnas a strong-bodied wine, and the red Smyrnas and Valencias a rich and full wine. The early spring months are the fittest time for the wine manufacture. The masses of raisins, on being taken out of the packages, are either beaten with mallets or crushed between rollers in order to loosen them, and are then steeped in water in large vats, between a perforated board at bottom and another at top. The water being after some time drawn off the swollen and softened fruit, pressure is applied to the upper board to extract all the soluble sweet matter, which passes down through the false bottom, and flows off by an appropriate pipe into fermenting tuns. The residuary fruit is infused with additional water, and then squeezed; a process which is repeated till all the sweets are drained off, after which the "rape" is subjected to severe pressure in a screw or hydraulic press. The wine, in the process of the vinous fermentation, is occasionally passed through a great body of the rape to improve its flavour, and also to modify the fermentative action; it is afterwards set to ripen in casks, clarified by being repeatedly racked off, and fined with isinglass.

Our *importations* of wines have been as follows: —

By "an Act to amend the laws relating to the customs," it was determined that:— In lieu of the duties and drawbacks of customs now charged or allowed on the articles under mentioned, the following duties of customs shall, on and after the twenty-ninth day of February, 1860, be charged thereon, on importation into Great Britain and Ireland, until the thirty-first day of December, 1860, inclusive, that is to say,—

* Duty on all sorts 2*s.* 10*d.* 13-20ths per gallon from the 13th August, 1853.
† Duty 5*s.* 9*d.* 3-10ths per gallon from the 13th May, 1840.

Wine of or from Foreign Countries:

		£	s.	d.
Red - - - - - -	the gallon	0	3	0
White - - - - -	„	0	3	0
Lees of such wine - - -	„	0	3	0

With an allowance for drawback on exportation until the said thirty-first of December, 1860, inclusive, of three shillings per gallon on such wine exported or used as ship's stores, but no drawback shall be granted on lees of wine.

On and after the 1st day of January 1861, and without any allowance for drawback: Wine containing less than the following rates of proof spirit, verified by Sykes's Hydrometer; viz.

	18 Degrees.			26 Degrees.			40 Degrees.			If imported in bottles.		
	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.
Wine of or from foreign countries:—												
Red - - - the gallon	0	1	0	0	1	6	0	2	0	0	2	0
White - - „	0	1	0	0	1	6	0	2	0	0	2	0
Lees of such wine „	0	1	0	0	1	6	0	2	0	0	2	0
Wine the growth and produce of any British possession:—												
Red - - - the gallon	0	1	0	0	1	6	0	2	0	0	2	0
White - - „	0	1	0	0	1	6	0	2	0	0	2	0
Lees of such wine „	0	1	0	0	1	6	0	2	0	0	2	0

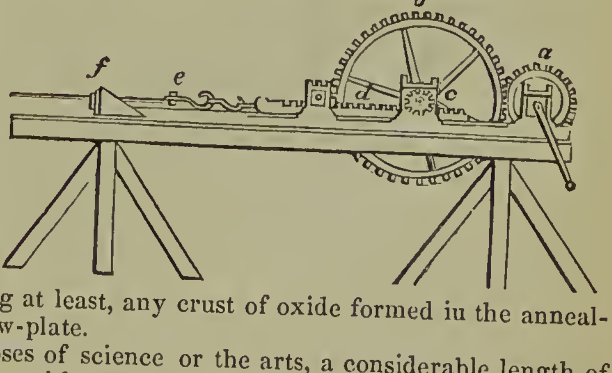
Provided always, that the commissioners of customs may by their order from time to time determine into what ports in Great Britain and Ireland wine may or may not be imported; and all wine imported into any port contrary thereto shall be forfeited or otherwise dealt with as the said commissioners may see fit to direct.

WINE-STONE is the deposit of crude tartar, called argal, which settles on the sides and bottoms of wine casks. See WINE.

WIRE-DRAWING. (*Tréfilerie*, Fr.; *Draht-ziehen*, *Drahtzug*, Germ.) When an oblong lump of metal is forced through a series of progressively diminishing apertures in a steel plate, so as to assume in its cross section the form and dimensions of the last hole, and to be augmented in length at the expense of its thickness, it is said to be wire-drawn. The piece of steel called the *draw-plate* is pierced with a regular gradation of holes, from the largest to the smallest; and the machine for overcoming the lateral adhesion of the metallic particles to one another is called the *draw-bench*. The pincers which lay hold of the extremity of the wire, to pull it through the successive holes, are adapted to bite it firmly, by having the inside of the jaws cut like a file. For drawing thick rods of gilt silver down into stout wire, the hydraulic press has been had recourse to with advantage.

Fig. 1938 represents a convenient form of the draw-bench, where the power is applied by a toothed wheel, pinion, and rack-work, moved by the hands of one or two men working at a winch; the motion being so regulated by a fly-wheel, that it does not proceed in fits and starts, and cause inequalities in the wire. The metal requires to be annealed, now and then, between successive drawings, otherwise it would become too hard and brittle for further extension. The reel upon which it is wound is sometimes mounted in a cistern of sour small beer, for the purpose of clearing off, or loosening at least, any crust of oxide formed in the annealing, before the wire enters the draw-plate.

1938



When, for very accurate purposes of science or the arts, a considerable length of uniform wire is to be drawn, a plate with one or more jewelled holes, that is, filled with one or more perforated rubies, sapphires, or chrysolites, can alone be trusted to, because the holes even in the best steel become rapidly wider by abrasion. Through a hole in a ruby 0·0033 of an inch in diameter, a silver wire 170 miles long has been drawn, which possessed at the end the very same section as at the beginning; a result determined by weighing portions of equal length, as also by measuring it with a micrometer. The hole in an ordinary draw-plate of soft steel becomes so wide, by drawing 14,000 fathoms of brass wire, that it requires to be narrowed before the original sized wire can be again obtained.

Wire, by being diminished one-half, one-third, one-fourth, &c., in diameter, is augmented in length respectively four, nine, sixteen times, &c. The speed with which it may be prudently drawn out depends upon the ductility and tenacity of the metal; but may be always increased the more the wire becomes attenuated, because its particles progressively assume more and more of the filamentous form, and accommodate themselves more readily to the extending force. Iron and brass wires, of 0·3 inch in diameter, bear drawing at the rate of from 12 to 15 inches per second; but when of 0·025 ($\frac{1}{40}$) of an inch, at the rate of from 40 to 45 inches in the same time. Finer silver and copper wire may be extended from 60 to 70 inches per second.

By enclosing a wire of platinum within one of silver ten times thicker, and drawing down the compound wire till it be $\frac{1}{300}$ of an inch, a wire of platinum of $\frac{1}{3000}$ of an inch will exist in its centre, which may be obtained apart, by dissolving the silver away in nitric acid. This pretty experiment was first made by Dr. Wollaston.

The French draw-plates are so much esteemed, that one of the best of them used to be sold in this country, during the late war, for its weight in silver. The holes are formed with a steel punch; being made large on that side where the wire enters, and diminishing with a regular taper to the other side.

WIRE ROPE. The manufacture of ropes made of wire, has, of late years, become a most important one. Not only are ropes of this description now employed in the most extensive coal mines of this country, and for winding generally, but they are used for much of the standing rigging of ships, and for numerous ordinary purposes. Perhaps the most important application of wire rope has been, however, in the construction of the electric cables. See Electro-telegraphy.

The following tables show the relative values of ropes of hemp, iron, and steel.

WOAD (*Vouëde, Pastel*, Fr.; *Waid*, Germ.; *Gualdo*, It. *Isatis tinctoria*, Linn.) is almost the only plant growing in the temperate zone which is known to produce indigo. It is an herbaceous, biennial plant, belonging to the natural order *cruciferæ*, and bears yellow flowers and large flattened seed vessels, which are often streaked with purple. The leaves, which are the only part of the plant employed in dyeing, are large, smooth, and glaucous, like cabbage leaves, but exhibit no external indication of the presence of any blue colouring matter, which indeed, according to modern researches, is not contained in them ready formed. The plant called by the Romans *glastum*, with which, according to Pliny, the Britons dyed their skins blue, is supposed to be identical with woad. Before the introduction of indigo into the dye-house of Europe, woad was generally used for dyeing blue, and was extensively cultivated in various districts of Europe, such as Thuringia, in Germany; Languedoc, in France; and Piedmont, in Italy. To these districts its cultivation was a source of great wealth. Beruni, a rich woad manufacturer of Toulouse, became surety for the payment of the ransom of his king, Francis I., then a prisoner of Charles V., in Spain. The term *pays de cocaigne*, denoting a land of great wealth and fertility, is indeed supposed to be derived from the circumstance that the woad balls, called in French *cocaignes*, were manufactured chiefly in Languedoc.

The woad-leaves were not employed by the dyer in their crude state, but were previously subjected to a process of fermentation, for the purpose of eliminating the colouring matter. The seed having been sown in winter, or early spring, the plants were allowed to grow until the leaves were about a span long, and had assumed the rich glaucous appearance indicative of maturity, when they were stripped or cut off. The cropping was repeated several times, at intervals of five or six weeks, until the approach of winter put a stop to the growth of the plant. The leaves sent up in the succeeding spring yielded only an inferior article (called in German *Komposowaid*), and it was therefore customary to keep only as many plants until the following year as were required for obtaining seed, which, the plant being biennial, is only produced in the second year. The leaves, after being gathered, were slightly dried, and then ground in a mill to a paste. In Germany it was usual to lay this paste into a heap for about twenty-four hours, and then form it by hand into large balls, which were first dried partially in the sun, on lattice work or rushes, and then piled up in heaps a yard high, in an airy place, but under cover, when they diminished in size and became hard. These balls, when of good quality, exhibited, on being broken, a light blue or sea-green colour. They were usually sold in this state to manufacturers, by whom they were subjected to a second process in order to render them fit for the use of the dyer. This process was conducted in the following manner:—The woad balls were first broken by means of wooden hammers, and the triturated mass was heaped up on a wooden floor, sprinkled with water, sometimes with a little wine, and allowed to ferment or putrefy. The mass became very hot, and emitted a strong ammoniacal odour, and much vapour. In order to regulate the process it was frequently turned over with shovels and again sprinkled with water. When the heat had subsided, the mass, which had become dry, was pounded, passed through sieves, and then packed in barrels ready for use. It had the appearance of pigeon's dung.

In France the paste obtained by pounding the woad leaves was taken to a room with a sloping pavement, open at one end, laid in a heap at the higher end of the room, and allowed to ferment for a period of twenty or thirty days. The mass swelled up and often showed cracks or fissures, which were always carefully closed as soon as they appeared, whilst a black juice exuded and ran away in gutters constructed for the purpose. When the fermented heap had become moderately dry, it was ground again and formed into cakes, called in French *coques*, which were then fully dried, and in this state brought to market. In France and Italy a second fermentation was not generally thought essential, but when performed it was conducted exactly in the manner just described.

At the present day woad is nowhere employed alone for the purpose of dyeing blue, since it is found more economical to use indigo, and the cultivation of the plant has therefore declined considerably, and has even become nearly extinct in districts where it was formerly carried on extensively. By woollen dyers, however, it is still used, but only as a means of exciting fermentation, and thus reducing the indigo blue in their vats; indeed, the woad employed by them contains little or no blue colouring matter. See Indigo.

Numerous attempts have been made to extract the blue colouring matter from woad, in the same way that indigo is extracted from the leaves of the indigofera in the East Indies and other countries. At the commencement of the present century, when the price of indigo on the continent of Europe was very high, a prize of 100,000 francs was even offered by the French government for the discovery of a method of obtaining from the *Isatis tinctoria*, or some other native plant, a dyeing material, which, both in regard to price and the beauty and solidity of its colour, should form a perfect substitute for indigo. The experiments which were made in consequence served to prove that it was quite possible to obtain genuine indigo from woad leaves, but that the process could never be carried on profitably on account of the very small proportion of colouring matter contained in the plant. Nine parts of fresh leaves yield only one part of the prepared material or pastel, and the latter does not afford more than 2 per cent. of its weight of indigo. According to Chevreul, the leaves of the *Indigofera anil*, even when grown in the neighbourhood of Paris, contain 30 times as much indigo-blue as those of the *Isatis tinctoria*, and, when cultivated in tropical countries, the amount is probably still higher. The comparatively high price of land and labour would probably itself prove a sufficient obstacle to the successful manufacture of indigo in most European countries, even if the yield were equal to what it is in the tropics.

In 1808 Chevreul published the results of his analysis of woad and pastel. It has more recently been made the subject of chemical investigation, for the purpose of ascertaining the state in which indigo-blue exists in plants and other organisms. See Indigo.—E. S.

WOOD-PRESERVING. Mr. Bethell's invention, which is much employed, consists in impregnating wood throughout with oil of tar and other bituminous matters containing creosote, and also with pyrolignite of iron, which holds more creosote in solution than any other watery menstruum.

The wood is put in a close iron tank, like a high-pressure steam-boiler, which is then closed and filled with the tar oil or pyrolignite. The air is then exhausted by air-pumps, and afterwards more oil or pyrolignite is forced in by hydrostatic pumps, until a pressure equal to from 100 to 150 pounds to the inch is obtained. This pressure is kept up by the frequent working of the pumps during six or seven hours, whereby the wood becomes thoroughly saturated with the tar oil, or the pyrolignite of iron, and will be found to weigh from 8 to 12 pounds per cube foot heavier than before.

In a large tank, like one of those used on the Bristol and Exeter Railway, 20 loads of timber per day can be prepared.

The effect produced is that of perfectly coagulating the albumen in the sap, thus preventing its putrefaction. For wood that will be much exposed to the weather, and alternately wet and dry, the mere coagulation of the sap is not sufficient; for although the albumen contained in the sap of the wood is the most liable and the first to putrefy, yet the ligneous fibre itself, after it has been deprived of all sap, will, when exposed in a warm damp situation, rot and crumble into dust. To preserve wood, therefore, that will be much exposed to the weather, it is not only necessary that the sap should be coagulated, but that the fibres should be protected from moisture, which is effectually done by this process.

The atmospheric action on wood thus prepared renders it tougher, and infinitely stronger. A post made of beech, or even of Scotch fir, is rendered more durable, and as strong as one made of the best oak; the bituminous mixture with which all its pores are filled acting as a cement to bind the fibres together in a close tough mass; and the more porous the wood is, the more durable and tough it becomes, as it imbibes a greater quantity of the bituminous oil, which is proved by its increased weight. The materials which are injected preserve iron and metals from corrosion; and an iron bolt driven into wood so saturated remains perfectly sound and free from rust. It also resists the attack of insects; and it has been proved by Mr. Prichard, at Shoreham Harbour, that the *teredo navalis*, or naval worm, will not touch it.

Wood thus prepared for sleepers, piles, posts, fencing, &c., is not at all affected by alternate exposure to wet and dry; it requires no painting, and after it has been exposed to the air for some days it loses every unpleasant smell.

For railway sleepers it is highly useful, as the commonest Scotch fir sleeper, when thus prepared, will last for centuries. Posts for gates or fencing, if prepared in this manner, may be made of Scotch fir, or the cheapest wood that can be obtained, and will not decay like oak posts, which invariably become rotten near the earth after a few years. The processes which have been introduced for impregnating wood with the protosulphate of iron, corrosive sublimate, chloride of lime, and similar substances, are not much employed, although many of them have been found to be very useful as preservative agents.

WOOF is the same as Weft.

WOOL. In reference to textile fabrics, sheep's wool is of two different sorts, the short and the long-stapled; each of which requires different modes of manufacture in the preparation and spinning processes, as also in the treatment of the cloth after it is woven, to fit it for the market. Each of these is, moreover, distinguished in commerce by the names of fleece wools and dead wools, according as they have been shorn at the usual annual period from the living animal, or are cut from its skin after death. The latter are comparatively harsh, weak, and incapable of imbibing the dyeing principles, more especially if the sheep has died of some malignant distemper. The annular pores, leading into the tubular cavities of the filaments, seem, in this case, to have shrunk and become obstructed. The time of year for sheep-shearing most favourable to the quality of the wool, and the comfort of the animal, is towards the end of June and beginning of July—the period when Lord Leicester holds his celebrated rural fête for that interesting purpose.

The wool of the sheep has been surprisingly improved by its domestic culture. The *mouflon* (*Ovis aries*), the parent stock from which our sheep is undoubtedly derived, and which is still found in a wild state upon the mountains of Sardinia, Corsica, Barbary, Greece, and Asia Minor, has a very short and coarse fleece, more like hair than wool. When this animal is brought under the fostering care of man, the rank fibres gradually disappear; while the soft wool round their roots, little conspicuous in the wild animal, becomes singularly developed. The male most speedily undergoes this change, and continues ever afterwards to possess far more power in modifying the fleece of the offspring than the female parent. The produce of a breed from a coarse-woolled ewe and a fine-woolled ram, is not of a mean quality between the two, but half-way nearer that of the sire. By coupling the female thus generated with such a male as the former, another improvement of one-half will be obtained, affording a staple three-fourths finer than that of the grandam. By proceeding inversely, the wool would be as rapidly deteriorated. It is, therefore, a matter of the first consequence in wool husbandry, to exclude from the flock all coarse-fleeced rams.

Long wool is the produce of a peculiar variety of sheep, and varies in the length of its fibres from 3 to 8 inches. Such wool is not carded like cotton, but combed like flax, either by hand or appropriate machinery. Short wool is seldom longer than 3 or 4 inches; it is susceptible of carding and felting, by which processes the filaments become first convoluted, and then densely matted together. The shorter sorts of combing wool are used principally for hosiery, though of late years the finer kinds have been extensively worked up into merino and mousseline-de-laine fabrics. The longer wools of the Leicestershire breed are manufactured into hard yarns, for worsted-pieces, such as waistcoats, carpets, bombazines, poplins, crapes, &c.

The wool of which good broad cloth is made should not be only shorter, but, generally speaking, finer and softer than the worsted wools, in order to fit them for the fulling process. Some wool-sorters and wool-staplers acquire by practice great nicety of discernment in judging of wools by the touch and traction of the fingers. The filaments of the finer qualities vary in thickness from $\frac{1}{1100}$ to $\frac{1}{1500}$ of an inch; their structure is very curious, exhibiting, in a good achromatic microscope, at intervals of about $\frac{1}{300}$ of an inch, a series of serrated rings, imbricated towards each other, like the joints of *Equisetum*, or rather like the scaly zones of a serpent's skin.

There are four distinct qualities of wool upon every sheep; the finest being upon the spine, from the neck to within 6 inches of the tail, including one-third of the breadth of the back; the second covers the flanks between the thighs and the shoulders; the third clothes the neck and the rump; and the fourth extends upon the lower part of the neck and breast down to the feet, as also upon a part of the shoulders and the thighs, to the bottom of the hind quarter. These should be torn asunder, and sorted, immediately after the shearing.

The harshness of wools is dependent not solely upon the breed of the animal, or the climate, but is owing to certain peculiarities in the pasture, derived from the soil. It is known, that in sheep fed upon chalky districts, wool is apt to get coarse; but in those upon a rich loamy soil, it becomes soft and silky. The ardent sun of Spain renders the fleece of the Merino breed harsher than it is in the milder climate of Saxony. The Angora, or Angola, or Angona wool, from Agnolia, 39° 53′ N. Lat., 32° 52′ E. Long., owes its beautiful character to the place of its growth. This wool is the same as *Mohair.* Smearing sheep with a mixture of tar and butter is deemed favourable to the softness of their wool.

All wool, in its natural state, contains a quantity of a peculiar potash-soap, secreted by the animal, called in this country the *yolk;* which may be washed out by water alone, with which it forms a sort of lather. It constitutes from 25 to 50 per cent. of the wool, being most abundant in the Merino breed of sheep; and however favourable to the growth of the wool on the living animal, should be taken out soon after it is shorn, lest it injure the fibres by fermentation, and cause them to become hard and brittle. After being washed in water, somewhat more than lukewarm, the wool should be well pressed, and carefully dried.

Mr. Hicks, of Huddersfield, obtained a patent some years ago for a machine for cleaning wool from burs. It consists of 4 rotary beaters, which act in succession. The wool having been opened and spread upon a feeding cloth is carried by it to the drawing rollers, and is then delivered to the action of the beater, by which it is carried along a curved grating to the feed cloth of another beater, so as to be made eventually quite clean.

Wool was first imported into this country in 1770. The gradual increase in the importation is shown in the following table:—

Year.	lbs.	Year.	lbs.
1771 - - -	1,829,772	1811 - - -	4,739,972
1781 - - -	2,478,332	1821 - - -	16,622,567
1791 - - -	3,014,511	1831 - - -	31,652,029
1801 - - -	7,371,774	1841 - - -	56,170,974

In the year 1800 a duty of 5*s.* 3*d.* per cwt. was imposed upon the import, which in 1813 was raised to 6*s.* 8*d.* per cwt., and in 1819 to the excessive duty of 6*d.* per lb; in 1824 it was reduced to 3*d.* per lb., and in 1825 to ½*d.* per lb. on wool under the value of 1*s.* per lb., and 1*d.* on wool above that price. The duty was removed in 1844:—

Quantities of Wool (Sheep, Lamb, and Alpaca) imported into the United Kingdom from various Countries.

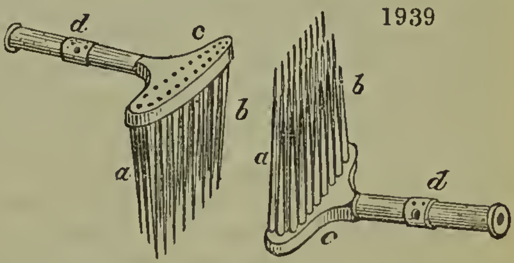
WOOL DYEING. See Dyeing.

WOOLLEN MANUFACTURE. In this branch of business, a long-stapled and firm fibre is required to form a smooth level yarn, little liable to shrink, curl, or felt in weaving and finishing the cloth. It must not be entangled by carding, but stretched in lines as parallel as possible by a suitable system of *combing,* manual or mechanical.

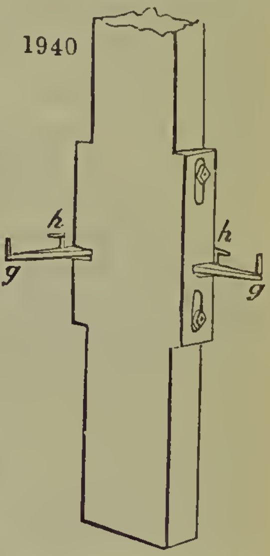
When the long wool is brought into the worsted factory, it is first of all washed by men with soap and water, who are paid for their labour by the piece, and are each assisted by a boy, who receives the wool as it issues from between the drying *squeezers* (see BLEACHING). The boy carries off the wool in baskets, and spreads it evenly upon the floor of the drying-room, usually an apartment over the boilers of the steam-engine, which is thus economically heated to the proper temperature. The health of the boys employed in this business is not found to be at all injured.

The wool, when properly dried, is transferred to a machine called the *plucker*, which is always superintended by a boy 12 or 14 years of age, being very light work. He lays the tresses of wool pretty evenly upon the feed-apron, or table covered with an endless moving webb of canvas, which, as it advances, delivers the ends of the long tufts to a pair of fluted rollers, whence it is introduced into a fanning apparatus, somewhat similar to the *willow* employed in the cotton manufacture, which see. The filaments are turned out at the opposite end of this winnowing machine, straightened, cleaned, and ready for the combing operation. According to the old practice of the trade, and still, for the finer descriptions of the long staple, according to the present practice, the wool is carded by hand. This is far more severe labour than any subservient to machinery, and is carried on in rooms rendered close and hot by the number of stoves requisite to heat the combs, and so enable them to render the fibres soft, flexible, and elastic. This is a task at which only robust men are engaged. They use three implements; 1, a pair of combs for each person; 2, a post, to which one of the combs can be fixed: 3, a comb-pot or small stove for heating the teeth of the combs. Each comb is composed either of two or three rows of pointed tapering steel teeth, *b* *fig.* 1939, disposed in two or three parallel planes, each row being a little longer that the preceding. They are made fast at the roots to a wooden stock or head *c*, which is covered with horn and has a handle *d*, fixed into it at right angles to the lines of the teeth. The spaces between these two or three planes of teeth is about one-third of an inch at their bottoms, but somewhat more at their tips. The first combing, when the fibres are most entangled, is performed with the two-row toothed combs; the second or finishing combing, with the three-row toothed.

1939



1940



In the workshops a post is planted, *fig.* 1940, upright, for resting the combs occasionally upon, during the operation. An iron stem *g*, projects from it horizontally, having its end turned up, so as to pass through a hole in the handle of the comb. Near its point of insertion into the post, there is another staple point, *h*, which enters into the hollow end of the handle; which, between these two catches, is firmly secured to the post. The stove is a very simple affair, consisting merely of a flat iron plate, heated by fire or steam, and surmounted with a similar plate, at an interval sufficient to allow the teeth to be inserted between them at one side, which is left open, while the space between their edges, on the other side, is closed to confine the heat.

In combing the wool, the workman takes it up in tresses of about four ounces each, sprinkles it with oil, and rolls it about in his hands, to render all the filaments equally unctuous. Some harsh dry wools require one-sixteenth of their weight of oil, others no more than a fortieth. He next attaches a heated comb to the post, with its teeth pointed upwards, seizes one-half the tress of wool in his hands, throws it over the teeth, then draws it through them, and thus repeatedly: leaving a few straight filaments each time upon the comb. When the comb has in this way collected all the wool, it is placed with its points inserted into the cell of the stove, with the wool hanging down outside, exposed to the influence of the heat. The other comb, just removed in a heated state from the stove, is planted upon the post, and furnished in its turn with the remaining two-ounce tress of wool; after which it supplants the preceding at the stove. Having both combs now hot, he holds one of them with his left hand over his knee, being seated upon a low stool, and seizing the other with his right hand, he combs the wool upon the first, by introducing the teeth of one comb into the wool stuck in the other, and drawing them through it. This manipulation is skilfully repeated, till the fibres are laid truly parallel like a flat tress of hair. It is proper to begin by combing the tips of the tress, and to advance progressively, from the one end towards the other, till at length the combs are worked with their teeth as closely together as is possible, without bringing them into collision. If the workman proceeded otherwise, he would be apt to rupture the filaments, or tear their ends entirely out of one of the combs. The flocks left at the end of the process, because they are too short for the comber to grasp them in his hand, are called *noyls*. They are unfit for the worsted spinner, and are reserved for the coarse cloth manufacturer.

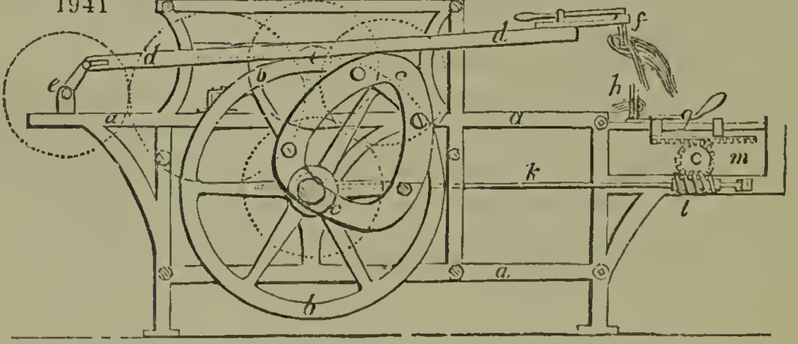
The wool finally drawn off from the comb, though it may form a uniform tress of straight filaments, must yet be combed again at a somewhat lower temperature, to prepare it perfectly for the spinning operation. From ten to twelve slivers are then arranged in one parcel.

To relieve the workman from this laborious and not very salubrious task has been the object of many mechanical inventions. One of these, considerably employed in this country and in France, is the invention of the late Mr. John Collier, of Paris, for which a patent was obtained in England, under the name of John Platt, of Salford, in November 1827. It consists of two comb-wheels, about ten feet in diameter, having hollow iron spokes filled with steam, in order to keep the whole apparatus at a proper combing heat. The comb forms a circle, made fast to the periphery of the wheel, the teeth being at right angles to the plane of the wheel. The shafts of the two wheels are mounted in a strong frame of cast-iron; not, however, in horizontal positions, but inclined at acute angles to the horizon, and in planes crossing each other, so that the teeth of one circular comb sweep with a steady obliquity over the teeth of the other, in a most ingenious manner, with the effect of combing the tresses of wool hung upon them. The proper quantity of long wool, in its ordinary state, is stuck in handfuls upon the wheel, revolving slowly, by a boy, seated upon the ground at one side of the machine. Whenever the wheel is dressed, the machine is made to revolve more rapidly, by shifting its driving-band on another pulley; and it is beautiful to observe the delicacy and precision with which it smoothes the tangled tress. When the wools are set in rapid rotation, the loose ends of the fleece, by the centrifugal force, are thrown out, in the direction of radii, upon the teeth of the other revolving comb-wheel, so as to be drawn out and made truly straight. The operation commences upon the tips of the tresses, where the wheels, by the oblique posture of their shafts, are at the greatest distance apart; but as the planes slowly approach to parallelism, the teeth enter more deeply into the wool, till they progressively comb the whole length of its fibres. The machine being then thrown out of gear, the teeth are stripped of the tresses by the hand of the attendant; the *noyls*, or short refuse wool, being also removed, and kept by itself.

This operation being one of simple superintendence, not of handicraft effort and skill, like the old combing of long wool, is now performed by boys or girls of 13 and 14 years of age; and places in a striking point of view the influence of automatic mechanism, in so embodying dexterity and intelligence in a machine, as to render the cheap and tractable labour of children a substitute for the high-priced and often refractory exertions of workmen too prone to capricious combinations. The chief precaution to be taken with this machine, is to keep the steam-joints tight, so as not to wet the apartments, and provide due ventilation for the operatives.

The following machine, patented by James Noble, of Halifax, worsted-spinner, in February 1834, deserves particular notice, as its mode of operation adapts it well also for heckling flax. In *fig.* 1941, the internal structure is exhibited. The frame-

1941



work *a*, *a*, supports the axle of a wheel, *b*, *b*, in suitable earings on each side. To the face of this wheel is affixed the eccentric or heart-wheel cam, *c*, *c*. On the upper part of the periphery of this cam or heart-wheel, a lever, *d*, *d*, bears merely by its gravity; one end of which lever is connected by a joint to the crank *c*. By the rotation of the crank *c*, it will be perceived that the lever *d*, will be slidden to and fro on the upper part of the periphery of the eccentric or heart-wheel cam *c*, the outer end of the lever *d*, carrying the upper or working comb or needle points *f*, as it moves, performing an elliptical curve, which curve will be dependent upon the position of the heart-wheel cam *c*, that guides it. A movable frame, *g*, carries a series of points, *h*, which are to constitute the lower comb or frame of needles. Into these lower needles the rough uncombed wool is to be fed by hand, and to be drawn out and combed straight by the movements of the upper or working comb.

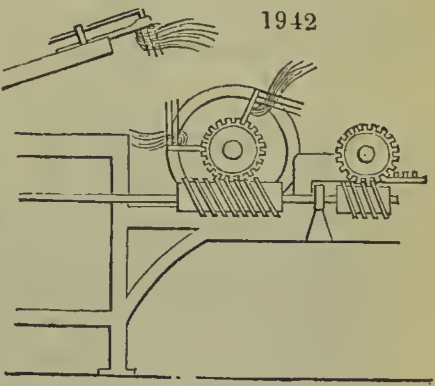
As it is important, in order to prevent waste, that the ends of the wool should be first combed out, and that the needle-points should be made to penetrate the wool progressively, the movable frame *g* is in the first instance placed as far back as possible; and the action of the lever *d*, during the whole operation, is so directed by the varying positions of the cam-wheel, as to allow the upper comb to enter at first a very little way only into the wool; but as the operation of combing goes on, the frame with the lower combs is made to advance gradually, and the relative positions of the revolving heart cam-wheel *c*, being also gradually changed, the upper or working needles are at length allowed to be drawn completely through the wool, for the purpose of combing out straight the whole length of its fibre.

In order to give the machine the necessary movements, a train of toothed wheels and pinions is mounted, mostly on studs attached to the side of the frame; which train of wheels and pinions is shown by dots in the figure, to avoid confusion. The driving power, a horse or steam-engine, is communicated by a band to a rigger on the short axle *i*; which axle carries a pinion, taking into one of the wheels of the train. From this wheel the crank *e*, that works the lever *d*, is driven; and also, by gear from the same pinion, the axle of the wheel *b*, carrying the eccentric or heart-wheel cam, is also actuated, but slower than the crank-axle.

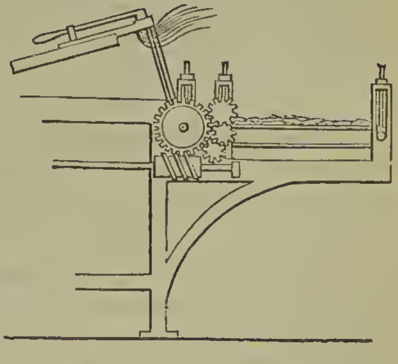
At the end of the axle of the wheel *b*, and cam *c*, a bevel pinion is affixed, which gears into a corresponding bevel pinion on the end of the lateral shaft *k*. The reverse end of this shaft has a worm or endless screw *l*, taking into a toothed wheel *m*; and this last-mentioned toothed wheel gears into the rack at the under part of the frame *g*.

It will hence be perceived, that by the movements of the train of wheels, a slow motion is given to the frame *g*, by which the lower needles carrying the wool are progressively advanced as the operation goes on; and also, that by the other wheels of the train, the heart-wheel cam is made to rotate, for the purpose of giving such varying directions to the stroke of the lever which slides upon its periphery, and to the working comb, as shall cause the comb to operate gradually upon the wool as it is brought forward. The construction of the frames which hold the needles, and the manner of fixing them in the machine, present no features of importance; it is therefore unnecessary to describe them farther, than to say, that the heckles are to be heated when used for combing wool. Instead of introducing the wool to be combed into the lower needles by hand, it is sometimes fed in, by means of an endless feeding cloth, as shown in *fig.* 1942. This endless cloth is distended over two rollers, which are made to revolve, for the purpose of carrying the cloth with the wool forward, by means of the endless screw and pinions.

1942



1943



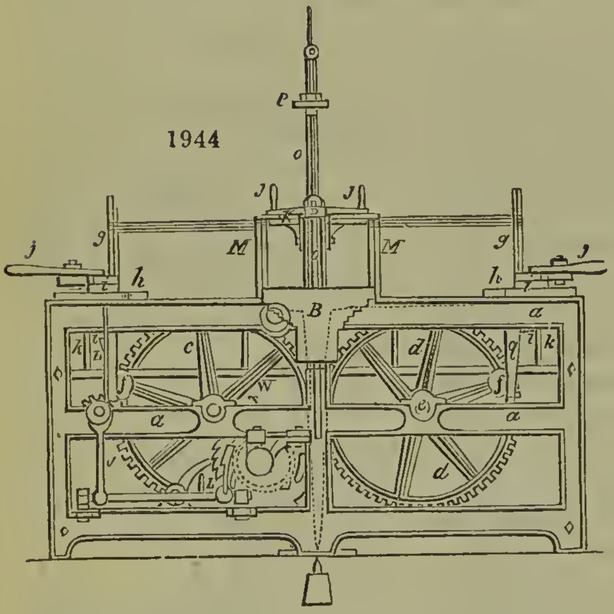
A slight variation in the machine is shown at *fig.* 1943, for the purpose of combing wool of long fibre, which differs from the former only in placing the combs or needle points upon a revolving cylinder or shaft. At the end of the axle of this shaft, there is a toothed wheel, which is actuated by an endless screw upon a lateral shaft. The axle of the cylinder on which the needles are fixed, is mounted in a movable frame or carriage, in order that the points of the needles may, in the first instance, be brought to act upon the ends of the wool only, and ultimately be so advanced as to enable the whole length of the fibres to be drawn through. The progressive advancement of this carriage, with the needle cylinder, is effected by the agency of the endless screw on the lateral shaft before mentioned.

Some combing-machines reduce the wool into a continuous sliver, which is ready for the drawing-frame; but the short slivers produced by the hand combing, must be first joined together, by what is called *planking*. These slivers are rolled up by the combers ten or twelve together, in balls called tops, each of which weighs a half pound. At the spinning-mill these are unrolled, and the slivers are laid on a long plank or trough, with the ends lapping over, in order to splice the long end of one sliver into the short end of another. The long end is that which was drawn off first from the comb, and contains the longer fibres; the short is that which comes last from the comb, and contains the shorter. The wool-comber lays all the slivers of each ball the same way, and marks the long end of each by twisting up the end of the sliver. It is a curious circumstance, that when a top or ball of slivers is unrolled and stretched out straight, they will not separate from each other without tearing and breaking, if the separation is begun at the short ends; but if they are first parted at the long ends they will readily separate.

The machine for combing long wool, for which Messrs. Donisthorpe and Rawson obtained a patent in April 1835, has been found to work well, and therefore merits a detailed description.

Fig. 1944 is an elevation, *fig.* 1945 an end view, and *fig.* 1946 a plan, in which *a*, *a*, is the framing; *b*, the main shaft, bearing a pinion which drives the wheel and shaft *c*, in gear with the wheel *d*, on the shaft *e*. Upon each of the wheels *c* and *d*, there are two projections or studs *f*, which cause the action of the combs *g*, *g*, of which *h*, *h*, are the tables or carriages. These are capable of sliding along the upper guide rails of the framing *a*. Through these carriages or tables *h*, *h*, there are openings or slits, shown by dotted lines, which act as guides to the holders *i*, *i*, of the combs *g*, *g*, rendering the holders susceptible of motion at right angles to the course pursued by the tables *h*. The combs are retained in the holders *i*, *i*, by means of the lever handles *j*, *j*, which move upon inclined surfaces, and are made to press on the surface of the heads of the combs *g*, *g*, so as to be retained in their places; and they are also held by studs affixed to the holders, which pass into the comb-heads. From the under side of the tables, forked projections *i*, *i*, stand out, which pass through the openings or slits formed in the tables *h*, *h*; these projections are worked from side to side by the frame *k*, *k*, which turning on the axis or shaft *l*, *l*, is caused to vibrate, or rock to and fro, by the arms *m*, moved by the eccentric grove *n*, made fast to the shaft *e*. The tables *h*, are drawn inwards, by weights suspended on cords or straps *o*, *o*, which pass over friction pulleys *p*, *p*; whereby the weights have a constant tendency to draw the combs into the centre of the machine, as soon as it is released by the studs *f*, passing beyond the projecting arms *g*, on the tables.

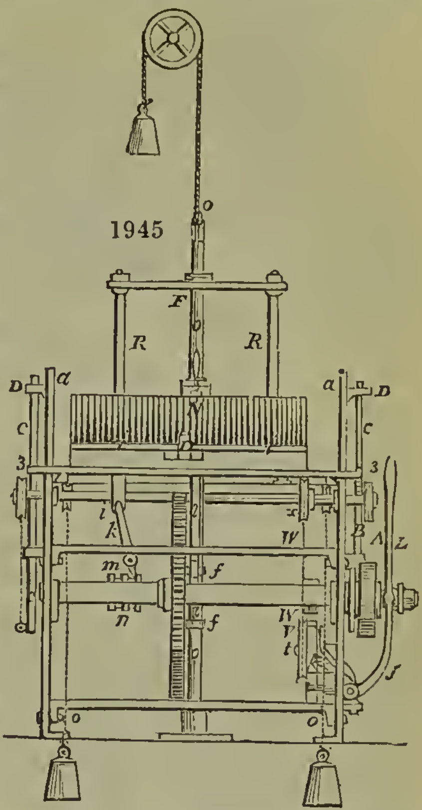
1944



On the shaft *c*, a driving-tooth or catch *r*, is fixed, which takes into the ratchet wheel *s*, and propels one of its teeth at every revolution of the shaft *c*. This ratchet wheel turns on an axis at *t*; to the ratchet the pulley *v* is made fast, to which the cord or band *w* is secured, as also to the pulley *x*, on the shaft *y*. On the shaft *y*, there are two other pulleys *z*, *z*, having the cords or bands A, A, made fast to them, and also to the end of the gauge-plates B, furnished with graduated steps, against which the tables *h*, *h*, are drawing at each operation of the machine. In proportion as these gauge-plates are raised, the nearer the carriages or tables *h* will be able to advance to the centre of the machine, and thus permit the combs *g*, *g*, to lay hold of, and comb, additional lengths of the woolly fibres. The gauge-plates B, are guided up by the bars C, which pass through openings, slots, or guides, made in the framing *a*, as shown by D.

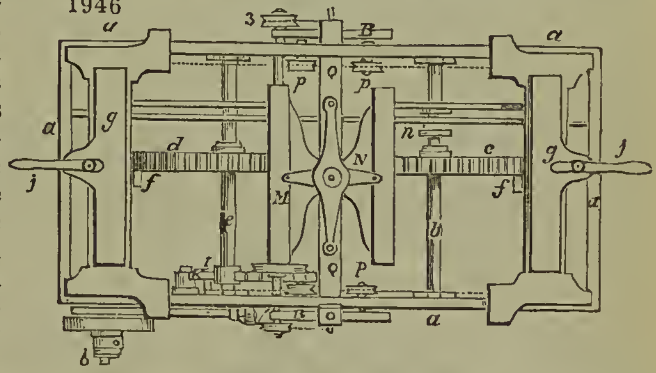
To the ratchet wheel *s*, an inclined projection F, is made fast, which in the course of the rotation of the ratchet wheel, comes under the lever F, fixed to the shaft G, that turns in bearings H. To this shaft the levers I and J, are also affixed; I serving to throw out the click or catch K, from the ratchet wheel, by which the parts of the machine will be released, and restored to positions ready for starting again. The lever J, serves to slide the drum upon the driving shaft *b*, out of gear, by means of the forked handle L, when the machine is to be stopped, whenever it has finished combining a certain quantity of wool. The combs which hold the wool have a motion upwards, in order to take the wool out of the way of the combs *g*, *g*, as these are drawn into the centre of the machine; while the holding combs descend to lay the wool among the points of the combs, *g*, *g*. For obtaining this upward and downward motion, the combs M, M, are placed between the frame N, and retained there just as the combs *g*, *g*, are upon the holders *i*, *i*. The framing N, is made fast to the bar or spindle O, which moves vertically through openings in the cross-head P, and the cross-framing of the machine Q; from top of which there is a strap passes over pulleys with a suspended weight to it; the cross-head being supported by the two guide-rods R, fixed to the cross-framing Q. It is by the guide-rods R, and the spindle O, that the frame N is made to move up and down; while the spindle is made to rise by the studs *f*, as the wheels *c* and *d* come successively under the studs *s*, on the spindle O.

1945



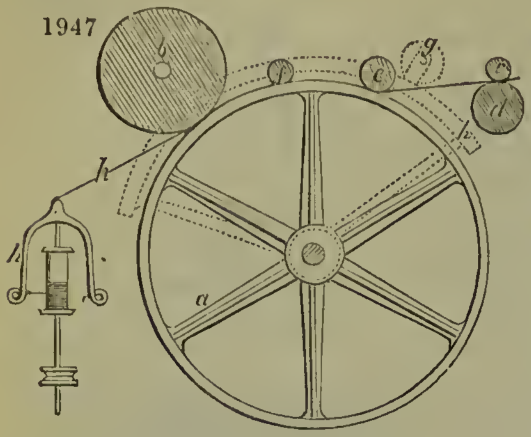
A quantity of wool is to be placed on each of the combs *g*, *g*, and M, M, the machine being in the position shown in *fig.* 1946. When the main-shaft *b*, is set in motion, it will drive by its pinion the toothed wheel *c*, and therefrom the remaining parts of the machine. The first effect of the movement will be to raise the combs M, M, sufficiently high to remove the wool out of the way of the combs *g*, *g*, which will be drawn towards the centre of the machine, as soon as they are released by the studs *f*, passing the projecting arms *q*, on the tables *h*; but the distance between the combs *g*, *g*, and the combs M, M, will depend on the height to which the gauge-plates B have been raised. These plates are raised one step at each revolution of the shaft *c*; the combs *g*, *g*, will therefore be continually approaching more nearly to the combs M, M, till the plates B, are so much raised as to permit the tables *h* to approach the plates B, below the lowest step or graduation, when the machine will continue to work. Notwithstanding the plates B continuing to rise, there being only parallel surfaces against which the tables come, the combs *g*, *g*, will successively come to the same position, till the inclined projection E, on the ratchet wheel *s*, comes under the lever F, which will stop the machine. The wool which has been combed, is then to be removed, and a fresh quantity introduced. It should be remarked that the combs *g*, *g*, are continually moving from side to side of the machine, at the same time that they are combing out the wool. The chief object of the invention is obviously to give the above peculiar motions to the combs *g*, *g*, and M, M, which may be applied also to combing goat-hair.

1946



For the purposes of the worsted manufacture, wool should be rendered inelastic to a considerable degree, so that its fibres may form long lines, capable of being twisted into straight level yarn. Mr. Bayliffe, of Kendal, has sought to accomplish this object, first, by introducing into the *drawing* machine a rapidly revolving wheel, in contact with the front drawing roller, by whose friction the filaments are heated, and at the same time deprived of their curling elasticity; secondly, by employing a movable regulating roller, by which the extent of surface on the periphery of the wheel that the lengths of wool is to act upon, may be increased or diminished at pleasure, and, consequently, the effect regulated or tempered as the quality of the wool may require; thirdly, the employment of steam in a rotatory drum, or hollow wheel, in place of the wheel first described, for the purpose of heating the wool, in the process of drawing, in order to facilitate the operation of straightening the fibres.

1947



These objects may be effected in several ways; that is, the machinery may be variously constructed, and still embrace the principles proposed. *Fig.* 1947, shows one mode: — *a* is the friction wheel; *b*, the front drawing roller, placed in the drawing-frame in the same way as usual; the larger wheel *a*, constituting the lower roller of the pair of front drawing rollers; *c* and *d* are the pair of back drawing rollers, which are actuated by gear connected to the front rollers, as in the ordinary construction of drawing machines, the front rollers moving very considerably faster than the back rollers, and, consequently, drawing or extending the fibres of the sliver of wool, as it passes through between them; *e* is a guide-roller, bearing upon the periphery of the large wheel; *f* is a tension roller, which presses the fibres of the wool down upon the wheel *a*.

Now, supposing the back rollers *c* and *d*, to be turned with a given velocity, and the front roller *b* to be driven much faster, the effect would be, that the fibres of wool constituting the sliver, passing through the machine, would be considerably extended between *b* and *d*, which is precisely the effect accomplished in the ordinary drawing frame; but the wheel *a*, introduced into the machine in place of the lower front drawing roller, being made to revolve much faster than *b*, the sliver of wool extended over the upper part of its periphery from *b*, to the tension roller *f*, will be subjected to very considerable friction from the contact; and, consequently, the natural curl of the wool will be taken out, and its elasticity destroyed, which will enable the wool to proceed in a connected roving down to the spindle or flyer *h*, where it becomes twisted or spun into a worsted thread.

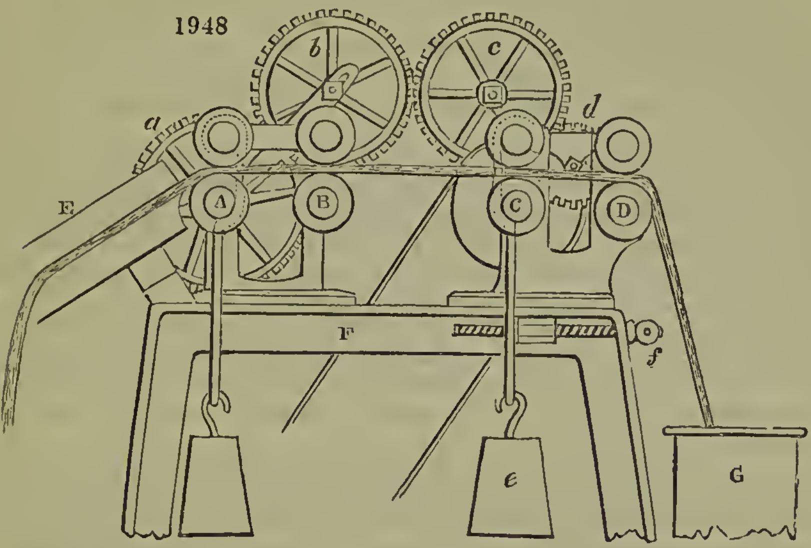
In order to increase or diminish the extent to which the fibres of wool are spread over the periphery of the wheel *a*, a regulating roller is adapted to the machine, as shown at *g*, in place of the tension roller *f*. This regulating roller *g*, is mounted by its pivots in bearings on the circular arms *h*, shown by dots. These circular arms turn loosely upon the axle of the wheel *a*, and are raised or depressed by a rack and a winch, not shown in the figure; the rack taking into teeth on the periphery of the circular arms. It will hence be perceived, that by raising the circular arms, the roller *g*, will be carried backward, and the fibres of wool pressed upon the periphery of the wheel to a greater extent. On the contrary, the depression of the circular arms will draw the roller *g*, forward, and cause the wool to be acted upon by a smaller portion of the periphery of the wheel *a*, and consequently subject it to less friction.

When it is desired to employ steam for the purpose of heating wool, the wheel *a*, is formed as a hollow drum, and steam from a boiler, in any convenient situation, is conveyed through the hollow axle to the interior of the drum, which, becoming heated by that means, communicates heat also to the wool, and thereby destroys its curl and elasticity.

Breaking-frame. — Here the slivers are *planked*, or spliced together, the long end of one to the short end of another; after which they are drawn out and extended by the rollers of the breaking-frame. A sketch of this machine is given in *fig.* 1948. It consists of four pairs of rollers A, B, C, D. The first pair A, receives the wool from the inclined trough E, which is the planking-table. The slivers are unrolled, parted, and hung loosely over a pin, in reach of the attendant, who takes a sliver, and lays it flat in the trough, and the end is presented to the rollers A, which being in motion, will draw the wool in; the sliver is then conducted through the other rollers, as shown in the figure: when the sliver has passed half through, the end of another sliver is placed upon the middle of the first, and they pass through together; when this second is passed half through, the end of a third is applied upon the middle of it, and in this way the short slivers produced by the combing are joined into one regular and even sliver.

The lower roller C, receives its motion from the mill, by means of a pulley upon the end of its axis, and an endless strap. The roller which is immediately over it, is borne down by a heavy weight, suspended from hooks, which are over the pivots of the upper roller. The fourth pair of rollers D, moves with the same velocity as C, being turned by means of a small wheel upon the end of the axis of the roller C, which turns a wheel of the same size upon the axis of the roller D, by means of an intermediate wheel *d*, which makes both rollers turn the same way round. The first and second pairs of rollers, A and B, move only one-third as quick as C and D, in order to draw out the sliver between B and C, to three times the length it was when put on the planking-table. The slow motion of the rollers A, is given by a large wheel *a*, fixed

1948



upon the axis of the roller A, and turned by the intermediate cog-wheels *b c*, and *d;* the latter communicates between the rollers C and D. The pinions on the rollers C and D, being only one-third the size of the wheel *a*. C and D turn three times as fast as A, for *b*, *c*, and *d*, are only intermediate wheels. The rollers B, turn at the same rate as A. The upper roller C is loaded with a heavy weight, similar to the rollers A; but the other rollers, B and D, are no further loaded than the weight of the rollers.

The two pairs of rollers A, B, and C, D, are mounted in separate frames; and that frame which contains the third and fourth pairs C, D, slides upon the cast-iron frame F, which supports the machine, in order to increase or diminish the distance between the rollers B and C. There is a screw *f*, by which the frame of the rollers is moved, so as to adjust the machine according to the length of the fibre of the wool. The space between B and C should be rather more than the length of the fibres of the wool. The intermediate wheels *b* and *c* are supported upon pieces of iron, which are movable on centres; the centre for the piece which supports the wheel *b* is concentric with the axis of the roller A; and the supporting piece for the wheel *c* is fitted on the centre of the wheel *d*. By moving these pieces the intermediate wheels *b* and *c* can be always kept in contact, although the distance between the rollers is varied at times. By means of this breaking-frame, the perpetual sliver, which is made up by planking the sliver together, is equalised, and drawn out three times in length, and delivered into the can G.

Drawing-frame.—Three of these cans are removed to the drawing-frame, which is similar to the breaking-frame, except that there is no planking-table E. There are five sets of rollers, all fixed upon one common frame F, the breaking-frame, which we have described, being the first. As fast as the sliver comes through one set of rollers it is received into a can, and then three of these cans are put together and passed again through another set of rollers. In the whole the wool must pass through the breaker and four drawing-frames before the roving is begun. The draught being usually four times at each operation of drawing, and three times in the breaking, the whole will be $3 \times 4 \times 4 \times 4 \times 4 = 768$; but to suit different sorts of wool the three last drawing-frames are capable of making a greater draught, even to five times, by changing the pinions; accordingly the draught will be $3 \times 4 \times 5 \times 5 \times 5 = 1500$ times.

The size of the sliver is diminished by these repeated drawings, because only three slivers are put together, and they are drawn out four times; so that in the whole the sliver is reduced to a fourth or a ninth of its original bulk.

The breaking-frame and drawing-frame which are used when the slivers are prepared by the combing-machines, are differently constructed; they have no planking-table, but receive three of the perpetual slivers of the combing-machine from as many tin cans, and draw them out from ten to twelve times. In this case all the four rollers contribute to the operation of drawing: thus the second rollers B, move $2\frac{1}{2}$ times as fast as the rollers A; the third rollers C move 8 times as fast as A; and the fourth rollers E move $10\frac{1}{3}$ times as fast as A. In this case the motion is given to the different rollers by means of beveled wheels, and a horizontal axis, which extends across the ends of all the four rollers, to communicate motion from one pair of rollers to another.

There are three of these systems of rollers, which are all mounted on the same frame; and the first one through which the wool passes is called the breaking-frame: but it does not differ from the others, which are called drawing-frames. The slivers which have passed through one system of rollers are collected four or five together and put through the drawing-rollers. In all the slivers pass through three drawings, and the whole extension is seldom less than 1000 times, and for some kinds of wool much greater.

After the drawing of the slivers is finished, a pound weight is taken, and is measured by means of a cylinder, in order to ascertain if the drawing has been properly conducted; if the sliver does not prove of the length proposed, according to the size of worsted which is intended to be spun, the pinions of some of the drawing-frames are changed, to make the draught more or less, until it is found by experiment that one pound of the sliver measures the required length.

Roving-frame.—This is provided with rollers, the same as the drawing-frames: it takes in one or two slivers together, and draws them out four times. By this extension the sliver becomes so small that it would break with the slightest force, and it is therefore necessary to give some twist; this is done by a spindle and flyer. See *Roving*, under COTTON MANUFACTURE.

Spinning-frame.—This is so much like the roving-frame that a short description will be sufficient. The spindles are more delicate, and there are three pairs of rollers, instead of two; the bobbins, which are taken off from the spindles of the roving-frame when they are quite full, are stuck upon skewers, and the roving which proceeds from them is conducted between the rollers. The back pair turns round slowly; the middle pair turns about twice for once of the back rollers; and the front pair makes from twelve to seventeen turns for one turn of the back roller, according to the degree of extension which is required.

The spindles must revolve very quickly in the spinning-frame, in order to give the requisite degree of twist to the worsted. The hardest twisted worsted is called tammy warp; and when the size of this worsted is such as to be 20 or 24 hanks to the pound weight, the twist is about 10 turns in each inch of length. The least twist is given to the worsted for fine hosiery, which is from 18 to 24 hanks to the pound. The twist is from 5 to 6 turns per inch. The degree of twist is regulated by the size of the whirls or pulleys upon the spindle, and by the wheel-work which communicates the motion to the front rollers from the band-wheel, which turns the spindles.

It is needless to enter more minutely into the description of the spinning machinery, because the fluted roller construction, invented by Sir Richard Arkwright, fully described under COTTON MANUFACTURE, is equally applicable to worsted. The difference between the two is chiefly in the distance between the rollers, which in the worsted-frame is capable of being increased or diminished at pleasure, according to the length of the fibres of the wool; and the draught or extension of the roving is far greater than in the cotton.

Reeling.—The bobbins of the spinning-frame are placed in a row upon wires before a long horizontal reel, and the threads from 20 bobbins are wound off together. The reel is exactly a yard in circumference, and when it has wound off 80 turns it rings a bell; the motion of the reel is then stopped, and a thread is passed round the 80 turns or folds which each thread has made. The reeling is then continued till another 80 yards is wound off, which is also separated by interweaving the same thread; each of these separate parcels is called a ley, and when 7 such leys are reeled it is called a hank, which contains 560 yards. When this quantity is reeled off, the ends of the binding thread are tied together, to bind each hank fast, and one of the rails of the reel is struck to loosen the hanks, and they are drawn off at the end of the reel. These hanks are next hung upon a hook, and twisted up hard by a stick; then doubled, and the two parts twisted together to make a firm bundle. In this state the hanks are weighed by a small index-machine, which denotes what number of the hanks will weigh a pound. And they are sorted accordingly into different parcels. It is by this means that the number of the worsted is ascertained as the denomination for its fineness: thus No. 24 means that 24 hanks each containing 560 yards will weigh a pound, and so on.

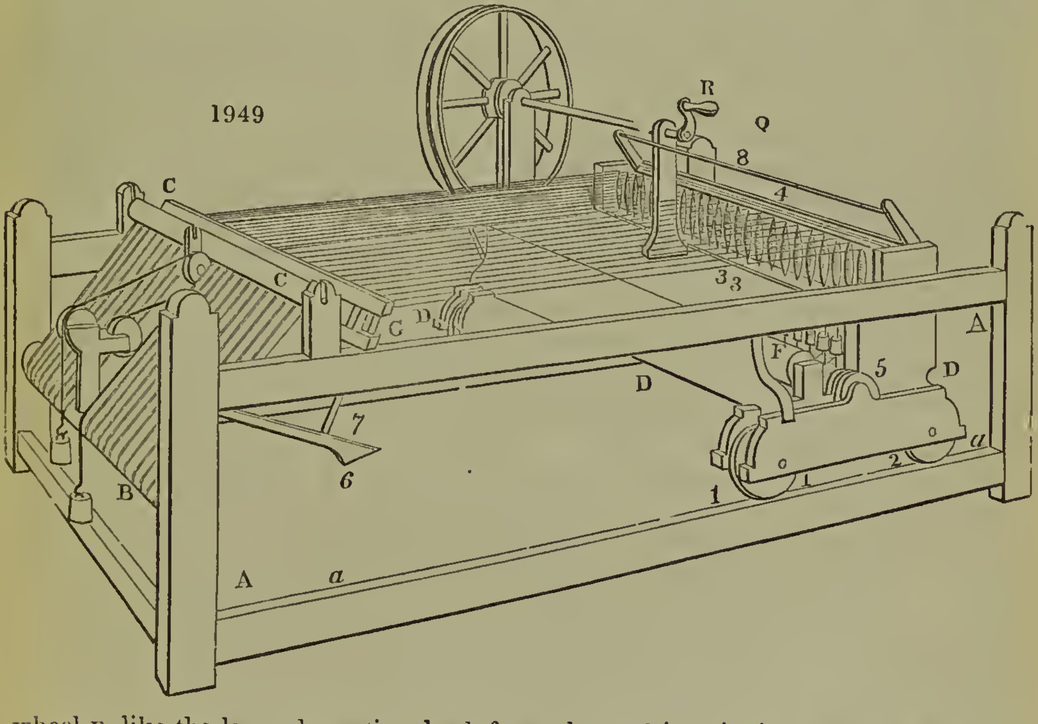
This denomination is different from that used for cotton, because the hank of cotton contains 840 yards instead of 560; but in some places the worsted hank is made of the same length as the cotton.

To pack up the worsted for market, the proper number of hanks is collected to make a pound, according to the number which has been ascertained; these are weighed as a proof of the correctness of the sorting, then tied up in bundles of one pound each, and four of these bundles are again tied together. Then 60 such bundles are packed up in a sheet, making a bale of 240 pounds ready for market.

Of the treatment of short wool for the cloth manufacture.—Short wool resembles cotton not a little in the structure of its filaments, and is cleaned by the *willy*, as cotton is by the *willow*, which opens up the matted fleece of the wool-stapler, and cleans it from accidental impurities. Sheep's wool for working into coarse goods must be passed repeatedly through this machine, both before and after it is dyed; the second last time for the purpose of blending the different sorts together, and the last for imbuing the fibres intimately with oil. The oiled wool is next subjected to a first carding operation called *scribbling*, whereby it is converted into a broad thin fleece or lap, as cotton is by the breaker-cards of a cotton mill. The woollen lap is then worked by the cards proper, which deliver it in a narrow band or sliver. By this process the wool expands greatly in all its dimensions; while the broken or short filaments get entangled by crossing in every possible direction, which prepares them for the fulling operation. See *Carding*, under Cotton Manufacture.

The *slubbing machine*, or *billy*, reduces the separate rolls of *cardings* into a continuous slightly twisted spongy cord, which is sometimes called a roving. *Fig.* 1949 is a perspective representation of the slubbing machine in most common use. A, A, is the wooden frame; within which is the movable carriage D, D, which runs upon the lower side rails at *a*, *a*, on friction wheels at 1, 2, to make it move easily backwards and forwards from one end of the frame to the other. The carriage contains a series of steel spindles, marked 3, 3, which receive rapid rotation from a long tin drum F, by means of a series of cords passing round the pulley or whorl of each spindle. This drum, 6 inches in diameter, is covered with paper, and extends across the whole breadth of the carriage. The spindles are set nearly upright in a frame, and about 4 inches apart; their under ends being pointed conically, turn in brass sockets called steps, and are retained in their position by a small brass collet, which embraces each spindle at about the middle of its length. The upper half of each spindle projects above the top of the frame. The drum revolves horizontally before the spindles, having its axis a little below the line of the whorls; and receives motion, by a pulley at one of its ends, from an endless band which passes round a

1949



wheel E, like the large domestic wheel formerly used in spinning wool by hand, and of similar dimensions. This wheel is placed upon the outside of the main frame of the machine, and has its shafts supported by upright standards upon the carriage D. It is turned by the spinner placed at Q, with his right hand applied to a winch R, which gives motion to the drum, and thereby causes the spindles to revolve with great velocity.

Each spindle receives a soft cylinder or carding of wool, which comes through beneath a wooden roller C, C, at the one end of the frame. This is the *billy roller*, so much talked of in the controversies between the operatives and masters in the cotton factories, as an instrument of cruel punishment to children, though no such machine has been used in cotton mills for half a century at least. These woollen rolls proceed to the series of spindles, standing in the carriage, in nearly a horizontal plane. By the alternate advance and retreat of the carriage upon its railway, the spindles are made to approach to, and recede from, the roller c, with the effect of drawing out a given length of the soft cord, with any desired degree of twist, in the following manner:—

The carding rolls are laid down straight, side by side, upon the endless cloth, strained in an inclined direction between two rollers, one of which is seen at B, and the other lies behind c. One carding is allotted to a spindle; the total number of each in one machine being from 50 to 100. The roller c, of light wood, presses gently with its weight upon the cardings, while they move onwards over the endless cloth, with the running out of the spindle carriage. Immediately in front of the said roller, there is a horizontal wooden rail or bar G, with another beneath it, placed across the frame. The carding is conducted through between these two bars, the movable upper one being raised to let any aliqnot portion of the roll pass freely. When this bar is again let down, it pinches the spongy carding fast; whence this mechanism is called the clasp. It is in fact the *clove*, originally used by Hargreaves in his cotton-jenny. The movable upper rail G, is guided between sliders, and a wire 7, descends from it to a lever c. When the spindle carriage D, D, is wheeled close home to the billy roller, a wheel 5, lifts the end 6 of the lever, which, by the wire 7, raises the upper bar or rail G, so as to open the clasp, and release all the card rolls. Should the carriage be now drawn a little way from the clasp bars, it would tend to pull a corresponding length of the cardings forward from the inclined plane B, C. There is a small catch, which lays hold of the upper bar of the clasp G, and hinders it from falling till the carriage has receded to a certain distance, and has thereby allowed from 7 to 8 inches of the cardings to be taken out. A stop upon the carriage then comes against the catch, and withdraws it; thus allowing the upper rail to fall and pinch the carding, while the carriage, continuing to recede, draws out or stretches that portion of the roll which is between the clasp and the spindle points. But during this time the wheel has been turned to keep the spindles revolving, communicating the proper degree of twist to the cardings in proportion to their extension, so as to prevent them from breaking.

It might be imagined that the slubbing cords would be apt to coil round the spindles; but as they proceed in a somewhat inclined direction to the clasp, they receive merely a twisting motion, continually slipping over the points of the spindles, without getting wound upon them. Whenever the operative or slubber has given a due degree of twist to the rovings, he sets about winding them upon the spindles into a conical shape, for which purpose he presses down the faller-wire 8, with his left hand, so as to bear it down from the points of the spindles, and place it opposite to their middle part. He next makes the spindles revolve, while he pushes in the carriage slowly, so as to coil the slubbing upon the spindle into a conical cop. The wire 8, regulates the winding on of the whole series of slubbings at once, and receives its proper angle of depression for this purpose from the horizontal rail 4, which turns upon pivots in its ends, in brasses fixed on the standards, which rise from the carriage D. By turning this rail on its pivots, the wire 8 may be raised or lowered in any degree. The slubber seizes the rail 4 in his left hand, to draw the carriage out; but in returning it, he depresses the faller-wire, at the same time that he pushes the carriage before him.

The cardings are so exceedingly tender, that they would readily draw out, or even break, if they were dragged with friction upon the endless cloth of the inclined plane. To save this injurious traction, a contrivance is introduced for moving the apron. A cord is applied round the groove in the middle part of the upper roller, and after passing over pulleys, as shown in the figure, it has a heavy weight hung at the one end, and a light weight at the other, to keep it constantly extended, while the heavy weight tends to turn the rollers with their endless cloth round in such a direction as to bring forward the rovings, without putting any strain upon them. Every time that the carriage is pushed home, the larger weight gets wound up; and when the carriage is drawn out, the greater weight turns the roller, and advances the endless apron, so as to deliver the carding at the same rate as the carriage runs out; but when the proper quantity is delivered, a knot in the rope arrives at a fixed stop, which does not permit it to move any further; while at the same instant the roller 5 quits the lever 6, and allows the upper rail G, of the clasp to fall, and pinch the carding fast; the wheel E, being then set in motion, makes the spindles revolve; and the carriage being simultaneously drawn out, extends the slubbings while under the influence of twisting. In winding up the slubbings the operative must take care to push in the carriage, and to turn the wheel round at such rates that the spindles will not take up faster than the carriage moves on its railway, or he would injure the slubbings. The machine requires the attendance of a child, to bring the cardings from the card-engine, to place them upon the sloping feed-cloth, and to join the ends of the fresh ones carefully to the ends of the others newly drawn under the roller. Slubbings intended for warp-yarn must be more twisted than those for weft; but each must receive a degree of torsion relative to the quality of the wool and of the cloth intended to be made. In general, however, no more twist should be given to the slubbings than is indispensable for enabling them to be drawn out to the requisite slenderness without breaking. This twist forms no part of the twist of the finished yarn, for the slubbing will be twisted in the contrary direction, when spun afterwards in the jenny or mule.

I may here remark, that various machines have been constructed of late years for making continuous card-ends, and slubbings, in imitation of the carding and roving of the COTTON MANUFACTURE; to which article I therefore refer my readers. The wool slubbings are now spun into yarn, in many factories, by means of the mule. Indeed, I have seen in France the finest yarn, for the *mousseline-de-laine* fabrics, beautifully spun upon the self-actor mule of Sharp and Roberts.*

Tentering.—When the cloth is returned from the fulling-mill (which see), it is stretched upon the tenter frame, and left in the open air till dry.

In the woollen manufacture, as the cloth suffers, by the operation of the fulling-mill, a shrinkage of its breadth to well nigh one half, it must at first be woven of nearly double its intended width when finished. Superfine six-quarter broad cloths must therefore be turned out of the loom twelve-quarters wide.

Burling is the name of a process, in which the dried cloth is examined minutely in every part, freed from knots or uneven threads, and repaired by sewing any little rents, or inserting sound yarns in the place of defective ones.

Teasling.—The object of this operation is to raise up the loose filaments of the woollen yarn into a nap upon one of the surfaces of the cloth, by scratching it either with thistle-heads, called teasels, or with teasling-cards or brushes, made of wire. The natural teasels are the balls which contain the seeds of the plant called *Dipsacus fullorum;* the scales which form the balls, project on all sides, and end in sharp elastic points, that turn downwards like hooks. In teasling by hand, a number of these balls are put into a small wooden frame, having crossed handles, eight or ten inches long; and when thus filled, form an implement not unlike a curry-comb, which is used by two men, who seize the teasel-frame by the handles, and scrub the face of the cloth, hung in a vertical position from two horizontal rails, made fast to the ceiling of the workshop. First, they wet the cloth and work three times over, by strokes in the direction of the warp, and next of that of the weft, so as to raise all the loose fibres from the felt, and to prepare it for shearing. In large manufactories, this dressing operation is performed by a machine called a gig-mill, which originally consisted, and in most places still consists, of a cylinder bristled all over with the thistle-heads, and made to revolve rapidly while the cloth is drawn over it in a variety of directions. If the thistle be drawn in the line of the warp, the points act more efficaciously upon the weft, being perpendicular to its softer spun yarns. Inventors who have tried to give the points a circular or oblique action between the warp and the weft, proceed apparently upon a false principle, as if the cloth were like a plate of metal, whose substance could be pushed in any direction. Teasling really consists in drawing out one end of the filaments, and leaving the body of them entangled in the cloth; and it should seize and pull them perpendicularly to their length, because in this way it acts upon the ends, which being least implicated, may be most readily disengaged.

When the hooks of the thistles become clogged with flocks of wool, they must be taken out of the frame or cylinder, and cleaned by children with a small comb. Moisture, moreover, softens their points, and impairs their teasling powers; an effect which needs to be counterbalanced, by taking them out, and drying them from time to time. Many contrivances have, therefore, been proposed, in which metallic teasels of an unchangeable nature, mounted in rotatory machines, driven by power, have been substituted for the vegetable, which being required in prodigious quantities, become sometimes excessively scarce and dear in the clothing districts. In 1818, several schemes of that kind were patented in France, of which those of M. Arnold-Merick, and of MM. Taurin frères, of Elbœuf, are described in the 16th volume of *Brevets d'Invention expirés.* Mr. Daniell, cloth manufacturer in Wilts, renewed this invention under another form, by making his rotatory cards with two kinds of metallic wires, of unequal lengths; the one set, long thin, and delicate, representing the points of the thistle; the other, shorter, stiffer, and blunter, being intended to stay the cloth, and to

* See this admirable machine fully described and delineated in Dr. Ure's *Cotton Manufacture of Great Britain*, vol. ii.

hinder the former from entering too far into it. But none of these processes have succeeded in discarding the natural teasel from the most eminent manufactories.

The French government purchased, in 1807, the patent of Douglas, an English mechanist, who had, in 1802, imported into France, the best system of gig-mills then used in the west of England. A working set of his machines having been placed in the *Conservatoire des Arts*, for public inspection, they were soon introduced into most of the French establishments, so as generally to supersede teasling (*lainage*) by hand. A description of them was published in the third volume of the *Brevets d'Invention*. The following is an outline of some subsequent improvements:—

1. As it was imagined that the seesaw action of the hand operative was in some respects more effectual than the uniform rotation of a gig-mill, this was attempted to be imitated by an alternating movement.

2. Others conceived that the seesaw motion was not essential, but that it was advantageous to make the teasels or cards act in a rectilinear direction, as in working by hand; this action was attempted by placing the two ends of the teasel-frame in grooves formed like the letter D, so that the teasel should act on the cloth only when it came into the rectlinear part. Mr. Wells, machine-maker, of Manchester, obtained a patent, in 1832, for this construction.

3. It was supposed that the teasels should not act perpendicularly to the weft, but obliquely or circularly upon the face of the cloth. Mr. Ferrabee, of Gloucester, patented, in 1830, a scheme of this kind, in which the teasels are mounted upon two endless chains, which traverse from the middle of the web to the selvage or list, one to the right, and another to the left hand, while the cloth itself passes under them with such a velocity, that the effect, or *resultant*, is a diagonal action, dividing into two equal parts the rectangle formed by the weft and warp yarns. Three patent machines of Mr. George Oldland—the first in 1830, the second and third in 1832—all proceed upon this principle. In the first, the teasels are mounted upon discs made to turn flat upon the surface of the cloth; in the second, the rotating discs are pressed by cork-screw spiral springs against the cloth, which is supported by an elastic cushion, also pressed against the discs by springs; and in the third machine, the revolving discs have a larger diameter, and they turn, not in a horizontal, but a vertical plane.

4. Others fancied that it would be beneficial to support the reverse side of the cloth by flat hard surfaces, while acting upon its face with cards or teasels. Mr. Joseph Cliseld Daniell, having stretched the cloth upon smooth level stones, teasels them by hand.

5. Messrs. Charlesworth and Mellor obtained a patent, in 1829, for supporting the back of the cloth with elastic surfaces, while the part was exposed to the teasling action.

6. Elasticity has also been imparted to the teasels, in the three patent inventions of Mr. Sevill, Mr. J. C. Daniell, and Mr. R. Atkinson.

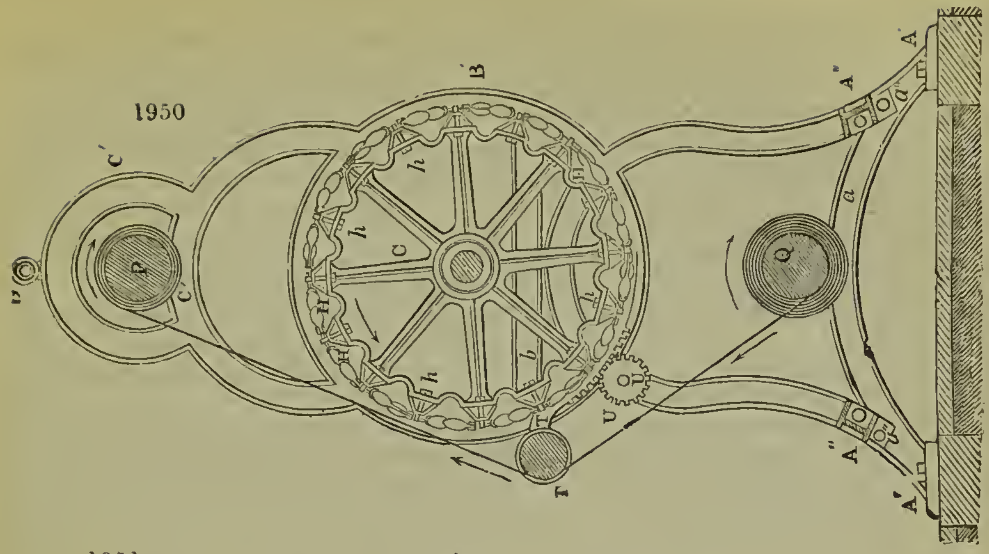
7. It has been thought useful to separate the teasel-frames upon the drum of the gig-mill, by simple rollers, or by rollers heated with steam, in order to obtain the combined effect of calendering and teasling. Mr. J. C. Daniell, Mr. G. Haden, and Mr. J. Rayner, have obtained patents for contrivances of this kind.

8. Several French schemes have been mounted for making the gig-drum act upon the two sides of the cloth, or even to mount two drums on the same machine.

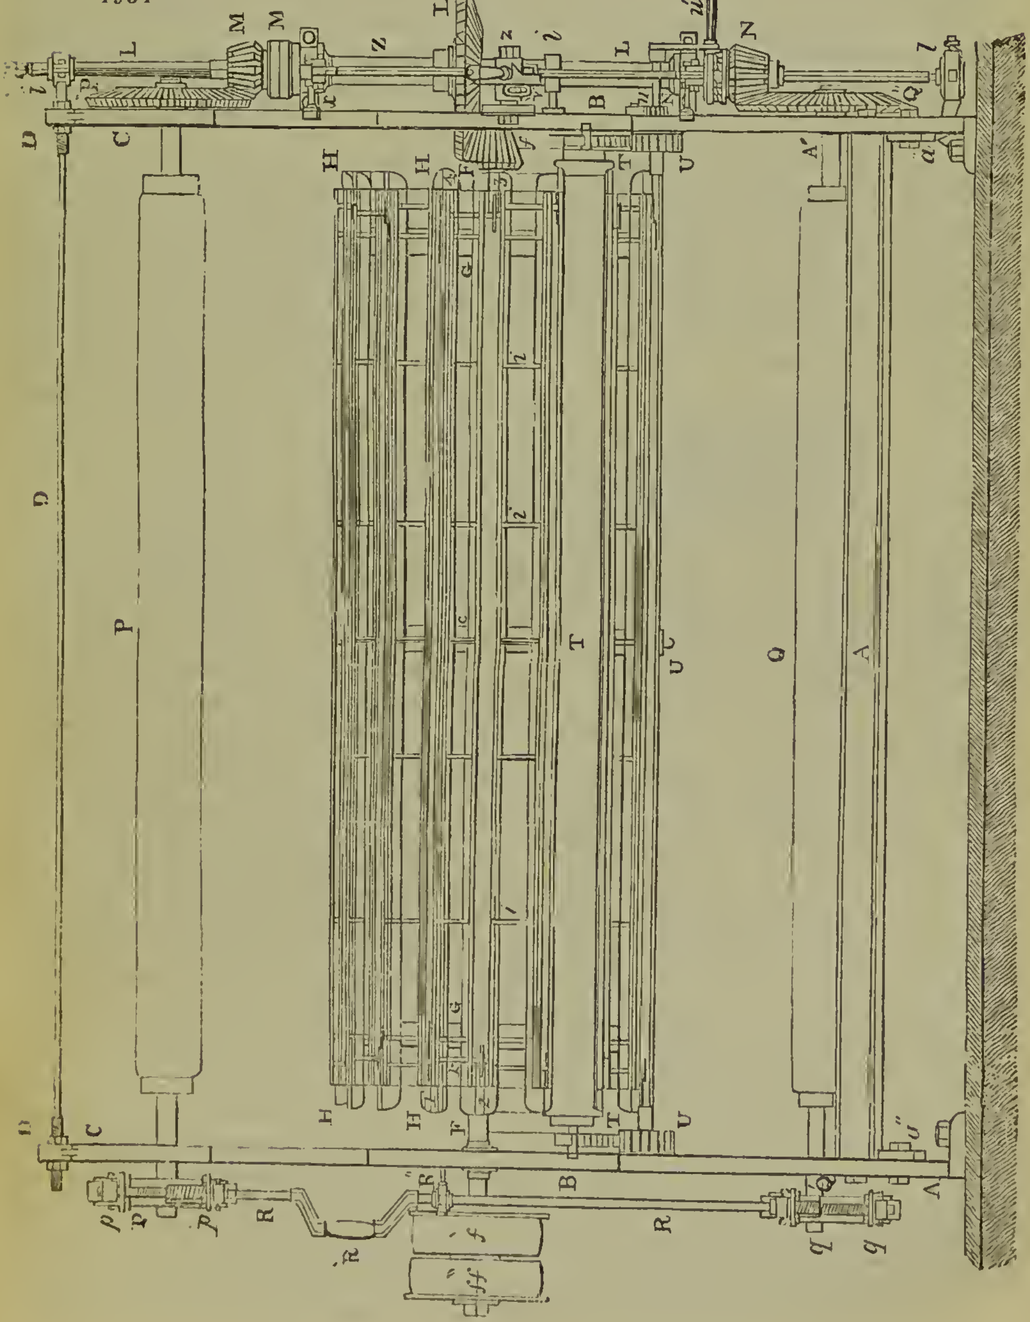
Mr. Jones, of Leeds, contrived a very excellent method of stretching the cloth, so as to prevent the formation of folds or wrinkles. (See *Newton's Journal*, vol. viii. 2nd series, page 126.) Mr. Collier, of Paris, obtained a patent, in 1830, for a greatly improved gig-mill, upon Douglas's plan, which is now much esteemed by the French clothiers. The following figures and description exhibit one of the latest and best teasling machines. It is the invention of M. Dubois and Co., of Louviers, and is now doing excellent work in that celebrated seat of the cloth manufacture.

In the fulling mill, the woollen web acquires body and thickness, at the expense of its other dimensions; for being thereby reduced about one-third in length, and one-half in breadth, its surface is diminished to one-third of its size as it comes out of the loom; and it has, of course, increased threefold in thickness. As the filaments drawn forth by teasling, are of very unequal lengths, they must be shorn to make them level, and with different degrees of closeness, according to the quality of the stuff, and the appearance it is desired to have. But, in general, a single operation of each kind is insufficient; whence, after having passed the cloth once through the gig-mill, and once through the shearing-machine (*tondeuse*), it is ready to receive a second teasling, deeper than the first, and then to suffer a second shearing. Thus, by the alternate repetition of these processes, as often as is deemed proper, the cloth finally acquires its wished-for appearance. Both of these operations are very delicate, especially the first; and if they be ill conducted, the cloth is weakened, so as to tear or wear most readily. On the other hand, if they be skilfully executed, the fabric becomes not only more

1950



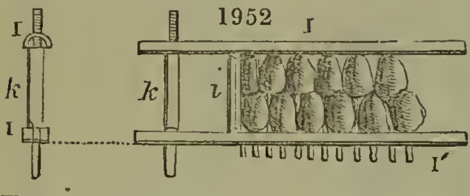
1951



sightly, but it acquires strength and durability, because its face is changed into a species of fur, which protects it from friction and humidity.

Figs. 1950, 1951, represent the gig-mill in section, and in front elevation. A, B, C, D, A′, B′, C′, D′, being the strong frame of iron, cast in one piece, having its feet enlarged a little more to the inside than to the outside, and bolted to large blocks in the stone pavement. The two uprights are bound together below by two cross-beams A″, being fastened with screw-bolts at the ears *a″*, *a″*; and at top, by two wrought-iron stretcher rods D, whose ends are secured by screw-nuts at D, D′. The drum is mounted upon a wrought-iron shaft F, which bears at its right end (*fig.* 1951), exterior to the frame, the usual riggers, or fast and loose pulley, *ff″*, *f′*, which give motion to the machine by a band from the main shaft of the mill. On its right end, within the frame, the shaft F, has a bevel wheel F′, for transmitting movement to the cloth, as shall be afterwards explained. Three crown wheels G, of which one is shown in the section, *fig.* 1950, are, as usual, keyed by a wedge to the shaft F. Their contour is a sinuous band, with six semi-cylindrical hollows, separated alternately by as many portions of the periphery. One of these three wheels is placed in the middle of the shaft F, and the other two, towards its extremities. Their size may be judged of, from inspection of *fig.* 1950. After having set them so that all their spokes or radii correspond exactly, the 16 sides H, are made fast to the 16 portions of the periphery, which correspond in the three wheels. These sides are made of sheet-iron, curved into a gutter form, *fig.* 1950, but rounded off at the end, *fig.* 1951, and each of them is fixed to the three felloes of the wheels by three bolts *h.* The elastic part of the plate iron allows of their being sufficiently well adjusted, so that their flat portions furthest from the centre may lie pretty truly on a cylindrical surface, whose axis wou'd coincide with that of the shaft F.

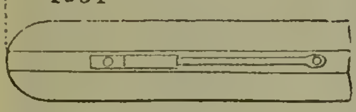
Between the 16 sides there are 16 intervals, which correspond to the 16 hollowings of each of the wheels. Into these intervals are adjusted, with proper precautions, 16 frames bearing the teasels which are to act upon the cloth. These are fitted in as follows:—Each has the shape of a rectangle, of a length equal to that of the drum, but their breadth only large enough to contain two thistle-heads set end to end, thus making two rows of parallel teasels throughout the entire length (see the contour in *fig.* 1950). A portion of the frame is represented in *fig.* 1952. The large side I, against which the tops of the teasels rest, is hollowed out into a semi-cylinder, and its opposite side is cleft throughout its whole length, to receive the tails of the teasels, which are seated and compressed in it. There are, moreover, cross-bars *i*, which serve to maintain the sides of the frame I, at an invariable distance, and to form short compartments for keeping the thistles compact.



The ends are fortified by stronger bars *k*, *k*, with projecting bolts to fasten the frames between the ribs. The distance of the sides of the frame I, I′, ought to be such, that if a frame be laid upon the drum, in the interval of two ribs, the side I will rest upon the inclined plane of one of the ribs, and the side I′ upon the inclined plane of the other (see *fig.* 1950); while at the same time the bars *k*, of the two ends of the frame rest upon the flat parts of the ribs themselves. This point being secured, it is obvious, that if the ends of the bars *k* be stopped, the frame will be made fast. But they need not be fixed in a permanent manner, because they must be frequently removed and replaced. They are fastened by the clamp, *figs.* 1953, 1954, which is shut at the one end, and furnished at the other with a spring, which can be opened or shut at pleasure. 2 and 4, in *fig.* 1951 (near the right end of the shaft F), shows the place of the clamp, *figs.* 1953, 1954. The bar of the right hand is first set in the clamp, by holding up its other end; the frame is then let down into the left-hand clamp.

1953

1954



The cloth is wound upon the lower beam Q, *fig.* 1950; thence it passes in contact with a wooden cylinder T, turning upon an axis, and proceeds to the upper beam P, on to which it is wound: by a contrary movement the cloth returns from the beam P to Q, over the cylinder T; and may thus go from the one to the other as many times as shall be requisite. In these successive circuits it is presented to the action of the teasels, under certain conditions. In order to be properly teasled, it must have an equal tension throughout its whole breadth during its traverse; it must be brought into more or less close contact with the drum, according to the nature of the cloth, and the stage of the operations; sometimes being a tangent to the surface, and sometimes embracing a greater or smaller portion of its contour, it must travel with a determinate speed, dependent upon the velocity of the drum, and calculated so as to produce the best result: the machine itself must make the stuff pass alternately from one winding beam to the other.

In *fig.* 1951, before the front end of the machine, there is a vertical shaft L, as high as the framework, which revolves with great facility, in the bottom step *l*, the middle collet *l′*, and top collet *l″*, in the prolongation of the stretcher D. Upon this upright shaft are mounted—1, a bevel wheel L′; 2, an upper bevel pinion M, with its boss M′; 3, a lower bevel pinion N, with its boss N′. The bevel wheel L′ is keyed upon the shaft L, and communicates to it the movement of rotation which it receives from the pinion *f*, with which it is in gear; but the pinion *f*, which is mounted upon the shaft F of the drum, participates in the rotation which this shaft receives from the prime mover, by means of the fast rigger-pulley *f′*. The upper pinion M is independent upon the shaft L; that is to say, it may be slidden along it, up and down, without being driven by it; but it may be turned in an indirect manner by means of six curved teeth, projecting from its bottom, and which may be rendered active or not at pleasure; these curved teeth, and their intervals, correspond to similar teeth and intervals upon the top of the boss M′, which is dependent, by feathered indentations, upon the rotation of L, though it can slide freely up and down upon it. When it is raised, therefore, it comes into gear with M. The pinion N, and its boss, have a similar mode of being thrown into and out of gear with each other. The bosses M′ and N′, ought always to be moved simultaneously, in order to throw one of them into gear, and the other out of gear. The shaft L serves to put the cloth in motion, by means of the bevel wheels P″ and Q″, upon the ends of the beams P and Q, which take into the pinions M and N.

The mechanism destined to stretch the cloth is placed at the other end of the machine, where the shafts of the beams, P, Q, are prolonged beyond the frame, and bear at their extremities P′ and Q′, armed each with a brake. The beam P (*fig.* 1950), turns in an opposite direction to the drum; consequently the cloth is wound upon P, and unwound from Q. If, at the same time as this is going on, the handle R, of the brake-shaft, be turned so as to clasp the brake of the pulley Q′ and release that of the pulley P′, it is obvious that a greater or smaller resistance will be occasioned in the beam Q, and the cloth which pulls it in unwinding, will be able to make it turn only when it has acquired the requisite tension; hence it will be necessary, in order to increase or diminish the tension, to turn the handle R′ a little more or a little less in the direction which clasps the brake of the pulley Q′; and as the brake acts in a very equable manner, a very equable tension will take place all the time that the cloth takes to pass. Besides, should the diminution of the diameter of the beam Q, render the tension less efficacious in any considerable degree, the brake would need to be unclamped a very little, to restore the primitive tension.

When the cloth is to be returned from the beam P, to the beam Q, Z must be lowered, to put the shaft L out of gear above, and in gear below; then the cloth-beam Q, being driven by that vertical shaft, it will turn in the same direction as the drum, and will wind the cloth round its surface. In order that it may do so, with a suitable tension, the pulley Q′ must be left free, by clasping the brake of the pulley P′ so as to oppose an adequate resistance.

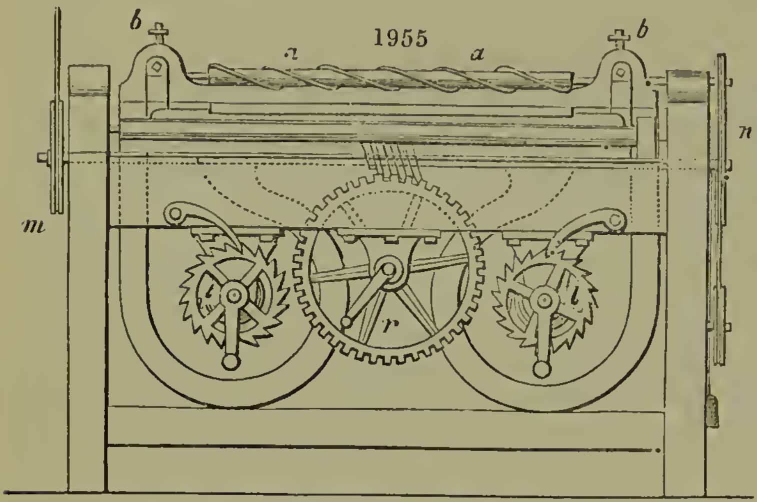
The cloth is brought into more or less close contact with the drum as follows:— There is for this purpose a wooden roller, T, against which it presses in passing from the one winding beam to the other, and which may have its position changed relatively to the drum. It is obvious, for example, that in departing from the position represented in *fig.* 1950, where the cloth is nearly a tangent to the drum, if the roller T′ be raised, the cloth will cease to touch it; and if it be lowered, the cloth will, on the contrary, embrace the drum over a greater or less portion of its periphery. For it to produce these effects, the roller is borne at each end, by iron gudgeons, upon the heads of an arched rack T″ (*fig.* 1950), where it is held merely by pins. These racks have the same curvature as the circle of the frame, against which they are adjusted by two bolts; and by means of slits, which these bolts traverse, they may be slidden upwards or downwards, and consequently raise or depress the roller T. But to graduate the movements, and to render them equal in the two racks, there is a shaft U, supported by the uprights of the frame, and which carries, at each end, pinions U′, U″, which work into the two racks T′, T″: this shaft is extended in front of the frame, upon the side of the head of the machine (*fig.* 1951), and there it carries a ratchet wheel *u*, and a handle *u′*. The workman, therefore, requires merely to lay hold of the handle, and turn it in the direction of the ratchet wheel, to raise the racks, and the roller T, which they carry; or to lift the click or catch, and turn the handle in the opposite direction, when he wishes to lower the roller, so as to apply the cloth to a larger portion of the drum.

Cloth Cropping.

Of machines for cropping or shearing woollen cloths, those of Lewis and Davis have been very generally used.

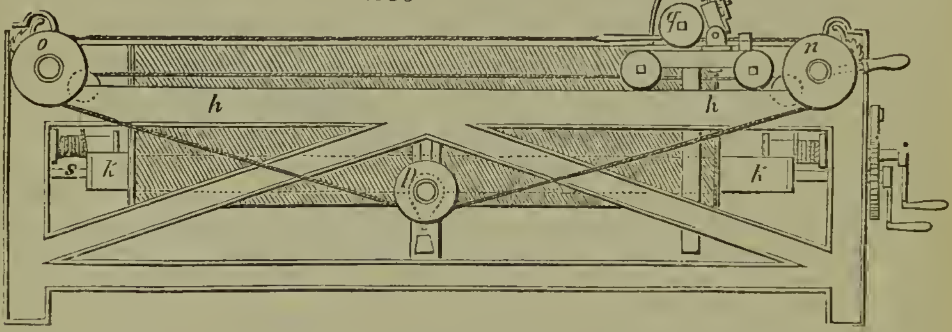
Fig. 1955 is an end view, and *fig.* 1956 is a side view, of Lewis's machine for shearing cloth from list to list. *Fig.* 1957 is an end view of the carriage, with the rotatory cutter detached from the frame of the machine, and upon a larger scale: *a*, is a cylinder of metal, on which is fixed a triangular steel wire; this wire is previously bent round the cylinder in the form of a screw, as represented at *a*, *a*, in *fig.* 1955, and, being hardened, is intended to constitute one edge of the shear or cutter.

1955



The axis of the cylindrical cutter *a*, turns in the frame *b*, which, having proper adjustments, is mounted upon pivots *c*, in the standard of the travelling carriage *d*, *d*; and *e*, is the fixed or ledger blade, attached to a bar *f*, which constitutes the other edge of the cutter; that is, the stationary blade, against which the edges of the rotatory cutter act; *f* and *g*, are flat springs, intended to keep the cloth (shown by dots) up against the cutting edges. The form of these flat springs *f*, *g*, is shown at *figs.* 1958 and 1959, as consisting of plates of thin metal cut into narrow slips (*fig.* 1958), or perforated with long holes (*fig.* 1959). Their object is to support the cloth,

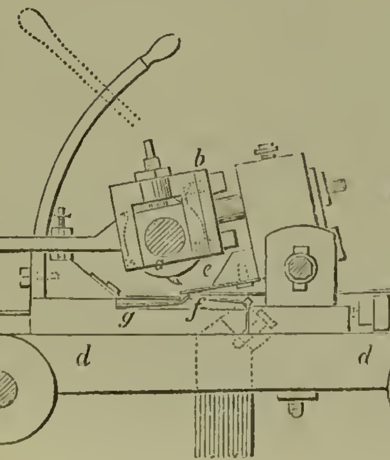
1956



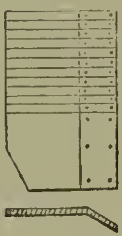
which is intended to pass between them, and operate as a spring bed, bearing the surface of the cloth against the cutters, so that its pile or nap may be cropped off or shorn as the carriage *d* is drawn along the top rails of the standard or frame of the machine *h*, *h*, by means of cords.

1958

1957



1959



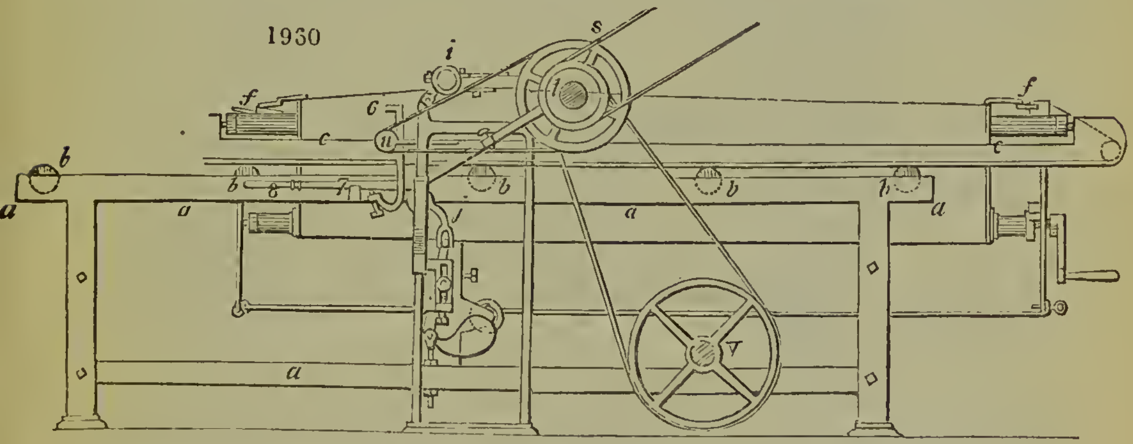
The piece of cloth to be shorn, is wound upon the beam *k*, and its end is then conducted through the machine, between the flat springs *f* and *g* (as shown in *fig.* 1957), to the other beam *l*, and is then made fast; the sides or lists of the cloth being held and stretched by small hooks, called habiting hooks. The cloth being thus placed in the machine, and drawn tight, is held distended by means of ratchets on the ends of the beams *k* and *l*, and palls. In commencing the operation of shearing, the carriage *d*, must be brought back, as in *fig.* 1957, so that the cutters shall be close to the list; the frame of the cutters is raised up on its pivots as it recedes, in order to keep the cloth from injury, but is lowered again previously to being put in action. A band or winch is applied to the rigger or pulley *m*, which, by means of an endless cord passed round the pulley *n*, at the reverse end of the axle of *m*, and round the other pulleys *o* and *p*, and the small pulley *q*, on the axle of the cylindrical cutter, gives the cylindrical cutter a very rapid rotatory motion; at the same time a worm, or endless screw, on the axle of *m* and *n*, taking into the teeth of the large wheel *r*, causes that wheel to revolve, and a small drum *s*, upon its axle, to coil up the cord, by which the carriage *d*, with the cutters *a* and *e*, and the spring bed *f* and *g*, are slowly, but progressively, made to advance, and to carry the cutters over the face of the cloth, from list to list; the rapid rotation of the cutting cylinder *a*, producing the operation of cropping or shearing the pile.

Upon the cutting cylinder, between the spiral blades, it is proposed to place stripes of plush, to answer the purpose of brushes, to raise the nap or pile as the cylinder goes around, and thereby assist in bringing the points of the wool up to the cutters.

The same contrivance is adapted to a machine for shearing the cloth lengthwise.

Fig. 1960, is a geometrical elevation of one side of Mr. Davis's machine. *Fig.* 1961, a plan or horizontal representation of the same, as seen at top; and *fig.* 1962, a section taken vertically across the machine near the middle, for the purpose of displaying the working parts more perfectly than in the two preceding figures. These three figures represent a complete machine in working condition, the cutters being worked by a rotatory motion, and the cloth so placed in the carriage as to be cut from list to list. *a*, *a*, *a*, is a frame or standard, of wood or iron, firmly bolted together by cross braces at the ends and in the middle. In the upper side-rails of the standard, there is a series of axles carrying anti-friction wheels, *b*, *b*, *b*, upon which the side-rails *c*, *c*, of the carriage or frame that bears the cloth runs, when it is passing under the cutters in the operation of shearing. The side-rails *c*, *c*, are straight bars of iron, formed with edges *v*, on their under sides, which runs smoothly in the grooves of the rollers *b*, *b*, *b*. These side-rails are firmly held together by the end stretchers *d*, *d*. The sliding frame has attached to it the two lower rollers *e*, *e*, upon

1930

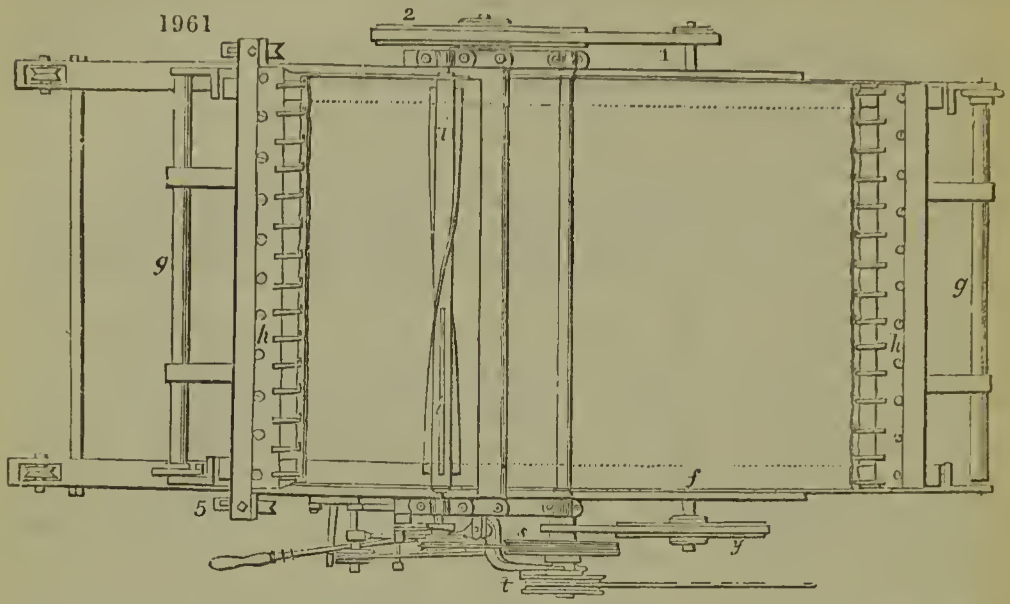


which the cloth intended to be shorn is wound; the two upper lateral rollers *f*, *f*, over which the cloth is conducted and held up; and the two end rollers *g*, *g*, by which the habiting rails *h*, *h*, are drawn tight.

In preparing to shear a piece of cloth, the whole length of the piece is, in the first place tightly rolled upon one of the lower rollers *e*, which must be something longer than the breadth of the cloth from list to list. The end of the piece is then raised and passed over the top of the lateral rollers *f*, *f*, whence it is carried down to the other roller *e*, and its end or farral is made fast to that roller. The hooks of the habiting rails *h*, *h*, are then put into the lists, and the two lower rollers *e*, *e*, with the two end rollers *g*, *g*, are then turned, for the purpose of drawing up the cloth, and straining it tight, which tension is preserved by ratchet wheels attached to the ends of the respective rollers, with palls dropping into their teeth. The frame carrying the cloth is now slidden along upon the stop standard rails by hand, so that the list shall be brought nearly up to the cutter *i*, *i*, ready to commence the shearing operation; the bed is then raised, which brings the cloth up against the edges of the shears.

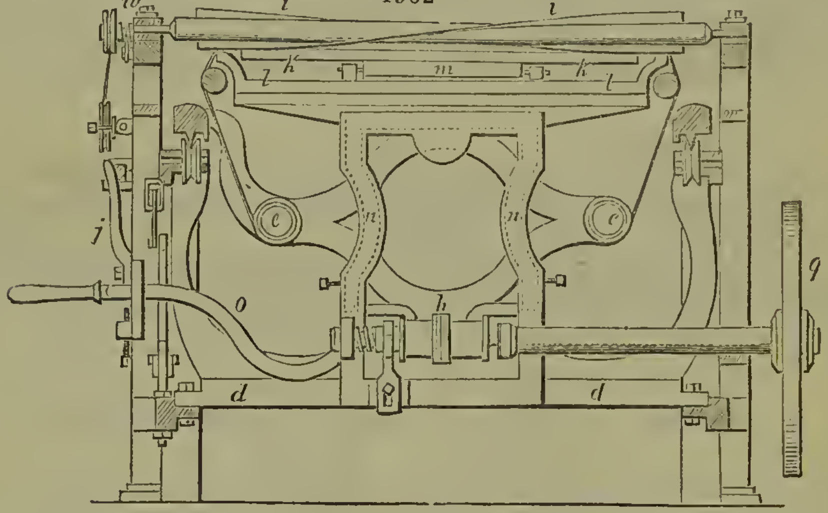
The construction of the bed will be seen by reference to the cross section *fig.* 1962. It consists of an iron or other metal roller, *k*, *k*, turned to a truly cylindrical figure, and covered with cloth or leather, to afford a small degree of elasticity. This roller is mounted upon pivots in a frame, *l*, *l*, and is supported by a smaller roller *m*,

1961



similarly mounted, which roller *m*, is intended merely to prevent any bending or depression of the central part of the upper roller or bed *k*, *k*, so that the cloth may be kept in close contact with the whole length of the cutting blades.

1962

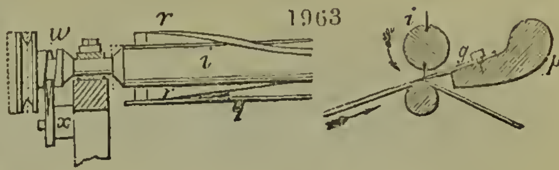


In order to allow the bed *k* to rise and fall, for the purpose of bringing the cloth up to the cutters to be shorn, or lowering it away from them after the operation, the frame *l*, *l*, is made to slide up and down in the grooved standard *n*, *n*, the movable part enclosed within the standard being shown by dots. This standard *n*, is situated about the middle of the machine, crossing it immediately under the cutters, and is made fast to the frame *a*, by bolts and screws. There is a lever, *o*, attached to the lower cross-rail of the standard, which turns upon a fulcrum-pin, the extremity of the shorter arm of which lever acts under the centre of the sliding-frame, so that by the lever *o*, the sliding-frame, with the bed, may be rased or lowered, and when so raised, be held up by a spring catch *j*.

It being now explained by what means the bed which supports the cloth is constructed, and brought up, so as to keep the cloth in close contact with the cutters, while the operation of shearing is going on; it is necessary, in the next place, to describe the construction of the cutters, and their mode of working; for which purpose, in addition to what is shown in the first three figures, the cutters are also represented detached, and upon a larger scale, in *fig.* 1963.

In this figure is exhibited a portion of the cutters in the same situation as in *fig.* 1957; and alongside of it is a section of the same, taken through it at right angles to the former; *p*, is a metallic bar or rib, somewhat of a wedge form, which is fastened to the top part of the standard *a*, *a*, seen best in *fig.* 1956. To this bar a straight blade of steel *g*, is attached by screws, the edge of which stands forward even with the centre or axis of the cylindrical cutter *i*, and forms the ledger blade, or lower fixed edge of the shears. This blade remains stationary, and is in close contact with the pile or nap of the cloth, when the bed *k*, is raised, in the manner above described.

1963



The cutter or upper blade of the shears, is formed by inserting two or more strips of plate steel, *r*, *r*, in twisted directions, into grooves in the metallic cylinder *i*, *i*, the edges of which blades *r*, as the cylinder *i* revolves, traverse along the edge of the fixed or ledger blade *g*, and by their obliquity produce a cutting action like shears; the edges of the two blades taking hold of the piled or raised nap, as the cloth passes under it, shaves off the superfluous ends of the wool, and leaves the face smooth.

Rotatory motion is given to the cutting cylinder *i*, by means of a band leading from the wheel *s*, which passes round the pulley fixed on the end of the cylinder *i*, the wheel *s* being driven by a band leading from the rotatory part of the steam-engine, or any other first mover, and passed round the rigger *t*, fixed on the axle *s*. Tension is given to this band by a tightening pulley, *u*, mounted on an adjustable sliding-piece, *v*, which is secured to the standard by a screw; and this trigger is thrown in and out of gear by a clutch-box and lever, which sets the machine going, or stops it.

In order to give a drawing stroke to the cutter, which will cause the piece of cloth to be shorn off with better effect, the upper cutter has a slight lateral action, produced by the axle of the cutting cylinder being made sufficiently long to allow of its sliding laterally about an inch in its bearings; which sliding is effected by a cam *w*, fixed at one end. This cam is formed by an oblique groove, cut round the axle (see *w*, *fig.* 1963), and a tooth, *x*, fixed to the frame or standard which works in it, as the cylinder revolves. By means of this tooth, the cylinder is made to slide laterally, a distance equal to the obliquity of the groove *w*, which produces the drawing stroke of the upper shear. In order that the rotation of the shearing cylinder may not be obstructed by friction, the tooth *x*, is made of two pieces, set a little apart, so as to afford a small degree of elasticity.

The manner of passing the cloth progressively under the cutters is as follows: — On the axle of the wheel *s*, and immediately behind that wheel, there is a small rigger, from which a band passes to a wheel *y*, mounted in an axle turning in bearings on the lower side-rail of the standard *a*. At the reverse extremity of this axle, there is another small rigger 1, from which a band passes to a wheel 2, fixed on the axle 3, which crosses near the middle of the machine, seen in *fig.* 1962. Upon this axle there is a sliding pulley 4, round which a cord is passed several times, whose extremities are made fast to the ends of the sliding carriage *d*; when, therefore, this pulley is locked to the axle, which is done by a clutch box, the previously described movements of the machine cause the pulley 4 to revolve, and by means of the rope passed round it, to draw the frame, with the cloth, slowly and progressively along under the cutters.

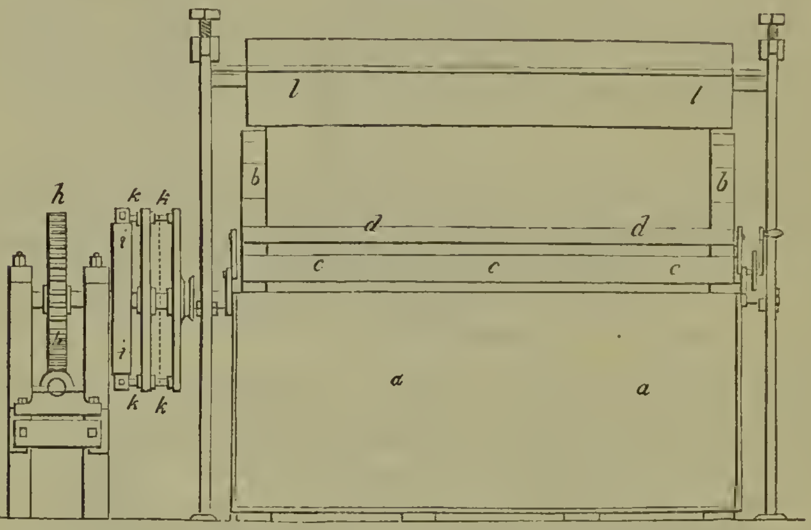
It remains only to point out the contrivance whereby the machinery throws itself out of gear, and stops its operations, when the edge of the cloth or list arrives at the cutters.

At the end of one of the habiting rails *h*, there is a stop affixed by a nut and screw 5, which, by the advance of the carriage, is brought up and made to press against a lever 6; when an arm from this lever 6, acting under the catch 7, raises the catch up, and allows the hand-lever 8, which is pressed upon by a strong spring, to throw the clutch-box 10, out of gear with the wheel 8; whereby the evolution of the machine instantly ceases. The lower part of the lever 6, being connected by a joint to the top of the lever *j*, the receding of the lever 6, draws back the lower catch *j*, and allows the sliding frame *l*, *l*, within the bed *k*, to descend. By now turning the lower rollers *e*, *e*, another portion of the cloth is brought up to be shorn; and when it is properly habited and strained, by the means above described, the carriage is slidden back, and, the parts being all thrown into gear, the operation goes on as before.

Mr. Hirst's improvements in manufacturing woollen cloths, for which a patent was obtained in February 1830, apply to that part of the process where a permanent lustre is given usually by what is called roll-boiling; that is, stewing the cloth, when tightly wound upon a roller, in a vessel of hot water or steam. As there are many disadvantages attendant upon the operation of roll-boiling, such as injuring the cloths, by overheating them, which weakens the fibre of the wool, and also changes some colours, he substituted, in place of it, a particular mode of acting upon the cloths, by occasional or intermitted immersion in hot water, and also in cold water, which operations may be performed either with or without pressure upon the cloth, as circumstances may require.

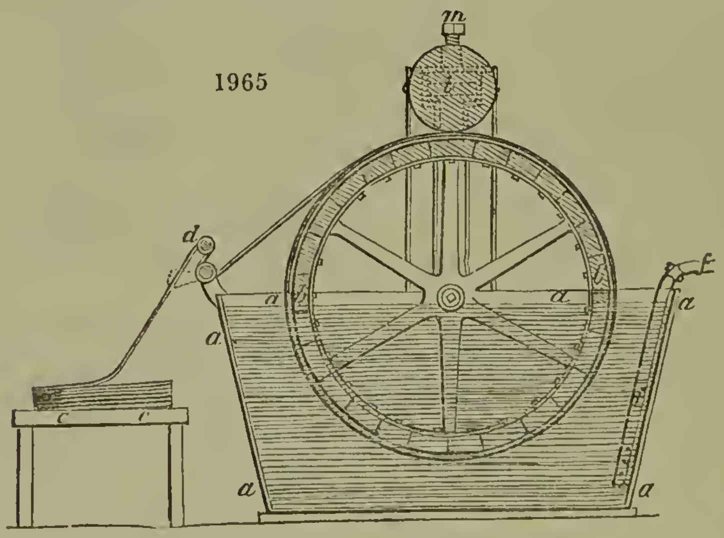
The apparatus which he proposes to employ for carrying on his improved process is shown in the accompanying drawing. *Fig.* 1964, is a front view of the apparatus, complete, and in working order; *fig.* 1965, is a section, taken transversely through the middle of the machine, in the direction of *fig.* 1966; and *fig.* 1966 is an end view of the same. *a*, *a*, *a*, is a vessel or tank, made of iron or wood, or any other suitable

1964



material: sloping at the back and front, and perpendicular at the ends. This tank must be sufficiently large to admit of half the diameter of the cylinder or drum *b*, *b*, *b*, being immersed into it, which drum is about four feet diameter, and about six feet long, or something more than the width of the piece of cloth intended to be operated upon. This cylinder or drum *b*, *b*, is constructed by combining segments of wood cut radially on their edges, secured by screw-bolts to the rims of the iron wheels, having arms, with an axle passing through the middle.

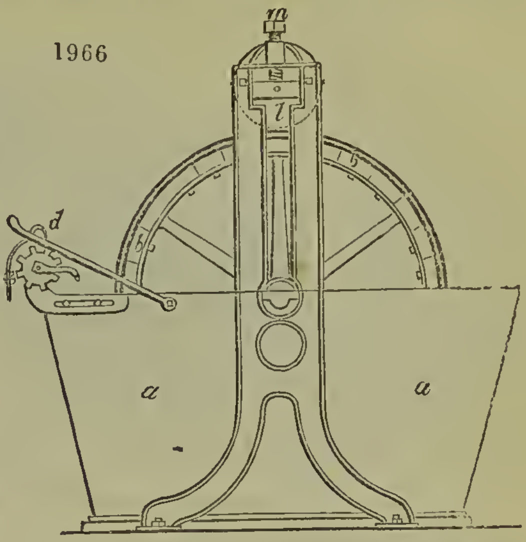
1965



The cylinder or drum being thus formed, rendered smooth on its periphery, and mounted upon its axle in the tank, the piece of cloth is wound upon it as tightly as possible, which is done by placing it in a heap upon a stool, as at *c*, *fig.* 1965, passing its end over and between the tension-rollers *d*, *e*, and then securing it to the drum, the cloth is progressively drawn from the heap, between the tension-rollers, which are confined by a pall and ratchet, on to the periphery of the drum, by causing the drum to revolve upon its axis, until the whole piece of cloth is tightly wound upon the drum; it is then bound round with canvas or other wrappers, to keep it secure.

If the tank has not been previously charged with clean and pure water, it is now filled to the brim, as shown at *fig.* 1965, and opening the stopcock of the pipe *f*, which leads from a boiler, the steam is allowed to blow through the pipe, and discharge itself at the lower end, by which means the temperature of the water is raised in the tank to about 170° Fahr. Before the temperature of the water has got up, the drum is set in slow rotatory motion, in order that the cloth may be uniformly heated throughout; the drum making about one rotation per minute. The cloth, by immersion in the hot water, and passing through the cold air, in succession, for the space of about eight hours, gets a smooth soft face, the texture not being rendered harsh, or otherwise injured, as is frequently the case by roll-boiling.

1966



Uniform rotatory motion to the drum is shown in *fig.* 1964, in which *g* is an endless screw or worm, placed horizontally, and driven by a steam-engine or any other first mover employed in the factory. This endless screw takes into the teeth of, and drives, the vertical wheel *h*, upon the axle of which the coupling-box *i*, *i*, is fixed, and, consequently, continually revolves with it. At the end of the shaft of the drum, a pair of sliding clutches *k*, *k*, are mounted, which, when projected forward, as shown by dots in *fig.* 1964, produce the coupling or locking of the drum-shaft to the driving wheel, by which the drum is put in motion; but on withdrawing the clutches *k*, *k*, from the coupling-box *i*, *i*, as in the figure, the drum immediately stands still.

After operating upon the cloth in the way described, by passing it through hot water for the space of time required, the hot water is to be withdrawn by a cock at the bottom, or otherwise, and cold water introduced into the tank in its stead; in which cold water the cloth is to be continued turning, in the manner above described, for the space of twenty-four hours, which will perfectly fix the lustre that the face of the cloth has acquired by its immersion in the hot water, and leave the pile or nap, to the touch, in a soft silky state.

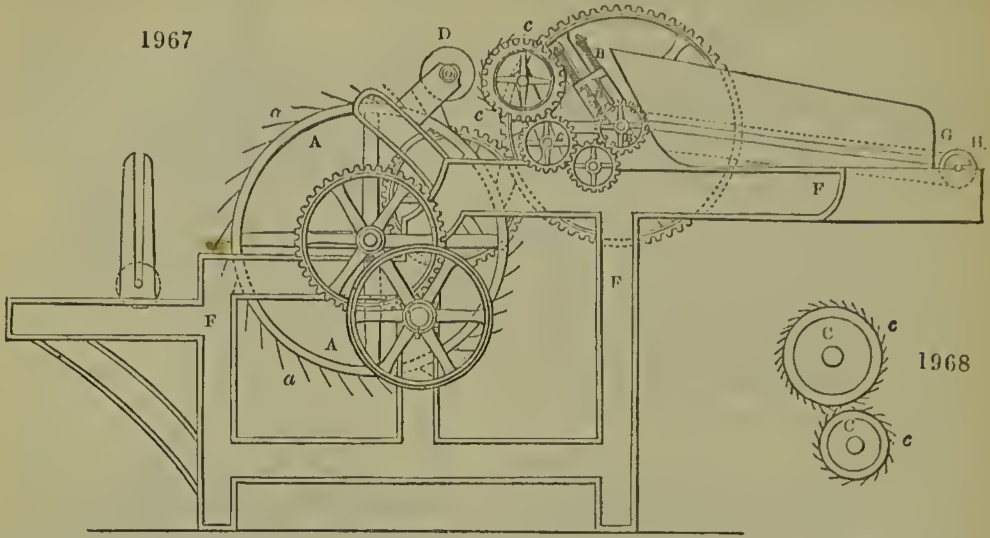
In the cold-water operation he sometimes employs a heavy pressing roller *l*, which being mounted in slots in the frame or standard, revolves with the large drum, rolling over the back of the cloth as it goes round. This roller may be made to act upon the cloth with any required pressure, by depressing the screws *m*, *m*, or by the employment of weighted levers, if that should be thought necessary.

Pressing is the last finish of cloth to give it a smooth level surface. The pieee is folded backwards and forwards in yard lengths, so as to form a thick package on the board of a screw or hydraulic press. Between every fold sheets of glazed paper are placed to prevent the contiguous surfaces of the cloth from coming into contact; and at the end of every twenty yards, three hot iron plates are inserted between the folds, the plates being laid side by side, so as to occupy the whole surface of the folds. Thin sheets of iron not heated are also inserted above and below the hot plates to moderate the heat. When the packs of cloth are properly folded, and piled in sufficient number in the press, they are subjected to a severe compression, and left under its influence till the plates get cold. The cloth is now taken out and folded again, so that the creases of the former folds may come opposite to the flat faces of the paper, and be removed by a second pressure. In finishing superfine cloths, however, a very slight pressure is given with iron plates but moderately warmed. The satiny lustre and smoothness given by strong compression with much heat is objectionable, as it renders the surface apt to become spotted and disfigured by rain.

Ross's patent improvements in wool combing machinery, March 13, 1851.— The first improvements described have relation to the machine for forming the wool into sheets of a nearly uniform thickness, technically known as the "sheeter," and consists chiefly in combining with the ordinary sheeting drum or cylinder rollers, designated, from their resemblance to porcupine quills, porcupine rollers; these rollers having their teeth or quills set in rows, and the rows of one roller gearing or taking into the spaces between the rows of the other.

Fig. 1967 is an elevation of a sheeting machine thus constructed:— F F is the general frame work upon which the several working parts of the machine are mounted. A is the main or sheeting drum or cylinder, which is studded with rows of comb or "porcupine" teeth *a*, *a*, *a*, the length and fineness of which are varied according to the length of the staple of the wool or other material to be operated upon. Instead of

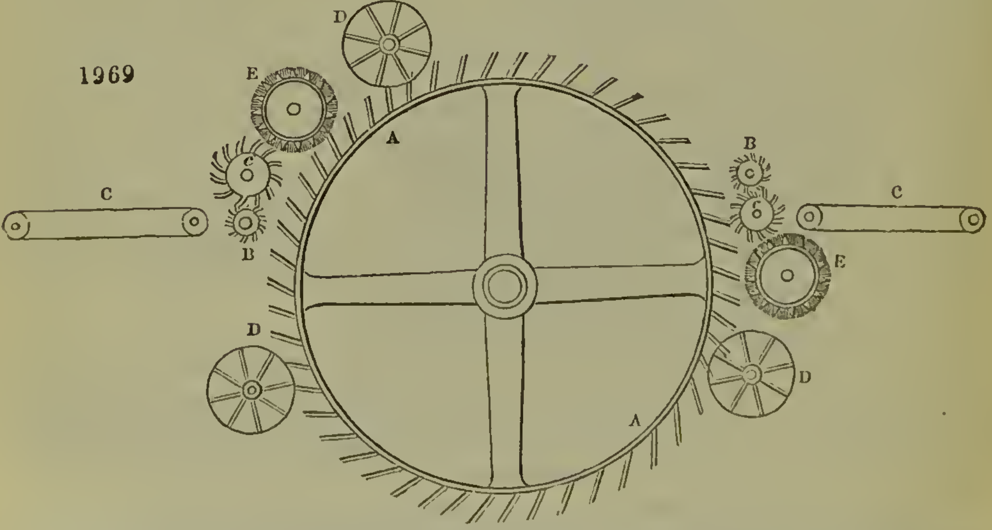
1967



1968

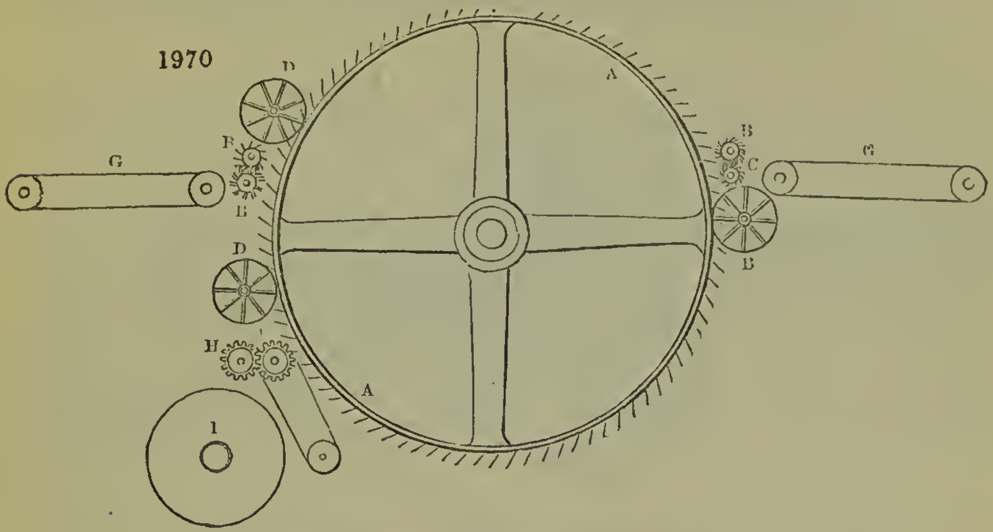
the rows consisting each of a single set of teeth, two, three, or more sets, may be combined together. The number of wires which may be placed on one line should vary with the quality of the wool or other material. In long staple machines, the number may vary from four to ten or more, and in short staple machines from five to twenty and more per inch. B, B, are two fluted feed-rollers. C, C, two porcupine combing rollers, by which the wool is partly combed while passing from the feed rollers to the surface of the sheeting drum; an end elevation of the porcupine combing rollers on an enlarged scale is given at *fig.* 1968. The teeth *c*, *c*, are set in rows, and the rows of one roller take or gear into the spaces between the rows of the other. D is a grooved guide roller for preventing the wool or other material escaping the combing action. The wool or other material is laid by the attendant evenly upon the upper surface of an endless web G, which works over the under feed rollers, and a plain roller H, which is mounted in bearings on the front of the machine. The feed-rollers gradually supply the wool thus spread upon the endless web to the two porcupine combing rollers, where it is partly combed and separated, and being so prepared, it is laid hold of by the teeth of the sheeting drum, by which it is still further drawn out on account of the greater velocity with which the surface of the sheeting drum travels. When a sufficient quantity of the wool or other material has been thus collected on the surface of the drum, it is removed by the attendant passing a hooked rod across the surface of the drum, and raising up one end of the sheet, when the whole may be easily stripped off and removed, being then in a fit state for being supplied to the comb-filling machine, next to be described.

1969



A modification of this sheeting machine is represented in *figs.* 1969, 1970, which differs from it in this, that it is fed from both ends. In this modification a double set of feeding rollers is employed, so that the machine may be fed from both ends. These rollers are grooved and gear into porcupine combing rollers similar to those

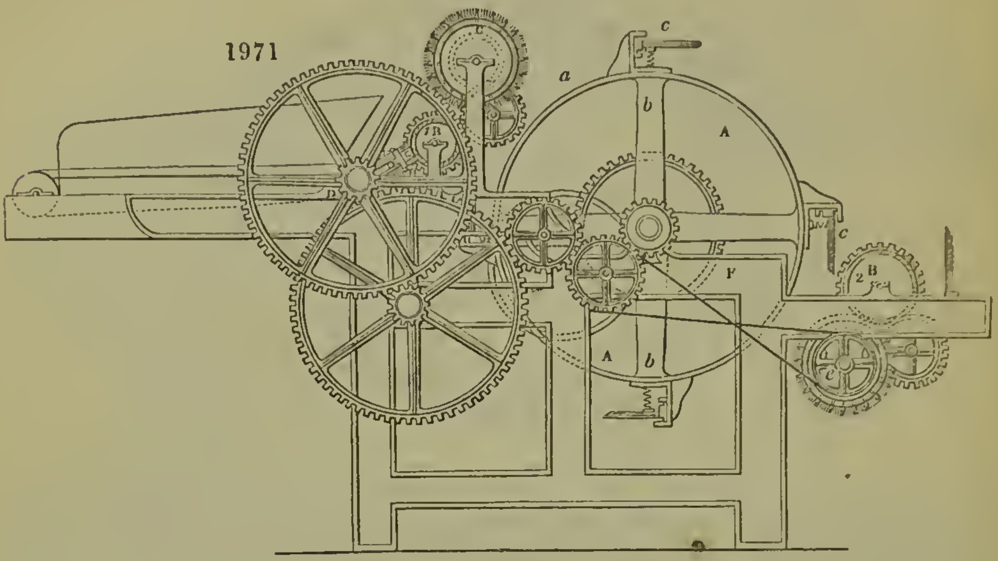
1970



before described, which are followed by brush cylinders or grooved guide rollers. A is the sheeting drum as before; B, B, the fluted feed-rollers. C, C, the porcupine combing rollers, which gear into the fluted ones ; D, D, are the grooved guide rollers; F, F, are brush cylinders, which may in the case of long work be dispensed with; G, G, are the endless webs upon which the wool is laid. The framing and gearing by which the several parts are put in motion are omitted in the drawings, for the purpose of clearly exhibiting the more important working parts of the machine. The arrangement of sheeting machines just described, in so far as regards the employment of a fluted feed roller in conjunction with a porcupine combing roller, and grooved guide roller, is more especially applicable to sheeting fine short wool, but may also be applied with advantage to wool or other material of a longer staple. In the case of fine short wool, the sheet may be drawn off by means of rollers, in the manner represented in *fig.* 1970. H, H, are the drawing or straightening rollers, and I the receiving roller. During the operation of drawing the wool and winding it on the receiving roller, the sheeting cylinder must have a motion imparted to it in the reverse direction.

The next head of Mr. Ross's specification embraces several improvements in comb-filling machines, which have for their common object the partial combing of the wool while it is in the course of being filled into the combs. We select for exemplification what the patentee regards as the best of these arrangements ; *fig.* 1971 is a side elevation of a comb filling mach ne as thus improved. A, A, is a skeleton drum, which is composed of two rings *a a*, affixed to the arms *b*, *b*, which last are mounted upon the main shaft of the machine, which has its bearings upon the general frame F, F ; B^1, B^2 are the porcupine combing rollers, and C^1, C^2 brushes by which the porcupine combing rollers are cleansed from the wool that collects upon them, and by which the wool is again delivered to the combs *e*, *e* ; D, D, are the feed-rollers, and E an endless web which runs over the lower feed-roller and the plain roller G, which is situated at the front of the machine ; H, H, are the driving pulleys, by which the power is applied to the machine, and I, I, I, the wheel gearing by which motion is communicated to the different parts. The wool which has undergone the process of sheeting in the machine first described is spread upon the endless web E, and in passing between the feed-rollers, and between or under or over the porcupine combing rollers, is taken hold of by the combs *e*, *e*, as they revolve, and, being drawn under the first porcupine roller B^1 and the brush C^1, the continued revolution of the drum, and combs causes the wool to be brought into contact with the other porcupine combing roller B^2 and brush C^2. As the combs get filled, the wool is thus continuously being brought under the action of the porcupine combing rollers and brushes ; and each new portion of the wool taken up is instantly combed out. For some purposes the combing will be found carried so far by this operation that the wool will require no further preparation previous to being formed into slivers in the machine just described, and which is calculated for filling the combs and combing the wool or other fibrous material, when the staple is some considerable length (say from 4 to 16 inches), there are two porcupine comb rollers with their brushes employed ; but I do not confine myself to that number, as in some cases a single porcupine combing roller and brush will be found sufficient for the purpose of facilitating the process of combing and filling the combs; three or more rollers and brush cylinders may be used with advantage; such as where the staple is short, or where the fibrous material operated upon is very close, and separated with difficulty.

1971



Mr. Ross next describes some improvements in the combing machine of his invention patented in 1841, and now extensively used. The following general description will indicate with sufficient distinctness to those familiar with the machine, the nature of the improvements.

" First, I give to the saddle combs in the said machine a compound to-and-fro and up-and-down movement, whereby they recede from and advance towards the comb gates, and simultaneously therewith alternately rise and fall, so that each time the comb gates pass the saddle combs, they do so in a different plane, and thus the position of the combs in relation to each other, as well as to the hold they take of the wool or other material, is constantly being changed. Secondly, I employ a fan to lash the wool in the comb gate or flying comb up against the saddle comb, which renders it impossible for the wool to pass by the saddle comb without being acted upon by it. Thirdly, I attach the springs by which the gates are actuated to the lower arms of the combing gates, instead of their being placed parallel to the upright shaft of the machine as formerly, whereby a considerable gain in space and compactness is effected; and, fourthly, I use breaks to prevent the sudden jerk which is caused when the wool in the comb gate leaves its hold of the saddle comb or incline plane, and also to counteract the sudden recoil of the springs by which the comb gates are pressed in when these springs are released from the grip or pressure of the incline plane."

Mr. Ross concludes with a description of an improved method of heating the combs which has for its object "the economising of fuel, the better heating of the combs, and the prevention of mistake in removing the combs before they have been a sufficient time exposed to the heat."

The body of the heating box or stove is divided by a partition into two portions, which communicate together at the back or further end of the stove, so that the flame and heated vapours, after having circulated under and along the sides of the two lower comb chambers, ascend into the upper portion of the stove, where they have to traverse along the sides and over the top of the two upper chambers, ultimately escaping into the chimney through a pipe. The length of the heating box, or the chambers, should be about double the length of the combs. The cold combs are inserted at one end, and on being put into their places push the more heated combs towards the other end of the chambers, from which they are removed. See Alpaca, Mohair.

WOOTZ, is the Indian name of Steel The Indian wootz is prepared in very rude furnaces, in a most primitive manner, from hematite iron; charcoal being the fuel employed.

WORSTED. Yarns made of wool drawn out into long filaments by passing it, when oiled, through heated combs, as described under Woollen Manufacture, page 1045. Numerous machines have been introduced for combing wool, and they are, for many purposes, very extensively employed; but as far as we can learn there has not yet been introduced a machine which is capable of producing long-fibred wool in any respect equal to that which is prepared by hand.

Of woollen or worsted manufactures our *imports* have been as follows:—

Woollen Manufactures:	1844.	1845.	1846.	1847.	1848.	1849.	1850.	1851.

WORT is the fermentable infusion of malt or grains. See Beer and Malt.

WOULFE'S APPARATUS, is a series of vessels, connected by tubes, for the purpose of condensing gaseous products in water. See Acetic Acid; also Muriatic Acid.

X.

XANTHINE, the name given by Kuhlmann to the yellow dyeing matter of madder. See Madder.

XYLOIDINE—*Nitramidine*. By acting on starch with fuming nitric acid a transparent jelly is formed, and on adding water xyloidine is precipitated as a white granular substance. Its composition, according to Ballol, is $C^{15}H^{12}O^{16}N$. See Collodion; Gun Cotton.

XYLOLE, $C^{16}H^{10}$, a hydrocarbon found in coal naphtha and in the oils which separate when crude wood-spirit is mixed with water. For a table of its physical properties see Carburetted Hydrogen.

Y.

YARN. (*Fil*, Fr.; *Garn*, Germ.) Wool, cotton, or flax, spun into thread.

YEAST. See Beer, and Fermentation.

YEAST, ARTIFICIAL. Mix 2 parts by weight of fine flour of pale barley malt, with 1 part of wheat flour; stir 50 pounds of this mixture gradually into 100 quarts of cold water, with a wooden spatula, till it forms a smooth pap. Put this pap into a copper over a slow fire; stir it well till the temperature rise to fully 155° to 160°, when a partial formation of sugar will take place, but this sweetening must not be pushed too far; turn out the thinned paste into a flat cooler, and stir it from time to time. As soon as the wort has fallen to 59° Fahr. transfer it to a tub, and add for every 50 quarts of it 1 quart of good fresh beer-yeast, which will throw the wort into brisk fermentation in the course of 12 hours. This preparation will be good yeast, fit for bakers' and brewers' uses, and will continue fresh and active for three days. It should be occasionally stirred.

The German yeast imported into this country in large quantities, and employed by our bakers in baking cakes, and other *fancy* bread, is made by putting the *unterhefe* (see BEER, *Bavarian*) into thick sacks of linen or hempen yarn, letting the liquid part, or beer, drain away; placing the drained sacks between boards, and exposing them to a gradually increasing pressure, till a mass of a thin cheesy consistence is obtained. This cake is broken into small pieces, which are wrapped in separate linen cloths; these parcels are afterwards enclosed in waxed cloth, for exportation. The yeast cake may also be rammed hard into a pitched cask, which is to be closed air-tight. In this state, if kept cool, it may be preserved active for a considerable time. When this is to be used for beer, the proportion required should be mixed with a quantity of worts at 60° Fahr., and the mixture left for a little to work, and send up a lively froth; when it is quite ready for adding to the cooled worts in the fermenting back.

YEAST, PATENT. Boil 6 ounces of hops in 3 gallons of water 3 hours; strain it off, and let it staud 10 minutes; then add half a peck of ground malt, stir it well up, and cover it over; return the hops, and put the same quantity of water to them again, boiling them the same time as before, straining it off to the first mash; stir it up, and let it remain 4 hours, then strain it off, and set it to work at 90°, with 3 pints of patent yeast; let it stand about 20 hours; take the scum off the top, and strain it through a hair sieve; it will be then fit for use. One pint is sufficient to make a bushel of bread.

YELLOW DYE. (*Teinture jaune*, Fr.; *Gelbfärben*, Germ.) *Annotto dyer's-broom* (*Genista tinctoria*), *fustic*, *fustet*, *Persian* or *French berries*, *quercitron bark*, *saw-wort*, (*Serratula tinctoria*), *turmeric*, *weld*, and *willow leaves*, are the principal yellow dyes of the vegetable kingdom; *chromate of lead*, *iron-oxide*, *nitric acid* (for silk), *sulphuret of antimony*, and *sulphuret of arsenic*, are those of the mineral kingdom. Under these articles, as also under CALICO-PRINTING, DYEING, and MORDANTS, ample instructions will be found for communicating this colour to textile and other fibrous substances. Alumina and oxide of tin are the most approved bases of the above vegetable dyes. A nankin dye may be given with *bablah*, especially to cotton oiled preparatory to the Turkey-red process. See MADDER.

YELLOW, KING'S, is a poisonous yellow pigment. See ARSENIC and ORPIMENT.

YTTRIA, is a rare earth, extracted from the minerals gadolinite and yttrotantalite, being an oxide of the metal yttrium.

Z.

ZAFFRE. See COBALT. Zaffre *imported* in 1858, 550 cwts.

ZEA. Indian corn or maize.

ZEDOARY. (*Zédoaire*, Fr.; *Zittwer*, Germ.) The root of a plant imported from Ceylon, Malabar, and Cochin-China, employed sometimes medicinally. It occurs in wrinkled pieces, externally ash-coloured, internally brownish-red; possessed of a fragrant odour, somewhat resembling camphor; and of a pungent, aromatic, bitterish taste. According to Morin this root contains besides an azotised substance, analogous to the extract of beef.

ZIMOME is a principle supposed by Taddei to exist in the gluten of wheat-flour. Its identity is not recognised by later chemists.

ZINC is a metal of a bluish-white colour, of considerable lustre when broken, but easily tarnished by the air; its fracture is hackly, and foliated with small facets, irregularly set. It has little cohesion, and breaks in thin plates before the hammer, unless it has been previously subjected to a process of lamination, at the temperature of from 220° to 300° Fahr., by which it becomes malleable and ductile. On this singular property a patent was taken out by Messrs. Hobson and Sylvester, of Sheffield, many years ago, for manufacturing sheet zinc for covering the roofs of houses, and sheathing ships; but the low price of copper at that time, and its superior tenacity, rendered their patent ineffective. The specific gravity of zinc varies from 6·9 to 7·2, according to the degree of condensation to which it has been subjected. It melts under a red heat, at about the 680th or 700th degree of Fahrenheit's scale. When exposed to this temperature with contact of air, the metal takes fire, and burns with a brilliant bluish-white light, while a few flocculi of a woolly-looking white matter, rise out of the crucible and float in the air. The result of this combustion is a white powder, formerly called flowers, but now oxide of zinc; consisting of 32·3 of metal, and 8 of oxygen, being their respective equivalents.

The principal ores of zinc are, the sulphide called *blende*, the silicate called *calamine*, and the sparry calamine, or carbonate.

1. *Blende* crystallises in rhombic dodecahedrons; its fracture is highly conchoidal; lustre, adamantine; colours, black, brown, red, yellow, and green; transparent or translucent; spec. grav. 4. It is a simple sulphide of the metal; and, therefore, consists in its pure state, of 32·3 of zinc, and 16 of sulphur. It dissolves in nitric acid, with disengagement of sulphuretted hydrogen gas. It occurs in beds and veins, accompanied chiefly by galena, iron pyrites, copper pyrites, and heavy spar. There is a radiated variety found at Przibram, remarkable for containing a large proportion of cadmium. Blende is found in great quantities in Derbyshire and Cumberland, as also in Cornwall and many other localities.

2. *Calamine*, or silicate of zinc, is divided into two species; the prismatic or electric calamine, and the rhomboidal; though they both agree in metallurgic treatment. The *first* has a vitreous lustre, inclining to pearly; colour, white, but occasionally blue, green, yellow, or brown; spec. grav. 3·38. It often occurs massive, and in botroidal shapes. This species is a compound of oxide of zinc with silica and water; and its constituents are — oxide of zinc, 66·37; silica, 26·23; water, 7·4, in 100 parts. Reduced to powder, it is soluble in dilute sulphuric or nitric acid, and the solution gelatinises on cooling. It emits a green phosphorescent light before the blowpipe. The second species, or rhombohedral calamine, is a carbonate of zinc. Its spec. grav. is 4·442, much denser than the preceding. It occurs in kidney-shaped, botroidal, stalactitic, and other imitative shapes; surface generally rough, composition columnar. Massive, with a granular texture, sometimes impalpable; strongly coherent. According to Smithson's analysis, Derbyshire calamine consists of — oxide of zinc, 65·2; carbonic acid, 34·8; which coincides almost exactly with one equivalent of oxide and one of acid, or $42 + 22 = 64$.

The mineral called *zinc-ore*, or red oxide of zinc, is denser than either of the above, its spec. grav. being 5·432. It is a compound of oxide of zinc 88, and oxide of iron and manganese 12. It is found massive, of a granular texture, in large quantities, in several localities in New Jersey. It is employed in several metallurgic processes, and according to Mitscherlich, occurs crystallised, in six-sided prisms of a yellow colour, in the smelting works of Kœnigshutte, in Silesia.

The zinc ores of England, like those of France, Belgium, and Silesia, occur in two geological localities.

The first is in veins in the carboniferous or mountain limestone. The blende and the calamine most usually accompany the numerous veins of galena which traverse that limestone; though there are many lead mines that yield no calamine; and, on the other hand, there are veins of calamine alone, as at Matlock, whence a considerable quantity of this ore is obtained.

In almost every part of England where metalliferous limestone appears, there are explorations for lead and zinc ores. The neighbourhood of Alston-moor, in Cumberland, of Castleton and Matlock, in Derbyshire, and the small metalliferous belt of Flintshire, are peculiarly marked for their mineral riches. On the north side of the last county, calamine is mined in a rich mine of galena at Holywell, where it presents the singular appearance of occurring only in the ramifications that the lead vein makes from east to west, and never in those from north to south; while the blende, abundantly present in this mine, is found indifferently in all directions.

The second locality of calamine is in the magnesian limestone formation of the English geologists, the alpine limestone of the French, and the zechstein of the Germans. The calamine is disseminated through it in small contemporaneous veins, which, running in all directions, form the appearance of a network. These veins have commonly a thickness of only a few inches; but in certain cases they extend to 4 feet, in consequence of the union of several small ones into a single mass. There were formerly explorations for calamine in the magnesian limestone, situated chiefly on the flanks of the Mendip Hills, a chain which extends in a north-west and south-east direction, from the canal of Bristol to Frome. Calamine was chiefly worked in the parishes of Phipham and Roborough, as also near Rickford and Broadfield-Doron, by means of a great number of small shafts. The miners paid for the privilege of working a tax of 1*l.* sterling per annum, to the Lords of the Treasury; and they sold the ores, mixed with a considerable quantity of carbonate of lime, at Phipham, after washing it slightly in a sieve. Very little is at present worked in this district. Calamine is now largely imported into this country from Spain and the United States of America.

Metallurgy of Zinc.

Roasting of Ores.—Blende, or sulphide of zinc is, previous to its treatment for metal, carefully roasted in a reverberatory furnace, over the bottom of which it is spread in a layer of about four inches in thickness. A strong heat is necessary for this purpose, and during the operation the charge is frequently stirred with a strong iron rake, with a view of exposing fresh surfaces to the gases of the furnace. The apparatus most commonly employed in this country for roasting sulphide of zinc consists of a reverberatory furnace about 36 feet in length and 9 feet in width, provided with a fireplace of the usual construction. The sole or hearth of this apparatus is divided into three distinct beds, of which that nearest the fire-bridge is 4 inches lower than that which is next it, which is again 4 inches lower than that nearest the chimney. In addition to the heat derived from the fire-place, the gases escaping from the reducing furnaces are usually introduced immediately before the bridge, and a considerable economy of fuel is thereby effected.

When the furnace has been sufficiently heated a charge of 12 cwt. of raw blende is introduced into the division nearest the chimney and equally spread over the bottom, care being taken to stir it from time to time by means of an iron rake, as before described. After the expiration of about eight hours this charge is worked on to the floor of the compartment forming the middle of the furnace, and a new charge is introduced into the division next the chimney. About eight hours after this charging the ore on the middle bed is worked on to the first, whilst that on the hearth next the chimney is equally spread on the middle one and a new charge introduced into the division next the stack. After the expiration of another period of eight hours the charge on the first hearth is drawn, the ore on the middle and third hearths moved forward, and a fourth charge introduced as before. In this way the operation is continuous and each furnace will effect the calcination of about 36 cwt. of ordinary blende in the course of 24 hours.

Calamine or silicate of zinc is usually prepared for smelting by calcination in a furnace resembling an ordinary lime kiln, the heat being often supplied by means of four fire places arranged externally, and so placed that the heated gases may be drawn into it, and regularly distributed through the interstices existing between the masses of ore. Calamine subjected to this treatment commonly loses abou one-third of its weight, and is at the same time rendered so friable as easily to admit of being reduced to fine powder by an ordinary edge-mill.

Reduction.

Belgian process.—When this method of treating zinc ore is employed the furnace represented in *fig.* 1972 is commonly used.

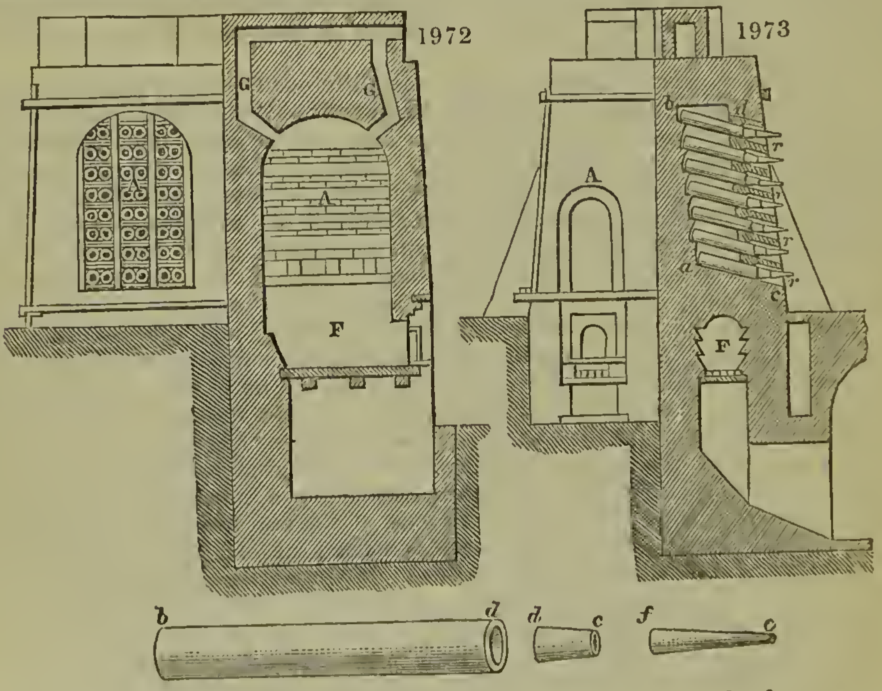

Fig. 1972 represents, on the left hand, a front elevation of the furnace, and on the right a sectional elevation through the ash-pit and fire-place. F is the fireplace, whilst A is the cavity into which are introduced the retorts destined for the distillation of the metal. The products of combustion escape by the openings G into a flue, by which they are conducted into the calciner for the purpose of economising the waste heat. These furnaees are either arranged in couples, back to back, or in groups of four, for the purpose of rendering the structure more solid, and economising heat. In the arched chamber A are placed 48 cylindrical retorts, 3 feet 6 inches in length from *b* to *d*, and 7 inches internal diameter. These are made of refractory fire clay, well baked and supported behind by ledges of masonry *a*, *b*, *fig.* 1973, whilst in front, at *c d*, they rest on fire-clay saddles let into an iron framing. Short conical fire-clay pipes, 10 inches in length from *d* to *c*, are fixed in the mouths of these retorts by means of moistened clay, and project for a short distanc e beyond the mouth of the furnace. To these are adapted thin wrought-iron cones 18 inches in length from *e* to *f*, tapering off at the smaller extremity to an orifice of about three quarters of an inch in diameter. The inclined position of the retorts, the method of adjusting the pipes, and the general arrangement of the apparatus is shown in *fig.* 1973, in which *r*, *r*, *r*, *r*, represent the nozzles of thin wrought iron. When a new furnace is first lighted the retorts are introduced without being previously baked, but care must be taken that they be perfectly dry and seasoned, and for this reason it is necessary to keep a large stock constantly on haud, in a store-house artificially heated by means of some the flues of the establishment. The heat is gradually increased during three or four days, at the end of which period charges of ore are introduced, the clay cones are luted in their places, and the furnaee is brought into full working order. The charge of a furnace consists of 1680 lbs. of roasted blende or calcined calamine and 840 lbs. of coal dust. The ore and eoal dust, after being finally divided and intimately mixed, is slightly damped and subsequently introduced into the retorts by means of a semi-cylindrical scoop, by the aid of which an experienced workman will effect the charging without spilling the smallest quantity of the mixture.

In this country the retorts in the lower tier are usually not charged, as they are extremely liable to be broken, and are therefore only employed to moderate the heat of the furnace. On the Continent, however, the fire-place is frequently covered by a hollow arch, and in that case every retort requires a charge of ore.

The mixture introduced into the retorts varies, to a certain extent, with their position in the furnace, for in spite of every precaution to prevent inequality of temperature, it is found impossible to heat the whole of them alike, and those next the fire, therefore, from being the most strongly heated, are liable to work off first. As soon as the retorts have been charged the clay cones are luted into their places, and earbonic oxide gas, which burns with a blue flame at the mouth of the cones, quickly makes its appearance. The quantity of this gas gradually diminishes, and as soon as the flame assumes a greenish-white hue, and white fumes are observed to be evolved, the sheet-iron cones are put on, and the furnace at once enters into steady action. From time to time, as the iron cones become choked with oxide, they are taken off and gently tapped against some hard substance, so as to remove it, and then replaced. The oxide thus collected is added to the mixture prepared for the next charge. After the expiration of about six hours from the time of charging the wrought iron tubes are suecessively removed, and the metallic zinc scraped from the clay pipes into an iron ladle. This, when full, is skimmed, and the oxide added to that obtained from the nozzles, whilst the pure metal is cast into ingots, weighing about 28 lbs. each. At the expiration of twelve hours from the time of charging the zinc is again tapped, amd the residue remaining in the retorts withdrawn. The retorts are immediately re-charged, and the operation of reduction is conducted as above described.

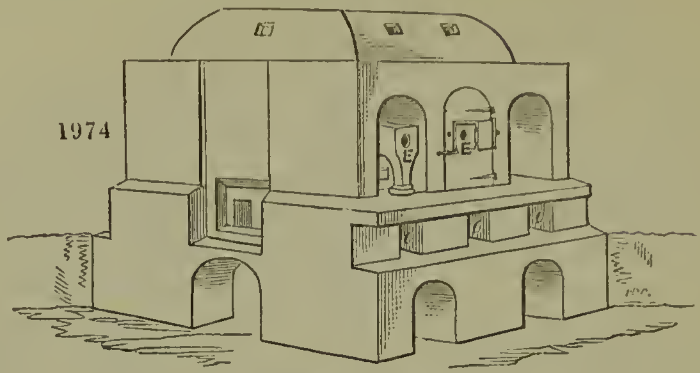
The residues obtained from the retorts, after the first working, are passed through a crushing-mill, mixed with a further quantity of small coal, and again treated for the metal they contain. The carthen adapters or cones, when unfit for further serviee, are crushed and treated as zinc ores.

In order to work these furnaces with economy, it is of the greatest importance that they should be constantly supplied with a full number of retorts, since the amount of fuel consumed, and the general expenses incurred for each furnace, will be the same if the apparatus has its full complement of retorts, or if one half of them are broken and consequently disabled.

It is therefore necessary, in all zinc smelting establishments, to keep a large stoek of well-seasoned retorts, which, before being introduced into the furnace, to make good any defieiency caused by breakage, are heated to full redness in a kiln provided for that purpose. The Belgian process of zinc smelting is that which is at present most employed in this country. The principal localities in which zinc ores are treated are Swansea, Wigan, Llannelly, and Wrexham.

Silesian process.—In the zinc works of Silesia the furnaces employed differ considerably from those used in the Belgian process.

1974



1975

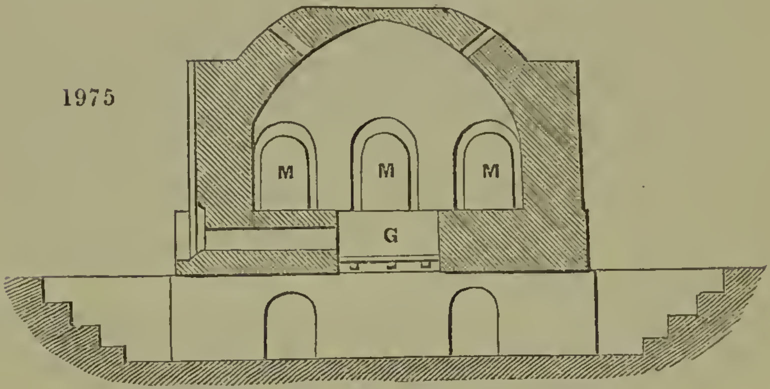


Fig. 1974, represents an elevation, and *fig.* 1975, a vertical section of the Silesian furnace. The distillation is effected in a sort of muffle of baked clay, M, *fig.* 1975, and *figs.* 1976, 1977, about 3 feet 3 inches in length, and 20 inches in height. The front of this muffle is pierced with two apertures. The lower opening, *d*, serves to remove the residues remaining in the retorts after each operation, and is closed during the process of distillation by a small door of baked clay, firmly luted in its place. In the upper opening is introduced a hollow clay arm, bent at right angles, *a*, *b*, *c*, and which remains open at *c*. An opening at *b*, permits of charging the retort by means of a proper scoop, and this, during the operation, is closed by a luted clay plug. From six to ten of these muffles or retorts are arranged in rows, on either side of a furnace provided with suitable apertures for their introduction. They are securely luted in their places, and the openings closed by sheet iron doors, by which the too rapid cooling of the pipe *a*, *b*, *c*, is prevented. The fuel employed is coal, which is burnt on the grate G, situated in the centre of the furnace. The retorts are charged with a mixture of calamine and small coal, or more frequently coke-dust, since, when coal is employed, the products of distillation are found to be liable to choke the pipe *a*, *b*, *c*.

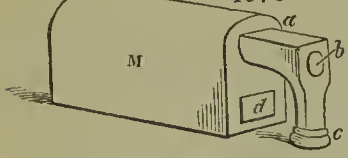
1976

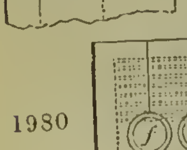


1977

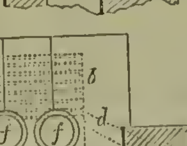
The zinc escapes by the opening *c*, of the adapter, and is received into the cavities *o*, of the furnace.

The furnace shown in *figs.* 1978, 1979, 1980, is for re-melting the metallic zinc. *Fig.* 1979, is a front view; *fig.* 1978, is a transverse section; *fig.* 1980, a view from above; *a*, is the fire-door; *b*, the grate; *c*, the fire-bridge; *d*, the flue; *e*, the chimney; *f*, *f*, *f*, cast-iron melting-pots, which contain each about 10 cwt. of metal. The heat

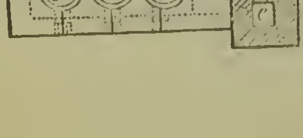
1979



1978



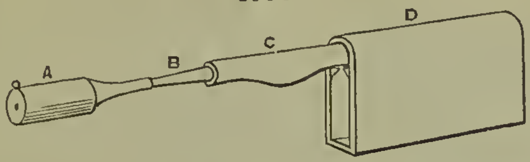
1980



is moderated by the successive addition of pieces of cold zinc. The inside of the pots is sometimes coated with loam, to prevent the iron being attacked by the zinc.

In some establishments, and particularly those at Stolberg in Prussia, the retorts have the form D, represented *fig.* 1981. C is an adapter also of fire clay; B a cone of wrought iron, and A a small vessel of the same material for the collection of the

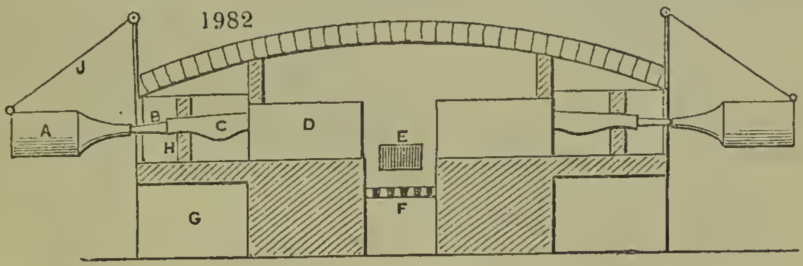
1981



oxide, and furnished in the bottom with an aperture for the escape of the gases generated.

These are arranged on either side of a grate as represented, *fig.* 1982, an internal opening serving for two retorts, and of which there are usually twelve in each furnace. E is the fire-door; F grate; G chamber in masonry of furnace; H diaphragm of fire-brick supporting adapter, in the depressed part of which the metallic zinc is col-

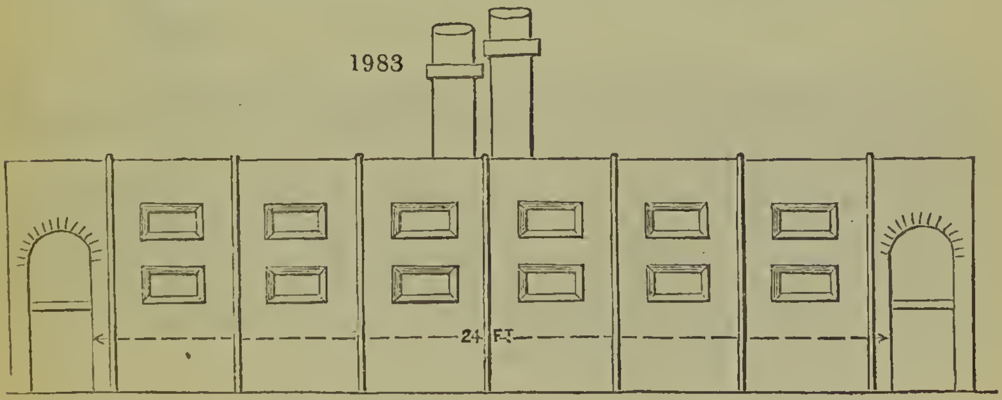
1982



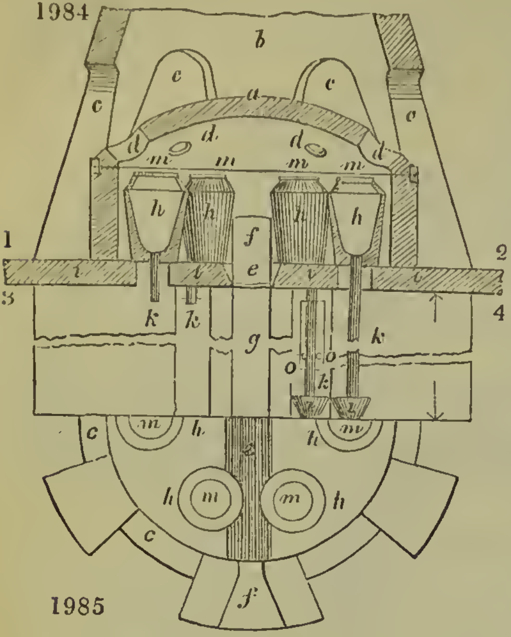
lected and subsequently removed by a scraper, as in the case of the cone of the Belgian retort. The wrought iron vessel A, is supported by a chain or wire J.

Fig. 1983 represents a longitudinal elevation of the roasting furnace employed.

1983



Old English process.—The English furnaces for smelting zinc ores are sometimes quadrangular, sometimes round; the latter form being preferable. They are mounted with from 6 to 8 crucibles or pots (see *fig.* 1984), arched over with a cupola *a*, placed under a conical chimney *b*, which serves to give a strong draught, and to carry off the smoke. In this cone there are as many doors *c*, *c*, *c*, as there are pots in the furnace; and an equal number of vents *d*, *d*, *d*, in the cupola, through which the smoke may escape, and the pots may be set. In the surrounding wall there are holes for taking out the pots when they become unserviceable; after the pots are set, these holes are bricked up. The pots are heated to ignition in a reverberatory furnace before being set, and are put in by means of iron tongs supported upon two wheels, as is the case with glass-house pots. *c*, is the grate; *f*, the door for fuel; *g*, the ash-pit. The pots, *h*, *h*, *h*, have a hole in the centre of their bottom, which is closed with a wooden plug, when they are set charged with calamine, mixed with coal; which coal prevents the mixture from falling through the orifice, when the heat rises and consumes the plug. The sole of the hearth *i*, *i*, upon which the crucibles stand, is perforated under each of them, so that they can be reached from below; to the bottom orifice of the pots, when the distillation begins, a long sheet-iron pipe *k*, is joined, which dips at its end into a vessel *l*, for receiving in drops the condensed vapours of the zinc. The pot is charged from above, through an orifice in the lid, which is left open after the firing until the bluish colour of the flames indicates the volatilisation of the metal, immediately whereupon the whole is covered with a fire-tile *m*. The iron tubes are liable to become obstructed during the distillation, and must therefore be occasionally cleared by means of an iron bar. When the operation is terminated the pipes must be removed, and the carbonaceous and other residual matters extracted from the pots.



1984

1985

1, 2 is the level of the upper floor; 3, 4, level of the lower ceiling of the lower floor.

Fig. 1985 ground plan on the level of 1, 2; only one half is here shown. — J. A. P.

The general consumption of Spelter throughout the world is about 67,000 tons per annum, of which about 44,000 tons are made to take the shape of rolled sheets, and these are estimated to be applied as follows, each quantity being somewhat below the truth: —

	Tons.
Roofing and architectural purposes - - -	23,000
Ship sheathing - - - - - -	3,500
Lining packing cases - - - - - -	2,500
Domestic utensils - - - - - -	12,000
Ornaments - - - - - - -	1,500
Miscellaneous - - - - - - -	1,500
	44,000

Fifteen years ago the quantity used for roofing did not exceed 5,000 tons; none was employed for ship sheathing or lining packing cases, and stamped ornaments in zinc date only from 1852.

From the low temperature at which zinc fuses, and from the sharpness of impressions possessed by castings in this metal it is much employed on the continent for the production of statues and statuettes. The uses of this metal in the preparation of alloys has already been noticed under the head of alloys. It is also employed like tin for coating iron, producing what is known as galvanised iron. The *disenfectant liquor* of Sir W. Burnett, is chloride of zinc, and the oxide of this metal is much employed as a pigment in place of white lead.

Zinc or Spelter *imports* in 1858: —

Crude in cakes.	Tons.	
Denmark - - - - - -	271	Computed real value. £470,195.
Prussia - - - - - -	9,034	
Hamburg - - - - - -	8,413	
Holland - - - - - -	1,259	
Belgium - - - - - -	240	
Other Parts - - - - -	302	
	19,519	

Rolled, but not otherwise manufactured.	Tons.	
Denmark - - - - - -	47	Computed real value. £128,738.
Prussia - - - - - -	304	
Belgium - - - - - -	3,818	
Other parts - - - - -	37	
	4,206	

ZINC PRINTING. Representations of the different departments of the Imperial establishment, etched on zinc, chemityped and printed with the common printing press — a new invention by Pül, for etching on zinc in a raised manner.

If this art be not calculated to supersede wood engraving, it can be applied with great advantage for certain purposes in the etching style, for maps, plans, drawings of machines, &c. A zinc plate is covered with an etching ground, the drawing etched in the usual manner with the needle, and bitten in. The etching ground is now removed, the deep lines cleaned with acid, and then the whole plate in a warm state, covered with an easily fusible metal, with which, of course, the lines of the drawing are filled up. When the metal thus laid on is cold and firm, the whole plate is planed until the zinc appears again, and only the lines of the drawing remain filled with the fusible metal, which is easily distinguished by its white colour from the gray of the zinc. The whole plate is now etched several times; the former lines of the drawing, filled with easily fusible negative metal, are not affected by the acid, while the pure zinc is eaten away. In this manner a drawing for printing in the copper-plate press can be converted into one in relief for use in the ordinary printing press.

ZINCING OF IRON. Iron may be conveniently coated, in the humid way, by a solution of sulphate of zinc, or one of the double salt of chloride of zinc and sal-ammoniac, as now used in soldering and welding. To secure success, the zinc solution should be weak, and only a weak galvanic current should be used, otherwise the zinc precipitated will again separate from the iron in scales. With proper precautions the deposit may be made as thick as strong paper. The article must be well cleansed before undergoing the operation.

ZIRCON. See Hyacinth and Lapidary.

ZIRCONIA, is a rare earth, extracted from the minerals zircon and hyacinth; it is an oxide of zirconium, a substance possessing externally none of the metallic characters, but resembling rather charcoal powder, which burns briskly, and almost with explosive violence.

THE END.

Under the article Crushing and Grinding Machinery will be found descriptions of several crushers. The wood-cut, *fig.* 1986 represents a small high-pressure engine, devised by Mr. T. B. Jordan, for driving crushing apparatus.
